A better test of the central respiratory drive, one that is independent of respiratory mechanics, is the mouth occlusion pressure, or Pm_{100}. Pm_{100} refers to the maximum negative mouth pressure generated during the first 100 ms of inspiration with complete airway occlusion. Because the Pm_{100} is obtained during early inspiration with only a fraction of total inspiratory time, it is not influenced by a conscious alteration in respiration. Similarly, because the Pm_{100} is only a fraction of the maximum inspiratory muscle strength, the result may remain valid even in the presence of moderately severe respiratory muscle weakness.

Pm_{100} is normal or increased in patients with mild to moderately advanced neuromuscular disorder.

In studies using Pm_{100}, central respiratory drive has been found to be normal or increased in patients with neuromuscular disease, despite substantial muscle weakness. Indeed, several studies have shown that despite significant reductions in respiratory muscle strength, the Pm_{100} in patients with Duchenne's muscular dystrophy, myotonic dystrophy, and a variety of neuromuscular diseases is one to twofold higher than in normal controls. Similar increases in Pm_{100} were observed in normal volunteers after severe muscle weakness induced by the administration of curare. Thus, it appears that central respiratory drive as measured by Pm_{100} is preserved in most patients with neuromuscular disease.

Respiratory Muscle Function

Respiratory muscle weakness may present clinically as exertional dyspnea, fatigue, poor cough, and recurrent respiratory tract infections.

The respiratory muscles consist of the upper airway muscles, diaphragm, chest wall muscles, and abdominal muscles. The respiratory muscles can be further divided functionally into inspiratory and expiratory muscles. The inspiratory muscles produce rib cage expansion and generate negative intrathoracic pressure, allowing inspiratory airflow. During rest, exhalation is passive and driven by lung and chest wall recoil pressures. However, the expiratory muscles may become active during periods of increased expiratory effort, such as coughing, exercise, and airflow obstruction. The innervation of the different respiratory muscle groups and their functions are shown in Table 29-3.

Patients with moderate-to-severe respiratory muscle weakness due to neuromuscular disease often complain of fatigue, poor sleep quality, and dyspnea, especially on exertion. Ineffective cough may lead to recurrent respiratory infections. Sleep disorders, acute or chronic respiratory failure, and secondary pulmonary hypertension may result as respiratory

muscle weakness progresses and hypoxemia and hypercapnia ensue.[4] However, a significant percentage of these patients may be asymptomatic despite the presence of significant respiratory muscle weakness. These patients can present in the ICU with acute hypercapnic respiratory failure, which is often associated with community-acquired pneumonia. Since these patients do not have prior respiratory complaints, respiratory muscle weakness is often not suspected until difficulty weaning from the ventilator is encountered. In one study, 27% of patients with moderately advanced neuromuscular disease who had severe reductions in both inspiratory and expiratory muscle function had no prior respiratory complaints.[4] In another report, 50% of patients with severe respiratory muscle weakness due to chronic neuromuscular disease were asymptomatic.[5] It is unclear why respiratory muscle weakness correlates so poorly with patient reported symptoms. It is possible that the presence of significant respiratory muscle weakness is masked by concomitant generalized muscle weakness and a sedentary lifestyle.

Many patients with significant respiratory muscle dysfunction are asymptomatic.

The severity and the pattern of involvement of the respiratory muscles by the different neuromuscular disorders are not uniform. Some diseases cause global respiratory muscle dysfunction, whereas others cause preferential weakness of the inspiratory or expiratory muscles. Moreover, a decrease in both inspiratory and expiratory muscle strength may not correlate with a general assessment of muscle strength. Primary muscle diseases like polymyositis cause more significant impairment of the respiratory muscles compared to the neuropathies. The relationship between inspiratory muscle strength and the onset of ventilatory insufficiency is not linear. Once maximum inspiratory mouth pressures decrease to less than 30% of that predicted, hypercapnia will usually ensue (Fig. 29-2).

Neuromyopathies may lead to different degrees of inspiratory and expiratory muscle weakness.

Respiratory failure ensues when maximum inspiratory pressure is <30% of predicted.

Lung and Chest Wall Mechanics

Lung volume studies in patients with chronic respiratory muscle weakness often show a restrictive ventilatory pattern with a reduction in forced vital capacity (FVC) and preserved forced expiratory volume in 1 s/forced vital capacity ratio (FEV_1/FVC). Lung volume studies typically reveal a moderate reduction in total lung capacity and functional residual capacity with a normal or elevated residual capacity. A moderate fall in both inspiratory and expiratory reserve volume occurs. The decline in FVC is mainly caused by respiratory muscle weakness, and the decrease in FVC, in the absence of obstructive lung diseases, parallels the progression of the underlying respiratory muscle function. Thus, serial FVC measurement can be performed in the ICU setting to detect impending respiratory failure. However, a significant reduction in lung compliance may also contribute to decreased FVC in patients with chronic neuromuscular disease. The exact causes of reduced lung distensibility are unclear, but may be due to failed maturation of normal lung tissue in congenital

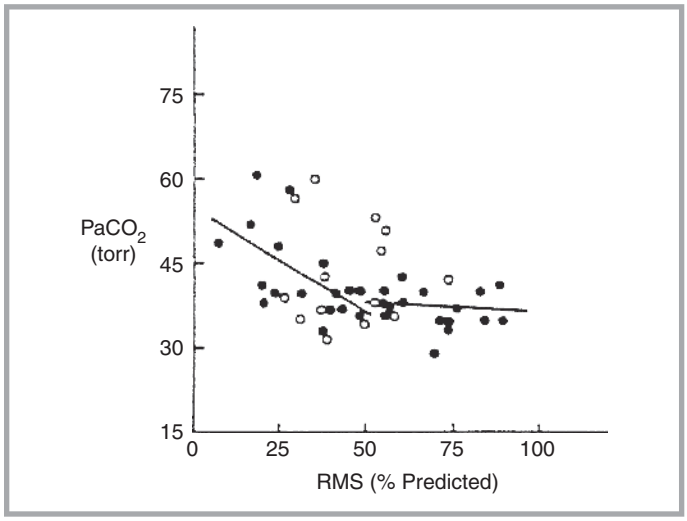

FIGURE 29-2

In patients with neuromyopathies, the relationship of respiratory muscle strength (RMS) and PCO_2 is discontinuous. Hypercapnia is likely to occur only when respiratory muscle strength is less than 30% of predicted.

neuromuscular diseases, the presence of micro or macroatelectasis increases in alveolar surface tension caused by breathing chronically at low tidal volumes, and alterations in lung tissue elasticity.

Patients with neuromuscular disease have a rapid shallow breathing pattern similar to patients with interstitial lung disease. The exact mechanism of this abnormal breathing pattern is unclear and is thought to be caused by less compliant lungs and increases in lung elastic recoil. Similar to the changes seen in the lungs, a significant reduction in chest wall compliance is thought to be due to increased rib cage stiffness caused by chest wall fibrotic changes (i.e., tendons, ligaments, and costovertebral and costosternal articulations).

Lung and chest wall compliance decreases in patients with neuromyopathies.

Gas Exchange Abnormalities

Hypoxemia and hypercapnia caused by ventilation/perfusion inequality are common in advanced disease.

Hypercapnia and hypoxemia are late findings in patients with stable chronic neuromuscular disease. Hypercapnia with a relatively normal FVC and static maximum respiratory pressures should suggest sleep-related breathing disorders (obstructive sleep apnea, obesity hypoventilation syndrome), the presence of parenchymal lung diseases such as chronic obstructive airway disease, problems with central respiratory drive such as the chronic hypoventilation syndrome, or hypothyroidism (as previously discussed). Even if daytime gas exchange parameters are normal, significant hypoxemia and alveolar hypoventilation may occur during sleep, especially during REM sleep when the activity of the accessory respiratory muscles is diminished. In advanced chronic neuromuscular disease, evidence of alveolar hypoventilation on blood gas examination is likely when the FVC is less than 55% of that predicted and maximum inspiratory mouth pressure (PI_{max}) and maximum expiratory mouth pressure (PE_{max}) are less than –30 cmH_2O (Fig. 29-3). However, the onset of hypercapnia in advanced neuromuscular disease may be abrupt. Ventilation perfusion inequality due to atelectasis is the most common cause of hypoxemia in these patients.

Effect of Neuromuscular Disease on Sleep

Hypoxemia and hypercapnia caused by nocturnal hypoventilation may occur in the absence of daytime gas exchange abnormalities.

Effects of REM sleep on respiratory physiology are alveolar hypoventilation, irregular breathing pattern, and upper airway obstruction due to decreased bulbar muscle tone.

Sleep-related breathing disorders such as impaired sleep quality and REM-related hypopnea are common in patients with respiratory muscle weakness caused by various neuromuscular diseases. Indeed, significant gas exchange abnormalities may be present and unsuspected even in the absence of daytime hypoxemia and hypercapnia.

Several physiologic changes occur in the respiratory system during sleep, particularly REM sleep, which can explain the predisposition of patients with poor pulmonary reserve in general, and respiratory muscle weakness in particular, to gas exchange abnormalities during sleep. Among the physiologic changes occurring during sleep are alveolar hypoventilation,

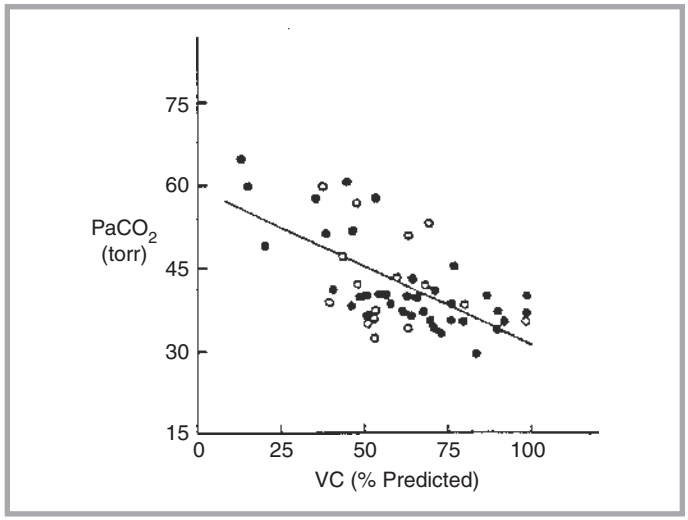

FIGURE 29-3

In patients with neuromyopathies, hypercapnia is likely to occur when the vital capacity (VC) is less than 55% of that predicted.

inhibition of accessory inspiratory muscle activity, and development of a chaotic breathing pattern during REM sleep that causes significant hypoventilation in patients with diaphragm weakness. In addition, pharyngeal muscle weakness, which is present in some neuromuscular diseases, may aggravate the physiologic loss of upper airway tone during REM sleep, thereby increasing the predisposition to obstructive sleep apnea and hypopnea.

If nocturnal hypoventilation is severe and remains clinically unrecognized, daytime hypercapnia and hypoxemia may ensue even in the absence of severe respiratory muscle dysfunction. Nocturnal gas exchange abnormalities usually precede and occur much earlier than abnormalities in daytime gas exchange. Indeed, patients with normal nocturnal gas exchange are unlikely to have abnormal daytime values.

Daytime gas exchange abnormalities and a decrease in FVC are useful in predicting patients with neuromuscular disease who are at risk for severe oxygen desaturation during sleep. In a study involving 20 patients with a variety of moderately advanced neuromuscular diseases, the degree of arterial oxygen desaturation during REM sleep was directly related to the severity of daytime hypercapnia and hypoxemia.[6] Both percent predicted FVC and the decrease in FVC from the sitting to supine positions were also found to correlate with the minimum oxygen saturation measured during REM sleep. Mean decrease in FVC from the seated to the supine positions in this study was 21%. Interestingly, the maximum static respiratory pressures were not predictive of nocturnal hypoventilation.

Upper Airway Dysfunction

Upper airway dysfunction, manifested as the inability to handle oral secretions, recurrent aspiration, hoarseness, or stridor, is common in patients with neuromuscular dysfunction, especially when respiratory muscle weakness is present. Endotracheal intubation and mechanical ventilation are often required to protect the airway, prevent aspiration, and support ventilation once upper airway dysfunction becomes evident.

The flow–volume loop is useful in excluding significant upper airway dysfunction. Indeed, an abnormal flow–volume loop has a high sensitivity and specificity in predicting bulbar and upper airway involvement in patients with neuromuscular dysfunction. A typical flow–volume loop in a patient with motor neuron disease with bulbar involvement is shown in Figure 29-4. A sawtooth pattern of the flow loop contour has been described in patients with Parkinson's disease. In addition, variable extrathoracic obstruction that reverses with drug therapy has been described in patients with myasthenia gravis.

The flow–volume loop is helpful in detecting upper airway dysfunction.

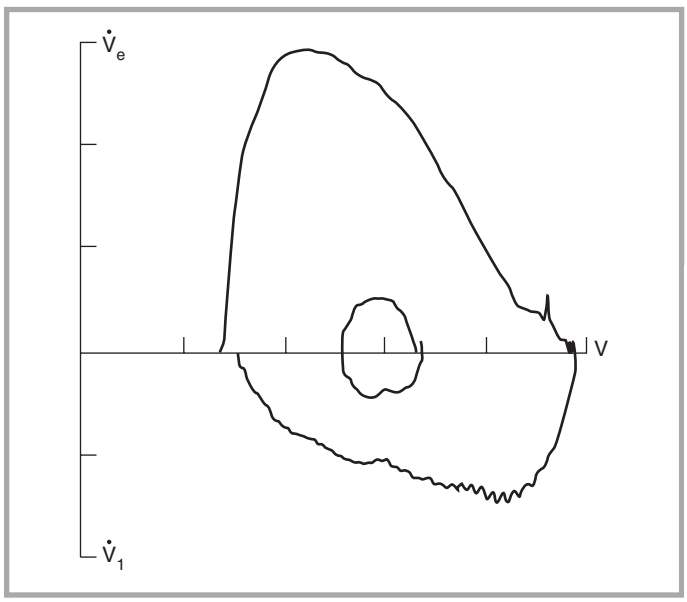

FIGURE 29-4

Upper airway obstruction caused by bulbar muscle involvement is common in patients with neuromuscular disease. The flow–volume loop may show a plateau of the inspiratory loop, suggesting extrathoracic upper airway obstruction.

CASE STUDY: PART 2

On physical examination, the patient appeared anxious but was not in any distress. Except for mild tachycardia, his vital signs were within normal limits. Cardiopulmonary examination was within normal limits. His hands and feet were cool to the touch. On neurologic examination, he had normal mental status. His cranial nerves were normal. On sensory examination, he had decreased sensation to touch on both lower extremities and loss of propioception at the level of the toes bilaterally. His muscle strength in both upper and lower extremities was 4/5 and 3/5, respectively. His reflexes were 1+ in the upper extremities, and no knee jerks could be elicited on both lower extremities. No ankle jerks were present.

EVALUATION OF PATIENTS WITH NEUROMUSCULAR DISEASE

Clinical History

Neuromuscular disorders should be suspected in patients with respiratory failure and sensorimotor symptoms.

The diagnosis of neuromuscular disease should be suspected in all patients who are admitted to the ICU with unexplained acute or chronic hypercapnic respiratory failure. Unless a high index of suspicion is used in the diagnosis of neuromyopathy, the diagnosis may be missed or delayed because the presence of neuromuscular dysfunction may be masked by the precipitating illness. Moreover, a detailed neurologic history is often not available in the ICU setting because patients may be intubated or are too breathless or confused to provide accurate information. In some cases, respiratory muscle weakness caused by a neuromuscular disease comes to light only after the patient has failed multiple weaning trials. Nevertheless, accurate historical details can often be obtained from family members, primary caregivers, and old medical records.

Inquiries about a preexisting neuromuscular disease are very important. Several neuromuscular diseases may cause sudden clinical deterioration, especially in advanced disease. Patients with congenital myopathies may develop cardiorespiratory failure or increased diaphragm weakness in the latter phases of their illness. The pattern of skeletal muscle weakness may suggest a particular diagnosis. Acute ascending paralysis of the lower extremities suggests Gullain–Barré syndrome; waxing and waning of neurologic symptoms are commonly seen in multiple sclerosis; and skeletal muscle weakness with repetitive action of a particular muscle group is highly suspicious of myasthenia gravis.

If possible, a detailed history of dietary intake over the last 48 h and drug and toxin ingestion should be obtained. Acute shellfish poisoning (saxatoxin) may lead to skeletal muscle weakness. A history of consumption of home-canned goods suggests botulinum toxin poisoning. Several commonly used drugs such as cholesterol-lowering agents, colchicine, cyclosporin, chloroquin, and L-tryptophan can cause myotoxicity.

Diseases that predominantly affect the pump function of the respiratory system (i.e., phrenic nerve injury) present as dyspnea on exertion, weak cough, and recurrent respiratory tract infections, whereas diseases that affect primarily the limb muscles (i.e., congenital myopathy, amyotrophic lateral sclerosis (ALS)) present as the inability to lift heavy objects, difficulty standing after sitting on a chair, or difficulty walking. However, some neuromuscular diseases such as ALS or mitochondrial myopathy can present initially as acute respiratory failure. Once the respiratory muscles are affected in advanced neuromuscular disease, respiratory failure may occur abruptly, due to an intercurrent illness, or slowly over months or years, finally culminating in hypercapnic respiratory failure. In most neuromuscular diseases, respiratory muscle weakness usually occurs insidiously and is typically associated with weakness of other skeletal muscle groups. However, up to 50% of patients with significant respiratory muscle weakness are asymptomatic until they develop respiratory failure.

Physical Examination

A thorough physical examination and a detailed neurologic assessment may reveal a previously undiagnosed neuromuscular disorder. However, physical examination may be limited

by sedation, the use of neuromuscular blocking agents, or the presence of edema. Certain neurologic findings are helpful in differentiating upper motor neuron versus lower motor neuron lesions (Table 29-4) and in differentiating neuropathy versus myopathy (Table 29-5).

In patients with early or mild neuromuscular weakness, respiratory muscle weakness may not be detected on routine physical examination. Tachypnea at rest is very common with the onset of respiratory muscle weakness. As respiratory muscle weakness progresses, the increase in respiratory rate may be followed by signs of increasing respiratory distress such as nasal flaring, recruitment of the accessory muscles of respiration, and intercostal as well as subcostal retractions. Progressive weakness of the diaphragm eventually leads to paradoxical inward motion of the upper abdomen, often associated with rostral rib cage movement. Alternating paradoxical motions of the rib cage and abdomen indicates either high inspiratory elastic loads or impending respiratory failure. Indeed, paradoxical inward movement of the abdomen on inspiration that worsens with the recumbent position is typically seen in severe diaphragm weakness or paralysis.

Signs of respiratory muscle weakness are tachypnea, use of accessory muscles of respiration, and paradoxical movement of the thorax and abdomen during breathing.

Ancillary Tests

Arterial Blood Gases

Abnormalities in arterial blood gases (e.g., hypoxemia and hypercapnia) occur late in patients with severe respiratory muscle weakness and may not be present before the need to implement ventilatory support. Hypoxemia is commonly the result of microatelectasis due to ineffective cough and retained secretions, causing ventilation–perfusion mismatch or intrapulmonary shunting. More importantly, alveolar hypoventilation caused by respiratory muscle weakness or decreased central respiratory drive may also contribute significantly to hypoxemia. Hypoxemia caused by alveolar hypoventilation occurs due to reductions in PaO_2 that are proportional to elevations in $PaCO_2$, and as a result, the alveolar–arterial oxygen

TABLE 29-4

gradient remains normal despite a lowered PaO_2. Pulse oximetry, which is a measure of arterial oxyhemoglobin saturation, is useful in detecting hypoxemia, but is not a sensitive indicator of hypoventilation.

Hypoxemia and hypercapnia are late findings in patients with respiratory muscle weakness.

Hypercapnia is a late finding in severe respiratory muscle weakness. In fact, hypercapnia does not occur until the respiratory muscle strength is less than 50% of that predicted. Careful analysis of the pH and bicarbonate level is helpful in determining acute from chronic hypercapnic respiratory failure. Sleep-induced breathing disturbances may also lead to hypercarbia and should be carefully sought in susceptible patients.

Pulmonary Function Tests

Spirometry and lung volume studies are helpful in the initial evaluation as well as in follow-up of patients with neuromuscular disease to determine the response to therapy. In general, spirometry is hallmarked by a restrictive pattern that is characterized by a reduction in FVC and a normal FEV_1/FVC ratio. Moreover, there is a decrease in effort-dependent expiratory flow such as peak expiratory airflow measurement, whereas FEV_1 and measurement of midexpiratory flow rates ($FEF_{25–75}$ or FEF_{50}) are often greater than normal predicted values because of increased elastic recoil. Increased elastic recoil pressure results from decreases in both lung and chest wall compliance. Lung volume studies typically show a decrease in total lung capacity (TLC) and an increase in residual volume (RV) due to expiratory muscle weakness. Diffusion capacity is usually normal.

The usual pulmonary function test results in patients with respiratory muscle weakness are decreased expiratory flow rates (FVC, FEV_1), increased RV, and decreased TLC.

Serial FVC measurement is a useful bedside test in predicting impending respiratory failure in patients with rapidly progressive neuromyopathies.

In the ICU setting, serial measurements of FVC are helpful in following the progression of respiratory muscle weakness and in evaluating the need for partial or full ventilatory support. In patients with rapidly progressive respiratory muscle weakness, as seen in Guillain–Barré syndrome, daily measurement of FVC (<10 mL/kg or <1 L) helps to determine when to consider elective airway intubation and institute mechanical ventilation. Alternatively, FVC can also be used as one of the criteria for the initiation of weaning trials and liberation from mechanical ventilation.

Radiographic Assessment

Chest radiographic findings suggestive of respiratory muscle weakness are small lung volumes, bilateral basal atelectasis, and elevated hemidiaphragm.

Radiographic findings in patients with neuromuscular disease are helpful in detecting pneumonia, atelectasis, and concomitant parenchymal lung disease. Although small lung volumes on chest X-ray may suggest the possibility of inspiratory muscle weakness, this is a very nonspecific finding in the ICU setting because portable chest X-rays are often used and a film at maximum inspiration may not be obtained. Nevertheless, in the right clinical setting, small lung volumes on chest radiograph and the presence of bilateral basal band-like atelectasis suggest chronic volume loss that may be the result of weak respiratory muscles as seen in bilateral hemidiaphragm paralysis. However, this radiographic picture could also be easily dismissed as a poor inspiratory effort. On the other hand, unilateral hemidiaphragm paralysis can be easily recognized on a routine chest radiograph as unilateral hemidiaphragm elevation. The elevation of a hemidiaphragm due to weakness or paralysis can be confirmed by performing a "sniff test" under fluoroscopy, which may demonstrate paradoxical upward movement of the affected hemidiaphragm during a rapid sniff maneuver or lack of contraction during ultrasound imaging.

Maximum Mouth Pressures

PI_{max} and PE_{max} are used to measure global inspiratory and expiratory muscle strength, respectively.

Maximum static respiratory pressures, measured at the airway opening during a voluntary contraction against an occluded airway, are the most sensitive tests to assess respiratory muscle dysfunction in patients with neuromuscular disease even in the absence of symptoms and normal ventilatory function. The extent of respiratory muscle weakness can be quantified by measuring the maximum inspiratory (PI_{max}) and expiratory pressures (PE_{max}) that can be generated by the respiratory muscles. It should be remembered that the measurement of static mouth pressures is affected by the underlying lung volume at which the test is performed. Thus, PI_{max} is measured near RV when the inspiratory muscles are at their greatest mechanical

advantage; PE_{max} is measured near TLC when the inward recoil pressure of the respiratory system and the ability of the expiratory muscles to generate force are the greatest.

In chronic neuromuscular diseases, the measurement of both maximum static inspiratory pressures and expiratory pressures (PI_{max} and PE_{max}) is frequently decreased. Here, PI_{max} and PE_{max} usually range from 37 to 52% of normal depending on the type and severity of neuromuscular disease. In a study of 16 patients with various chronic neuromuscular diseases, the mean static inspiratory pressure measured by using an esophageal balloon was 43% of that predicted.[7] In patients with proximal myopathies, hypercapnic respiratory failure has been reported to occur when PI_{max} and PE_{max} values were less than 30% or if the FVC was less than 55% of that predicted.[8] Even in patients with only mild generalized muscle weakness, profound reductions in maximum static respiratory pressures may occur. In another study of 30 patients with stable chronic neuromuscular weakness, 30% of patients with relatively good general muscle strength had unsuspected severe respiratory muscle weakness (less than 50% predicted).[8] Because of the frequent involvement of the respiratory muscles in neuromuscular diseases, the measurement of maximum static respiratory pressures should be routine in the assessment of neuromuscular disease patients, regardless of the severity or stage of the disease.

Respiratory insufficiency occurs when PI_{max} and PE_{max} are <30% of those predicted.

The PI_{max} and PE_{max}, in addition to FVC, are useful parameters to monitor the progression of respiratory muscle weakness in patients with acute neuromuscular disease, who are admitted to the ICU. These tests are reproducible, inexpensive, and easy to perform serially at the bedside to predict impending respiratory failure in patients with respiratory muscle weakness and the need for *ventilatory support. Ventilatory support is often required when VC is less than 10–15 mL/kg or* PI_{max} is less than 20–25 cmH_2O. In certain circumstances such as pneumonia, atelectasis, or the inability to clear secretions, mechanical ventilation may be required before these parameters are met.

Serial measurement of FVC, PI_{max}, and PE_{max} provides useful parameters to follow in the ICU to predict need for ventilatory support.

Although measurement of maximum static respiratory pressures is useful in quantifying global respiratory muscle strength, it does not distinguish selective weakness of a particular respiratory muscle group and does not provide any information on respiratory muscle endurance. In contrast to maximum static pressures, which measure global respiratory parameters, transdiaphragmatic pressure (P_{di}) specifically measures diaphragm strength. Although transdiaphragmatic pressure measurement is more invasive and not readily available in clinical practice, it may be useful when phrenic nerve injury is suspected, as can be seen following cardiac surgery or trauma.

Transdiaphragmatic pressure measures diaphragm muscle strength.

SPECIFIC NEUROMUSCULAR DISORDERS

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder of both upper and lower motor neurons leading to the loss of skeletal muscle function. The incidence of ALS is 1–2 per 100,000 people with peak incidence occurring between the ages 55–75. The majority of cases are sporadic (classical ALS), but 5–10% of cases result from autosomal dominant inheritance (familial ALS). There is a male predilection with a male to female ratio of 2:1. Death is usually the result of progressive respiratory failure and respiratory infections. Mean survival from the initial onset of symptoms is 3–4 years.

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder of the skeletal muscles.

The exact etiology of ALS is unknown. A gene mutation located on chromosome 21q22 encoding copper–zinc superoxide dismutase, a free oxygen radical scavenger, has been identified in 10–15% of familial ALS patients. This finding suggests that the disease may be triggered by the susceptibility of the neurons to oxidative stress. Recent evidence suggests that the motor neurons are susceptible to glutamate-induced neurotoxicity. Glutamate is the principal excitatory neurotransmitter in the brain. The decreased uptake of glutamate is thought to lead to overstimulation of the glutamate receptors, which increases intracellular calcium. The increase in intracellular calcium activates proteolytic enzymes that cause cell membrane injury.

The usual clinical presentation in two-thirds of ALS patients is progressive weakness of the distal extremities, although early involvement of the bulbar muscles occurs in 25% of

Progressive weakness of distal extremities is the most common complaint in patients with ALS.

cases. Early involvement of the phrenic nerve motorneurons in some ALS patients can lead to acute respiratory failure or nocturnal hypoventilation even before clinical symptoms become apparent. Involvement of the upper airway and expiratory muscles can lead to abnormal swallowing and inadequate cough.

Although respiratory muscle impairment is usually evident only in advanced disease, abnormalities in pulmonary function tests may arise even in patients with only mild extremity weakness. Serial lung function studies in ALS patients invariably show a progressive reduction in FVC and maximum voluntary ventilation (MVV), as well as a progressive increase in residual volume (RV). The decline in FVC correlates with poor outcome. Both the maximum inspiratory (PI_{max}) and maximum expiratory pressures (PE_{max}) are reduced, to about 34 and 47% of predicted, respectively. In symptomatic patients with relatively preserved pulmonary function, MIP and MEP are frequently abnormal. An MIP of less than –60 cmH_2O is 100% sensitive for predicting less than 18-month survival.

Progressive decline in FVC and maximum inspiratory pressure (MIP) has a poor prognosis.

The shape of the flow–volume curve may identify a subset of patients with greater weakness of the expiratory muscles. With severe weakness of the expiratory muscles, the flow–volume loop shows a concavity of the maximal expiratory curve with a sharp drop in flow at lower lung volumes. This group of ALS patients has lower maximal expiratory pressures, smaller vital capacities, and higher residual volumes compared to ALS patients with normal flow–volume loops.

A flow–volume loop with a concave-shaped maximum expiratory curve suggests expiratory muscle weakness in patients with ALS.

Adequate oxygenation is usually well maintained even in those with severe abnormalities in spirometry. Monitoring the arterial blood gas is not useful in the early presentation of ALS. Spirometry, however, is still important in the initial evaluation of ALS patients because impairment in ventilatory function is frequently underestimated even by an experienced examiner.

Noninvasive positive pressure ventilation (NPPV) and an antiglutamate drug, riluzole, have been shown to prolong survival in ALS.

The comprehensive management of the ALS patient should include measures to alleviate symptoms and evaluate the feasibility of specific drug therapy to alter its progressive clinical course. Riluzole, an antiglutamate drug, is FDA-approved for the treatment of ALS. Riluzole is the only treatment that has been shown to prolong survival in ALS or mechanical ventilation by approximately 3 months. It should be given to patients once a diagnosis of ALS is made. Therefore, despite optimal medical therapy, disease progression invariably occurs, resulting in respiratory insufficiency requiring some form of ventilatory assistance. The onset of respiratory failure often signals a rapid decline in global functional status as well. The need for mechanical ventilation should be discussed by the clinician with the patient and family early on in the disease course to prevent a rapid decline in the clinical symptoms of respiratory failure due to a rapid decline in lung function. In a survey of ALS patients, patients with early disease are more receptive to long-term ventilatory support compared to patients with advanced disease. ALS patients who develop respiratory symptoms, or who have a moderate reduction in lung function or a rapid decline in lung function, should be offered noninvasive positive pressure ventilation (NPPV) with techniques such as Biphasic (inspiratory and expiratory) positive airways pressure (BIPAP). In patients who can tolerate NPPV, the risk of death is decreased. In one study, 122 patients with ALS were offered BIPAP therapy once they developed dyspnea, or FVC less than 50%, or a fall of more than 15% in FVC in 3-month follow-up. Those patients who used BIPAP more than 4 h/day not only showed a slower decline in lung function, but also had decreased mortality rates.[9]

Some patients with acute respiratory decompensation may have a slight improvement in respiratory muscle strength after a period of ventilatory assistance. A randomized controlled trial assessed the effect of noninvasive mechanical ventilation versus standard care on survival and quality of life in a cohort of patients with ALS. Ninety-two patients were randomly assigned to noninvasive ventilation or standard care when they developed orthopnea with MIP of <60% or in the presence of hypercarbia. NPPV improved survival and improved the quality of life in patients with no bulbar, or at most, only mild bulbar symptoms.[10] In patients with severe bulbar symptoms, NPPV only improved the quality of life. In the ICU setting, NPPV should be tried first in ALS patients who experience acute-on-chronic respiratory insufficiency especially in the absence of significant bulbar symptoms. Patients with significant bulbar symptoms usually cannot tolerate NPPV because of difficulty handling oral secretions. Theophylline may improve respiratory muscle strength and can be used in the absence

of tachyarrhythmias. In patients with ALS, theophylline improved the negative inspiratory pressure, FVC, and peak inspiratory flow by 28%, 10%, and 12%, respectively.[11]

Phrenic Nerve Injury

Unilateral diaphragm weakness usually does not cause any symptoms. Bilateral diaphragm weakness causes dyspnea that is aggravated by lying down.

Unilateral or bilateral diaphragm weakness can follow phrenic nerve injury. Reported causes of phrenic nerve injury are listed in Table 29-6. In most cases of diaphragm weakness, the exact diagnosis remains elusive. In diaphragm dysfunction following cardiac surgery, phrenic nerve injury occurs secondary to cold exposure and/or to mechanical stretching during surgery.

Cold exposure and mechanical stretching of the phrenic nerve during open heart surgery are the two causes of phrenic nerve injury.

The diagnosis of bilateral diaphragm weakness is often delayed. The symptoms of diaphragm weakness are often nonspecific, and the routine physical findings are insensitive and unreliable. In the absence of parenchymal lung disease or heart failure, dyspnea that is made worse by lying down is an important clue to the diagnosis. The cephalad displacement of the abdominal contents in the supine position further increases the workload of the already weakened diaphragm. Significant diaphragmatic weakness can often be confirmed during physical examination by the presence of thoracoabdominal paradox in the recumbent position and the used of accessory muscles of respiration during tidal breathing.

Unilateral diaphragm weakness, in contrast, is usually well tolerated even if the pulmonary function test (PFT) reveals a mild reduction in FVC and TLC. The diagnosis of unilateral diaphragm weakness is often suspected only after review of a chest radiograph that was ordered for another clinical indication. Extensive workup is usually not warranted unless severe symptoms are present.

Pulmonary function test (PFT) findings in bilateral diaphragm weakness are decreased FVC, RV, and TLC. FVC is reduced by more than 50% from sitting to supine position.

Once the diagnosis of diaphragm weakness is clinically suspected, measurement of respiratory muscle strength and fluoroscopic findings on the sniff test may confirm the diagnosis. On routine pulmonary function testing, bilateral diaphragm paralysis reveals a restrictive ventilatory defect characterized by a decrease in FVC, RV, and TLC. The VC is typically reduced to less than 50% of that predicted in the erect posture and is further reduced in the recumbent posture. In the upright posture, contraction of the abdominal muscles during expiration and relaxation during early inspiration results in an outward motion of the abdomen and facilitates passive descent of the diaphragm. In the recumbent posture, diaphragm function is further impaired by the increase in the inspiratory workload imposed by cephalad displacement of the abdominal viscera. As in any other neuromuscular disease, chronic hypercapnic respiratory failure may be seen in moderate-to-severe bilateral diaphragm weakness.

Elevated unilateral or bilateral diaphragms may be seen on chest X-ray. Diaphragm weakness can be confirmed by visualizing diaphragm movement on the fluoroscopy sniff test or by measuring P_{di}.

Radiographic findings in patients with diaphragm weakness typically show either unilateral or bilateral elevation of the diaphragm, depending on the location of the phrenic nerve injury. However, parenchyma and pleural diseases such as atelectasis, pulmonary fibrosis, subpulmonic fluid collections, or atelectasis may also show the same radiographic picture. A fluoroscopic technique to evaluate diaphragmatic excursion known as the sniff test is helpful to further evaluate the presence of diaphragm paralysis. As described earlier, the paralyzed diaphragm exhibits an upward paradoxical movement into the chest cavity because of the development of negative intrapleural pressures during the sniff maneuver. The sniff test is not useful in the evaluation of bilateral diaphragm paralysis and may result in an apparently false-normal study. A false negative test may result when both hemidiaphragms appear to descend normally during a sniff maneuver, despite profound weakness, due to a sudden relaxation of the abdominal muscles (i.e., passive inspiration). In addition, a positive sniff test should also be interpreted with caution because this can be seen in up to 6% of normal

TABLE 29-6

individuals. Paradoxical diaphragm movement should be at least 2 cm to increase the test's specificity.

The measurement of transdiaphragmatic pressure (P_{di}), despite its limitations discussed earlier (e.g., intersubject variability, invasive procedure, need for full patient cooperation), is useful in the diagnosis and quantitation of diaphragm weakness. Total diaphragm paralysis is diagnosed when there is no pressure difference measured across both sides of the diaphragm ($P_{di} = 0$) during a forced inspiratory maneuver against an occluded airway.

The recovery of diaphragm weakness depends on the etiology. In phrenic nerve injury following cardiac surgery, 80% of patients recover nerve function in 6 months and 90% in 1 year.

Guillain–Barré Syndrome

Guillain–Barré syndrome (GBS) is an acute idiopathic polyneuritis that is usually preceded by a viral illness.

Guillain–Barré syndrome (GBS) is a form of acute demyelinating inflammatory polyneuropathy that usually presents clinically as a rapidly ascending, symmetrical paralysis of the lower extremities, loss of tendon reflexes, mild or absent sensory signs, and autonomic dysfunctions. Involvement of the bulbar and respiratory muscles may lead to swallowing dysfunction, increased risk of aspiration, and respiratory failure. Although the exact etiology is unknown, in approximately 70% of cases an antecedent viral or bacterial infection, 1–4 weeks prior to presentation, can be identified from the history. The current concept suggests that GBS is a self-limited, reactive autoimmune disease in which an aberrant immune response is directed against bacterial lipopolysaccharides that share similar epitopes with the myelin sheath or Schwann cell basement membrane. Viral infections associated with GBS include Cytomegalovirus, Epstein–Barr virus, human immunodeficiency virus, and Varicella-zoster virus. Cytomegalovirus is the most frequently identified viral infection; it has been documented to precede GBS in 11–22% of cases.[12] In such cases, serologic testing may reveal positive anti-CMV immunoglobulin M (IgM) antibody, high serum antibody titers to GM2 gangliosides or to sulfated glycolipids of peripheral myelin. GBS associated with CMV infections has the predilection to affect female and younger patients, and is commonly associated with facial and bulbar palsies, respiratory failure, and severe sensory loss. *Campylobacter jejuni* is the most frequent bacterial infection preceding the diagnosis of GBS. In 23–45% of sporadic cases of GBS, recent *C. jejuni* infections can be documented by serologic testing or bacterial culture. The actual risk of developing GBS following *C. jejuni* is 1 in 1,000, suggesting that host susceptibility plays an important role in the pathogenesis of GBS. Unlike GBS preceded by CMV infection, *C. jejuni* associated GBS often presents as pure motor axonal neuropathy, and seldom involves the cranial nerves. However, it can present as Miller-Fischer syndrome characterized by opthalmoplegia, ataxia, and areflexia. Serum from such patients often contains high titers of antibodies against gangliosides. High serum GQ1b titer is considered pathognomonic of Miller-Fischer syndrome. *Mycoplasma pneumoniae* infection is the second most common cause of bacterial infection linked to GBS occurring in approximately 5% of GBS cases. Some cases of GBS have been linked to influenza vaccination, recent surgery, trauma, and malignancy (lymphoma).

Cytomegalovirus is the most common viral infection linked to GBS. *Campylobacter jejuni* infection is the most common bacterial infection associated with GBS.

CMV-related GBS predominantly affects female and younger patients. Clinical presentation often includes facial and bulbar palsies, respiratory failure, and unusually severe sensory loss.

C. jejuni-related GBS often present with pure motor axonal neuropathy, which often spares the cranial nerves.

The Miller–Fisher syndrome consists of ophthalmoplegia, ataxia, and areflexia.

The symptoms caused by GBS peak 4 weeks after the onset of symptoms.

The clinical signs and symptoms of GBS are shown in Table 29-7. The symptoms typically begin with a sensory phase consisting of numbness and tingling in the fingers, toes, and trunk lasting 7–10 days. Pain over the extremities or flank is commonly reported as a "charley horse," but objective sensory impairment is minimal despite complaints of paresthesias. This stage is classically followed by an ascending pattern of limb weakness progressing from the lower to upper extremities. The extent of motor weakness is variable, ranging from mild paresis to complete paralysis. In 50% of GBS cases, weakness of the lower extremities usually peaks within several days of diagnosis. The muscle weakness usually does not progress beyond 4 weeks. Autoimmune dysfunction is very common. Other variants of Guillain–Barré syndrome with asymmetric involvement of the extremities, presence of ataxia, or the absence of paresthesias have been described. It is important to recognize the Miller–Fisher syndrome (ophthalmoplegia, ataxia, and areflexia), variant of GBS.

Abnormal CSF examinations and nerve conduction studies are confirmatory for the diagnosis of Guillain–Barré syndrome. Cerebrospinal fluid (CSF) examination characteristically

CASE STUDY: PART 3

Initial laboratory examination showed a normal hemogram and routine blood chemistries. Cerebrospinal fluid examination revealed WBC of 4/mm^3, RBC of 0/mm^3, glucose of 55 mg/dL, and protein of 96 mg/dL. EMGs of both lower and upper extremities showed prolonged sensory and motor latencies with decreased conduction velocities. A diagnosis of Guillain–Barré syndrome was made. The patient was admitted to the neurology service and was immediately started on intravenous immunoglobulin. On admission, his FVC was 2.8 L and his PI_{max} was 110 cmH_2O. An arterial blood gas showed a pH of 7.39, $PaCO_2$ of 42 mmHg, PaO_2 of 80 mmHg, and a HCO_2 of 24 mEq/dL. He appeared comfortable, and denied shortness of breath. On the third hospital day, he complained of shortness of breath after going to the bathroom. A repeat FVC was 2.0 L, a notable decrease compared to admission. He was transferred to the ICU.

TABLE 29-7

USUAL CLINICAL SIGNS AND SYMPTOMS OF GUILLAIN–BARRÉ SYNDROME

SYMPTOMS	INCIDENCE(%)
Ascending paralysis of the lower extremities	95
Paresthesias	85
Facial muscle weakness	60
Oropharyngeal muscle weakness	50
Ocular muscle weakness	15
Autonomic dysfunction	65
Cardiac arrhythmia	
Blood pressure lability	
Gastrointestinal dysfunction	
Pupillary dysfunction	
Sweating abnormalities	
Urinary retention	

shows increased CFS fluid protein with a cell count of less than 10 mononuclear leukocytes per cubic millimeter. This CSF finding is commonly referred to as albuminocytologic dissociation. A cerebrospinal spinal fluid cell count of greater than 50 mononuclear cells per cubic millimeter may indicate an associated HIV infection. Other abnormalities include elevated liver enzymes that are observed in 40% of the patients. Because of increased secretion of antidiuretic hormone, hyponatremia is detected in 25% of patients. The clinical significance of the presence of specific antigangliosides is uncertain and routine assessment is not recommended since their presence has no impact on therapy. Nerve conduction studies typically show multifocal demyelination. Slowing of nerve conductions and a partial or complete block of conduction in motor fibers are the cardinal electrophysiologic findings. In later stages of the disease, the signs of axonal degeneration are suggested by reduced amplitudes of motor and sensory compounds' action potentials. The proposed diagnostic criteria for typical Guillain–Barré syndrome are shown in Table 29-8.

Cerebrospinal fluid (CSF) findings in GBS: high protein content with few cells, referred to as albuminocytologic dissociation. EMG findings in GBS show multifocal demyelination.

Acute respiratory failure is one of the well-recognized complications of GBS. In 15–30% of cases of GBS, acute respiratory failure is profound and requires mechanical ventilation. The incidence of acute respiratory failure increases by twofold once respiratory muscle dysfunction is detected and the patient requires ICU care. Other common complications are pneumonia, recurrent aspiration, and pulmonary thromboembolic disease.

Acute respiratory failure occurs in 15–30% of GBS patients.

All patients suspected of having GBS and showing signs of respiratory muscle dysfunction should be transferred to the ICU for closer monitoring. Other clinical indications for admission to the ICU are listed in Table 29-9. Severe weakness of diaphragm force-generating capacity is shown by a marked reduction in maximum transdiaphragmatic pressures during acute ventilatory failure and early recovery from the illness. Serial FVC is the most useful test in predicting the need for mechanical ventilation and should be performed once or twice daily depending on the clinical condition of the patient. Figure 29-5 shows the changes in respiratory function with the progressive decline in FVC and its suggested treatment. Several studies have shown that a FVC of 12–15 mg/kg is a sign of imminent respiratory failure.[13,14] In patients

Indications for ventilatory support in GBS include FVC < 12–15 mL/kg, upper airway dysfunction, and hypoxemia and hypercapnia.

TABLE 29-8

DIAGNOSTIC CRITERIA FOR TYPICAL GUILLAIN–BARRÉ SYNDROME AS PROPOSED BY ASBURY AND CORNBLATH

Features required for diagnosis	Progressive weakness of both upper and lower extremities
	Areflexia
Features strongly supporting the diagnosis	Progression of symptoms over days to 4 weeks
	Symmetry of symptoms
	Mild sensory symptoms or signs
	Cranial nerve involvement, especially bilateral weakness of facial muscles
	Recovery beginning 2–4 weeks after progression ceases
	Autonomic dysfunction
	Absence of fever at the onset
	Elevated protein concentration in CSF with fewer than 10 cells/mL^3
	Typical electrodiagnostic features
Features making the diagnosis doubtful	Sensory level
	Marked, persistent asymmetry of symptoms or signs
	Severe and persistent bladder and bowel dysfunction
	More than 50 cells/mL^3 in CSF
Features excluding the diagnosis	Diagnosis of botulism, myasthenia, poliomyelitis, or toxic neuropathy
	Abnormal porphyrin metabolism
	Recent diphtheria
	Purely sensory syndrome without weakness

TABLE 29-9

CLINICAL INDICATIONS FOR ADMISSION TO THE ICU IN PATIENTS WITH GUILLAIN–BARRÉ SYNDROME

C	Conduction block, bradycardia, asystole
R	Rapid progression of motor weakness
I	Infection
T	Tachyarrhythmias
I	Intensive care monitoring of respiratory and autonomic dysfunction
C	Complications of critical illness: pulmonary embolism, myocardial infarction
A	Airway: ventilatory failure, bulbar weakness
L	Labile blood pressure: hypertension/hypotension

The word "critical" is used as a mnemonic for the different indications

who develop respiratory failure due to Guillain–Barré syndrome, FVC measured serially decreased from a mean of 2.5–0.9 L within 2 weeks. In a recent study of 81 GBS patients who required mechanical ventilation, the average FVC at the time of intubation was 33 ± 11%.[13] Other indications for intubation and ventilatory support include respiratory distress, inability to handle oral secretions, hypoxemia ($PaO_2 < 70$ mmHg on room air or alveolar–arterial O_2 difference >300 mmHg while inspiring 100% oxygen), and hypercapnia. Blood gas analysis is used to ensure adequate oxygenation and ventilation. Hypercapnia is a late sign of ventilatory failure and should not be relied upon as an indication for when to start mechanical ventilation. The average $PaCO_2$ at the time of intubation when FVC is less than 12 mL/kg was 43 mmHg in two large series of GBS patients.[13] Other predictors of the need for mechanical ventilation include time between onset of disease and hospital admission of ≤7 days, inability to lift head, presence of bulbar dysfunction, and the presence of anti-GQ1b antibodies.[15-18] A recent study suggests that neurophysiological testing is helpful in predicting the need for mechanical ventilation. Of the 154 patients included in this study, patients with the demyelinating form of GBS required mechanical ventilation more often than patients with axonal or equivocal findings on electrophysiology.[19] The risk of acute respiratory failure was only 2.5% if the proximal/distal compound muscular amplitude potential (p/dCMAP) ratio was >55.6% and a forced vital capacity was >81%.

CASE STUDY: PART 4

In the ICU, the patient was started on subcutaneous heparin for prophylaxis against deep venous thrombosis. Daily range-of-motion exercises were also performed to prevent the development of limb contractures. Over the next 2 days in the ICU, the patient's FVC decreased further, to 1.5–1.6 L (weight, 100 kg). In addition, his limb weakness continued to worsen despite repeated plasma infusions. He was now unable to get out of the bed without nursing assistance. His chest x-ray showed bibasilar atelectasis and mild pulmonary vascular congestion. Because of his continued clinical deterioration and chest radiographic findings of fluid overload, the plasma infusion was stopped and plasmapheresis was initiated. On the third hospital day, he was noted to have a nasal voice and complained of difficulty in swallowing liquids. A repeat arterial blood gas showed a pH of 7.35, $PaCO_2$ of 45 mmHg, PaO_2 of 70 mmHg, and HCO_2 of 22 mEq/dL. He was electively intubated and placed on mechanical ventilation.

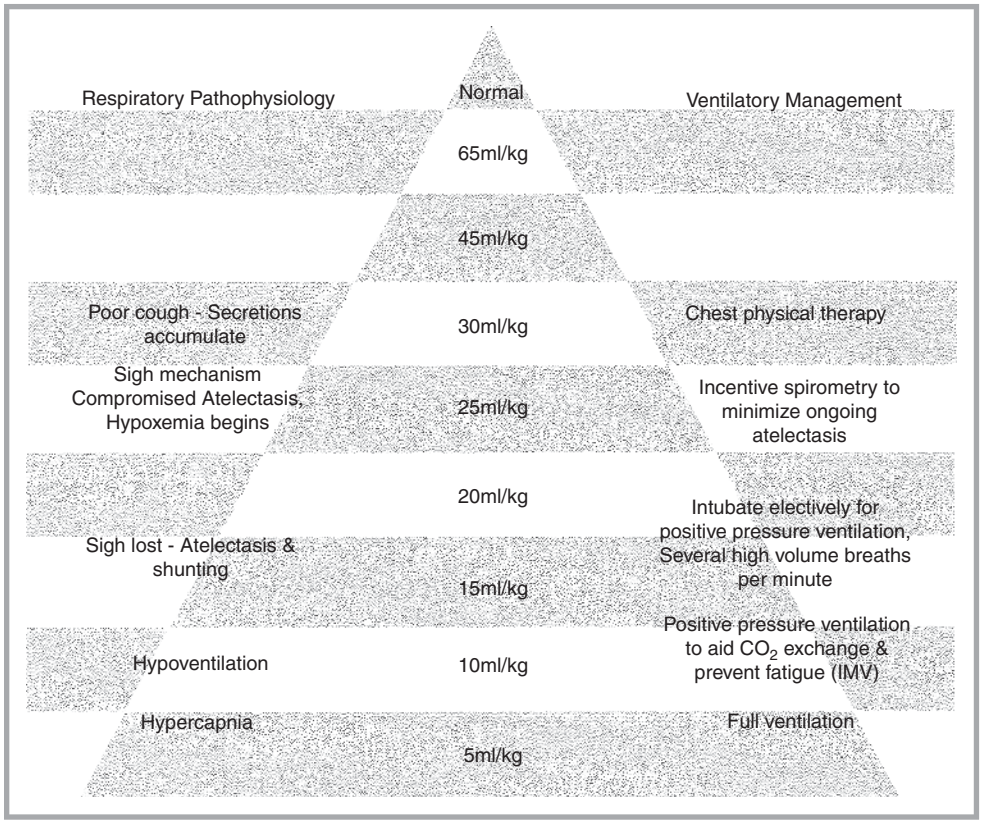

FIGURE 29-5

Progressive decline in forced vital capacity (FVC) due to respiratory muscle weakness in patients with acute or chronic progressive neuromuscular disease is reflected in a similar decline in respiratory system function. Serial FVC can be used to institute timely intervention to avert or delay the onset of respiratory failure.

Upper airway dysfunction due to bulbar muscle dysfunction in GBS may cause inability to swallow oral secretions and increase the risk for pulmonary aspiration. Clinical signs of bulbar muscle dysfunction such as a nasal voice, abnormal gag reflex, dysarthria, and poor mobility of pharyngeal muscles must be sought frequently. In addition, swallowing dysfunction can be assessed at the bedside by asking the patient to drink sips of water and observe for the temporal occurrence of coughing. Early intubation may be necessary to protect the airway even if respiratory muscle strength is still adequate. A recent study suggested that delaying intubation may increase the risk of early onset of pneumonia.[15]

Weaning may be started once FVC exceeds 8–10 mL/kg, adequate oxygenation is achieved with a FiO_2 of 40% or less, and patients are able to double their minute ventilation. The maximum negative inspiratory force at the time of successful weaning is usually greater than 40 cmH_2O. The average duration of mechanical ventilation in two large series was 50–55 days.[13] Some patients may require tracheostomy because of the need for prolonged mechanical ventilation and pulmonary toilet. In patients who have shown a favorable

CASE STUDY: PART 5

On the sixth ICU day, the patient showed signs of motor strength recovery. Both hip and knee flexion and extension were 4/5. Similar increases in muscle strength were observed in his upper extremities. Weaning parameters showed FVC of 2.2 L, maximum negative inspiratory pressure of 38 cmH_2O, and a minute ventilation of 6 L/min. He was successfully extubated after 2 h of a T-piece weaning trial. He was transferred from the ICU the following day without further incident.

response to treatment, tracheostomy may be delayed for up to 10 days in an attempt to avoid the procedure in patients who rapidly improve.

Aggressive pulmonary toilet is indicated to prevent as well as treat atelectasis. Atelectasis may require repeated bronchoscopy and may decrease the incidence of nosocomial pneumonia. Bulbar involvement increases the risk of aspiration pneumonia. In a study of 81 GBS patients who required mechanical ventilation, 78% developed pneumonia that was largely attributed to aspiration.[15] Subcutaneous heparin is the preferred therapy for deep venous thrombosis prophylaxis when compared to pneumatic boots, which may lead to prolonged foot drop secondary to compression of the peroneal nerve.

Autonomic dysfunction can occur in 65% of patients with GBS. Common manifestations of autonomic dysfunction include labile blood pressure, sinus tachycardia, excessive sweating, urinary retention, and ileus. Autonomic dysfunction is commonly prevalent in patients who required mechanical ventilation and during the progressive and plateau phases of the illness. Particular care should be observed during endotracheal suctioning since it can precipitate tachy and brady-arrhythmias and even asytole from vagal stimulation. Moreover, patients may be overly sensitive to vasoactive medications. Management of severe ileus includes bowel rest and therapeutic trials with erythromycin or neostigmine. The use of promotility agents is contraindicated in patients with dysautonomia.

Treatment for GBS: supportive care, ventilatory support, and intravenous immunoglobulin or plasmapheresis.

Immune modulation using either plasma exchange or intravenous immune globulin infusion is the mainstay of therapy in GBS.[20-23] In two multicenter trials,[21,22] plasmapheresis using either albumin or fresh-frozen plasma (50 mL/kg, given on five separate occasions in course of 2 weeks) as replacement fluids showed short-term benefits in early motor recovery and ambulation, reduced the number of patients who required assisted ventilation, and shortened the duration of mechanical ventilation. Immunotherapy should be started within 2 weeks of the onset of symptoms or as early as possible. However, in patients with rapidly deteriorating clinical symptoms, plasmapheresis may still offer some benefits even if the duration of the disease is greater than 3 weeks. In approximately 10% of patients, relapse of neurologic symptoms may follow plasma exchange treatment due to antibody rebound. In such circumstances, additional plasma exchange treatment or intravenous immunoglobulin treatment is helpful. Intravenous immunoglobulin (IVIG) (usually given at a dose of 2 g/kg divided over 2–5 days) given within 2 weeks is as effective as plasma exchange therapy. Since IVIG is easier to administer, it is preferred over plasma exchange unless there are specific contraindications to its use such as low serum immunoglobulin, a presence of uncontrolled hypertension, and a hyperosmolar state. There is no additional benefit conferred by sequential treatment, consisting initially of plasmapheresis followed by IVIG, when compared to either treatment alone.[24] Corticosteroids alone confer no therapeutic benefit and may slow recovery in GBS; it is not recommended.[25] The combination of IVIG and intravenous methylprednisolone may hasten recovery, but there has been no documented beneficial effect on the long-term outcome.

Factors that are associated with a poor prognosis in GBS include older age, mean compound muscle action potential amplitudes < 20%, need for ventilatory support, and rapid progression of symptoms.

With the advent of modern ICU care, mortality from GBS has decreased from 15% in the 1970s to 3–4% in the 1980s. Prognosis is good, but a minority of patients will have no neurologic residual; 50–65% of patients will have persistent mild neurologic dysfunction such as mild distal weakness or numbness. Factors associated with poor prognosis are age greater than 60 years, mean compound muscle action potential amplitudes from distal stimulation less than 20% of normal, need for ventilatory support, and rapid progression to severe weakness (less than 1 week).

Critical Illness Polyneuropathy and Neuromyopathy

Critical illness polyneuromyopathy (CIPNM) is the most common cause of acquired neuromuscular weakness in both surgical and medical ICU patients. The incidence of CIPNM depends on the severity of illness, the diagnostic criteria used, and the timing of examination from the onset of the critical illness. In prospective studies, 25–63% of patients who required mechanical ventilation for at least 7 days developed CIPNM.[26,27] Patients with sepsis and sepsis syndrome have the highest incidence of CIPNM and it approaches 70–100%.[28] Axonal polyneuropathy was initially thought to be the main pathologic changes in ICU-acquired weakness. However, electromyography (EMG) and muscle biopsy studies showed that acute myopathy coexists with polyneuropathy, and in fact, often exists as separate clinical entity. Accordingly, CIPNM is divided into four categories, namely critical illness myopathy, critical illness polyneuropathy, neuromuscular junction abnormalities, and combined polyneuromyopathy[29] (Table 29-10). In a prospective study of 30 patients with critical illness polyneuropathy, biopsy of the quadriceps femoral muscle showed neuropathic changes in 37%, myopathy in 40%, and both neuropathic and myopathic changes in 23% of patients.[30] Muscle necrosis was also present in 30% of the muscle biopsies specimen.

Critical illness polyneuropathy is the most common cause of muscle weakness in the ICU. Acute myopathy and acute axonal polyneuropathy, or the combination of both, are often present in patients with critical illness polyneuropathy.

Sepsis and sepsis syndrome is an important risk factor of critical illness polyneuropathy.

Several risk factors commonly encountered in the ICU setting have been identified in the development of CIPNM. These include severe systemic inflammation especially due to sepsis, sepsis syndrome, multisystem organ failure, use of corticosteroids and neuromuscular blocking agents, hyperglycemia and hyperosmolality, immobility, use of aminoglycosides, and duration of mechanical ventilation. Indices that measure the severity of critical illness, such as the Acute Physiology, Age, and Chronic Health Evaluation (APACHE) III, or the Sequential Organ Failure Assessment Score (SOFA), are also important predictors of the occurrence of CIPNM.[31] The detrimental effect of hyperglycemia on neuromuscular function is supported by a recent study showing that intensive insulin therapy to maintain normoglycemia (blood glucose levels between 80 and 110 mg/dL) decreases the incidence of critical illness polyneuropathy by 44% compared to conventional insulin therapy (blood glucose level between 180 and 200 mg/dL).[32-35] In addition, the cases of CIPNM in the intensive insulin treatment group resolved faster. The risk of CIPNM was linearly correlated with the mean blood glucose level. In multivariate analysis, independent predictors of polyneuropathy include conventional insulin treatment (odds ratio 2.6; 95% confidence interval 1.6–4.2), vasopressor support of more than 3 days (odds ratio 2.5; 95% confidence interval 1.4–4.2), bacteremia (odds ratio 2.3, 95% confidence interval 1.3–4.1), and dialysis (odds ratio 1.9, 95% confidence interval 1.0–3.8). Similarly, intensive insulin therapy decreased the incidence of CIPNM in patients who required mechanical ventilation for more than 7 days in the medical ICU compared to conventional treatment with an absolute risk reduction of –11.6%. Moreover, the cumulative risk of CIPNM over time was also significantly reduced compared to conventionally treated patients, partially explaining the decrease in the duration of mechanical ventilation.[36]

Insulin therapy to control hyperglycemia to euglycemic levels can decrease the risk of critical illness polyneuropathy.

Sepsis and multisystem organ failure are the two most common causes of acquired acute weakness syndrome in the ICU.

The pathogenesis of CIPNM is not well understood. Since the systemic inflammatory response and multisystem organ failure almost always precedes CIPNM, an exaggerated immune response to injury is thought to be the main pathogenic pathway leading to nerve and muscle injury. The resulting unmitigated systemic and local inflammatory response, in

Axonal degeneration of the motor and sensory nerves, loss of muscle contractile (myosin) proteins, and muscle membrane inexcitabilty are the pathophysiologic changes in CIPNM.

TABLE 29-10

ACUTE WEAKNESS SYNDROME IN THE ICU: CRITICAL ILLNESS NEUROMYOPATHY

Myopathy	Acute necrotizing myopathy
	Cachectic
	Acute rhabdomyolysis
	Thick filament (myosin) loss
Neuromuscular junction abnormalities	Myasthenia-like syndrome
	Prolonged neuromuscular blockade
Neuropathy	Critical illness
	Polyneuropathy
	Acute motor neuropathy
Polyneuromyopathy	Combination of neuropathy and myopathy

particular, the release of tumor necrosis factor alpha, interleukin 1 and 12, and the recruitment of T-helper 1 cells, monocyte, macrophages, and neutrophils, leads to endothelial cell injury. This causes increased microvascular permeability and endoneural edema that decreases blood flow to the nerve and muscle tissue. The end result of this inflammatory cascade is primary axonal degeneration of the sensory and motor fibers and muscle atrophy with loss of contractile proteins and membrane inexcitability. An animal model of sepsis showed that sepsis triggers enhanced muscle protein proteolysis through the ubiquitin-proteosome and calpain system causing myofibillar degradation and disruption of the sarcomere. Recent studies suggest that critical illness myopathy is not only due to selective myosin loss, but also due to muscle fiber membrane electrical inexcitability caused by defective sodium channel regulation.[37] Animal models of critical illness myopathy reveal altered membrane expression and function of the sodium channels.[38]

Critical illness polyneuropathy should be suspected in patients who fail weaning from mechanical support, develop areflexic limbs weakness, or have a complicated ICU course as a result of sepsis.

The syndrome is often initially suspected because of distal symmetrical muscle weakness seen after 5–7 days of mechanical ventilation in awake patients, or in those patients who are difficult to wean from mechanical ventilation. These patients usually have no prior history of neuropathy or myopathy. The muscle weakness is most prominent in the lower extremities and is accompanied by muscle wasting and reduced or absent tendon reflexes. Facial muscle weakness, presence of asymmetrical weakness of the limb, or pyramidal signs should prompt further workup to rule out other neurologic causes of weakness. Assessment of peripheral muscle strength can be difficult because of sedation, delirium, or the presence of metabolic encephalopathy. Nevertheless, if motor strength assessment is possible, a standardized muscle examination can be used to assess the degree of weakness in individual muscle groups. The Medical Research Council (MRC) Scale for muscle examination includes strength assessment of three different muscle groups on each limb and ranks them on a scale from 0 to 5 as seen in Table 29-11.[23] The MRC score is easy to use, and reproducible even in mechanical ventilated patients. Three muscle functions are evaluated in the upper and lower limbs. Each function score ranges from 0, which denotes no detectable movement, to 5 denoting normal power. The total score ranges from 0 to 60. A score of less than 48 reflects significant weakness.

Symmetrical muscle weakness without facial weakness in an awake patient who has been on mechanical ventilation for more than a week is a common clinical presentation of CIPNM.

Electrodiagnostic testing is useful in confirming the diagnosis of CIPNM, and in detecting the presence of combined myopathy and polyneuropathy. Muscle necrosis and atrophy of type 1 muscle fibers are commonly seen on muscle biopsy.

The diagnosis of CINM can often be made based on typical clinical presentation. Nerve conduction studies and electromyography are useful in detecting the presence of sensorimotor axonal polyneuropathy and associated myopathy. In axonal polyneuropathy, ENMG testing shows a reduction in the amplitude of the compound action potential with normal conduction velocity on motor nerve stimulation, and spontaneous electrical activity on muscle needle recording. This EMG pattern can be seen in 70–100% of ICU with severe sepsis and after 5–7 days of mechanical ventilation. A myopathic pattern on ENMG is suggested by the presence of a prolonged compound muscle action potential and a short duration and low amplitudes of motor unit potentials on voluntary activation. Creatine phosphokinase levels (CPK) are either normal or slightly elevated in CIPNM. Muscle and nerve biopsy can be used to confirm the diagnosis, but are not routinely indicated. Muscle biopsy usually

EMG is the ancillary test of choice to confirm the diagnosis of critical care polyneuropathy and to exclude other causes of weakness. The EMG finding in critical illness polyneuropathy (CIP) is primary axonal polyneuropathy.

TABLE 29-11

MRC SCALE FOR MUSCLE EXAMINATION

Functions assessed
Upper extremity: wrist flexion, forearm flexion, shoulder abduction
Lower extremity: ankle dorsiflexion, knee extension, hip flexion
Score for each movement
0 – No visible contraction
1 – Visible muscle contraction, but no limb movement
2 – Active movement – but not against gravity
3 – Active movement against gravity
4 – Active movement against gravity and resistance
5 – Active movement against full resistance
Maximum score: 60 (four limbs, maximum of 15 points per limb) Normal
Minimum score: 0 (quadriplegia)

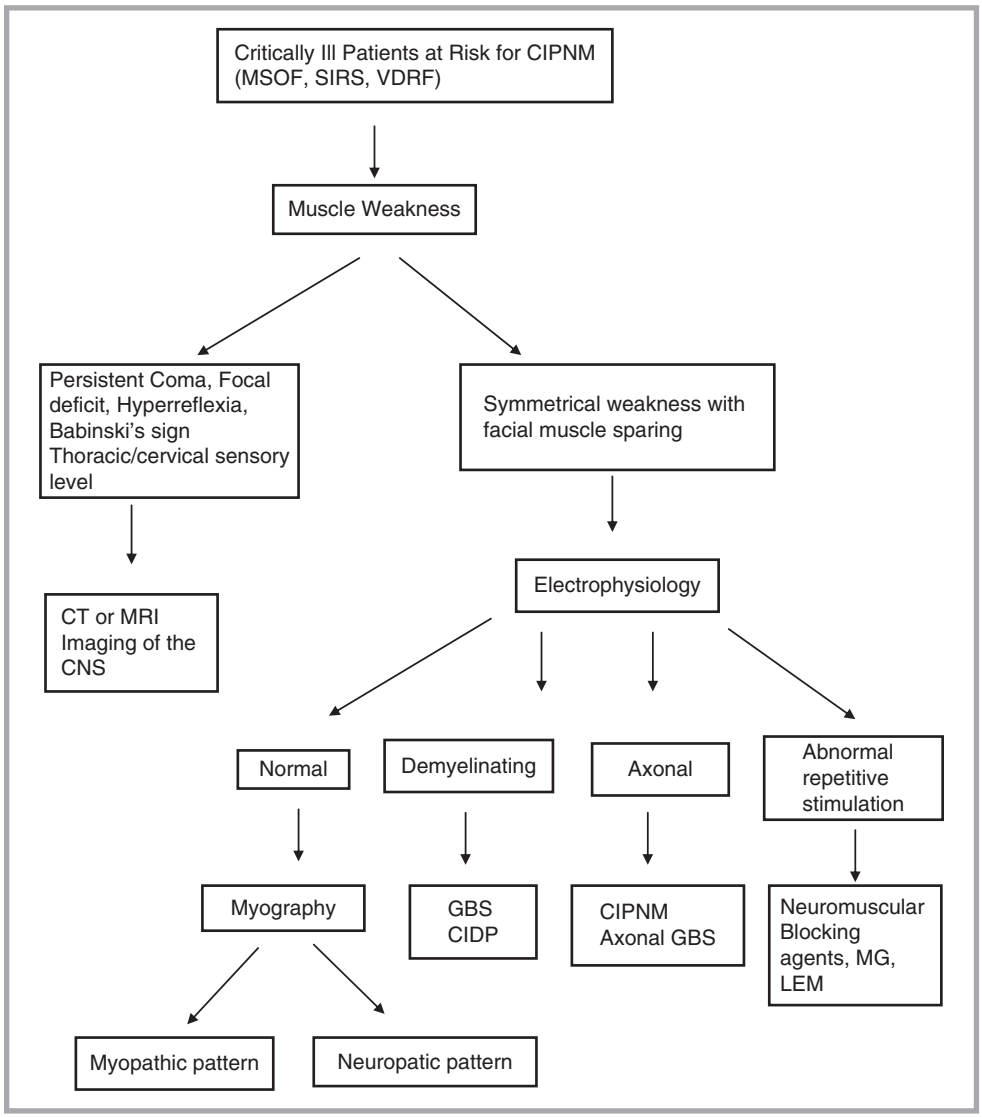

FIGURE 29-6

Diagnostic approach to patients with acquired muscle weakness in the intensive care unit. *MSOF* multisystem organ failures; *SIRS* systemic inflammatory response; *VDRF* ventilator dependent respiratory failure; *GBS* Guillian–Barre syndrome; *CIDP* chronic inflammatory demyelinating polyneuropathy; *CIPNM* critical illness polyneuromyopathy; *MG* myasthenia gravis; *LEMS* Lambert–Eaton myasthenia syndrome.

shows type II fiber atrophy and occasionally type I atrophy and muscle necrosis. Immunohistochemistry and electron microscopy show a loss of myosin thick filaments. In the right clinical setting, extensive neurologic testing or biopsy of the nerve or muscle are not required to make a confident diagnosis of CIPNM. A diagnostic algorithm for the diagnosis of ICU-acquired weakness is shown in Figure 29-6.

The differential diagnosis of muscle weakness in the ICU setting encompasses multiple central nervous system pathologies, including head and spinal cord injury. In acute spinal injury, spinal shock may cause quadriparesis and areflexia mimicking polyneuropathy. Muscle weakness associated with ptosis and bulbar weakness suggest neuromuscular junction diseases such as myasthenia gravis. Axonal variants of the Guillain–Barré Syndrome are distinguished by the presence of weakness before admission to the ICU, a preceding history of *Campylobacter jejuni* infection and positive serologic test for anti-GM1 or anti-GD1a antibodies. Prolonged use of neuromuscular blocking agents, especially in the presence of hepatic and renal failure, can lead to persistent neuromuscular blockade due to delayed clearance of the drugs (see Chap. 58).

Primary neurologic diseases that can mimic CIPNM include acute spinal injury, myasthenia gravis, axonal variants of Guillain–Barre syndrome, and prolonged neuromuscular blockade due to delayed clearance of neuromuscular agents.

Since there is no specific treatment for CIPNM, avoidance of recognized risk factors is important in decreasing the incidence and morbidity and mortality associated with this disease process. Preventive measures include tight blood glucose control, avoidance or minimization of corticosteroids and/or neuromuscular blocking agents, early mobilization and

ICU management strategies that may decrease the risk of CIPNM include tight blood sugar control, minimization of corticosteroids and/or neuromuscular blocking agents, early physical therapy, and daily interruption of sedation.

physical therapy, and the institution of a daily interruption of sedation to avoid sedation-related immobilization.

CIPNM increases duration of ICU and hospitalization length-of-stay, and time on mechanical ventilation. Clinical recovery of muscle function may be prolonged and incomplete.

For those patients who survive the acute phase of their injury, CIPNM prolongs the ICU and hospital length-of-stay, prolongs the duration of mechanical ventilation, and increase the mortality.[39,40] Critical illness neuromyopathy is an independent predictor of prolonged weaning. Clinical recovery of nerve function is often prolonged and is usually associated with residual weakness that causes persistent functional impairment. In a cohort of 100 ARDS patients followed for 1 year, muscle wasting and weakness were the most significant extrapulmonary complications that contributed to persistent functional impairment.[41] The detrimental effect of CIPNM on long-term outcome is best shown by a composite review of 36 studies involving 263 patients.[42] Complete functional recovery occurred in 68% of patients; however, persistent neurologic deficits in the form of absent or reduced deep tendon reflexes, glove and stocking sensory loss, muscle atrophy, painful hyperesthesia, and persistent severe disability due to quadriparesis, quadriplegia, or paraplegia occurred in 28% of patients.

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disease characterized by impaired transmission of neural impulses across the neuromuscular junction due to the destruction of the postsynaptic acetylcholine receptors. It is the most common neuromuscular transmission disorder with an estimated incidence of 10–20 cases per million people and a prevalence of 100–200 per million. In the U.S., approximately 18,000 people are affected. Younger women of child bearing age are affected twice as frequently as men. Thymic tumors are seen in 10% of cases, mostly in older men.

Ocular, facial, and neck muscles are all commonly involved in myasthenia gravis. Respiratory muscle weakness may occur as the primary symptom.

The disease is recognized clinically as fluctuating weakness of the ocular, bulbar, limb, and respiratory muscles. The most common clinical presentation in 50% of the patients is weakness in extraocular muscles manifesting initially as ptosis and diplopia. This is recognized as the ocular form of the disease. In the generalized form of the disease, variable involvement of bulbar, limb, and respiratory muscles also occurs. Bulbar muscle weaknesses such as dysarthria, dyaphagia, and fatigable chewing are the initial presenting symptoms in 15% of cases. Approximately 50–60% of patients with the ocular form of the disease develop generalized weakness involving the oropharyngeal muscles, diaphragm, other respiratory muscles, and limbs, within the first 2 years of the onset of symptoms. Respiratory muscle weakness is seen in one third of patients and may occur in the absence of peripheral muscle weakness. On physical examination, fatigability of the involved muscles can be elicited by asking the patient to do repetitive or sustained muscle activity such as looking upward for several minutes elicits lid or ocular muscle weakness.

Weakness due to myasthenia gravis is characterized by progressive weakness during repetitive use of a particular muscle group and by improvement of strength with rest.

The Tensilon test is a simple test that can be done at the bedside to confirm the diagnosis of myasthenia gravis. Tensilon (edrophonium) is a short-acting inhibitor of acetylcholinesterase and can be given intravenously to elicit a transient improvement in muscle weakness. A positive Tensilon test highly suggests myasthenia gravis, but a positive test has also been reported in patients with Lambert–Eaton syndrome, botulism, and ALS. In patients with moderately generalized myasthenia gravis, pulmonary function testing reveals a mild reduction in FVC and a moderate reduction in both inspiratory and expiratory strength, indicating respiratory muscle weakness. Treatment with pyridostigmine, both available in IV and tablet formulation, may improve FVC, MIP, and MEP, although respiratory muscle strength does not normalize. As in other chronic neuromuscular diseases, the breathing pattern is rapid and shallow. Arterial blood gas examination is frequently normal even with severe impairment of transdiaphragmatic pressures (P_{di}). Arterial blood gases are, therefore, not useful in monitoring the severity of respiratory muscle dysfunction.

Diagnosis of myasthenia gravis: abnormal tensilon test, acetylcholine receptor antibodies, and abnormal EMG.

Pulmonary function testing in moderately advanced myasthenia gravis shows a decrease in forced expiratory flow rates, maximum static inspiratory pressures, and normal gas exchange by arterial blood gas testing.

A serologic test may also be used to support the diagnosis of myasthenia gravis. Antibodies to acetylcholine receptors are seen in 80% of patients with generalized myasthenia and 60% with ocular myasthenia. The concentration of the acetylcholine receptor antibodies does not correlate with the severity of disease. Acetylcholine receptor antibodies have been found in Lambert–Eaton syndrome and in systemic lupus erythematosus. Recent studies showed that the presence of antimuscle specific kinase (MuSK) antibodies identifies a subgroup of

patients with myasthenia gravis who have a higher incidence of bulbar weakness (100% vs. 58%) and respiratory failure (46% vs. 7%) compared to seronegative patients.[43,44] Moreover, greater involvement of the respiratory muscles was also reported in patients who tested positive for antimuscle specific kinase.

Electrodiagnostic EMG studies are nonspecific for myasthenia gravis, but a decrease of 10–15% in the amplitude of the action potential during slow repetitive nerve stimulation is seen in 77% of myasthenic patients. Single-fiber EMG is abnormal in 92% of the patients and is thought to be the most sensitive test, even in patients with a negative serum antibody against acetylcholine receptor or a normal repetitive nerve stimulation test.

Causes of myasthenic crisis: discontinuation of the anticholinergic drugs, surgery, neuromuscular blocking drugs, and emotional crisis.

Myasthenic crisis is defined as an exacerbation of myasthenia gravis leading to respiratory failure that necessitates the use of mechanical ventilation or the need for prolonged mechanical ventilation after surgery. Approximately 15–20% of myasthenia gravis patients will experience myasthenic crises, often within the first year of illness. Thymomas are associated with a more fulminate course of MG and are present in one third of patients who experienced myasthenic crises. Acute respiratory failure has been reported as the initial presentation of MG.[45] The most common causes of myasthenic crises are respiratory infections (including aspiration) and surgery. Other precipitating factors include discontinuation or decreased dosage of anticholinergic or immune modulating medications, or the administration of new medications that precipitate MG. Commonly used medications such as corticosteroids, aminoglycosides and fluoroquinolones class of antibiotics, neuromuscular blocking agents, and neuropsychiatric drugs may precipitate myasthenic crises and should be avoided if possible. The initiation of corticosteroid therapy can paradoxically cause a transient increase in muscle weakness during the first or second week of therapy, especially in patients with severe bulbar symptoms and generalized myasthenia gravis. Cholinergic crisis due to excessive dosing of an anticholinesterase medication can mimic myasthenic crisis; this is thought to be due to a depolarization blockade at the neuromuscular junction. Other clinical signs of cholinergic crisis that are not present in myasthenic exacerbations include the presence of muscarinic symptoms such as miosis, hypersalivation, increased bronchial secretions, bradycardia, gastrointestinal symptoms (abdominal cramps, nausea, vomiting, and diarrhea), sweating, and muscle fasciculation. The Tensilon test has been used routinely in the past to differentiate myasthenic from cholinergic crises. However, this practice is currently not recommended because of the potential for respiratory arrest due to cholinergic weakness and increased secretions and mucus plugging, especially in patients with renal insufficiency. Moreover, it is now common practice to avoid dose escalation of cholinergic agents during myasthenic crises, to discontinue the use of cholinesterase inhibitors following intubations, and to reduce muscarinic complications.

Cholinergic crisis is a worsening of the neurologic symptoms of myasthenia gravis due to an excess of anticholinesterase medications.

Clinical predictors of postoperative respiratory failure in myasthenia gravis include: bulbar muscle involvement and low vital capacity.

Surgery, particularly thymectomy, is a recognized cause of myasthenic crises. In a series of 22 patients, the mean duration of mechanical ventilation was 8 days, with 6 patients (32%) requiring tracheostomy for prolonged mechanical ventilation.[46] Postoperative monitoring is important because respiratory failure occurs within 24 h of surgery in more than 50% of patients. In a series of 14 of 122 patients who developed respiratory failures following trans-sternal thymectomy, independent predictors of postoperative myasthenic crises causing acute respiratory failure included preoperative bulbar symptoms, higher serum levels of acetylcholine receptor antibodies (>100 nmol/L), and intraoperative blood loss.

Respiratory complications of myasthenia gravis include: acute respiratory failure, upper airway obstruction, and sleep-related breathing disorders.

Serial measurements of FVC, maximum static respiratory pressures, and MVV are helpful in detecting significant respiratory muscle involvement and identifying patients at risk of acute respiratory failure. Both maximum static pressures and MVV correlated with clinical worsening of myasthenia gravis in a relatively stable outpatient setting. The dosing schedule of anticholinesterase medications will affect the measurement of these respiratory parameters. The maximum improvement in respiratory muscle strength occurs about 2 h after the drug is given and slowly declines until the next dose is given. Consequently, FVC, PI_{max}, and PE_{max} should be measured 30 min before the next dose of anticholinesterase agents. When FVC is below 15 mL/kg and the maximum static respiratory pressures are less than ±30 cm, assisted ventilation is likely required. No single respiratory parameter reliably predicts the need for mechanical ventilation. Other clinical signs of impending respiratory failure include upper airway obstruction due to vocal cord paralysis or the inability to handle oropharyngeal

secretions due to severe bulbar involvement. Flow–volume loops may show variable extrathoracic airway obstruction with the characteristic inspiratory plateau. Bilateral basal atelectasis on chest radiograph signifies poor clearance of airway secretions due to a weak cough and is often accompanied by a rapid shallow breathing pattern. Hypercapnia is a late sign of respiratory muscle fatigue.

Treatment of myasthenia gravis includes: anticholinesterase agents, corticosteroids, plasmapheresis, intravenous immunoglobulin infusion, and thymectomy.

Treatment of myasthenia gravis includes anticholinesterase agents, high-dose corticosteroids, immunosuppressive medications such as azathioprine and mycophenolate, and cyclosporine as corticosteroid sparing agents. Anticholinesterase agents are the first line of treatment. Although anticholinesterase agents do not alter the natural course of the disease, most patients improve significantly with this treatment, but only a few patients regain normal function. Remission can be induced in up to 80% of patients with corticosteroids. However, initiation of corticosteroids therapy may cause temporary worsening of muscle weakness, usually on the 6th to 10th day of therapy. Thymectomy has also been shown to improve survival and clinical symptoms in patients with myasthenia gravis compared to patients who were treated medically, even in the absence of thymoma. Thymectomy can lead to clinical improvement and myasthenia gravis remission even in the absence of thymoma. Thymectomy is indicated in young patients (<55 years old) and in patients with thymoma because of the risk of malignant transformation. Because there are no randomized controlled studies documenting the benefit of thymectomy in myasthenia gravis, and given the presence of confounding variables such as age, gender, and severity of myasthenia gravis, the American Academy of Neurology recommends thymectomy in patients with nonthymomatous autoimmune myasthenia gravis only as an option to increase the probability of remission or improvement.

In patients with myasthenic crisis, plasmapheresis or intravenous immune globulin (IVIG) are effective short-term treatments and help to prepare the symptomatic myasthenia patient for surgery. Plasmapheresis is usually performed every other day utilizing exchanges of 2–3 L; a total of 5–6 exchanges is normative. Improvement in muscle strength is usually apparent in 2–3 days, but the improvement does not continue beyond several weeks unless immune suppressant agents are administered concurrently. Intravenous immune globulin given at 1.2–2 g/kg over 2–5 days has also been shown to result in a clinical response comparable to plasmapheresis.[47] However, in a retrospective multicenter study of patients with myasthenic crises, plasmapheresis increased the ability to extubate the patient and improved the patient's functional status at 2 weeks.[48]

Plasmapheresis and IVIG are the treatments of choice in myasthenic crises. NPPV is useful in early acute respiratory failure.

Plasmapheresis has a higher rate of cardiovascular and infectious complications compared to IVIG. Intravenous immune globulin infusion is an alternative treatment if plasmapheresis cannot be initiated because of vascular access problems or cannot be tolerated because of hemodynamic instability. Immunosuppressant medications are not appropriate therapy in myasthenic crises because a therapeutic response is often delayed for weeks to months. Corticosteroids have been used in patients who were refractory to plasmapheresis or IVIG; however, steroids may cause a transient worsening of muscle weakness. Corticosteroids and cholinesterase inhibitors are best started several days after a clinical response to plasmapheresis is observed, in order to avoid weakness due to corticosteroids and to avoid cholinergic crises.

Acute respiratory failure in patients with myasthenia gravis is usually treated with invasive mechanical ventilation. Noninvasive mechanical ventilation is an alternative ventilatory strategy in patients with severe myasthenia crises with early respiratory failure even in the presence of bulbar symptoms. In a retrospective study of 60 episodes of acute respiratory failure in 52 patients, bilevel positive airway pressure (BiPAP) and invasive mechanical ventilation were the initial method of ventilatory support in 24 and 36 episodes acute respiratory failure, respectively. In the BiPAP group, 14 (58%) were successfully treated with BiPAP alone and 10 eventually required invasive mechanical ventilation.[49] The use of BiPAP avoids the need for airway intubation, decreases the duration of mechanical ventilation, and decreases both ICU and hospital length-of-stay. The only predictor of failure of using NPPV to initially treat respiratory failure in MG was a $PaCO_2$ of >45 mmHg. Thus, NPPV should be used early in acute respiratory failure before the onset of hypercapnia. In patients who required invasive ventilatory support, aggressive respiratory management including the use

of sighs, positive end expiratory pressure, frequent suctioning, chest physiotherapy, turning in bed, and the use of antibiotics decreased the prevalence of both atelectasis and bronchopneumonia.[50] Weaning trials can be initiated once an improvement in respiratory status is documented. This includes a maximum inspiratory pressure (MIP) < −20 cmH_2O, maximum expiratory pressure > 40 cmH_2O, and FVC > 10 mL/kg.[51] In a retrospective study of 46 episodes of acute respiratory failure due to myasthenia gravis, extubation failure defined as the need for reintubation, or tracheostomy and death while on the ventilator occurred in 44% of cases. Risk factors associated with extubation failures include male sex, history of previous myathenic crises, atelectasis, and >10 days of mechanical ventilation. The FVC (16 vs. 19 mL/kg, $p = 0.32$), MIP (−46 vs. –56 cmH_2O, $p = 0.43$), and MEP (41 vs. 54, $p = 0.14$) were lower in patients who failed extubation, but were not statistically different compared to patients who were successfully extubated. Those patients who had lower pH, lower FVC, the presence of atelectasis, and the need for BiPAP support had a higher risk for reintubation.[52] These data suggest that other factors such as respiratory muscle fatigue, the presence bulbar weakness, and the inability to handle upper airway secretions are not measured by standard weaning parameters and should be considered before attempting extubation.

Steroid Myopathy

Myopathy is a well-recognized side effect of glucocorticoids therapy. Myopathy induced by glucocorticoids is largely due to their direct catabolic effects via gluconeogenesis and interference with the insulin-like growth factor-1 signaling, which leads to increased myocyte apotosis. Steroid myopathy usually presents subacutely as proximal limb weakness, although high-dose corticosteroid therapy can induce clinically important weakness within 2 weeks of therapy. High-dose glucocorticoids given in conjunction with neuromuscular blocking agents may lead to critical illness myopathy as previously discussed (see Chap. 58). Myopathy can occur with any glucocorticosteroid preparation, but is unusual in patients treated with less than 10 mg/day of prednisone or its equivalent. Muscle enzymes are usually normal. EMG is either normal or reveals slight myopathic changes. In contrast to critical illness myopathy, a steroid-induced myopathy biopsy usually shows loss of type IIa muscle fibers with no evidence of inflammation or fiber necrosis. There is poor correlation between the total dose of steroids administered and the severity of muscle weakness. However, a gradual improvement in muscle strength follows discontinuation or reduction of administered corticosteroids.

Acute myopathy is the most common acquired neuromyopathy in the ICU.

Risk factors for the development of acute ICU myopathy include sepsis, multisystem organ failure, and prolonged use of neuromuscular drugs.

Characteristics of chronic steroid myopathy include proximal muscle weakness, normal muscle enzymes, mild myopathic changes on EMG, and loss of type IIa muscle fiber on muscle biopsy.

TREATMENT OF NEUROMUSCULAR DYSFUNCTION IN THE ICU

The specific medical therapy for each of the neuromuscular disorders has been discussed previously. The proper care of these complicated patients often requires a multidisciplinary team of health care workers consisting of a pulmonary specialist, neurologist, respiratory therapist, physiatrist, physical therapist, and nutritionist. Once the acute life illness has resolved, some patients who have experienced difficulty weaning from the ventilator require prolonged care in a respiratory rehabilitation unit. Frequent family interaction with the health care team is beneficial to facilitate the transition of care from the ICU to a step-down unit.

Mechanical Ventilation

Ventilatory insufficiency leading to chronic respiratory failure is a common sequelae of progressive neuromuscular diseases. Acute respiratory failure is also common and is often precipitated by recurrent aspiration, lower respiratory tract infections, or other acute illnesses that place an additional burden on a limited ventilatory reserve. Pneumonia is strongly linked to the significant morbidity and mortality that patients with advanced chronic neuromuscular disease face. Once impending respiratory failure is recognized, mechanical ventilation

Common causes of respiratory failure in neuromyopathy include progressive respiratory muscle weakness, pneumonia, and an inability to handle upper airway secretions and recurrent aspirations.

should be used early to support spontaneous breathing until the acute precipitating event is identified and treated. The indications for mechanical ventilation are shown in Table 29-12. In patients who present with new onset of severe dyspnea, acute hypercapnia with respiratory acidosis, or moderate to severe hypoxemia associated with hemodynamic instability, endotracheal intubation and mechanical ventilation are necessary and preferred over noninvasive mechanical ventilation. In certain clinical situations, noninvasive positive pressure ventilation (NPPV) may be used to augment minute ventilation in patients who present with acute hypercapnic respiratory failure and who remain alert and cooperative with intact upper airway function and minimal airway secretions. All the patients described previously should be treated in the ICU, even those patients who tolerate the initial application of noninvasive positive pressure ventilation. Invasive and noninvasive mechanical ventilation are compared in Table 29-13.

Noninvasive ventilation can be delivered two ways: as noninvasive positive pressure ventilation (NPPV) or as negative pressure ventilation.

Noninvasive ventilation has been shown to attenuate the decline in lung function and improve gas exchange, cognitive function, and survival in patients with neuromuscular disease. Noninvasive mechanical ventilation can be delivered as either NPPV or negative pressure ventilation (NV). The benefits and limitations of both forms of noninvasive mechanical ventilation are listed in Table 29-14.

Common problems with negative pressure ventilation include upper airway obstruction, limited portability, and limited nursing care access to patient.

Negative pressure ventilation, the iron lung in particular, was the first widely used method of mechanical ventilatory support in the management of respiratory failure due to neuromuscular diseases. During the poliomyelitis epidemics in the 1930s, negative pressure was highly effective in augmenting alveolar ventilation and decreasing the mortality due to poliomyelitis. The early success of NV in the treatment of acute respiratory failure due to poliomyelitis has since been repeated in patients with chronic respiratory failure from other forms of neuromuscular and chest wall diseases.

Noninvasive ventilation is the preferred mode of ventilatory support in patients with advanced neuromyopathies.

In recent years, NPPV has become the first choice of ventilatory support in patients with chronic respiratory failure due to a wide variety of neuromuscular diseases who have associated upper airway dysfunction. Because of the limitations of NV discussed earlier, it is now used only in patients unable to tolerate NPPV or is used during the daytime in combination

TABLE 29-12

INDICATIONS FOR MECHANICAL VENTILATION IN PATIENTS WITH NEUROMUSCULAR DISORDERS

Acute respiratory failure	Severe dyspnea
	Marked accessory muscle use
	Inability to handle secretions
	Unstable hemodynamic status
	Hypoxemia refractory to supplemental O_2
	Acute respiratory acidosis
Chronic respiratory failure	
Nocturnal hypoventilation	Morning headache
	Lethargy
	Nightmares
	Enuresis
Nocturnal oxygen Desaturation	$SaO_2 < 88\%$ despite supplemental O_2
Cor pulmonale	Due to hypoventilation with $PaCO_2 > 45$ mmHg, pH < 7.32

TABLE 29-13

COMPARISON OF CLINICAL FACTORS FAVORING INVASIVE VS. NONINVASIVE MECHANICAL VENTILATION IN PATIENTS WITH NEUROMUSCULAR DISEASE

Invasive ventilation (endotracheal intubation)
Copious secretions
Upper airway dysfunction
Inability to tolerate or failure of noninvasive ventilation
Impaired mental status
Unstable vital signs
Noninvasive ventilation
Awake, cooperative patient
Intact upper airway function
Minimal secretions
Stable vital signs

TABLE 29-14

ADVANTAGES AND DISADVANTAGES OF POSITIVE AND NEGATIVE PRESSURE VENTILATION USED IN PATIENTS WITH NEUROMUSCULAR DISEASE

TYPE	ADVANTAGES	DISADVANTAGES
Negative pressure ventilators	Dependable	Cumbersome
Tank	Airway cannulation not required	Predisposes to obstructive apnea
Pulmowrap	Minimal hemodynamic effect	Limits nursing care
Cuirass	Maintenance of speech	Controlled ventilation
Positive pressure by mask or mouthpiece	Avoids upper airway obstruction	Aerophagia
		Pressure sores
	Pressure preset, compensates leak	Leaks
	Patient-initiated machine breaths	Problems with interface

with NPPV. In the ICU setting, we prefer NPPV over NV because of the ease of use and access to patients, its portability, and the maintenance of upper airway patency during sleep. Different types of masks may be used (nasal, oronasal, full face mask) for the application of NPPV depending on the patient's comfort and preference, as well as to provide proper fit to minimize air leak. In patients with significant air leaks from mouth, chin straps may help close the mouth. Alternatively, an oronasal or full facemask often solves the problem of mouth leak in patients who are mouth breathers. Occasionally, facial ulcers or erythema may develop due to contact pressure from a particular mask interface. In this situation, using two different mask interfaces and rotating their use may promote healing of the facial ulcers and prevent recurrence, or allow a longer rest period between applications of NPPV that may improve patient tolerance.

Common problems with NPPV: air leaks, facial contact ulcers, and aerophagia.

Once a proper mask interface has been chosen, a wide variety of positive pressure ventilators may be used to deliver NPPV. In the intensive care setting, we prefer to use standard ICU ventilators because of the option of using either assist/control or pressure support mode or the combination of the two, depending on the clinical situation and patient preference. For example, synchronous intermittent mandatory ventilation (SIMV) combined with pressure support is useful in patients with nocturnal hypoventilation who have a decreased spontaneous respiratory rate as may occur during sleep. Some features that are available on standard ventilators that are useful in the acute clinical setting are the ability to monitor respiratory pattern and to supply variable amounts of enriched oxygen. In patients with acute or chronic respiratory failure who are otherwise hemodynamically stable, small pressure-limited, flow- or time-cycled portable ventilators (bilevel positive airway pressure) have been used with success. These devices are particularly useful in partial chronic ventilator support in patients with progressive neuromuscular dysfunction once the acute illness that requires ICU care has resolved.

The initial tidal volume or inspiratory setting of the ventilator should start at a low setting and ramp up gently, usually every 3–5 min based on patient tolerance, to achieve an increase in assisted tidal volume of 30–50% above baseline or a decrease of 5–10 mmHg in $PaCO_2$. The expiratory airway pressure on BIPAP is usually set at 4 cm to ensure continuous flow of gas during expiration, thereby flushing out the expired gas. If supplemental oxygen is required, oxygen tubing is connected to the ventilator tubing using a T-connector. The expiratory airway pressure may also be titrated up to increase FRC and improve gas exchange. The initial duration of ventilatory assistance depends on the severity of respiratory failure and patient tolerance. In an acute setting, ventilatory assistance of 20 h/day may be needed. In a chronic setting, we allow the patient to use NPPV during the daytime for a few hours, followed by nocturnal use of 6–8 h once they are accustomed to NPPV.

SUMMARY

The diagnosis of neuromuscular dysfunction should be considered in all patients with unexplained acute hypercapnic respiratory failure, acute-on-chronic hypercapnic respiratory failure, and in patients who fail to wean from ventilatory support after resolution of their acute

illness. In patients with rapidly worsening respiratory weakness, FVC less than 12–15 mL/kg indicates impending respiratory failure and the need to initiate ventilatory support. Other indications for ventilatory support include upper airway dysfunction, abnormal gas exchange, and hemodynamic instability. Noninvasive positive pressure ventilation may be used to provide partial ventilatory support in neuromuscular patients with hypercapnic respiratory failure who are awake, cooperative, hemodynamically stable, and with preserved upper airway function. The prognosis of patients with neuromuscular dysfunction who require ICU admission depends on the type and clinical stage of the neuromuscular disease, the nature of the precipitating illness, and the therapeutic response of the patient to medical interventions. In many cases of neuromuscular disorder, therapy is primarily supportive; avoidance of complications arising from the chronic illness is also crucial to patient recovery.

REVIEW QUESTIONS

1. **Clinical predictors for the need of mechanical ventilation in patients with Guillaim-Barre syndrome include:**
   - **A.** Inability to lift the head
   - **B.** Rapid progression of clinical signs and symptoms
   - **C.** Difficulty swallowing
   - **D.** Presence of anti-GQ1b antibodies
   - **E.** All the above

2. **The following statements about the central respiratory drive are correct except:**
   - **A.** In normal individuals, there is an inverse linear relationship between oxyhemoglobin saturation and minute ventilation
   - **B.** The increase in minute ventilation following an increase in $PaCO_2$ is much steeper compared to a similar unit decrease in oxygenation
   - **C.** In patients with moderately advanced neuromuscular disease, central respiratory drive is uniformly depressed with the onset of chronic hypercapnic respiratory failure
   - **D.** Assessment of central respiratory drive can be affected by profound respiratory muscle weakness
   - **E.** P_{100} is the best measure of the central respiratory drive

3. **The common causes of muscle weakness in the ICU following life-threatening illness are these, except:**
   - **A.** Acute myopathy
   - **B.** Critical illness polyneuropathy
   - **C.** Protracted use of neuromuscular blocking agents
   - **D.** Aminoglycoside-induced neuromuscular blockade

4. **Optimal treatment strategies in myasthenic crises include all the following except:**
   - **A.** Immediate institution of plasmapheresis, or intravenous immunoglobulin infusion
   - **B.** Temporary discontinuation of the anticholinergic agents for a few days until clinical improvement occurs following plasmapheresis to minimize the possibility of concomitant cholinergic crises
   - **C.** Serial measurement of FVC and maximum inspiratory pressure to detect impending respiratory failure
   - **D.** Rapid institution of NPPV when impending respiratory failure is eminent
   - **E.** Immediate use of high-dose corticosteroid and dose escalation of anticholinergic agents

5. **Risk factors in the development of critical illness polyneuropathy:**
   - **A.** Prolonged use of high-dose corticosteroids
   - **B.** Hyperglycemia
   - **C.** Prolonged mechanical ventilation of more than 7 days
   - **D.** Vasopressors use of more than 3 days
   - **E.** All the above

ANSWERS

1. The answer is E. Serial measurement of FVC is a useful test to detect impending acute respiratory failure. Early intubation should be strongly considered once the FVC is < 12 mL/kg. other signs of impending respiratory failure include severe bulbar symptoms, inability to hold the head up, hypoxemia, and inability to handle oral secretions. The presence of anti-GQ1b and demyelinating form of GBS have also been reported as predictors of acute respiratory failure.

2. The answer is C. Except for some form of congenital myopathies, central respiratory is usually normal or slightly elevated in patients with neuromuscular disease. There is a linear increase in minute ventilation with every 1% decrease in oxyhemoglobin or 1 mmHg increase in $PaCO_2$. The linear relationship between hypercapnia and minute ventilation can be used to assess central respiratory drive. However, significant respiratory muscle weakness makes the

test inaccurate. P_{100}, by measuring the pressure generated very early during the inspiratory effort, is a more accurate test of the central respiratory drive since it is unaffected by the degree of respiratory muscle weakness.

3. The answer is D. Aminoglycosides may potentiate muscle weakness in susceptible patients with neuromuscular disorders. Acquired weakness in the ICU is most commonly the result of acute myopathy and critical illness polyneuropathy. Risk factors commonly associated with these conditions are sepsis, multisystem organ failure, shock, and prolonged use of neuromuscular blocking agents, especially in the presence of renal and hepatic failure.
4. The answer is E. Plasmapheresis is the treatment of choice in patients experiencing myasthenic crisis. IVIG can be used in lieu of plasmapheresis in patients who have hemodynamic instability or difficulty with central venous access. It is prudent to discontinue the anticholinergic agent during myasthenic crisis because of the possibility of concomitant cholinergic crisis. Corticosteroids can cause paradoxical weakness 5–7 days after starting corticosteroid treatment and should be withheld until clinical improvement is documented following plasmapheresis. NPPV decreases the need for invasive mechanical ventilation, and decrease the duration of ICU and hospitalization.
5. The answer is E. All have been identified as risk factors in ICU-acquired weakness. Approximately 70 to as high as 100% of patients with sepsis develop varying degrees of critical illness polyneuropathy. Prolonged use of mechanical ventilation; the need for vasopressor support for more than 3 days. Aggressive control of stress-induced hyperglycemia with intravenous insulin therapy has been done to decrease the incidence of critical illness polyneuropathy.

CHAPTER 30

ZAKARIA HAKMA AND MICHAEL WEAVER

Neurosurgical Emergencies

CHAPTER OUTLINE

LEARNING OBJECTIVES

Upon completion of this chapter, the reader should be able to:

- Identify and triage true neurosurgical emergencies.
- Discuss the most current diagnostic methods and system-oriented approach to neurosurgical emergencies.
- Describe and apply the most current data on the intensive care management of acute neurosurgical conditions.

TRAUMATIC HEAD INJURY

The problem:

1. What is the role of intracranial pressure (ICP) monitoring in patients with traumatic brain injury?
2. What is the optimal ICP and, cerebral perfusion pressure (CPP) that is needed to improve patient outcome?
3. What are the available options to treat refractory elevated ICP?

CASE STUDY: 1

A 28-year-old man was hit by a car while crossing the road. He lost consciousness immediately at the scene for 10 min, and then awakened in the ambulance. On arrival at the emergency room, his Glascow Coma Scale (GCS) was 13, but 4 h later, it deteriorated to 6. Subsequently, he was intubated and paralyzed. His CT scan showed small bifrontal contusions and generalized brain swelling and slit-like ventricles. He was admitted to the intensive care unit (ICU). Neurosurgery was not able to place a ventriculostomy, and an intracranial cerebral pressure (ICP) parenchymal monitor was used instead. The initial ICP was 30 mmHg and came down to 18 after giving 100 g of mannitol. On the second day of his ICU stay, the ICP became elevated again and was refractory to repeated boluses of mannitol. He had partial response to hypertonic saline (HTS); however, due to persistent intracranial hypertension, he was started on pentobarbital. The dose was titrated to achieve burst suppression on continuous EEG monitoring. A regimen of acetominophenol and cooling blanket was initiated to maintain normothermia. After 3 days of continuous infusion, pentobarbital was slowly weaned off. Four weeks later, the patient was discharged to traumatic brain injury (TBI) rehab with a GCS of 14.

Introduction

Traumatic brain injury (TBI) is the leading cause of death and disability in children and adults from ages 1 to 44. An estimated 1.5 million head injuries occur annually in the United States. At least 5.3 million Americans, 2% of the U.S. population, currently live with disabilities resulting from TBI.[1] Moderate and severe head injuries are associated with a 2.3 and 4.5 times increased risk of Alzheimer's disease, respectively. Every year, approximately 52,000 deaths occur from TBI. The leading causes of TBI are falls, motor vehicle crashes, being struck by or against objects, and assaults, with males being twice as likely as females to experience a TBI.

Emergency medical service personnel are usually the first to arrive at the accident scene and provide initial but important basic medical treatment, making prehospital care an essential component in the TBI treatment paradigm. A greater understanding of the importance of prehospital care appropriate triage and the development of regional trauma centers has led to improved patient outcome and survival.

Safe and quick transportation is paramount in getting the traumatic brain-injured patient to the nearest level-one trauma center. Special attention must be directed to airway-control and spine-injury precautions during transport.

A major component of TBI treatment is the prevention of secondary injury. Secondary brain injury is defined as any subsequent injury to the brain that occurs after the initial insult. It can result from systemic hypotension, hypoxia, and an increase in ICP, or as the biochemical result of a series of physiologic changes initiated by the original trauma. The potential for secondary injury begins at the scene and continues throughout transport and into the emergency department. Prevention of hypoxemia, hypercarbia, and hypotension are essential in preventing secondary injury. Following the A, B, C paradigm (airway, breathing, and circulation) is the initial step in treating the head-injured patient.

The specific goals in the acute management of severe TBI are to protect the airway and oxygenate, ventilate to normocapnia, and correct hypovolemia and hypotension. A head CT scan without contrast should be performed as soon as possible; observation in an ICU will allow further patient monitoring and management.

Airway management: Securing the airway is the first step in resuscitating a TBI patient; however, this can prove difficult in the patients with facial trauma and possible cervical spine instability. Endotracheal intubation is always preferred even in the presence of facial trauma; if this cannot be performed, then a surgical cricothyrotomy or needle circothyrotomy may be necessary.

Breathing: Ensuring adequate oxygenation is critical to avoid secondary brain injury. Prophylactic hyperventilation (HPV) should be avoided.[2] The currently recommended range is a $PaCO_2$ of 35–40 mmHg, and HPV (i.e., $PaCO_2$ <30 mmHg) has been shown to worsen cerebral perfusion in the brain-injured patient.

Maintain MAP>90 mmHg and CPP>60 mmHg. CPP=MAP–ICP; in practical terms, CPP is the net pressure of blood delivery to the brain.

Circulation: Recognition and treatment of hypotension is the next step that follows airway-control and ventilation. Establishing a large bore IV line and infusing an isotonic solution is the standard treatment, but there is evidence that (hypertonic saline) HTS is effective in treating hypotension and decreasing intracranial pressure (which is often elevated in cases of moderate to severe TBI).[3] Mean arterial blood pressure (MAP) should be maintained >90 mmHg and the CPP >60 mmHg by infusing IV fluids. A quick neurological assessment

TABLE 30-1

HIGH-RISK CRITERIA FOR POSTTRAUMATIC SEIZURES

Acute intracranial bleed (subdural, epidural, or intraparenchymal hematoma)
Open depressed skull fracture with parenchymal injury
Seizure within 24 h of injury
Glascow Coma Scale <10
Penetrating brain injury
History of heavy alcohol abuse

SOURCE: Data from Greenberg MS, Arredondo N, Duckworth EAM, Nichols TA, eds. *Greenberg Handbook of Neurosurgery*, 6th ed. New York: Thieme; 2006 [79]

in the field can establish a neurological baseline that can then be followed to ensure optimum resuscitation.

Serial assessment of the patient's neurological status is vital. Patients may arrive with a mildly abnormal GCS and rapidly deteriorate due to expanding intracranial hematomas or progressive cerebral swelling. Pupils may be initially normal and then dilate as intracranial pressure rises and herniation syndromes (i.e., uncal herniation, subfalcine herniation, tonsillar herniation) develop.

Prophylactic administration of mannitol in the emergency room should be avoided because of its hypotensive and volume-depleting effect.

Posttraumatic epilepsy is reported in 2–5% of closed head injuries, but in up to 50% or more patients following penetrating head injury. This posttraumatic epilepsy can be classified into early (<7 days after head trauma) and late (≥7 days after head trauma). The routine use of anticonvulsants anti-epileptic drugs (AED) in TBI does not prevent the development of late posttraumatic epilepsy.

AEDs may be considered for short-term use (usually for 1 week),[4] especially if a seizure could be detrimental. Early posttraumatic seizures (within the first 7 days after head trauma) were effectively reduced when phenytoin was used for 2 weeks following head injury with no significant increased risk for adverse effects.[5]

See Table 30-1 for high-risk criteria for development of posttraumatic seizures.

After 1 week, the AEDs are usually tapered except in the presence of penetrating brain injury, patient undergoing craniectomy, or if the patient develops late (>7 days following traumatic head injury) seizures.[6]

The use of steroids is not recommended for improving outcome or reducing ICP in patients with severe head injury.[7]

The routine use of sedatives and paralytics in brain-injured patients may lead to a higher incident of pneumonia, longer ICU stays, and sepsis. These agents also limit serial neurological assessments, and their use should be restricted to patients with signs of elevated intracranial pressure (ICP) and to help transport the neurotrauma patient.

A CT scan of the head is critical in managing the head injury patient, and magnetic resonance imaging (MRI) is playing a progressively greater role in managing spinal trauma. However, other patient injuries can affect the ability to obtain these tests in a timely manner. This is especially true in the patient with multiorgan trauma. In general, hemodynamically unstable patients should not be transported to radiology for a CT or MRI imaging study. The benefits of adequate resuscitation and oxygenation outweigh the risk of delaying imaging studies. Additionally, initiation of ICP monitoring can usually be accomplished during resuscitation, and will provide useful information to help guide management of the unstable patient.

MANAGEMENT OF INTRACRANIAL HYPERTENSION

Introduction

Elevated intracranial pressure is a leading cause of morbidity and mortality in the brain-injured patient. The skull is a rigid container with a fixed volume-capacity normally that

consists of brain (80–90%), spinal fluid, and blood. The essential rule of intracranial pressure is that the expansion of one component occurs at the expense of the others (the Monro-Kellie doctrine). For example, if a patient has an intracranial hematoma, the pressure inside the skull rises linearly until a critical point is reached, at which time the intracranial contents can no longer compensate for the increase in volume. At this point, a precipitous, exponential rise in intracranial pressure is seen. As ICP increases, the body compensates by increasing systemic blood pressure in a reflex attempt to maintain CPP. If this process is not interrupted, cerebral ischemia results, which further contributes to the rising ICP and death eventually results.

Indications for Intracranial Pressure Monitoring

Patients with a sustained ICP>20 mmHg have higher mortality and poorer outcomes.[9]

The decision to place a patient on continuous ICP monitoring should not be taken lightly, but in general any patient with a condition that could lead to an elevated ICP and is amenable to medical or surgical treatment should have ICP monitoring. The Brain Trauma Foundation guidelines recommend ICP monitoring in patients with severe head injury (GCS 3–8) and an abnormal admission head CT demonstrating hematomas, contusions, compression of basal cisterns, or edema; or with a normal head CT if two or more of the following is present: age >40, systolic pressure <90, or the presence of motor posturing on exam.[8] The hematomas demonstrated on CT scan can be either subdural (SDH), epidural (EDH), or intraparenchymal (IPH). The most important goal of ICP monitoring is to maintain an adequate CPP, and monitor the response to medical or surgical treatments.

Contraindications and Complications with ICP Monitoring

In the awake patient, ICP monitoring is not necessary and the patient can be followed clinically. Coagulopathy is a relative contraindication to placing an ICP monitor. Coagulopathy is a common and frequently overlooked problem especially in the severely injured head trauma patient and may occur in up to 30% of patients. In these circumstances, the placement of the ICP monitor should be delayed until the coagulopathy is corrected using fresh frozen plasma (FFP), Novoseven (a recombinant human coagulation factor VIIa (rFVIIa), intended for promoting hemostasis by activating the extrinsic pathway of the coagulation cascade), platelets, or other blood products.

In patients with severe brain edema and compressed lateral ventricles, placement of a ventriculostomy catheter can be particularly challenging. Under these circumstances, placement of an IPH or a subarachnoid monitor is an alternative to the placement of a ventriculostomy catheter.

The two major complications of ICP monitoring are:

1. *Intracerebral hemorrhage*: In one large study the rate of ICH was 1.4% and was related to coagulopathy and/or difficult placement. The risk of significant intracranial hemorrhage that requires surgical evacuation is 0.5%.
2. *Infection (ventriculitis)*: Infection is a more common complication and is closely related to the duration of monitoring. Mayhall et al. found that 85% of external ventricular drains (EVD)-related infections occurred in patients who had been monitored >5 days and no infections occurred in patients who were monitored <3 days.[10] However, more recent experience with tunneled catheters under the scalp has called these findings into question. A recent analysis found nonlinear increase of the risk during the first 10–12 days after which the rate diminished rapidly, with no significant reduction in the infection rate in patients undergoing prophylactic change of catheters ≤5 days.

ICP treatment should be initiated for an ICP >20–25. The goal is to keep the ICP <20 mmHg and maintain a CPP of at least 70 mmHg. The EVD or monitor should be removed as soon as possible to minimize the risk of infection. If long-term therapy is needed, a permanent cerebrospinal fluid (CSF) diversion device (i.e., ventriculoperitoneal shunt) should be placed.

Other complications of EVD placement include malfunction due to incorrect placement or occlusion with clot or debris, and brain swelling from repeated attempts to cannulate the ventricles.

The types of intracranial pressure monitors are listed in Table 30-2.

TABLE 30-2

TYPES OF INTRACRANIAL PRESSURE MONITORS

TYPE	ADVANTAGES	DISADVANTAGES	COMMENTS
Ventriculostomy, AKA external ventricular drainage (EVD)	Ability to drain CSF Accurate, reliable, and able to recalibrate to minimize measurement shift Low cost	Most invasive, risk of hemorrhage and infection Maybe difficult to insert in the presence of compressed ventricles	ICP monitor of choice in most circumstances
Parenchyma	Less invasive, easily placed	Inability to drain CSF, cannot be recalibrated after insertion	Can be a good choice in a patient with compressed ventricles
Subarachnoid bolt	Less invasive	Inability to drain CSF and tends to be less accurate over time	
Subdural	Less invasive	Inability to drain CSF and tends to be less accurate over time	

General Measures for the Treatment of Elevated Intracranial Pressure

Head and Neck Positioning

Head and neck positioning can affect the ICP and CPP by altering mean arterial pressure, jugular venous drainage, and cerebral blood volume (CBV). Recent data indicate that head elevation to 30° reduces ICP without affecting CPP and cerebral blood flow (CBF).[11] Compression of the jugular veins can alter CPP and should be avoided by maintaining the neck in a neutral position and ensuring proper placement of cervical collars.

Sedation and Paralytics

Agitation can result from pain, intoxication, brain injury, or it can be an early sign of increased ICP. Agitation contributes to increased cerebral metabolic demands and ICP elevation. Thus, sedation can play a significant positive role in treating an elevated ICP. However, it will affect the neurological exam and may cause a decrease in blood pressure and CPP.

Different approaches can be utilized to treat agitation in the head-injured patient. Drugs can be given on an as-needed basis to minimize the amount of sedatives the patient receives, though this approach carries the risk of a fluctuating ICP because sedatives are not started until the patient shows signs of agitation. Or, it may be preferable to give sedatives on a scheduled basis or as a continuous infusion if the adverse effects of periodic periods of agitation cannot be tolerated from a neurological standpoint.

There is no particular preference for a specific sedative-hypnotic, but in neurosurgical ICUs the administration of propofol has grown dramatically. Its short half-life allows treating physicians to perform frequent neurological exams; additionally, propofol is a strong anticonvulsant. However, caution should be exercised when using propofol. It can contribute excessive calories and cause an elevation in triglyceride levels. It can also cause hypotension, especially in hypovolemic patients, and when used for a prolonged period, it can lead to hepatic dysfunction and metabolic acidosis. A rare complication that was initially reported in children and has subsequently been observed in adults is the "Propofol syndrome" characterized by heart failure, metabolic acidosis, and rhabdomyolysis (See Chap. 57).

Other agents used for sedation include midozolam and lorazepam. When used as a prolonged, continuous infusion, the effects of lorazepam clear more quickly compared to midazolam. This is due to midazolam having long-acting metabolites that also have sedating properties. The prolonged use of lorazepam may lead to propylene glycol toxicity, especially when high doses are used for extended periods. Although benzodiazepines are effective sedatives, they have no analgesic properties; thus, an opioid is often administered in combination with the sedative-hypnotic agent.

Neuromuscular blocking agents can reduce ICP by controlling agitation and preventing a patient from "bucking" the ventilator, but their routine use in this setting has not been shown to improve outcome and may actually be harmful. Paralytics tend to prevent coughing, which is helpful in clearing secretions and avoiding pneumonia. The use of paralytics will mask seizure activity and has been linked to the development of prolonged weakness and myopathies (See Chap. 58). Though there has been concern that succinylcholine (a nondepolarizing agent) may increase ICP, this does not consistently occur. Patients receiving neuromuscular blockade should be assessed both clinically and by train-of-four (TOF) monitoring, with a goal of adjusting the degree of neuromuscular blockade to achieve one or two twitches. Before initiating neuromuscular blockade, patients should be medicated with sedative and analgesic agents to assure adequate sedation and analgesia.

Hyperventilation (HPV)

The use of prophylactic HPV during the first 24 h of severe TBI should be avoided because of compromised autoregulation, which can exacerbate ischemia. However, in the patient who presents with a herniation syndrome, HPV may be utilized in attempts to reduce mortality.

HPV is an effective and proven method for decreasing ICP, but there is growing evidence that excessive HPV can precipitate or exacerbate cerebral ischemia by producing global cerebral vasoconstriction, thereby decreasing CBF and blood volume.[12]

However, HPV can be useful in the acute management of intracranial hypertension and to allay herniation syndromes. HPV is useful as a temporary measure while preparing for other lasting interventions. The effective lower limit of $PaCO_2$ has not been established, but lowering it to 30–35 mmHg appears to be safe. The effect on ICP is rapid with an initial reduction in intracranial hypertension occurring within 30 s and peak effect observed at 8 min.

Osmotic Therapy

Osmotic agents are routinely used to treat elevated ICP and cerebral edema. Mannitol, and more recently, HTS are the main agents utilized.

Mannitol

Mannitol is a very hypertonic solution (20–25%), which when added to the blood (0.9%) produces a sudden rise in extracellular fluid osmolality. The intact blood–brain barrier (BBB) prevents mannitol from leaving the intravascular compartment, thereby creating a gradient for water to leave the intra and extracellular compartments and move to the intravascular compartment. This usually takes place over 15–30 min, but the effects last for 1.5–6 h.

Another proposed mechanism of action for mannitol is that it increases the erythrocytes' cell membrane flexibility and decreases blood viscosity (improved rheology), which results in increased CBF and O_2 delivery. Mannitol may also act as a free radical scavenger.

Intermittent bolusing of mannitol (0.25–1 g/kg) every 3–6 h is recommended over continuous infusion; the latter may cause rebound intracranial hypertension once the infusion is stopped. Prolonged continuous infusion can actually contribute to worsening cerebral edema. In TBI, the BBB is disrupted and mannitol can "leak" into the parenchyma and draw fluid into the injured brain.[13,14]

- Mannitol is effective in treating elevated ICP.
- Intermittent boluses of mannitol are more effective than continuous infusions.
- Euvolumeia should be maintained by fluid replacement.
- Serum osmolarity should be kept below 320.

Mannitol is a potent diuretic and may lead to hypovolemia and hypotension during its infusion. A Foley catheter should be placed and urine output monitored and replaced with isotonic saline; the goal is to maintain a hyperosmolar and euvolemic state. Routine measurement of serum electrolytes and osmolality every 6 h is important. The ceiling value for serum osmolarity is 320 mOsm/L. Mannitol may contribute to acute renal failure in the presence of a serum osmolarity>320, with concurrent use of nephrotoxic drugs, sepsis, and preexisting renal disease.[15]

Loop diuretics may also aid in the reduction of intracranial pressure by increasing the intravascular oncotic pressure via hypoosmolar diuresis, which reduces cerebral edema and CSF production. Its effects may be synergistic with mannitol.

Hypertonic Saline (HTS)

There has been recent interest in the use of HTS as an alternative or adjunct to mannitol for the treatment of intracranial hypertension. HTS, like mannitol, increases the osmotic gradient between the brain and the blood, and subsequently causes fluid to shift from the intracellular and extracellular compartments into the intravascular compartment, resulting in a reduction of cerebral edema.[16]

Experimental data have demonstrated that HTS is highly effective in lowering ICP, even when mannitol has lost its therapeutic value. However, the use of HTS is still considered investigational. Studies are currently underway to determine the optimal concentration, volume, and timing of delivery.

It has been widely documented in both animal studies and human trials that HTS can improve and maintain mean arterial pressure (MAP).[17,18] This is probably the result of volume expansion, but may also be due to a centrally mediated effect on increasing cardiac output. The increased MAP and subsequent improvement of CPP can lead to better perfusion of the injured region of the brain. There is no evidence yet supporting one concentration over another in efficacy in controlling ICP and cerebral edema. Solutions used at our institution include 3% saline as continuous infusion or 7.5% saline as boluses of 2 mL/kg every 4–6 h. As with mannitol therapy, frequent measurements of serum electrolytes and serum osmolarity are recommended.

HTS is very effective in controlling ICP especially when the patient is hypovolemic. Hypertonic solutions must be given through a central line.

HTS therapy is not without complications and adverse effects. Osmotic demyelination syndrome (ODS), acute renal insufficiency, and hematologic abnormalities can develop with the use of HTS. Most of our knowledge of ODS comes from animal models. The mechanism of ODS involves the destruction of myelinated structures following a rapid rise in serum sodium. However, the rate of increase in serum sodium required to induce ODS in animal models is generally five times the rates used in human trials, and there is no report of ODS in human trials. Although acute renal insufficiency is primarily associated with the use of mannitol, it has also been reported with the use of HTS. Huang et al. reported that renal failure was four times more likely to occur in patients treated with HTS compared to those treated with lactated Ringer's solution.[19]

Corticosteroids are well known to reduce vasogenic edema surrounding brain tumors, but they have no role in treating cytotoxic edema resulting from stroke, intracerebral hemorrhage, or head injury.

Barbiturates

The suppression of cerebral metabolic activity can be accomplished by using barbiturates (i.e., pentobarbital) that lead to lowered oxygen requirements and decreased CBF, CBV, and subsequently ICP. Other theoretical benefits of barbiturates include free radical scavenging, reduced intracellular calcium, and lysosomal stabilization.[20] There is no question that barbiturates are effective in lowering intracranial pressure even when other treatments have failed. However, conflicting data exist in regard to improved clinical outcome with the use of barbiturates.[21]

Barbiturate coma is usually reserved for cases of severe intractable intracranial hypertension when all previous conventional treatments have failed.

Adjunctive measures that are required before starting barbiturates include:

1. Swan-Ganz PA catheter. Barbiturates in the doses needed to induce an isoelectric EEG can be cardiotoxic, so cardiac output needs to be followed closely.
2. EEG monitoring: the goal of the barbiturate is to induce a "chemical coma." EEG is utilized to assess the degree of burst suppression. The goal is to have <3 bursts/min.
3. High-dose barbiturates cause paralytic ileus, so a naso-gastric tube should be placed. Hyperalimentation is usually required.

The barbiturate coma protocol used at our institution is:

(a) Pentobarbital 10 mg/kg is given IV over 30 min.
(b) Then 5 mg/kg boluses q1h for 3 h are given to establish an isoelectric EEG.
(c) Followed by maintenance pentobarbital of 1 mg/kg/h, which is titrated to achieve burst suppression.

High-dose barbiturates may be considered in hemodynamically stable and "salvageable" patients with an elevated ICP that is refractory to treatment using conventional measures.

Hypotension and myocardial depression with the use of barbiturate coma are very common and vasoactive agents (i.e., dobutamine, dopamine, epinephrine, neosynephrine) are usually required. Complications of barbiturate coma include sepsis, pneumonia, acute renal failure, and pulmonary embolism.

Hypothermia

Like barbiturate coma, hypothermia also reduces the cerebral metabolic rate and lowers CBV, CBF, and ICP in the brain-injured patient. Hypothermia to a target temperature of between 32 and 33°C, for duration of 24 h and rewarming within 24 h, has been reported to reduce the risks for poor neurological outcome, compared with normothermia.[22] Patients must be monitored for decreased cardiac output, thrombocytopenia, coagulopathy, and pancreatitis. Shivering, which raises the ICP, must be avoided.

Surgical treatments for elevated intracranial pressure include CSF diversion through a ventriculostomy, evacuation of mass lesions (hematoma, tumor or ischemic or contused brain tissue in extreme cases), or decompressive craniectomy.[23]

Figure 30-1 outlines the approach to use these procedures in the brain-injured patients.

Conclusion

Although recommendations for management of TBI and elevated intracranial pressure are to a large degree based on class II and III evidence, treatment guidelines and protocol-driven therapy for the management of these patients have increased the favorable outcomes when compared to historical controls. Intracranial pressure monitoring has developed into a very useful tool for management of patient with intracranial hypertension. Ventricular ICP monitoring is the most reliable method and still considered the gold standard because of the several advantages including the ability to recalibrate and to drain CSF as well as low cost.

PITUITARY APOPLEXY

Pituitary apoplexy is a rare yet potentially fatal disease, clinically characterized by the abrupt onset of severe headache accompanied by neurological and or endocrine deterioration. The diagnosis is easily missed, because in the majority of patients, the pituitary adenoma is undiagnosed, and clinically, the picture can be mistaken for a subarachnoid hemorrhage (SAH) or meningitis. Pituitary apoplexy is a neurosurgical emergency in which rapid intervention may halt and even reverse neurological deficits and a life-threatening situation.

Pituitary apoplexy occurs secondary to sudden expansion of a mass within the sella turcica, usually as a result of hemorrhage and/or infarction. A well-described theory is that with rapid growth, the tumor outstrips its blood supply, resulting in ischemia and subsequent hemorrhage. Cardoso and Petersen[24] have postulated that an intrinsic vasculopathy in pituitary adenomas renders them more susceptible to infarction and hemorrhage. This may explain why pituitary adenomas are more susceptible to vascular injury than any other tumor.

Although the majority of cases of pituitary apoplexy are spontaneous, numerous precipitating factors have been suggested. Biousse et al.[25] reduced the multiple factors reported as precipitants of apoplexy into four categories: (1) reduced blood flow in the gland, (2) an acute increase in blood flow in the pituitary gland, (3) overstimulation of the pituitary gland, and (4) the anticoagulated state. The institution and withdrawal of dopamine agonist therapy (i.e., bromocriptine and cabergoline) have also been associated with apoplexy.

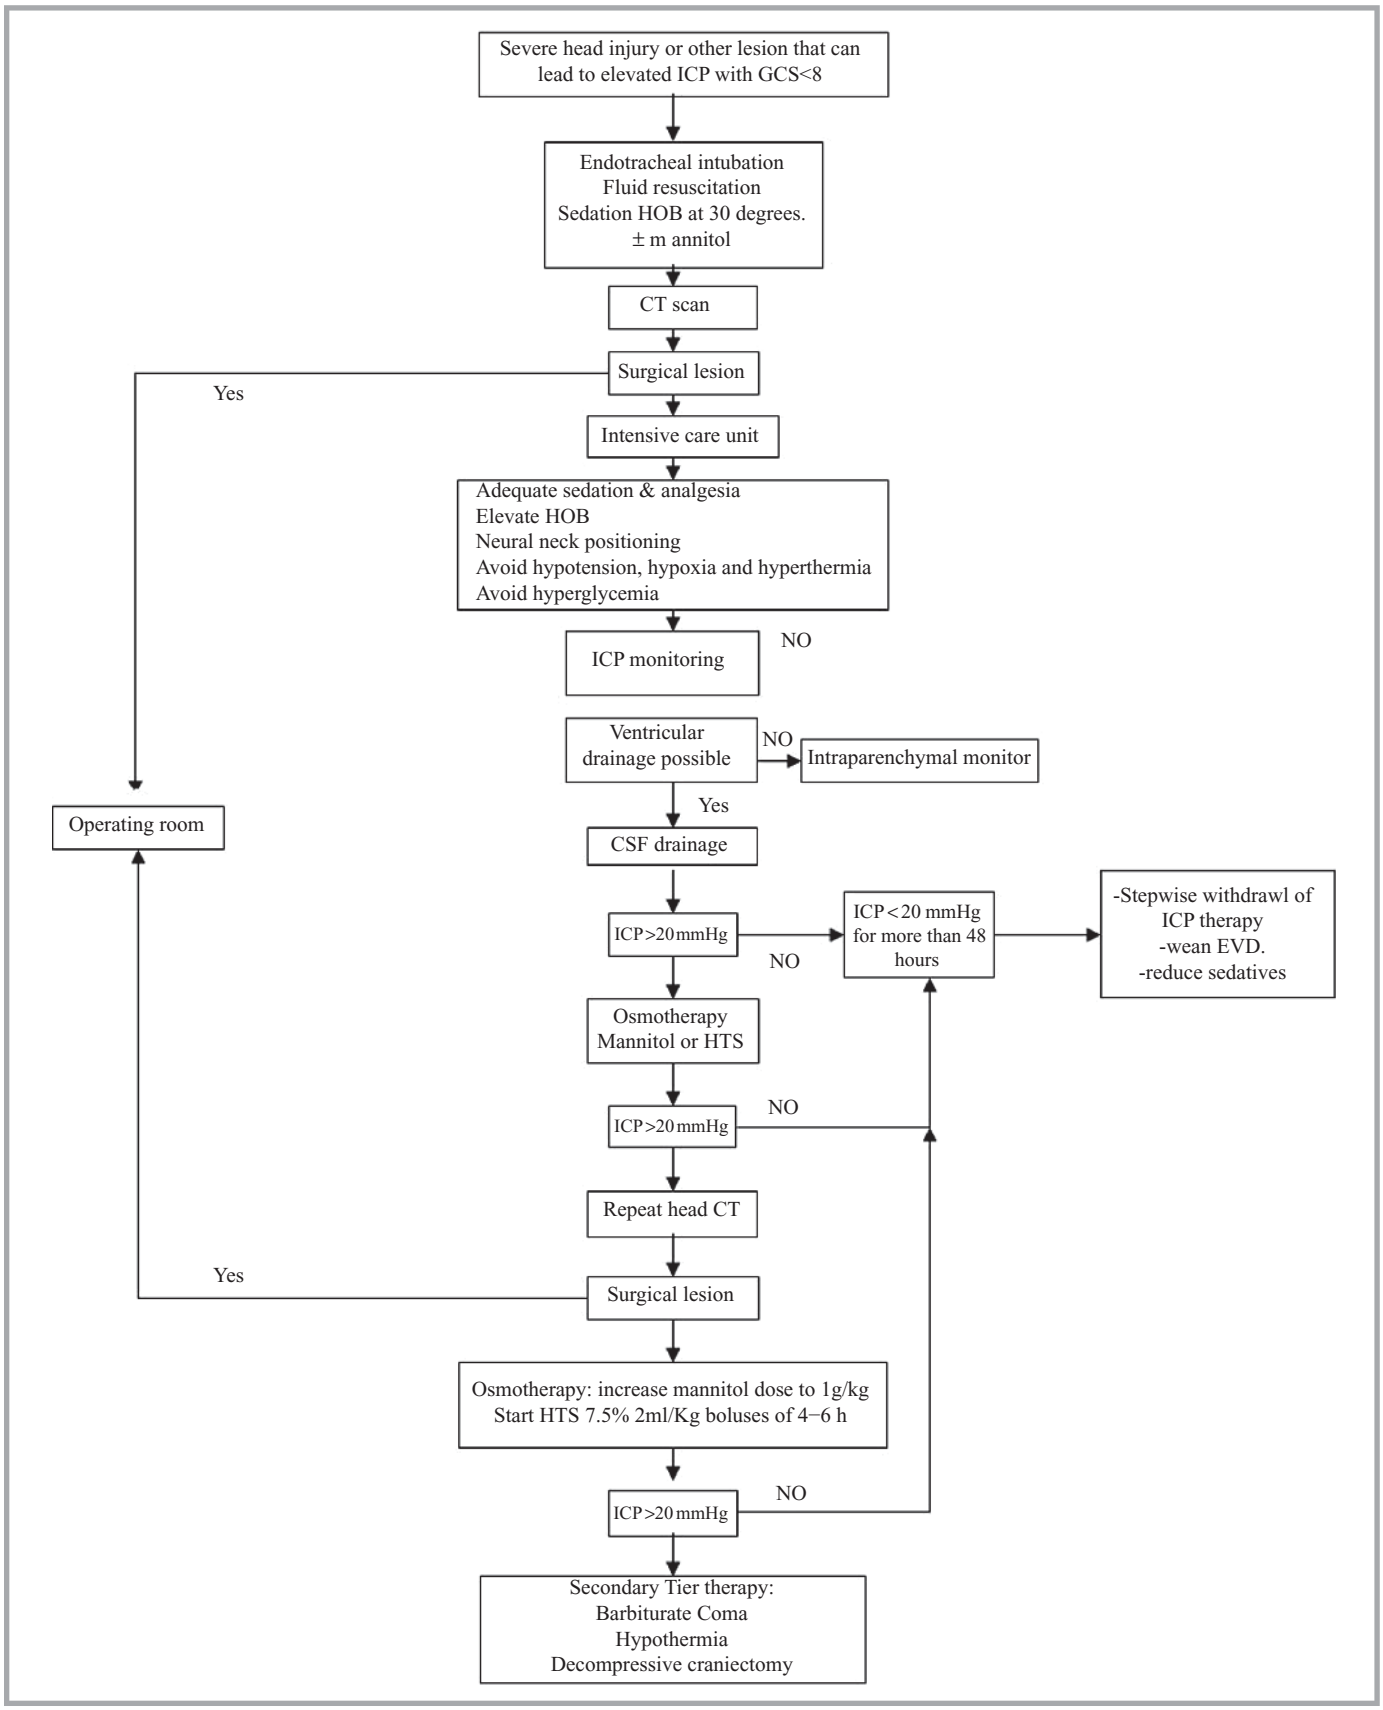

FIGURE 30-1

Algorithm for severe head injury treatment and evaluation.

The clinical features associated with pituitary apoplexy can be variable and range from mild symptoms to a catastrophic presentation that can result in permanent neurological deficit or even death. Headache is present in 95% of cases. The headache is sudden and frequently retro-orbital in location. The headache is usually accompanied by vomiting, with the mechanism attributed to meningeal irritation and/or increased intracranial pressure. The proximity of the pituitary gland to the visual apparatus and ocular motility cranial nerves (i.e., the cavernous sinus) accounts for the visual deficits (64%) and the ocular paresis (78%) seen with pituitary apoplexy. The classic visual field deficit is a bitemporal superior quadrantanopsia. The oculomotor nerve is involved most commonly, which results in a unilateral dilated pupil, ptosis, and an inferiorly and laterally deviated globe. Patients may also have a decreased mental status secondary to hydrocephalus or hyponatremia (Addisonian crisis). Other clinical finds are a Horner's syndrome, nuchal rigidity, photophobia, hypotension, seizures, and hypothalamic dysfunction.

Radiographic evaluation by head CT may show a hemorrhagic mass in the region of the sella turcica; however, MRI is the imaging modality of choice, because it clearly demonstrates the features of hemorrhage and infarction, the suprasellar extension, compression of the chiasm, and extension into the cavernous sinuses. Cerebral angiography is sometimes needed to differentiate pituitary apoplexy from aneurysmal SAH.

The pituitary gland remains capable of secreting adequate amounts of hormones when as little as 10% of residual tissue remains; however, insufficient hormone can lead to adrenal crisis. Immediate initiation of steroid replacement is paramount in the treatment of patients presenting with pituitary apoplexy. One hundred milligrams of hydrocortisone should be administered IV every 8 h. The definitive treatment for pituitary apoplexy is surgery for decompression, especially in patients with decreases in visual acuity or visual field deficits, a decreased level-of-consciousness, or progressive deterioration of visual or oculomotor abilities. The trans-sphenoidal surgical route is adequate in most instances. The visual outcome is related to the duration of impairment, severity of the initial visual defect, the appearance of the optic disc, and early decompression.[26]

The classic presentation of pituitary apoplexy is paroxysmal headache with neurologic and endocrinologic deficit.

Management: immediate administration of hydrocortisone and trans-sphenoidal decompression.

In a minority of published papers, cases of isolated and stable meningismus and/or opthalmoplegia have been shown to be managed medically. Medical management includes close monitoring of endocrine, neurological, and ophthomalogical function, hormone administration, and support with intravenous fluids and electrolytes.

ACUTE ICU MANAGEMENT OF ANEURYSMAL SUBARACHNOID HEMORRHAGE

SAH is the pathologic condition that exists when there is blood in the subarachnoid space. The most common cause is head injury. The incidence of SAH in head-injured patients increases with increasing severity of the injury and with penetrating injuries. The most common cause of spontaneous SAH is aneurysm rupture. Not all SAHs are due to aneurysm rupture, and not all aneurysm ruptures are primarily into the subarachnoid space. Intracerebral and intraventricular hemorrhages are more common than subdural hemorrhage following aneurysm rupture.

Each year, 3,000 patients die secondary to aneurysmal SAH before reaching the hospital, and of those who survive, more than one third of survivors suffer long-term disabilities.[29]

A ruptured cerebral artery aneurysm is associated with a high morbidity and mortality. Roughly 12% of patients die of aneurymal SAH before coming to medical attention. Epidemiological studies estimate that about 40% of those reaching a hospital die.[27] Based on the autopsy series reported by McCormick, it is likely that 10–15 million Americans harbor occult aneurysms.[28]

The rupture of an intracranial aneurysm is a medical emergency and rapid identification and stabilization of the aneurysm is of great importance in patient management.

As a result of the aneurysmal rupture, blood flows into the subarachnoid space until the local or generalized intracranial pressure increases such that the bleeding stops. This can lead to acute hydrocephalus secondary to disruption of CSF flow and absorption, focal clot formation, parenchymal edema, and irritation. These intracranial events can have systemic ramifications, such as cardiac arrhythmias, myocardial infarction, and the development of pulmonary edema, all of which can exacerbate the underlying brain injury.

CASE STUDY: 2

A 38-year-old man presented to the emergency room with acute onset severe headache while at work. His neurological exam was significant for lethargy, GCS 13, and right third cranial nerve palsy. He also had significant photophobia and nuchal rigidity. A CT scan demonstrated diffuse SAH and CT angiogram showed an 8 mm right posterior communicating artery aneurysm; subsequently, the patient went to have an arteriogram with endovascular coiling of this aneurysm. He was admitted to the neurosurgical intensive care unit (NSICU) with close observation and daily transcranial Dopplers (TCDs).

On bleed day 6, he started to complain of worsening headache and became more somnolent. Repeat CT Angio showed vasospasm involving the proximal right M1 and A1 segments; triple H therapy was escalated and the vasospasm was treated with endovascular angioplasty and verapamil infusion. During his ICU stay, he required three more endovascular treatments of his vasospasm, but eventually the vasospasm started to resolve and he was discharged to rehabilitation with good neurological outcome.

There are two main stages in the development of brain damage as a result of SAH: (1) primary damage, which occurs at the moment of the bleed; and (2) secondary damage produced by complicating processes that are initiated at the moment of the bleed, but do not present clinically until later. More than two-thirds of patients who die from SAH have pathological evidence of secondary brain injury, namely, diffuse edema, herniation, or necrosis. These injuries are attributable to a reduced cerebral oxygen supply as a result of hypoxia, systemic hypotension, and relative hypoperfusion caused by increased ICP.

Patient Evaluation

Patients usually present with a sudden, severe headache (80%) associated with nausea, vomiting (77%), dizziness, syncope (53%), nuchal rigidity (35%), photophobia, or focal neurological signs. Between 25 and 50% of patients give a history of a "warning leak" (i.e., sentinel hemorrhage) a few days or weeks prior to major SAH. Approximately 10–25% of patients with SAH have a seizure, usually in the first few minutes after hemorrhage. This is due to the sudden rise in ICP and/or direct cortical brain irritation by blood. Seizures occur more commonly with anterior circulation aneurysms and middle cerebral artery (MCA) lesions. Approximately 30–40% of patients are at rest at the time of SAH. Physical or emotional strain, defecation, coitus, and head trauma may contribute to a variable degree in the remaining 60–70% of cases.

Acute third cranial nerve palsy with new headache is likely secondary to ruptured posterior communicating artery aneurysm until proven otherwise.

Ruptured aneurysms at specific sites may produce distinct clinical features. Transient bilateral lower extremity weakness may be due to anterior cerebral artery aneurysm rupture. SAH from a MCA aneurysm is more likely to produce hemiparesis, paresthesia, hemianopsia, and dysphasia. Third nerve palsy or unilateral retro-orbital pain suggests an aneurysm arising from the internal carotid/posterior communicating artery junction or superior cerebellar artery origin. Carotid-ophthalmic artery aneurysms may produce unilateral vision loss or visual field defect. The focal neurological deficit after SAH may be due to mass effect from the aneurysm, vasospasm, seizures, or hematomas in the brain or subdural/subarachnoid space.

The most common incorrect diagnoses in order of decreasing frequency are: systemic infection or viral illness, migraine, hypertensive crisis, cervical spine disorders such as arthritis or herniated disc, brain tumor, aseptic meningitis, sinusitis, and alcohol intoxication.[30]

See Table 30-3 for The Hunt and Hess scale that is used to classify the severity of a SAH based on clinical presentation.

Diagnosis

An unenhanced head computed tomography (CT) scan is the first step in the investigation of patients with suspected SAH. Approximately 95% of patients will have evidence of SAH on unenhanced CT if done within 48 h of aneurysmal rupture. Maximum sensitivity is within 24 h after the event; sensitivity is 80% at 3 days and 50% at 1 week. The volume and location of subarachnoid blood on head CT gives important prognostic information about vasospasm

TABLE 30-3

HUNT AND HESS SCALE

GRADE	DESCRIPTION
1	Asymptomatic, or mild headache and slight nuchal rigidity
2	CN palsy, moderate-to-severe headache, nuchal rigidity
3	Mild focal deficit, lethargy, confusion
4	Stupor, moderate-to-severe hemiparesis, early decerebrate posture
5	Deep coma, decerebrate rigidity

Add one grade for serious systemic disease (e.g., HTN, DM, COPD) or severe vasospasm on angiography, CN, cranial nerve

TABLE 30-4

FISHER CT GRADING SCALE

CT FISHER GRADE	CT SAH	% WITH ANGIOGRAPHIC VASOSPASM	% WITH CLINICAL VASOSPASM
1	No blood	4	0
2	Diffuse thin layer <1 mm	3	0
3	Localized clot or thick layer >1 mm	24	23
4	Intracerebral or intraventricular blood with diffuse or no subarachnoid blood	2	0

and outcome after SAH. Fisher et al. in a prospective study, correlated the location and thickness of subarachnoid blood on CT with clinical outcome and likelihood of developing vasospasm.[31] (Table 30-4)

Lumbar Puncture (LP)

Lumbar puncture is indicated to diagnose SAH when the CT is normal. The scan may be normal because only a very small SAH occurred or because an inordinate amount of time has elapsed between the SAH and the first scan. Contraindications to LP include abnormal blood clotting, increased ICP due to a space-occupying lesion, suspected spinal arteriovenous malformation, and infection at the puncture site. The risks include neurologic deterioration from aneurysmal re-bleeding or from cerebral herniation.

Angiography

Catheter-based four vessels cerebral angiography remains the test of choice to diagnose a cerebral aneurysm. The risks of angiography include ischemic events (1–2%), neurologic deterioration (1.5%), allergic reaction to contrast, and renal insufficiency/failure. Rupture of an aneurysm during angiography is uncommon.

Recently, CT angiography has been utilized to diagnose cerebral aneurysms.

Negative angiographic findings do not rule out the presence of a cerebral aneurysm.

Cerebral CT angiography has an equal sensitivity to digital subtraction angiography (DSA) in the detection of intracranial aneurysms >3 mm. It also has a 100% detection rate in anterior communicating aneurysms (AcoA) and MCA bifurcation aneurysms; some locations, such as posterior communicating artery aneurysms, remain problematic.[32]

Approximately 10–20% of patients with clinically diagnosed SAH (CT and/or lumbar puncture [LP]) have negative angiographic findings. The aneurysm may be missed initially if it thromboses totally after bleeding. A repeat angiogram is usually required in 10–21 days.

Management

A complete history, physical, and neurological examination should be obtained. The initial emergency care may include assessment of adequacy of the airway, breathing, and circulatory function. A brief neurological assessment of level-of-consciousness, the cranial nerves, and motor function will determine if emergent surgical interventions (i.e., placement of an

EVD and evacuation of intracerebral hematoma) are required. Other than lifesaving procedures such as these to reduce severely increased ICP, treatment of the aneurysm has as its main goal reducing the risk of re-bleeding.

Blood Pressure and Volume Management

Ideal blood pressure in unsecured aneurysms is controversial and must take in account patients' baseline blood pressure, but in general systolic blood pressure by cuff should be between 120–140 mmHg and MAP 70–100 mmHg.

The optimal blood pressure depends on multiple factors that include the time since the SAH occurred, whether the aneurysm has been treated, the ICP and the patient's premorbid condition. The theoretical treatment goals are to optimize perfusion to the brain while minimizing the transmural pressure gradient across the aneurysm. Clearly, these goals run counter to one another, and the information necessary to determine an optimal blood pressure may not be available. Unless a ventricular catheter or ICP monitor is in place, the ICP will not be known. Optimal perfusion pressure also depends upon the premorbid blood pressure. If the patient had uncontrolled hypertension prior to hemorrhage, reducing the blood pressure below "normal" levels may compromise cerebral perfusion. In general, blood pressure should be reduced to decrease the risk of re-bleeding in patients with untreated aneurysms. Hypertension should be avoided, particularly in the early hours after SAH; transport and angiography are periods of increased risk for hypertension.

Once the aneurysm is obliterated, an elevated blood pressure is not treated except at extreme elevations or when infarction has already occurred; in that setting CBF may be pressure-dependent due to loss of autoregulation. At any time after SAH, the blood pressure may be elevated as a homeostatic response to increased ICP or vasospasm.

Hydrocephalus

Ventriculostomy, when done correctly, is a relatively low-risk procedure that results in dramatic and immediate clinical improvement in approximately two-thirds of patients.[33]

Since acute hydrocephalus is associated with a lower preoperative grade and poorer prognosis, the clinician must carefully monitor the patient for early signs of acute hydrocephalus. The most reliable clinical measure is the patient's level-of-consciousness. Any change in the level-of-consciousness requires an emergent head CT scan to evaluate ventricular size. An obtunded patient with dilated ventricles needs an immediate ventriculostomy.

After a ventriculostomy is placed, the ICP should not be rapidly lowered dramatically in order to avoid the increase of transmural pressure, which may enhance the risk of re-bleeding.[34]

Re-Bleeding

The peak risk for re-bleeding is within the first 24 h of the first SAH.[35] On the first day of SAH, the risk of re-bleeding is 4.1%; this risk decreases steadily until the third day when the risk plateaus at 1.5% per day. The cumulative risk at 2 weeks is 19%, and at 6 months, 50% of patients will experience a second bleed. The optimal method for prevention of re-bleeding is early treatment with intravascular coiling or surgical clipping of the aneurysm.

Vasospasm

Vasospasm accounts for 14% of poor outcomes compared with re-bleeding, which accounts for only 7%.

The exact mechanism(s) by which SAH induces arterial vasospasm continues to be a subject of considerable research and debate.

Vasospasm is a delayed focal ischemic neurological deficit following SAH.[36] Symptomatic cerebral ischemia secondary to vasospasm peaks in onset between 7 and 10 days after the initial bleed and almost never occurs prior to 3 days post-SAH. The risk of symptomatic vasospasm can be predicted from the admission CT as those with thick clot around the basal cisterns have a much higher risk compared to those with a thin layer.[37]

Diagnosing cerebral vasospasm (CVS) can be challenging and requires ruling out other conditions that may lead to delayed neurological deterioration, such as re-bleeding, hydrocephalus, edema, seizures, and sepsis.

The following tests are helpful in diagnosing CVS.

1. Transcranial dopplers (TCDs): changes may precede clinical symptoms and it is helpful to have a baseline study (performed early) rather than obtaining the first study when you suspect vasospasm.
2. A CT scan of the head is helpful in ruling out other etiologies of decreased mental status and may show hypodensities indicating cerebral infarct.

3. CT angiography and CT perfusion studies may demonstrate vasospasm and decreased perfusion in the affected areas.
4. Cerebral angiography remains the gold standard for diagnosing cerebral vasopasm and can be both diagnostic and therapeutic via angioplasty and/or intra-arterial infusion of verapamil and papaverine.

Triple H therapy (hypervolemic, hypertensive, hemodilution) is used to elevate the CPP and improve blood flow to regions of the brain with marginal perfusion due to vasospasm.[40]

The cerebroselective calcium channel blocker nimodipine (60 mg p.o. q4h) may decrease the incidence of vasospasm.[38] Clinical studies showed an improvement in outcome, although a change in mortality could not be documented.[39]

By securing the aneurysm early, one can be aggressive with this therapy without concern of aneurysm reruptures. Initiating prophylactic triple H therapy in patients at high risk for vasospasm may minimize morbidity.[41] The systolic blood pressure goal with this therapy is 160–220 mmHg, with a CVP range of 8–12 mmHg and a PCWP goal of 12–14 mmHg. The target hematocrit with hemodilutional therapy is between 25 and 33%.

Cardiac Problems Following SAH

In one prospective study of 70 patients admitted with SAH, cardiac arrhythmias were detected in 64 of the 70 patients (91%). Twenty-nine of the 70 patients (41%) showed serious cardiac arrhythmias; malignant ventricular arrhythmias, i.e., Torsade de Pointe and ventricular flutter or fibrillation, occurred in three cases. Serious ventricular arrhythmias were associated with QTc prolongation and hypokalemia.[42] Occasionally, SAH may produce EKG abnormalities indistinguishable from an acute MI.[43,44] The catecholamine surge during SAH can induce subendocardial damage. A reversible form of cardiac injury may occur in patients with neurogenic pulmonary edema (NPE) following SAH, and is associated with characteristic clinical findings. Impaired LV hemodynamic performance in this setting may contribute to cardiovascular instability, pulmonary edema formation, and complications from cerebral ischemia.[45] Stunned myocardium is a reversible myocardial dysfunction that is occasionally seen after SAH. It may appear compatible with acute MI on echocardiography, yet serial cardiac enzymes are typically negative and the condition is transient and usually resolves within 5 days.[46]

Pulmonary Complications

Pulmonary complications challenge the medical management of patients who have sustained aneurysmal SAH. Occasionally, this can progress to full blown adult respiratory distress syndrome (ARDS).

Electrolytes Disturbances

If hyponatremia is due to CSWS, fluid restriction may actually aggravate the clinical condition (especially in the setting of vasospasm following SAH) and lead to cerebral infarction.

Patients respond to salt and volume replacement (i.e., opposite treatment).

Electrolytes disturbances are quite common in patients with SAH. The causes of volume depletion and hyponatremia after SAH are not fully understood, but may in part be due to natriuresis or cerebral salt wasting syndrome (CSWS). A markedly increased atrial natriuretic factor concentration precedes natriuresis in some patients, and with other abnormalities of water handling (possibly including a relatively diminished vasopressin concentration), may cause volume depletion. Patients with natriuresis appear to be at increased risk for delayed cerebral infarction after SAH.[47] Hypoosmolality can aggravate cerebral edema and lead to neurologic deterioration; it may precipitate seizures and a decreased level-of-consciousness. Factors useful in discriminating CSWS from the syndrome of inappropriate diuretic hormone (SIADH) are described in Table 30-5.

Management of CSWS involves volume replacement and maintaining adequate hydration usually with intravenous isotonic saline solutions (0.9% NaCl) and blood products (especially if the patient is anemic). Colloids may also be used to expand volume and absorb interstitial/third-space fluid and one may need to add oral salt or HTS to ensure a positive sodium balance. Fludrocortisone enhances sodium reabsorption by acting directly on tubule and can also be used in the treatment of CSWS.

TABLE 30-5

DIFFERENTIATING CSWS FROM SIADH

1. Both share the same laboratory characteristics with reduced serum osmolality, high urine osmolality (greater than serum)
2. Major difference is volume status (low in CSWS)
3. Poor skin turgor, dry mucous membranes, absence of perspiration, tachycardia
4. Orthostatic hypotension (CSWS)
5. Loss of weight on serial testing since admission (increased in SIADH)
6. Negative water balance on ins/outs charting (CSWS)
7. Low pulmonary capillary wedge pressure (PCWP <8 mmHg) or low central venous pressure (CVP <6 mmHg) if invasive measurement of volume status available (CSWS)
8. Urine Na+ markedly elevated (variable in SIADH) and urine volume increased in CSWS
9. High BUN and Hematocrit supports CSWS (prerenal azotemia and hemoconcentration)
10. Elevated serum K+ not usually seen in SIADH and implies CSWS
11. Serum uric acid often increased in volume depletion (CSWS) while low in SIADH

Infections

Infections are common in SAH patients because of the multiple catheters that are placed (central lines, arterial lines, ventriculostomies, Foley catheters). Since a large percentage of these patients are intubated, respiratory infections and ventilator-associated pneumonias (VAP) are common.

Venous Thrombosis

Venous thrombosis presents a particular problem in patients with SAH, especially early in the course before the aneurysm is controlled because of concern with using standard prophylaxis regimes (heparin, low molecular weight heparins). The reported incident of deep venous thrombosis (DVT) is approximately 2%, and documented pulmonary embolism (PE) is 1%. The recommended prophylaxis is the use of thigh high TEDs and pneumatic compression stockings and early postoperative ambulation when possible. Our current practice also includes placing removable inferior vena cava filters in high-risk patients.

Conclusion

SAH is associated with significant morbidity and mortality.

Many survivors are left with persistent physical, cognitive, behavioral, or emotional changes that will affect their daily life. The most important predictor of death and disability is the patient's clinical condition at presentation. Age, medical comorbidities, aneurysm type, and the size of the hemorrhage are also correlated with poor outcome.

Concurrent steps are taken in each case to achieve quick and accurate diagnosis, systemic stabilization, and management of the neurological sequelae. These measures are taken while planning as early as possible for definite treatment of the cause of the SAH and to prevent the devastating risks of re-bleeding.

CENTRAL NERVOUS SYSTEM INFECTIONS

Spinal Infections

Spinal infections are potentially fatal neurosurgical emergencies and a high index of suspicion is required for their diagnosis. Spinal infections can be divided into the following categories:

- Spinal osteomyelitis

  Discitis, which can be spontaneous or postoperative
- Epidural abscess
- Subdural empyema
- Meningitis

Pyogenic Osteomyelitis

The most common organisms found in pyogenic osteomylitis is *Staphylococcus aureus* (60%), followed by Enterobacter (30%). Nonspinal infections may lead to spinal infections via hematogenous spread or by direct extension. The most common route for infection to spread to the spine is via the hematogenous route. Batson demonstrated retrograde flow from the pelvic venous plexus to the prevertebral plexus via a series of valveless veins (Batson's plexus); this network of veins allows tumors and infections to spread from the pelvis to the vertebral column. The arteriolar theory, which was proposed by Wiley and Trutea, suggests that bacteria can become lodged in the end-arteriolar network in the vertebral endplate leading to osteomyelitis (OM) and diskitis.

The second most common route is contiguous spread from adjacent soft-tissue infections.

Disease states and therapies that lead to an immunocompromised state, such as HIV, malignancy, chronic steroid use, intravenous drug users, diabetes, renal failure, recent spinal surgery, or a prior spinal procedure, can predispose patients to develop spinal abscess or OM.

Clinical presentation usually involves localized pain with or without fever, but a more common presentation is vague symptoms of low-grade fever, back pain, and chronic nonspecific illness, and a delay in diagnosis is common.

The lumbar spine is the most frequently affected location followed by the thoracic spine.

Neurologic findings are absent initially. Motor symptoms and long tract signs are more common than sensory, mostly because the vector of compression is anterior from the vertebral body.

Evaluation: the algorithm for evaluation of vertebral osteomyelitis should include the following:

– Lab tests: CBC (WBC is elevated in only 35%), blood cultures (positive in about 50%), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are nonspecific, but are elevated in almost all cases and CRP tends to normalize quickly with appropriate treatment.

Imaging findings on plain radiographs are delayed (at least 4 weeks after the onset of the infection) and the earliest findings are narrowing of the disc space followed by lucency in the vertebral endplates. CT scanning plays a significant role in demonstrating the degree of bony destruction (better than MRI). However, MRI remains the modality of choice in diagnosing spinal infections with a superior detailed picture of the vertebral bodies, soft tissues, and neural elements. Bone scan can be positive within 1–2 days after the infection, but false-positive findings can be secondary to degenerative changes, surgery, or fracture.

In the absence of positive blood culture, biopsy of the presumed osteomyelitis site is essential to provide a definitive diagnosis and identify the organism; the yield of needle biopsy cultures ranges between 60 and 90%.

Approximately 90% of vertebral OM can be managed nonsurgically. The criteria for nonsurgical treatment include identified organism with good antibiotic sensitivity, single disc space involvement with little vertebral body involvement, no or little neurological deficit, and little or no spinal instability. Nonoperative treatment includes intravenous antibiotics, treatment of the underlying disease, and immobilization with braces. Intravenous antibiotics should be continued for at least 6 weeks provided there is satisfactory clinical and radiographic improvement and a decrease in ESR occurs (Table 30-6).

Nonpyogenic Osteomyelitis (OM)

Nonpyogenic OM is usually caused by tuberculosis (Pott's disease) and fungus (aspergillosis, blastomycosis, coccidiomycosis).

TABLE 30-6

OPERATIVE INTERVENTIONS ARE INDICATED FOR THE FOLLOWING

Open biopsy is needed
Failure of medical treatment alone
Drainage of an abscess
Decompression of spinal cord or nerve root compression associated with neurologic deficit
Correction of spinal deformity and instability

Metastatic tumor, particularly lymphoma
Transverse myelitis
Spinal cord tumor
Syrinx
Epidural hematoma
Spinal cord infarct, ischemia

TABLE 30-7

DIFFERENTIAL DIAGNOSIS FOR SPINAL EPIDURAL ABSCESS (SEA)

Discitis

Discitis is an infection of the nucleus pulposus with secondary involvement of cartilaginous endplates and possibly the vertebral bodies. Can occur spontaneously (most common) or following a procedure. It is often self-limited and benign.

Spinal Epidural Abscess (SEA)

SEA should be considered in any patient with fever, back pain, and spinal tenderness. The classical presentation with a skin furuncle occurs in only 15% of patients.

An epidural abscess is a rare but potentially life-threatening disease that requires early detection and prompt management. It is most commonly encountered in the lumbar spine followed by the thoracic and cervical spine.[48] Peak age of occurrence is 57 years of age and there is a male predominance. SEA is often associated with vertebral body osteomyelitis and discitis. Risk factors for SEA are similar to those mentioned for vertebral OM and include diabetes, intravenous drug use, renal failure, alcoholism, chronic steroid use and recent surgery, or diagnostic spinal procedures.

Suppuration within the epidural space can occur in one of three ways: (1) direct extension from a contiguous site of infection (decubitus ulcer, psoas abscess, penetrating trauma, pharyngeal abscess), (2) hematogenous spread from a distant source with skin infection being the most common (furuncle may be found in 15% of cases), and (3) direct contamination during a spinal procedure (lumbar puncture, epidural anesthesia, steroid injections, or spinal surgery). No source of infection is identified in about 50% of patients in some reported series (Table 30-7).

Pathophysiology and Clinical Features

Symptoms may be related to direct neural elements compression, ischemia secondary to thrombosis of arteries and veins supplying and cord, impairment of microcirculation, and infectious vasculitis.

Fever, sweats, or rigors are common in SEA, but normal WBC and temperature can occur.

One of the important aspects of epidural abscess is its variable presentation; therefore, one must have a high index of suspicion in order to make the diagnosis early and prevent irreversible neurologic deficits. Heusner has described the classical clinical presentation as having four stages: (1) spinal pain with tenderness to percussion, (2) radicular pain, (3) motor and sensory deficits, sphincters dysfunction leading to incontinence, and (4) complete paralysis.

Organisms Causing SEA

Staphylococcus aureus is identified in 50% of SEA cases, aerobic and anaerobic streptococcus is the second most common organism; in recent years gram-negative aerobes (*E. coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumonia*, *Citrobacter*) have accounted for an increasing percentage of cases. Multiple organisms are found in 10% of cases and no organism can be identified in 30–50 % of cases.

Laboratory findings in SEA are usually nonspecific; the majority of cases have mild leukocytosis, elevated ESR and CRP; blood cultures can be positive in as many as 67%.

Lumbar puncture can be performed at a level distant from the suspected site of the SEA, though it carries a risk of spreading the infection to the subarachnoid space and cord. CSF usually demonstrates finding consistent with a parameningeal process with mild pleocytosis, elevated protein, and normal glucose.

Radiographic Studies

Plain films are usually normal unless there is an associated discitis and vertebral OM, then a loss of the disc space height and lucency of the endplates may be seen. CT scan can be normal or show evidence of associated bony destruction if there is an accompanying vertebral OM. Administration of intravenous contrast may show a collection in the epidural space. MRI with Gadolinium is the imaging modality of choice for the diagnosis of SEA. Additionally, MRI can exclude other entities included in the differential diagnosis such as herniated disc, transverse myelitis, neoplasm, and hematoma. In cases where a MRI is contraindicated, a CT myelogram will rule out a SEA; however, it carries the risks of seeding the infection.

Treatment

Immobilization is indicated when pain is a significant symptom or there is a potential for spinal instability. In the thoracic and lumbar spine, immobilization is accomplished using a thoracolumbosacral orthosis. This may be sufficient to allow a patient to resume walking. The cervical spine should be immobilized in a Philadelphia collar (or another hard cervical collar). Immobilization is maintained until pain resolves and evidence of spinal stability is documented on neuroimaging. Antibiotics should be started as soon as possible, preferably after obtaining blood cultures and/or a biopsy to identify the organism. Empiric treatment usually includes (1) vancomycin until methicillin resistant *Staphylococcus aureus* (MRSA) infection can be excluded, (2) a third-generation cephalosporin, and (3) rifampin p.o.; the antibiotic regimen should be modified as culture results become available. The duration of treatment is usually 3–4 weeks of IV antibiotics followed by 4 weeks of oral antibiotics. If there is evidence of an associated osteomyelitis, then the recommended duration is at least 6 weeks of IV antibiotics.

If the conservative approach is selected, careful and close observation of the patient´s neurological exam is mandatory and repetitive MRI studies are essential to ascertain that the patient is responding to the treatment.

Traditionally, SEA has been considered a surgical condition that requires immediate intervention. However, more recently, some authors have advocated conservative management, particularly in patients who are neurologically intact, and in patients with a very high operative risk.

Any sign of neurological deterioration should prompt the physician to proceed with surgical decompression. Conservative treatment has been considered also in patients with complete paralysis for more than 3 days.[49]

Surgery

There is good evidence that patient outcome is closely related to neurological status at the time of surgery. For abscesses that are located dorsally, a laminectomy and evacuation of the abscess are usually appropriate. However, in the presence of vertebral body OM and a ventrally located abscess, an anterior exposure or transpedicular or lateral extracavitary approach may be necessary with corpectomy, graft placement, and instrumentation (Table 30-8).

Rath et al. conducted a retrospective review of 43 consecutive surgically treated patients with osteomyelitis of the thoracic (19 patients) and lumbar (24 patients) spine, and found that the use of spinal instrumentation and autogenous bone grafts in the presence of infection does not appear to lead to a higher risk of persistence or recurrence of infection.[50]

TABLE 30-8

INDICATIONS AND GOALS OF SURGERY

Decompression of the neural elements
Isolation of the organism
Debridement of the necrotic and dead tissue
Stabilization of the spine and correction of deformities.
Relief of persistent severe pain
Unreliable patient and Inability to follow the patient closely with serial MRI
Failure of the abscess to resolve, despite 6 weeks of IV antibiotics

Outcome

Due to concomitant serious illnesses and patient status, the mortality rate from spinal infections remains as high as 20%.[51] Reversal of paralysis if present for more than a few hours is rare; however, a few series have shown improvement with treatment within 36 h. Neurological impairment is a serious complication associated with spinal infections. Its prevalence correlates strongly with the degree of neurological deficit at the time of surgery. Factors associated with worse neurological outcome are the presence of diabetes, rheumatoid arthritis, cervical spine involvement, and a treatment delay of 72 h after neurological impairment.[52] (Fig. 30-2)

CEREBRAL ABSCESS

Intracranial abscesses are uncommon, serious, life-threatening infections. Approximately 1,500–2,500 cases are reported in the USA per year. Most cases occur in the first four decades of life with a median age of between 30 and 40 years.[53] The incidence may be rising with the increasing prevalence of AIDS and organ transplantation. Risk factors commonly associated with brain abscesses include congenital cyanotic heart disease, pulmonary abnormalities such as AV fistulas, infection of contiguous structures (e.g., otitis media, dental infection, mastoiditis, sinusitis), skull trauma or surgery, and rarely following meningitis.

Pathogenesis

Prior to 1980, spread from contiguous structures was the most common etiology, but now the hematogenous spread is most common. Abscesses that are due to direct extension are generally singular while abscesses from hematogenous spread are often multiple. Cultures can be sterile in up to 25% of cases.

In general, Streptococcus and Bacteroides are the most frequent organisms isolated in cerebral abscess, with 33–50% being anaerobic or microaerophilic.

Immunocompromised patients, including transplant and AIDS patients, have a higher incidence of fungal infections such as *Toxoplasma, Nocardia, Candida, Listeria,* and *Aspergillus*. Infants have a higher incidence of gram-negative infection because the IgM fraction does not cross the placenta.

Clinical Presentation

Symptoms of cerebral abscess are most commonly the result of their size and location. While the abscess cavity may be significant, the associated vasogenic edema is often a greater factor in producing symptoms. Symptoms can also be related to an increased ICP (nausea, vomiting, headache, lethargy). Headache of less than 2 weeks of duration is the most common finding and is present in 75% of patients. Other focal neurologic signs can develop depending on the location of the abscess (Fig. 30-3).

Evaluation

Routine blood work has proven to be of a little value. Peripheral WBC may be normal or mildly elevated in 60–70% of cases; ESR and CRP are usually elevated, but are nonspecific. Blood cultures are routinely done, but they are often negative.

The role of lumbar puncture is controversial. Although the LP is abnormal in 90% of cases, there are no characteristic findings. The opening pressure is usually elevated and the WBC and protein may also be elevated. The organism is rarely isolated from the CFS unless the abscess has ruptured into the ventricles. The risk of causing or worsening a herniation by performing an LP is increased in large lesions with significant mass effect and edema. In general, we tend to avoid LP.

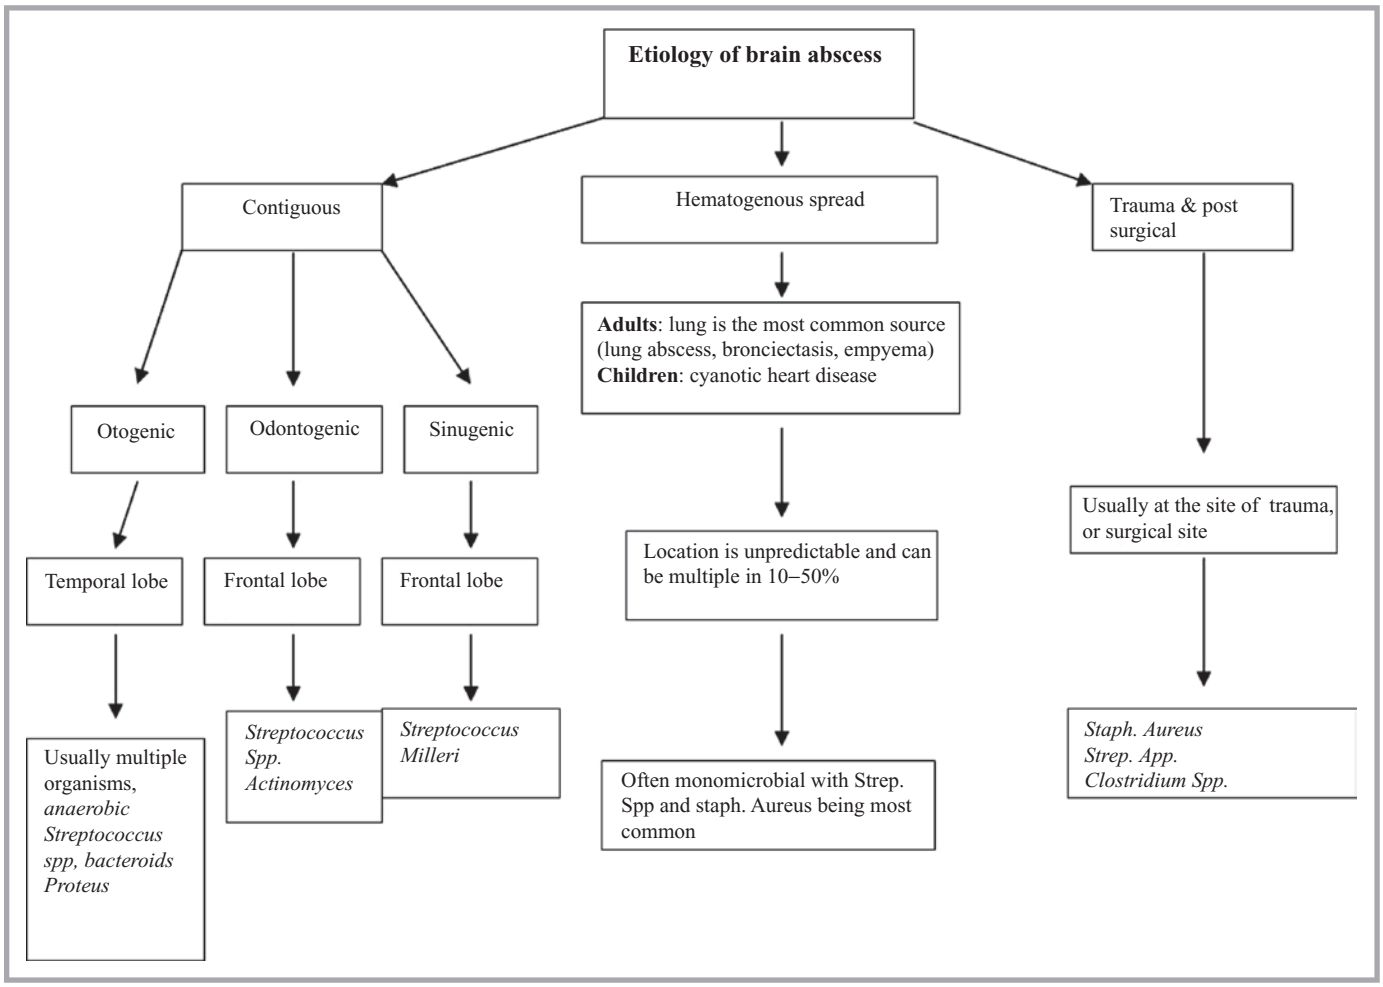

FIGURE 30-3

Etiology of abscesses brain.

Imaging

The development of CT and MR imaging represents the single most important factor in the improved management of the patient with a brain abscess. Diffusion-weighted MRI (DWI) may be useful in differentiating abscess from necrotic tumor. Diffusion-weighted echo planar images (DWI) demonstrate an abscess as high signal intensity with a corresponding reduction in the apparent diffusion coefficient. The brightness on DWI is related to the cellularity and viscosity of the contents within the abscess cavity. Tumors with central necrosis have marked hypointensity on diffusion-weighted images and much higher apparent diffusion coefficient values. Of note, the pattern described above for an abscess has also been noted for acute cerebral infarction (Table 30-9).

Management of Cerebral Abscess

Although once considered an urgent surgical emergency, the advent of CT and MR allows detection of brain abscesses at an early stage and gives us a noninvasive and accurate method to follow these lesions. Medical treatment alone may be employed and can be successful if the treatment begins in cerebritis stage (although many of these lesions can go on to become capsulated despite antibiotic therapy). Smaller abscesses (the suggested cut-off is less than 3 cm), duration of symptoms of less than 2 weeks, and isolation of the causative organism

TABLE 30-9

HISTOLOGIC STAGING OF BRAIN ABSCESS AND CORRESPONDING CT AND MRI FINDINGS

STAGE	HISTOLOGIC CHARACTERISTICS	CT FINDINGS	MRI FINDINGS
Early cerebritis day 1–3	Poorly demarcated from adjacent brain, perivascular infiltrates	Poorly defined are of hypodensity with little or no enhancement with IV contrast	Edema may be readily apparent, hyopintense on T1WI and hyperintense on T2WI
Late cerebritis days 4–9	Developing of necrotic center and reticular matrix	Hypodense area with poor margination, poor enhancement on early phase, ring-enhancement begins in later phase	Early pattern of enhancement more easily detectable
Early capsule days 10–13	Necrotic center, neovascularity, reticular network that is less well developed along the side of the ventricles	Faint rim is present on precontrast CT (necrotic center with surrounding edema causes the collagen capsule to be seen) Enhancement of well-defined capsule Capsule usually thin, uniform and smoothly contoured on the inner surface	The collagenous abscess capsule is visible prior to contrast as a comparatively thin-walled isointense to slightly hyperintense ring that becomes hypointense on T2-weighted MRIs
Late capsule >14 days	Collagen capsule, necrotic center, gliosis around the capsule	Ring-enhancement of capsule which become thicker, daughter abscesses may be seen budding from the capsule	Necrotic center that is very bright on diffusion MR

Surgical intervention should be pursued in the following circumstances: presence of significant mass effect, unclear diagnosis and unknown organism, and proximity to the ventricles.

Improvement in the CT images usually lags behind clinical improvement and so the presence of residual enhancement on CT should not in and of itself dictate the need for additional treatment.

with evidence of improvement within the first week of antibiotic therapy argue for medical treatment.

Surgical management (includes aspiration, stereotactic aspiration, craniotomy, and excision) of brain abscess can be both diagnostic and therapeutic.

If the abscess ruptures into the ventricles, the morbidity and mortality increase dramatically. Stereotactic aspiration has multiple advantages; it can be accomplished safely and rapidly through a single burr hole, which can be performed under local anesthesia alone. Open craniotomy and excision is usually reserved for posterior fossa abscesses, multiple lesions, traumatic abscess with retained foreign body and fungal abscesses, because of the poor penetration of antifungal agents. Prophylactic anticonvulsants are administered in most cases because of the higher incidence of early and late epilepsy. Steroids should be reserved for use in selected patients with significant edema and mass effect resulting in neurologic deficit or impending herniation, because they may reduce antibiotic utility. Antibiotic treatment is an essential part of management of brain abscess; the initial antibiotic regimen should include vancomycin (until MRSA is ruled out), plus a third-generation cephalosporin, plus one of the following – metronidazole or chloramphenicol or in cases of posttraumatic abscess, oral rifampin. As culture data become available, the antibiotic regimen can be tailored to specific organisms. IV antibiotics can be discontinued at 6–8 weeks even if abnormalities on CT scan persist; neovascularity and enhancement take longer to resolve (6–9 months on CT scan and longer on MRI).

The duration of IV antibiotic therapy may be shortened if the abscess and its capsule are surgically excised.

Follow-up is critical and it is important that there is frequent clinical and radiographic evaluation to determine the response to therapy. Weekly CT scans are recommended during the course of therapy, 1 week after finishing the antibiotic course, and then every 1–2 months for 1 year to ensure complete resolution of the abscess. MRI can be utilized, but there is no

advantage over CT for follow-up. It is also logical to use the same modality throughout the course of treatment for comparative reasons.

Management of Ruptured Cerebral Abscess

Intraventricular rupture of a cerebral abscess is a rare but potentially fatal complication. If it is an intracerebral pyogenic abscess, it has historically been associated with a mortality rate as high as 85%.[54] Rupture frequently manifests as a catastrophic deterioration in the clinical status of patients, with coma ensuing. Cerebral abscesses tend to rupture toward the lateral ventricle, rather than toward the subarachnoid space because the capsule is more complete on the cortical side compared with the ventricular side.[55] The mortality rate in recent series has improved to 38%. This is thought to be due to administration of appropriate intravenous and intrathecal antibiotics (gentamicin) in association with aspiration or excision of the brain abscess, and placement of ventriculostomies to allow CSF drainage and prevent hydrocephalus.[56]

Conclusion

CNS infections represent true neurosurgical emergencies that require prompt diagnosis followed by appropriate medical therapy, and in most cases, surgery. Despite improved antimicrobial agents and imaging modalities, surgical interventions are still essential for diagnosis and decompression of neural elements.

INTENSIVE CARE MANAGEMENT OF SPINAL CORD INJURY (SCI)

Annually in the USA, approximately 10,000 patients are rendered paraplegic or quadriplegic as a result of SCI; in this country about 200,000 patients are living with significant SCI. SCI most often occurs in teenagers and young adults. The mean age at injury is 30.7 years, with injury most frequently occurring at age 19. Men are four times more likely to be affected than females; the four most common causes of spinal fracture are MVA (50%), falls (25%), gun shot wounds (12–21%), and sports injuries (10%). Early management begins in the field with immobilization of the spine and rapid transport to tertiary care centers.

Initial Evaluation

The consequences of a neck injury range from simple neck pain to quadriplegia, or even death. The SCI occurs at the time of trauma in 85% of patients and as a late complication in 15%. The initial postinjury period is critical with regard to neurological recovery or deterioration. Delayed recognition of an injury or improper stabilization of the cervical spine may lead to irreversible SCI and permanent neurological damage (Table 30-10).

Ruling out significant spinal injury early is important as unnecessary cervical collars or other immobilizers inhibit nursing care. However, in patients with multiple injuries and comorbidities, it may be necessary to maintain the collar and spinal precautions until more severe injuries are addressed and the spine is properly cleared.

TABLE 30-10

CRITERIA FOR EXCLUDING CERVICAL SPINE INJURY ON A CLINICAL BASIS

Absence of neck pain
Absence of neck tenderness on palpations
Full range of motion without pain
No history of LOC
No mental status change/intoxication
No neurologic deficit
No distracting injury

SOURCE: Data from Greenberg MS, Arredondo N, Duckworth EAM, Nichols TA, eds. *Greenberg Handbook of Neurosurgery*, 6th ed. New York: Thieme; 2006 [79]

CASE STUDY: 3

A 56-year-old man was brought to the emergency department after a motor vehicle accident. He was an unrestrained driver who steered off the road and rolled over. The patient was amnestic to the details of the accident. In the trauma bay he was complaining of bilateral arm and leg weakness. His neurological exam was significant for bilateral upper and lower extremities weakness 2/5 and decreased sensation to pinprick in from C4 down. He was hypotensive with BP 82/55 mmHg and HR 75 beats/min. The rest of his trauma evaluation was negative.

Patient was resuscitated with intravenous fluids; however, he had refractory hypotension and needed to be on vasopressors to bring his pressure up. X-ray and CT of his cervical spine demonstrated C4-5 bilateral locked facets. After starting intravenous infusion of methylprednisolone and stabilizing his blood pressure, the patient was taken for MRI of his cervical spine. The MRI revealed evidence of ligamentous injury and increased T2 signal in the spinal cord, the C5 consistent with spinal cord injury (SCI).

Closed reduction was attempted with cervical traction without a satisfactory result and subsequently the patent was taken to the operating room for closed reduction and fusion. Postoperatively, the patient was not able to wean off the ventilator and required a tracheostomy and gastrostomy. His motor strength gradually improved to 3/5, and he weaned off the ventilator and pressors and was discharged to SCI rehab.

Imaging Studies

Plain films provide the quickest way to survey the cervical spine. An adequate spine series includes three views: a true lateral (which must include all seven cervical vertebrae as well as the C7-T1 junction), an AP view, and an open-mouth odontoid view. At many institutions, the quality and availability of CT scans make it the modality of choice to evaluate the cervical spine, especially since it can easily be done at the same time as a head CT. Ligamentous injuries are relatively common in the cervical spine. In the presence of significant injury to the neck region, or if the patients is comatose, it is recommended that standard X-rays and CT scans be supplemented with either an MRI or a fluroscopic exam, to exclude ligamentous instability. In an awake patient with a normal neurological exam and a normal CT scan who continues to complain of neck pain or tenderness on palpation, flexion–extension X-rays should be obtained to rule out ligamentous injury.

Halo-Vest immobilizers are well known to cause significant pulmonary complications, especially in the elderly with SCI leading to dysphagia, decreased effective coughing, aspiration, and decreased respiratory function.

Immobilization devices are not without complications. Decubitus ulcers are found under cervical collars in 44% of patients within 6 days of placement.[57] This makes regular inspection and early removal an important priority. Improperly fitted or placed cervical collars can increase intracranial pressure by compressing the jugular veins.

Furthermore, Lind et al.[58] found that halo fixation restricted pulmonary function such that vital capacity decreased 10–30% immediately after halo placement, and the greatest restriction was observed in patients with neurological injuries.

Acute Medical Management

As with any trauma patient, assessment begins with airway, breathing, and circulation, and should include inline stabilization of the entire spine until it is cleared of injury. It is recommended that acute spinal cord injuries be managed in an ICU.

Steroids

The use of steroids remains highly controversial even among experts. The national acute spinal cord injury study (NASCIS II) demonstrated improvement in neurological outcome when methylpredinsolone was administered as an IV bolus of 30 mg/kg over 15 min, followed by 5.4 mg/kg/h continuous infusion for 23 h, if started within 8 h of initial injury. However, it is generally agreed that the benefits from steroids are small and increase the risk for hyperglycemia, pulmonary complications, sepsis, and pneumonia.

It is important not to assume severe hypotension is secondary to spinal-shock as patients may have hypovolemic shock from other injuries. In such instances, compensatory tachycardia may not be observed due to the lack of sympathetic innervation.

Blood Pressure Management

Ischemia of the spinal cord is thought to be one of the most important contributors to neuronal injury and neurological deficit after acute SCI. Most patients with high thoracic and

cervical injuries have mild hypotension, vasodilatation, and bradycardia secondary to loss of sympathetic innervation; this is known as spinal-shock. These patients usually respond to IV fluid administration, but will occasionally need to be placed on vasopressors.

The preferred vasopressor in spinal-shock is dopamine, which has both alpha and beta agonist actions. However, it is important to maintain appropriate intravascular volume.

Clinical outcomes may be improved by maintaining good perfusion to the spinal cord. A MAP > 85 mmHg can be achieved with a combination of fluid resuscitation and vasopressors and should be continued for the first week.[59]

The optimal pulmonary capillary wedge pressure (PCWP) to obtain the best cardiac performance and systemic perfusion is between 12 and 18 mmHg. Occasionally, the patient may remain dependent on vasopressors for longer periods of time. Adding fludrocortisone (FLORINEF®) and/or oral sympathomimetics such as ephedrine may be beneficial.

Prevalence rates for pressure ulcers in chronic SCI are difficult to obtain, but have been estimated at approximately 30% at 20 years following SCI.[60]

Pressure ulcers result from tissue damage due to unrelieved pressure that typically occurs over bony prominences. Shear friction, poor nutrition, and changes in skin physiology below the level of the lesion contribute to the development of pressure ulcers. The prevention of pressure decubitus ulcers is very important and early employment of specialty beds that allow gradual, continued alteration of the body position and pressure points may be helpful in this regard.

Meeting the health care needs of the spinal cord-injured patient is an immense challenge to the critical care team. Gastrointestinal atony can result in significant gastric dilatation and may worsen respiratory dysfunction by applying upward pressure on the diaphragm; this problem can be alleviated by decompression of the stomach with a naso-gastric tube. Gastrointestinal dysfunction may persist for several weeks; additionally, cervical cord injury patients usually develop negative nitrogen balance and so a parenteral form of nutrition may be necessary.

Oral bowel regimen medications (stool softener, docusate sodium; bowel stimulants, senna and bisacodyl; bulking agents psyllium) are often used during the initial phase of establishing a regular bowel pattern, and are then slowly eliminated.[61]

Autonomic Dysreflexia

Sympathetic decentralization leads to altered regulation of autonomic function with numerous clinical consequences, regardless of the intact parasympathetic (vagal) afferent and efferent pathways in patients with SCI.[62] More specifically, severe autonomic dysreflexia can be defined as "an increase in systolic blood pressure of at least 20% associated with a change in heart rate and accompanied by at least one of the following signs (sweating, piloerection, facial flushing), or symptoms (headache, blurred vision, stuffy nose)[63]" it is usually limited to patients with spinal cord lesions above the T6 level.

It is worthwhile to emphasize that the resting systolic and diastolic blood pressures in acute SCI patients are lower than in uninjured individuals, and therefore, an elevation of greater than 20%, which would ordinarily be considered within the normal range, can be life-threatening for these patients.

The management of autonomic dysreflexia should include the following steps: First, the individual should be immediately put in a sitting position if the person is supine. Second, clothing or constrictive devices need to be loosened. Third, potential triggers including bladder distension and bowel impaction should be investigated. If the systolic blood pressure is as elevated to 150 mmHg or higher, clinicians may consider pharmacological management with a rapid-onset, short-duration antihypertensive agent (such as nifedipine or nitrates) prior to additional sensory stimulation, such as a rectal examination.[64] Anticholinergics can alleviate these episodes, but can also worsen GI and bladder atonia; gabapentin, which acts as a neuromodulator, may be beneficial. Spontaneous temperature fluctuations are common and can make early detection of infection difficult.

Pulmonary Care

The pulmonary system requires careful attention, with frequent mobilization and deep incentive spirometry to minimize atelectasis and pneumonia. If the cord injury level is above C4, a ventilator or a diaphragmatic stimulator may be required to support ventilation. Injuries at

the C3–C5 levels cause variable impairment of diaphragmatic strength. Mechanical ventilation frequently is necessary during acute hospitalization, but recovery of ventilatory strength generally occurs, so that permanent ventilatory support is usually not needed.[65] Improvements in pulmonary function are due primarily to a functional descent of the neurologic injury level as spinal cord inflammation resolves, enhanced recruitment of accessory ventilatory muscles, retraining of deconditioned muscles, and the evolution from flaccid to spastic paralysis.[66]

Patients with complete SCI at levels C5 through C8 inhale via the use of an intact diaphragm and accessory muscles in the neck; exhalation occurs primarily through the passive recoil of the chest wall and lungs, but may be augmented by the clavicular portions of the pectoralis major muscles.[67]

In addition to respiratory muscle function, several other issues must be considered in the respiratory management of patients with SCI. These include direct injury of the lung at the time of trauma, aspiration, pulmonary edema (often neurogenic), and ARDS. It is common for this patient population to have increased airway reactivity and increased bronchial secretions.

These patients are also at risk for mixed or obstructive sleep apnea. Possible mechanisms for the increased prevalence of sleep apnea include obstruction produced by hypertrophy of neck musculature, ventilatory muscle spasticity, use of sedative antispasmodic medications, obesity, or an effect of SCI upon an undefined spinal cord pathway involved with control of sleep.[68]

Neurogenic pulmonary edema (NPE) can occur during either the acute or the chronic phases of SCI, but rarely occurs with complete injuries at or above the C7 level[69].

The pathophysiology of NPE is incompletely understood, but protein-rich edema fluid is believed to result from increased sympathetic activity due to medullary dysfunction, possibly leading to a combination of pulmonary venoconstriction, reduced pulmonary vascular compliance, enhanced pulmonary capillary permeability, lymphatic constriction, and/or elevated systemic vascular resistance.[70]

Tracheostomy may facilitate optimal pulmonary toilet and assist in weaning the patient from the ventilator. This procedure, however, should be avoided or delayed if there is a need for an anterior surgical approach for spinal cord decompression and stabilization.

Because of impaired cough and difficulty mobilizing lung secretions, patients after SCI are at an increased risk for pneumonia. Although the incidence of pneumonia is highest in the first year following SCI, these patients remain at increased risk for pneumonia over their lifetime.[71]

Chest physiotherapy appears to decrease the risk of atelectasis, mucous retention, and pneumonia in patients with SCI. This strategy should include incentive spirometry, frequent changes in position, postural drainage of secretions, nasotracheal suctioning, and manually assisted coughing. Manually assisted coughing is achieved by using forceful upper abdominal thrusts in a posterior and cephalad direction; this is termed a "quad cough."

Venous Thromboembolism

DVT and PE are common complications in patients with acute SCI.[72] Immobility is a major risk factor for venous thromboembolism (VTE), particularly in tetraplegic patients. Given that the susceptibility to VTE after SCI declines with time, other underlying mechanisms for the development of VTE have been suggested, such as altered fibrinolytic activity, abnormal platelet function, and impaired circadian variations of hemostatic and fibrinolytic parameters.[73]

Subcutaneous unfractionated heparin 5,000 units b.i.d or t.i.d has been shown to reduce the incidence of DVT.[74] The use of low molecular weight heparin has been studied as well and has had favorable results compared with unfractionated heparin in both preventing DVT and decreasing bleeding complications.[75] Because most pulmonary emboli occur within the first 2–3 months of injury, prophylaxis with anticoagulation usually spans an 8–12-week period; patients with useful motor function in the lower extremity may be at a lower risk for developing DVTs.[76]

Several studies have shown that IVC filters are safe and effective in critically ill surgical and trauma patients and allow an aggressive approach to the prevention of VTE.[78]

Use of IVC filters in patients with SCI remains controversial. In a randomized trial that evaluated routine placement of vena cava filters as an adjunct to anticoagulation in patients

with proximal DVT, filters were shown to reduce the frequency of PE during the initial 12 days, but they almost doubled the long-term risk of recurrent DVT.[77] This led to the development of retrievable temporary IVC filters.

SUMMARY

Patients who suffered spinal cord injuries encounter significant obstacles during their hospitalization and recovery. Early management begins in the field with immobilization and quick transport to tertiary care units. A multidisciplinary approach is usually necessary to improve quality of life, decrease the morbidity and mortality rates, and facilitate functional recovery of these critical patients.

REVIEW QUESTIONS

1. **The most likely pathogen in subdural emyema occurring after meningitis in an infant is:**
   - **A.** *Escherichia coli*
   - **B.** *Listeria*
   - **C.** *Neisseria*
   - **D.** *Staphylococcus*
   - **E.** *Haemophilus influenzae*

2. **A 43-year-old woman presented with new onset severe headache and lethargy. Her head CT in emergency room demonstrated a diffuse SAH. She was admitted to the NICU, and cerebral angiogram showed L Posterior communicating artery aneurysm that was treated with endovascular coil embolization. Four days later, her Na started to trend down to a low of 127, what is the best way to correct her hyponatremia?**
   - **A.** Fluid restriction because this likely to be SIADH.
   - **B.** Supplemental p.o. Salt or hypertonic saline.
   - **C.** No treatment needed as the patient is a symptomatic.
   - **D.** Fludrocortisone acetate.

3. **A 23-year-old man was involved in a head-on motor vehicle accident. His GCS score in the field was 8, pupils were reactive, and he was localizing to painful stimuli. All of the following are correct in his management except:**
   - **A.** Secure his airway by endotracheal intubation.
   - **B.** Prophylactic hyperventilation.
   - **C.** Start fluid resuscitation and maintain SBP > 90
   - **D.** Consider placing ICP monitor
   - **E.** CT scan of his head when hemodynamicaly stable.

4. **When managing posttraumatic seizure all the following are correct except:**
   - **A.** Anticonvulsants may be used to reduce early posttraumatic seizures.
   - **B.** Prophylactic anticonvulsants may reduce the frequency of late posttraumatic seizures.
   - **C.** Discontinue anti-epileptic drug (AED) after week except in cases with higher risk such as penetrating injuries.
   - **D.** No study has shown that reducing early seizure improves outcome.

5. **A 57-year-old man was brought in to the emergency department after sustaining a fall down the steps while intoxicated. He was not able to move and was found by a relative about 9 h later when he did not answer his phone. He was immobilized on a back board with a cervical collar and transferred to the ED. His examination was significant for motor paralysis and sensory loss from C6 level down. CT scan showed C6 burst fracture and significant central canal stenosis. All of the following are appropriate in his critical care management except:**
   - **A.** Maintain SBP ≥90 mmHg by infusing colloids and using pressors if needed.
   - **B.** Maintain MAP at 85–90 mmHg for the first 7 days after SCI to improve spinal cord perfusion.
   - **C.** Start methylprednisolone infusion as soon as possible.
   - **D.** Place an NG tube to decompress his abdomen and prevent vomiting and aspiration.

6. **All the following statements regarding vasospasm following SAH are correct except:**
   - **A.** Almost never occurs before day 3 post-SAH.
   - **B.** There is a good correlation between the amount of blood seen on the CT scan and the severity of the cerebral vasospasm.
   - **C.** A history of cigarette smoking is an independent risk factor for developing vasospasm.
   - **D.** Blood clots are especially spasmogenic when in direct contact with the proximal ACA, MCA.
   - **E.** Radiographic vasospasm is reported in 20–30% of arteriograms performed around the seven day following SAH.

7. **All the following statements regarding intracranial pressure monitoring and treatment of elevated ICP in traumatic brain injury are correct except:**
   - **A.** CPP should be maintained ≥70 mmHg.
   - **B.** ICP treatment should be initiated for ICP >20–25 mmHg.
   - **C.** The use of glucocorticoids is recommended to reduce ICP and improve outcome in patients with severe TBI.
   - **D.** ICP monitoring should be initiated for patients with GCS ≤8 and abnormal CT or normal CT, but age <40, SBP < 90 mmHg or posturing on exam.

8. All the following statements regarding mannitol are correct except:
- **A.** Continuous infusion is more effective than intermittent blousing.
- **B.** Mannitol causes immediate plasma expansion that reduces the hematocrit and blood viscosity.
- **C.** The mannitol osmotic effect starts after 15–30 min and lasts 1.5–6 h.
- **D.** High doses of mannitol carry the risk of acute renal failure.

9. A 45-year-old man presents to the emergency room with altered mental status following a severe headache. He mutters incomprehensible words, opens his eyes to commands, and withdraws to pain. Pupils are equal and reactive, but there is a right facial droop and right hemiparesis. A CT scan showed large left thalamic hemorrhage. His breathing appears satisfactory and he is able to maintain oxygen saturation of 94%. All the following statements are correct in his airway management except:
- **A.** There is no need for intubation as long as he maintains a reasonable saturation.
- **B.** Rapid sequence intubation is the safest approach for patients with suspected elevated ICP.
- **C.** Succinylcholine may increase ICP by inducing widespread fasiculation.
- **D.** Patients with lower cranial nerves palsies may suffer airway compromise at higher level-of-consciousness because they depend on conscious effort to maintain airway patency.

ANSWERS

1. A. In children < years, subdural empyema is usually due to bacterial meningitis with *H. influenzae* or in neonates, gram-negative bacilli.
2. B. Restriction of fluids, which is the treatment of SAIDH, may be hazardous in the case of cerebral salt wasting (which is more likely to occur after SAH than is SIADH) since dehydration increases blood viscosity and exacerbates ischemia. The neurological effects of hyponatremia may mimic delayed ischemia and hyopnatermic patients have three times higher incident of delayed cerebral infarction than normonatremic patients. Fludrocortisone is the next step after supplemental p.o. salt and hypertonic saline.
3. B. Hyperventilation before ICP monitoring is established should be reserved for patients with signs of transtentorial herniation or progressive neurological deterioration not attributed to extracranial mass. The use of prophylactic HPV during the first 24 h after severe TBI should be avoided because it can compromise cerebral perfusion.
4. B. Posttraumatic seizure is often divided (arbitrarily) into two categories, early (<7 days) and late. AED may be used to prevent early seizure, but it does not prevent to reduce the frequency of late seizure and there is no evidence that reducing the frequency of early seizure does improve outcome.
5. C. It has been asserted by several prospective studies that beneficial (sensory and motor) effects at 6 weeks, 6 months, and 1 year are seen (for both complete and incomplete injuries) when methylprednisolone is administered within 8 h of injury.
6. E. Radiographic cerebral vasospasm (CVS) is identified in 30–70% of arteriograms performed around the seven day after a SAH, whereas symptomatic CVS occurs in only 20–30% of the patients.
7. D. Although steroids are effective in reducing the vasogenic edema (e.g., surrounding brain tumors), they have little effect on cytotoxic edema that is usually associated with TBI.
8. A. Mannitol can cause rebound intracranial hypertension by crossing the damaged blood–brain barrier and drawing fluids into the parenchyma. This can be minimized by using repeated boluses rather than continuous infusion, and when it is time to stop the mannitol, it should be tapered down to prevent ICP rebound.
9. A. Critically ill neurological patients often require intubation and mechanical ventilation to protect the airway, and prevent hypoxia and hypercarbia that can result in secondary neurological injury. Patients with neurological injury and depressed mental status (GCS ≤8) have better outcomes when endotracheal intubation is performed early.

CHAPTER 31

FREDERIC H. KAUFFMAN AND JOANNE E. HULLINGS

Disorders of Thermoregulation

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Discuss the major mechanisms of normal thermoregulation.
- Define heatstroke and list predisposing factors.
- Describe the clinical manifestations of heatstroke and its treatment modalities and goals.
- List the major factors that affect prognosis in heatstroke.
- Define malignant hyperthermia and list the ways in which it differs from heatstroke.
- Define hypothermia and differentiate the general clinical manifestations associated with declining core temperature.
- Describe various clinical procedures used to lower core temperature.
- Know the clinical significance of core temperature afterdrop, the situations in which it occurs, and ways to avoid it.
- Interpret arterial blood gas (ABG) results in a clinically useful manner.

The body's ability to maintain core temperature within a very precisely defined range is truly remarkable. Intricate physiologic mechanisms are constantly at work to prevent wide swings in body temperature, despite the effects of changing environmental conditions. These mechanisms take place subconsciously and are vital to the preservation of normal subcellular, cellular, organ, and total body function. Significant alterations in these mechanisms, resulting in profound elevation or depression of core temperature, may be life-threatening. Heatstroke and profound hypothermia are the two major medical emergencies of disordered thermoregulation encountered in clinical practice, with malignant hyperthermia representing a special case of elevated core temperature.

NORMAL THERMOREGULATION

Maintenance of normal core body temperature requires that mechanisms designed to promote heat loss and heat conservation respond to changing environmental conditions. Control of body temperature is dependent on hypothalamic and peripheral temperature-sensitive neurons that allow for the appropriate dissipation or conservation of heat. A basic understanding of normal thermoregulation is essential for the logical management of both heatstroke and profound hypothermia.

Mechanisms of Heat Loss

Hypothalamic and peripheral temperature-sensitive neurons are required for normal control of core body temperature.

The evaporation mechanism of heat loss is limited in the setting of high environmental humidity.

The heat conductivity of water is far greater than that of air.

In the presence of heat stress, peripheral mechanisms respond to blood temperature perfusing the hypothalamus. Cutaneous vasodilation, coupled with sweat gland activation, promotes heat loss via convection and evaporation.[1] Cardiovascular responses in the form of increased stroke volume and heart rate are critical to the delivery of increased blood flow to the peripheral circulation. Evaporation is the most critical mechanism by which heat is lost when environmental temperature exceeds core temperature, but is limited in the setting of high environmental humidity.[2] Radiation plays a role when skin is exposed, prompting heat loss to the environment.[2] Conduction plays only a minor role in the dissipation of heat, except when the body is exposed to substances with high conductivity. For example, water has conductivity 25–50 times that of air and plays a major role in the precipitous loss of heat in submersion accidents.[3]

Mechanisms of Heat Conservation

Shivering is a heat-generating mechanism.

Peripheral vasoconstriction promotes heat conservation.

Cutaneous cold-sensitive neurons initiate the normal physiologic responses to a cold environment.[2] Afferent impulses directed to the hypothalamus initiate shivering, a heat-generating mechanism, and piloerection, a heat-conserving mechanism.[2] Shivering increases heat production by 100–400%.[3] Subsequent efferent sympathetic fiber impulses from the hypothalamus promote peripheral vasoconstriction, a heat-conserving mechanism, and mobilization of glucose and fat stores.[2] Utilization of increased fuel stores increases endogenous heat production.

Effects of Exercise and Gender

Increased core temperature is a normal response to strenuous exercise.

Dehydration occurs in the setting of exercise and predisposes to the development of heat illness.

Males are much more prone to the development of heat illness than females.

Quite a number of physiologic responses occur in the setting of exercise, most of which alter core temperature in an upward direction and, as such, may play a role in the development of heat illness syndromes. Respiratory rate and minute ventilation increase, resulting in respiratory alkalosis. Lactic acidosis also occurs due to conversion to anaerobic metabolism, and pH levels as low as 7.0 have been documented during strenuous exercise. In addition, there is a normal increase in core body temperature during exercise, first documented during the Boston Marathon of 1903. Transient temperatures as high as 107°F have been documented in athletes undergoing strenuous exercise in the setting of significant environmental heat stress. With normal elevations in body temperature, cellular metabolism and heat production increase, thereby predisposing the athlete to heat illness. A number of cardiovascular processes also come into play. Peripheral vascular resistance decreases. Stroke volume, heart rate, and cardiac output all increase. There is a normal loss of sodium and potassium through loss of body fluids, and athletes experience a mild to moderate degree of dehydration during exercise. Renal blood flow is decreased and transient myoglobinuria, proteinuria, hematuria, and pyuria may be noted. Transient leukocytosis and mild coagulation abnormalities also develop.[4]

Of great interest is the observation that gender affects the physiologic response to heat stress. It is extremely rare for females to develop exercise-induced heatstroke. Sweating is less profound in females, and evaporation mechanisms are postulated to be more efficient than in male counterparts. The greater surface area to mass ratio in females allows

CASE STUDY 1: PART 1

A 75-year-old male boarding home occupant was found unresponsive by his son in the patient's fourth-floor room. It is not known when he last left his apartment, or when he last ate or drank. His son informed the paramedics that his father has a history of hypertension and congestive heart failure, and that in addition to a calcium channel blocker and diuretic, he takes phenothiazines for chronic schizophrenia. The son also commented that his father "drinks a bit." All windows in the apartment are shut and there is no functioning air conditioning. The local region has experienced a heat wave over the past 2 weeks, with daily environmental temperatures between 92 and 100°F. Vital signs include a pulse of 120/min, blood pressure of 90/palp., respirations of 8–10/min, and a rectal temperature of 106°F.

for more efficient transfer of heat to the environment. And finally, it is well known that females develop lower baseline core temperatures during the preovulatory phase of their menstrual cycles. All these mechanisms are believed to protect females against the development of heat illness syndromes, especially during strenuous exercise in a hot and humid environment.

HEATSTROKE

Diagnosis

Heatstroke is the only heat illness syndrome in which normal thermoregulatory mechanisms are lost, thereby resulting in significant morbidity and mortality. Three essential elements must be present for a diagnosis of heatstroke: (1) the patient must have been exposed to a major form of heat stress, (2) core body temperature must be elevated, usually greater than 104°F, and (3) the patient must display major central nervous system dysfunction.[5] It must be emphasized that no specific temperature defines heatstroke, but in the presence of the other two features, a profoundly hyperthermic patient must be treated as if they have heatstroke. In addition, at the time of presentation to the emergency department, not all patients with heatstroke will have core temperatures greater than 104°F. Such may be the case when treatment has been initiated in the field, or when evaporation is maximized in route to the hospital, thereby resulting in a fall in core temperature. In such cases, prehospital personnel are invaluable in assisting with the establishment of the diagnosis. The most common forms of central nervous system dysfunction seen in patients with heatstroke are seizures and alteration in mental status.[6] However, any form of central nervous system dysfunction can occur, including tetanic contractures, oculogyric crisis, delirium, psychosis, stupor, coma, and focal neurologic findings. A common misconception is that patients who sweat do not have heatstroke; in reality, many heatstroke patients are noted to be sweating appropriately at the time of presentation.[6,7] The presence of sweating should never be used to exclude the diagnosis.

No specific temperature defines heatstroke, but most victims have core temperatures in excess of 104°F.

Major central nervous system dysfunction is essential to the diagnosis of heatstroke.

Predisposing Factors

A veritable multitude of factors predispose to the development of heat stroke. General categories include environmental factors, cardiovascular disorders, increased endogenous heat load, altered dissipation of heat, certain pharmaceutical agents, lack of acclimatization, and a history of heatstroke. Table 31-1 delineates these factors in greater detail, and Table 31-2 details common drug categories known to predispose to the development of heatstroke.

Lack of acclimatization and a history of heatstroke deserve special attention. Acclimatization is the process by which individuals who undergo strenuous exercise on a regular basis over a period of several weeks to months develop tolerance to heat stress.[6] Such individuals display physiologic effects similar to those of well-conditioned athletes. During exercise in the setting of heat stress, the acclimatized individual has a lower

Classic heatstroke tends to occur in the elderly and generally occurs during heat wave epidemics.

TABLE 31-1

FACTORS PREDISPOSING TO HEATSTROKE

Environmental factors	Altered heat dissipation
High temperature	Scleroderma
High humidity	Cystic fibrosis
Low wind velocity	Drugs (see Table 25-2)
Cardiovascular disorders	Lack of acclimatization
Congestive heart failure	History of heat stroke
Coronary artery disease	Extremes of age
Increased endogenous heat load	Male gender
Status epilepticus	Social isolation
Febrile illnesses	
Overt psychosis	

TABLE 31-2

DRUG FAMILIES THAT PREDISPOSE TO HEATSTROKE

Anticholinergics: impair sweat glands/evaporation
Sympathomimetics: decrease cutaneous heat loss and increase endogenous heat production
Myocardial depressants: decrease cardiac output/cutaneous heat loss
Diuretics: decrease cardiac output
CNS stimulants/depressants: alter behavioral response to heat stress

temperature and physical exertion threshold for sweating, sweats more profusely, develops a lesser rise in core temperature, and demonstrates decreased oxygen utilization and increased oxygen consumption compared to the unacclimatized individual.[4] As such, the unacclimatized individual who exercises strenuously during periods of high environmental temperature and humidity is at significantly greater risk for the development of heatstroke.

Whether an individual with a history of heatstroke is forever intolerant to heat stress is a matter of some debate. Based upon prior studies, heat intolerance does exist after an episode of heatstroke,[8] but other researchers have found that over time (5–12 months) most victims of exertional heatstroke regain heat tolerance.[9] Nonetheless, any patient with a history of heatstroke who returns to settings of significant heat stress would be prudent to be extra vigilant in heatstroke prophylaxis.

Clinical Manifestations

Heatstroke can affect nearly every organ in the body. In addition to a dramatic increase in core body temperature, patients with heatstroke have major alterations in their central nervous system function. Cardiovascular manifestations may be variable; the elderly commonly demonstrate a hypodynamic response, whereas younger healthy individuals often present with tachycardia, increased cardiac output, and decreased systemic vascular resistance. The presenting circulatory state is determined by the patient's underlying volume status and cardiac function, and represents the patient's ability to respond to the hemodynamic stresses of heat stroke. Pulmonary vascular resistance in patients with heatstroke is quite variable, and central venous pressure monitoring generally reflects accurately the volume status of the central circulation. Electrocardiographic findings are nonspecific, and autopsy findings have yielded varying degrees of myocardial fiber degeneration, necrosis, and hemorrhage.

Gastrointestinal symptoms are quite common, frequently including nausea, vomiting, diarrhea, and gastrointestinal hemorrhage. Signs and symptoms of liver injury typically occur several days after presentation, though frank hepatic failure is uncommon. Classically, transaminitis with normal bilirubin and alkaline phosphatase is seen.[10]

Bleeding disturbances are multifactorial in etiology, and when present, denote a poor prognosis. Elevated prothrombin time and thrombocytopenia may be demonstrated as early as 30 min after presentation, but do not necessarily herald the development of disseminated intravascular coagulation (DIC).

Exertional heatstroke often is associated with severe rhabdomyolysis.

Rhabdomyolysis, although not universal, is very common in heatstroke victims.[11] Acute tubular necrosis is seen in greater than 30% of patients with heatstroke attributable to exertion, though it is less common in the elderly. Other renal findings that may not be directly

TABLE 31-3

CLASSIC VS. EXERTIONAL HEATSTROKE

FEATURE	CLASSIC	EXERTIONAL
Age	Elderly	Young
Rhabdomyolysis	Moderate	Severe
ATN	<5%	>30%
DIC	Mild	Severe
Epidemic	Yes	No
Chronic illness	Yes	No

ATN acute tubular necrosis; *DIC* disseminated intravascular coagulopathy

associated with acute tubular necrosis include proteinuria and evidence of myoglobinuria and interstitial nephritis. Other common metabolic derangements include hyperglycemia, hypernatremia, hypokalemia, hypophosphatemia, hypocalcemia, hyperuricemia, lactic acidosis, and respiratory alkalosis.

Heatstroke is classified into two different, although not always distinct, categories: classic heatstroke and exertional heatstroke. Table 31-3 indicates the typical differences between these two classifications of the disorder.

Treatment

Rapid cooling is the most essential aspect in preventing morbidity and mortality in the patient with heatstroke.

As with all patients, the initial priority of management is stabilization of the airway. Many patients with heatstroke require endotracheal intubation as an initial intervention. Oxygen is administered to all patients, and appropriate intravenous access established, along with rapid acquisition of necessary blood studies. The patient must be totally undressed to allow full medical assessment and to facilitate cooling techniques. Once the ABCs are evaluated and stabilization begun, immediate and aggressive cooling is imperative if morbidity and mortality are to be avoided. All patients with heatstroke should be cooled to a core temperature of no higher than 101°F[6] utilizing evaporation, or immersion techniques, or both. Debate continues as to the optimal cooling technique, though ice water packing and immersion promote faster cooling when compared to evaporation techniques.[12-14] If facilities are not prepared for full-body ice water immersion or if patient numbers overwhelm departmental facilities, aggressive evaporation techniques are in order, often coupled with trunk or full-body packing in ice. The essential point is that whichever approach is utilized, institutional preparation and in-servicing are essential, and all efforts must be taken to achieve adequate cooling in the shortest possible time.[6,15] It should also be stated that antipyretics do not have a role in the management of heatstroke.

Aggressive monitoring, not only of core temperature but also of all vital functions, is essential to optimal treatment. Respiratory management is guided by the usual principles of critical care, with frequent utilization of arterial blood gas (ABG) measurements to guide oxygenation and ventilation therapy. Most patients with uncomplicated heatstroke require less than 2 L of intravenous fluid for stabilization; ideal management includes placement of a CVP line to guide initial therapy, with pursuit of other causes of hypotension should it persist. Consideration should be given to the administration of $D_{50}W$ and thiamine initially, and blood should be drawn to evaluate electrolytes, renal function, liver function, coagulation parameters, and complete blood count at a minimum.

Most complications of heatstroke respond to aggressive cooling.

Complications of heatstroke should be anticipated, including violent shivering, seizures, renal failure, rhabdomyolysis, acid–base disturbances, and cardiac dysrhythmias. Most of these problems respond to aggressive cooling. Should shivering be problematic (it promotes increased heat production), benzodiazepines are the treatment of choice.[2] In the past, phenothiazines were administered, but their use is no longer recommended because of their slow onset of action, propensity to produce hepatotoxicity, reduction of the seizure threshold, and exacerbation of hypotension.[2] Volume status must be optimized if renal failure is to be avoided or minimized. The use of bicarbonate or mannitol therapy to prevent or treat rhabdomyolysis-induced acute tubular necrosis is controversial.

CASE STUDY 1: PART 2

Airway assessment revealed lack of airway tone and loss of protective reflexes; the patient was intubated and ventilatory support instituted with 100% inspired oxygen. Multiple large-bore intravenous lines were inserted and 0.9% normal saline solution was rapidly administered. Cardiac monitor revealed sinus tachycardia, and pulse oximetry revealed an oxygen saturation of 99% on the ventilator. General inspection revealed evidence of dehydration and no evidence of trauma. The lung exam was clear, cardiac exam was remarkable only for the tachycardia, and abdominal exam revealed diminished bowel sounds without organomegaly. Rectal exam revealed normal tone and stool was negative for occult blood. Neurologic exam revealed pupils to be 3 mm, equal, and reactive to light; corneal reflexes were intact, and the patient had spontaneous respirations. There was no response to verbal stimuli, and deep painful stimuli initiated decorticate posturing. Deep tendon reflexes were normoreactive and symmetric; plantar response was downgoing bilaterally. Immediate cooling techniques were instituted; the patient's torso was packed in ice, all other exposed skin surfaces were sprinkled with water, and large fans were run at the bedside to promote evaporation. Core body temperature declined to 101.6°F within the first 20 min of resuscitation; pulse decreased to 100/min, and blood pressure rose to 128/72 mmHg.

Prognosis

The most important prognostic factors in heatstroke are the level and duration of hyperthermia and the duration of coma.

The prognosis in patients with heatstroke is related to several factors. The level and duration of hyperthermia play the most important role, along with the duration of coma.[16,17] Patients who have prolonged coma, DIC, and acute renal failure generally die within several days from multisystem organ failure. Patients who have coma less than 10 h in duration have a reasonable chance of survival. Their hepatic and renal injuries tend to be less severe, but permanent central nervous system damage is common. Coma that lasts ≤3 h generally indicates a good prognosis.[17] Data from the 1995 heat wave in Chicago revealed 21% in-hospital mortality, with an overall 36% 1-year mortality. Significant neurologic impairment was seen in 76% of survivors.[18] Pooled data from multiple studies indicate mortality rates ranging from 5 to 80%. Mortality should not exceed approximately 10% when adequate and aggressive treatment is administered.[6]

MALIGNANT HYPERTHERMIA: A SPECIAL CASE

Dantrolene sodium is the treatment of choice for malignant hyperthermia, but is not effective in the management of heatstroke.

A very rare congenital disturbance of calcium regulation in striated muscle, malignant hyperthermia develops following exposure to general inhalational anesthetics, depolarizing muscle relaxants, antipsychotic medications, or, rarely, extreme exertion. Uncontrolled calcium influx into the sarcoplasmic reticulum of striated muscle following exposure to one of these agents gives rise to severe muscle rigidity, increased endogenous heat production, and profound hyperthermia. Dantrolene sodium is the treatment of choice for malignant hyperthermia. It has not been demonstrated to have beneficial effects for patients with heatstroke.[19]

HYPOTHERMIA

Diagnosis

Hypothermia is defined as a core temperature less than 95°F.

Metabolic activity and tissue oxygen requirements decline as core temperature decreases.

Perhaps the most overlooked vital sign in the acute resuscitation phase of the critically ill patient is core temperature. The foregoing case illustrates just how important is accurate measurement of the core temperature to diagnosis and management of such patients. Typically, hypothermia is defined as a core temperature less than 95°F.[2] The diagnosis of hypothermia is essential in that many patients have achieved meaningful survival, despite profound drops in core temperature (as low as 48°F in controlled settings), if hypothermia is clinically recognized and the patient is rewarmed appropriately.[20,21] In addition, as temperature declines, metabolic activity and tissue oxygen requirements decline, thereby rendering a protective effect to vital organs. Cerebral autoregulation is preserved and provides central nervous

CASE STUDY 2: PART 1

A 35-year-old homeless man was found unresponsive on a sidewalk during a rainstorm. His clothing was soaked and he was not wearing a coat or hat. An empty bottle of wine was found beside him. Environmental temperature was 38°F. The patient was brought to the emergency department by concerned citizens. On examination, the man appeared somewhat cachectic, wet, and not shivering. Vital signs included an irregularly irregular pulse of 46/min, blood pressure of 75/palp., respirations of 8/min, and a rectal temperature of 83°F. There was no evidence of trauma. The patient only groaned in response to verbal stimuli. Pupils were 6 mm, equal, and sluggishly reactive to light. Corneal reflexes were intact, as were gross extraocular movements. The neck was supple. Lung exam was clear. Cardiac exam revealed an irregularly irregular pulse without murmur or rub. Abdominal examination was remarkable only for absent bowel sounds, and stool exam was negative for occult blood. Deep tendon reflexes were absent throughout, and plantar response was downgoing bilaterally.

system protection even in the setting of profound hypothermia. As such, it is imperative to understand that traditional clinical criteria for brain death are not applicable in the hypothermic patient, leading to the clinical adage that "no patient is dead until warm and dead."

Clinical criteria for brain death do not apply in the setting of hypothermia.

Causes

Although environmental exposure is a common cause of profound hypothermia, many other causes and contributing factors must be entertained. Table 31-4 lists factors in the differential diagnosis of hypothermia, many of which play a contributing role in the cited case.

Clinical Manifestations

The clinical findings in patients with hypothermia are fairly predictable, depending on the degree of core temperature depression. Hypothermia can be divided into three categories based upon core temperature; such categorization is useful not only for the description of clinical manifestations, but for the therapeutic decision-making as well.

TABLE 31-4

DIFFERENTIAL DIAGNOSIS OF HYPOTHERMIA

Environmental exposure
Massive fluid and blood administration
Decreased heat production
Malnutrition
Hypoglycemia
Hypopituitarism
Hypothyroidism
Hypoadrenalism
Cholinergic drugs
Beta-blockers
Increased heat loss
Erythrodermas
Ethanol
Loss of central regulation
CNS trauma
Cerebrovascular accident
Uremia
Drugs: benzodiazepines, phenothiazines, barbiturates, opiates, carbon monoxide, cyclic antidepressants
Loss of peripheral regulation
Spinal cord injury
Alpha-blockers
Phenothiazines
Miscellaneous
Sepsis
Malignancy

Mild Hypothermia (90–95°F)

Patients with mild degrees of hypothermia typically present with no immediate life-threatening complications, but often feel rather uncomfortable because of the change in their body temperature. Such patients maintain their shivering mechanism and stable vital signs in the absence of other complicating factors. Mental status may be normal, although typically such patients exhibit varying levels of amnesia, coupled with mild ataxia and dysarthria.[22]

Moderate Hypothermia (80–90°F)

Hypothermia in the moderate range characteristically begins to alter vital signs and function and must be treated carefully to avoid life-threatening complications. General depression of metabolism takes place, with progressive decline as core temperature continues to fall. By 81°F, shivering, a normal heat-producing response to hypothermia, is abolished.[2] Mental status continues to decline, with varying levels of confusion and even obtundation.[2] Cardiovascular status now becomes altered significantly. As core temperature drops, an initial increase in heart rate and cardiac output will be followed by a steady decline in pulse and blood pressure.[3] A critical threshold for the development of atrial fibrillation occurs at 86°F[3] and for ventricular fibrillation at 83°F.[3] Of importance is that atrial fibrillation, once it develops, typically is slower than expected for patients with new-onset atrial fibrillation, even in the absence of conduction system disease. Respiratory function is also affected, with an initial increase in respiratory rate followed by a progressive decline in minute ventilation and the loss of protective airway reflexes. Bronchorrhea is also noted as core temperature drops.[3]

Progressive bradycardia and hypotension develop as core temperature declines.

Severe Hypothermia (<80°F)

Severe hypothermia represents an immediate threat to life. Mental status is profoundly altered, with nearly universal development of stupor and coma.[2] Cardiovascular deterioration continues with more profound degrees of bradycardia and hypotension; ventricular fibrillation is a feared complication at this stage and often extremely difficult to successfully treat.[2] Ultimately, asystole develops. Respiratory function and airway reflexes also significantly diminish.

Ventricular fibrillation is a major contributor to death in the setting of hypothermia, but responds poorly to traditional treatment in the absence of rewarming.

Common Laboratory and EKG Findings

There are no diagnostic or pathognomonic laboratory findings in hypothermia, but many abnormalities must be anticipated and treated with hypothermia; this is particularly true for ABG assessment, which is discussed separately.

Insulin production and release are impaired in hypothermic patients, as is end-organ effect. The net result is hyperglycemia.[3,23] Rewarming alone will reverse these effects and often returns the patient to a euglycemic state. Over aggressive administration of insulin will very likely result in hypoglycemia upon rewarming and should be avoided.

Hyperglycemia should be treated with caution in hypothermia because of altered insulin release and end-organ effect.

Sodium and water resorption are impaired in hypothermia, the latter because of a decreased renal response to antidiuretic hormone (ADH). The resultant "cold diuresis" is very common in profoundly hypothermic patients, and the need for volume repletion should be anticipated in all patients.[24] In addition, renal failure may ultimately ensue and generally is multifactorial in origin; etiologic factors include volume depletion, rhabdomyolysis, or associated sepsis.

Expect the need for volume repletion in the hypothermic patient.

Hemoconcentration is a common finding as a result of fluid losses and plasma shifts. In addition, leukopenia and thrombocytopenia may be severe in the setting of severe hypothermia. DIC, although not common, may develop as well.

The acid–base changes that occur in the setting of hypothermia are complex and vary from patient to patient, but certain alterations are quite characteristic. Respiratory rate and tidal volume increase, and then fall progressively as the level of hypothermia worsens, giving rise to an initial respiratory alkalosis. Increased lactate production and decreased hepatic and renal clearance of acid contribute to a metabolic acidosis. The solubility of carbon

CASE STUDY 2: PART 2

The patient was carefully intubated and placed on ventilatory support with administration of 100% oxygen. Two large-bore intravenous catheters were placed, appropriate blood studies obtained, and a Foley catheter placed. Administration of $D_{50}W$, naloxone, and thiamine resulted in no change in the patient's clinical status. An ABG was sent to the laboratory. Cardiac monitoring revealed atrial fibrillation and what appeared to be Osborn waves; EKG confirmed these findings. Portable chest X-ray suggested early noncardiogenic pulmonary edema. Initial warming measures included administration of warmed humidified oxygen and warmed intravenous fluids. Preparation was made for warmed thoracostomy lavage and peritoneal lavage in case initial rewarming techniques were not adequate. In addition, the cardiothoracic service was notified of the patient's condition, and extracorporeal rewarming was discussed as a therapeutic option if clinical deterioration ensued.

dioxide rises as core temperature falls. The subsequent decline in carbon dioxide partial pressure leads to a respiratory alkalosis. As would be predicted, many patients with hypothermia develop mixed acid–base disorders.[3]

EKG findings in hypothermia are progressive and varied. After an initial rise in heart rate, a progressive change from tachycardia to bradycardia occurs. Atrial fibrillation and atrial flutter typically start to occur around 86°F,[3] and demonstrate lesser degrees of relative tachycardia than in the euthermic patient. The threshold for ventricular fibrillation is lowered starting at 83°F[3], and asystole is nearly universal by 64°F.[3] Before the development of ventricular fibrillation, prolongation of the PR, QRS, and QT intervals typically occurs.[25] ST-T wave changes are variable, but may suggest myocardial ischemia due to hypothermia-induced alterations in coronary autoregulation. Below 86°F, terminal elevation and widening of the QRS complex may be seen; these J-wave abnormalities, known as Osborn waves, are quite characteristic of profound degrees of hypothermia.[26] (see Fig. 31-1) Cardiac dysrhythmias solely caused by hypothermia (and not related to underlying heart disease) typically resolve with rewarming.

Osborn waves are characteristic of profound hypothermia.

Treatment Principles and Techniques

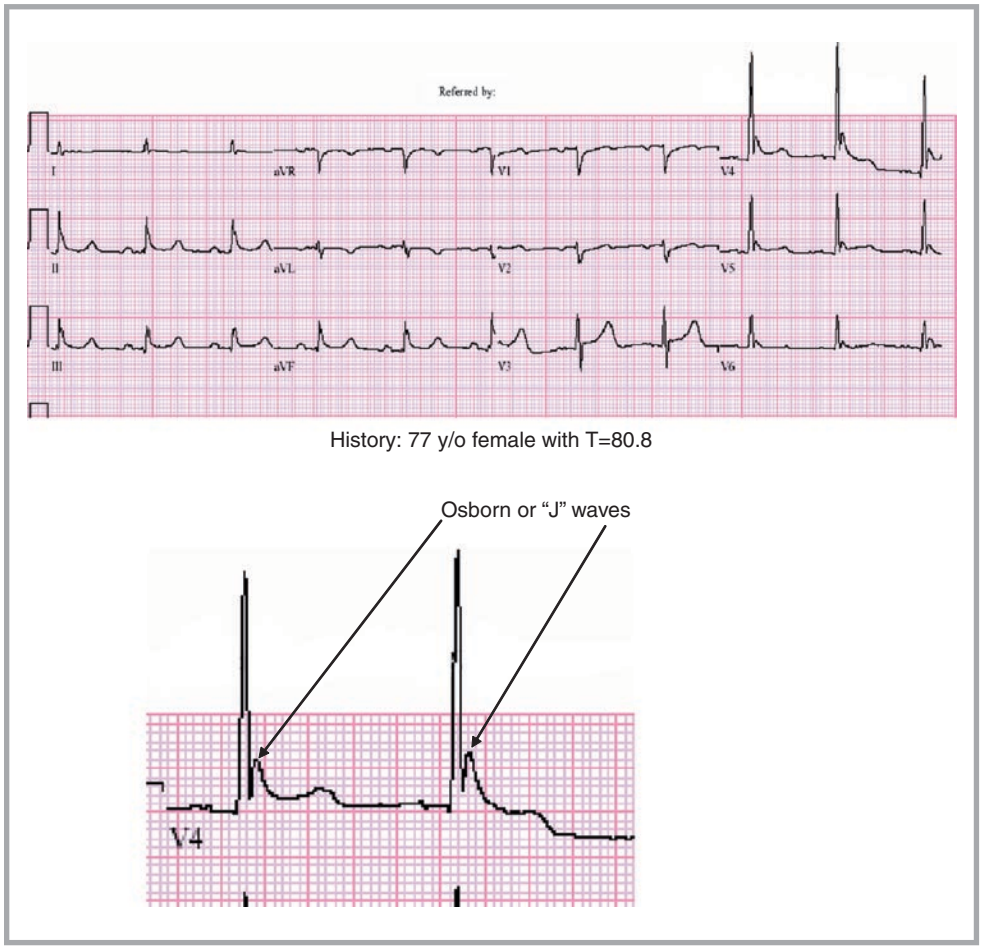
Appropriate clinical management in the setting of significant hypothermia is based upon the accurate diagnosis of the disorder, coupled with the findings at the bedside. As with all critically ill patients, the primary goal of resuscitation is to stabilize airway, breathing, and circulation (the ABC's). Indeed, it is well known by clinicians experienced in managing hypothermic patients that physical manipulation of the patient may precipitate ventricular fibrillation, a dreaded and difficult to treat complication. This fear has led some clinicians to be hesitant to provide aggressive airway protection, such as endotracheal intubation, in patients who otherwise would be candidates for the procedure. It has been well documented in animal studies that endotracheal intubation, performed carefully by skilled clinicians, is a safe and often lifesaving procedure.[27] As such, the assessment of airway protection and management should proceed in the usual, albeit careful, fashion; 100% oxygen should be administered to all patients, along with $D_{50}W$, naloxone, and thiamine in the appropriate settings. Intravenous access is essential, and should a central venous catheter be necessary, it should be placed without touching the myocardium and risking the precipitation of ventricular fibrillation. The use of prophylactic vasopressors or antiarrhythmics in the setting of severe hypothermia has been suggested by some but is not included in American Heart Association recommendations.[28] Finally, during the initial resuscitation phase, volume depletion should be anticipated and treatment begun with warmed intravenous normal saline solution.

Careful intubation is safe in the setting of hypothermia and should be performed as indicated utilizing the usual criteria.

Many potential rewarming techniques are available to the treating physician. The combination of treatment techniques should be determined by the patient's core temperature and overall clinical condition. The aggressiveness of rewarming techniques utilized will be based on the degree of hypothermia balanced by the extent of clinical derangement.

FIGURE 31-1

EKG showing Osborn waves.



Passive rewarming is appropriate for patients who are clinically stable with mild levels of hypothermia. All patients should be dried thoroughly to avoid heat loss due to the conductivity of water, and covered with dry blankets. Underlying causes of hypothermia should be sought and corrected. Intravenous fluids, warmed to 109–111°F, are sensible and may be given safely, but should not be relied upon for aggressive rewarming of any patient. The use of warmed nasogastric, bladder, and colorectal lavage tends to be ineffective.[29]

Active external rewarming includes the use of heating blankets, hot water bottles, and total immersion of the patient in warm water. Such techniques have a tendency to produce core afterdrop (discussed later) and generally are not used.

Warmed humidified oxygen administration is a useful rewarming therapy for most hypothermic patients.

Patients with severe levels of hypothermia are treated more aggressively. The use of warmed humidified oxygen (temperatures up to 111°F can be administered without threat of tracheal damage)[29] is considered standard treatment. This technique takes advantage of the large pulmonary surface area, but care must be taken to measure the oxygen temperature at the point of entry to the patient and not at the point of oxygen source on the wall. The use of warmed humidified oxygen is particularly effective in the intubated patient, but can be delivered through noninvasive devices in the nonintubated patient.

Warmed peritoneal lavage is also an effective means to rewarm the hypothermic patient. Potassium-free dialysate is used and warmed to 111°F.[29] Due to volume shifts and cold diuresis, coupled with the volume deficits associated with peritoneal dialysis, aggressive fluid therapy and monitoring are essential.

Warmed thoracostomy lavage is an often used technique. Descriptive case studies consistently indicate effective rewarming. Once again, lavage fluid warmed to 111°F may be used

safely.[30,31] Two chest tubes are placed on the same side of the patient, the higher one for influx of warmed fluid and the lower one for fluid efflux. Careful attention to input and output volumes is essential to avoid iatrogenic hydrothorax. This technique, along with warmed peritoneal lavage, is particularly useful for the hemodynamically compromised or deteriorating patient when extracorporeal rewarming is not available.

Active core rewarming is indicated in the profoundly hypothermic, unstable, or deteriorating patient.

Extracorporeal rewarming, via traditional cardiopulmonary bypass or continuous arteriovenous rewarming, is the most aggressive technique available to rewarm the severely hypothermic patient. Once instituted, rewarming takes place within minutes.[32,33] Because technical expertise and a team approach are required, this technique is reserved for the most critically ill of patients. As would be predicted, it is not available at all institutions and is not always immediately available at institutions that possess the capability. Thus, all support staff should be alerted as soon as a potential patient candidate is identified.

Avoidance of Core Temperature Afterdrop

Core afterdrop is the paradoxical fall in core body temperature, despite the institution of rewarming techniques. As already noted, cardiovascular instability is directly related to a fall in core temperature. Thus, there is the concern of increased risk to the patient should core temperature continue to drop after presentation to the hospital. Several causative factors probably contribute to the development of core afterdrop. The classic reason given for its development is that as the peripheral circulation is vasodilated via active external rewarming techniques, cold blood and lactic acid are returned to the central circulation, thereby promoting a further fall in core temperature and a worsening metabolic acidosis. This mechanism may play some role in the development of core afterdrop, but it is of more than just academic interest to realize that a vascular system is not necessary for this phenomenon to occur in experimental models.[34] In addition, core temperature afterdrop does not occur in patients who have acquired hypothermia over many hours to days; rather, it tends to occur only in patients who have experienced a rapid and precipitous drop in core temperature (e.g., submersion victims).

Experimental models of hypothermia have been developed using gelatin molds and legs of beef with temperature thermisters placed at progressively deeper levels relative to the central core of the model. The systems were then placed in a surrounding bath that allowed cooling and rewarming of the surrounding environment, thereby simulating submersion with rapid cooling, followed by external rewarming. These systems demonstrated a fall in core temperature (i.e., core afterdrop) so long as a temperature gradient existed between the surface of the model and the central core. Once the temperature gradient was abolished, core temperature began to rise with further heating of the surrounding bath. As such, core afterdrop developed in the absence of a circulatory system and was caused solely by the temperature gradients established between the surface and core of the experimental model.[34] In victims who have acquired hypothermia over many hours to days, enough time has elapsed for the temperature gradients to be abolished, and during rewarming, core afterdrop is not observed. Clearly, when core temperature afterdrop is a potential concern (i.e., in victims with rapid development of hypothermia), core rewarming techniques as noted here prevent dangerous core afterdrop and its potentially lethal complications.

Development of core temperature afterdrop does not require a vascular tree; transfer of heat along temperature gradients plays a key role in its development.

Interpretation of Arterial Blood Gases

The interpretation of ABG values in the profoundly hypothermic patient represents one of the great dilemmas for critical care practitioners. The pH of water increases as temperature decreases because of inhibition of dissociation of water molecules. The pH change of blood exactly parallels this change in electrochemically neutral water, and as such, the pH gradient between the inside of the cell and its external environment remains constant despite changes in temperature. In addition, the partial pressures of both oxygen and carbon dioxide decrease

TABLE 31-5

TREATMENT "PEARLS" IN HYPOTHERMIA

Always stabilize the ABCs
If you need to intubate, you need to intubate
Avoid jostling the patient: this may precipitate full cardiac arrest
Make sure the patient is dry: the conductivity of water is very high
Search for underlying causes of hypothermia
Expect the need for volume expansion because of "cold diuresis"
Atrial fibrillation and bradycardia are best treated by rewarming alone. An organized rhythm is a good sign in hypothermia, whereas ventricular fibrillation is to be feared
Avoid chest compressions with an organized rhythm, so long as the degree of bradycardia correlates with the degree of hypothermia
Do not miss occult trauma
Arterial blood gas values need not be corrected for temperature (except, perhaps, for pO_2)
Patients are not dead until warm and dead

with falling temperature despite the lack of change in absolute blood content of these gases. The net result is that ABG values in a hypothermic patient, measured at patient temperature rather than at 98.6°F, yield a marked respiratory alkalosis (assuming no change in metabolic parameters).

ABGs are best interpreted without temperature correction in the hypothermic patient.

If one assumes, however, that the critical aspect of cellular survival in hypothermia is the maintenance of the intracellular to extracellular pH gradient, such "abnormal" values would be perfectly appropriate. Thus, the conventional wisdom in managing hypothermia is to maintain the aforementioned gradient, utilizing uncorrected or euthermic ABG values, and treating the acid–base status of the patient as if they were euthermic. This approach also prevents the development of hypoventilation, alveolar collapse, and subsequent impairment in oxygenation. The literature suggests that this maintenance of ventilation yields lesser degrees of hypothermic-induced myocardial irritability and necrosis.[35-37] One final exception, however, is that it is not clear whether uncorrected values of partial pressure of oxygen should be used. Most authorities err on the side of accepting the lower, corrected value, thereby working more aggressively to improve the oxygenation status of the patient.

Treatment "Pearls"

Management of the hypothermic patient requires an individualized approach. Not all patients respond in identical fashion to the same level of hypothermia or to the same treatment modality. Patient prognosis is most closely correlated with underlying disease and not with the absolute degree of hypothermia.[38] Isolated hypothermia yields mortality rates as low as 0–10%, whereas mortality rates may rise as high as 90% in the presence of serious underlying medical conditions.[2,39] Despite these variables, certain principles of evaluation and management are important for all patients. These clinical "pearls" are listed in Table 31-5.

SUMMARY

Core temperature is one of the many vital parameters the human body normally maintains within a narrow range. Profound alterations in core temperature, whether upward or downward, may represent life-threatening syndromes that require a firm understanding of thermoregulation, differential diagnoses and etiologies, and treatment options. Fortunately, aggressive resuscitation can be, and often is, lifesaving when coupled with full supportive care techniques. No organ system is immune from potential damage due to alterations in core temperature, and all systems must be monitored and treated aggressively to optimize patient outcome.

REVIEW QUESTIONS

1. **Which of the following statements is true?**
   - **A.** Conduction is the most critical mechanism of heat loss during times of high environmental temperature
   - **B.** Heat loss due to evaporation is limited by high environmental humidity
   - **C.** The conductivity of water is 25–40 times that of air
   - **D.** Shivering is a heat-generating mechanism capable of increasing heat production upward of 400%

2. **The diagnosis of heatstroke involves all the following except:**
   - **A.** Exposure to significant environmental heat stress
   - **B.** Lack of sweating
   - **C.** Elevation in core body temperature, generally greater than 104°F
   - **D.** Manifestation of major central nervous system dysfunction

3. **Acclimatization**
   - **A.** To heat stress can be developed over a period of several days when strenuous training
   - **B.** Allows for increased oxygen utilization and consumption during heat stress
   - **C.** Results in less sweating and evaporation during heat stress
   - **D.** Helps to prevent the development of heat disorders during exercise in high environmental temperatures and humidity

4. **Characteristics of malignant hypothermia include all of the following except:**
   - **A.** Disordered calcium regulation in smooth muscle
   - **B.** Development after exposure to general inhalational anesthetics, depolarizing neuromuscular blocking agents, and antipsychotics
   - **C.** Development of severe muscle rigidity, endogenous heat production, and profound hyperthermia
   - **D.** Dantrolene sodium is the treatment of choice

5. **Which of the following statements regarding hypothermia is not true?**
   - **A.** Hypothermia is defined as a core body temperature less than 95°F
   - **B.** Traditional clinical criteria for death do not apply in the setting of hypothermia
   - **C.** Avoid chest compressions with an organized bradycardic rhythm if the degree of bradycardia corresponds to the degree of hypothermia
   - **D.** Shivering is abolished, even in the setting of mild hypothermia

6. **Severe hypothermia**
   - **A.** Is defined as a core temperature less than 80°F only if an immediate threat to life exists
   - **B.** Nearly always is accompanied by stupor and coma
   - **C.** Indicates clinical death in the setting of asystole
   - **D.** Generally is associated with cardiovascular collapse, but not profound respiratory dysfunction

7. **Treatment modalities for severe hypothermia include**
   - **A.** Warmed humidified oxygen
   - **B.** Warmed peritoneal lavage
   - **C.** Warmed thoracostomy lavage
   - **D.** Extracorporeal rewarming
   - **E.** All the above

ANSWERS

1. The answer is B, C, and D. Conduction plays a critical role in the dissipation of heat when the body is exposed to substances of high conductivity, such as water. During times of high environmental temperature exceeding core temperature, evaporation becomes the most critical mechanism of heat loss.
2. The answer is B. It is a common misconception that patients who sweat do not have heatstroke. The presence of sweating should never be used to rule out the diagnosis of heatstroke.
3. The answer is D. Acclimatization is a process by which strenuous exercise on a regular basis over weeks to months results in physiologic tolerance to heat stress. The acclimatized athlete develops a lower temperature and physical exertion threshold for sweating, sweats more profusely, develops fewer rises in core temperature, and demonstrates decreased oxygen utilization and increased oxygen consumption compared to the unacclimatized individual. Acclimatization is essential to lower the risk of strenuous exercise during periods of high environmental temperature and humidity.
4. The answer is A. Malignant hyperthermia is a rare congenital disorder of calcium regulation in striated muscle which may develop after exposure to general anesthetics, depolarizing agents, or antipsychotics. It is characterized by the development of severe muscle rigidity and hyperthermia, and is treated with dantrolene sodium. Of importance is the fact that dantrolene sodium has not been shown to be effective in the management of exertional heatstroke.
5. The answer is D. Shivering is a normal heat-generating mechanism that is maintained in mild hypothermia, defined as core temperatures between 90 and 95°F. Shivering is not abolished until core temperature drops below mild levels of hypothermia.
6. The answer is B. Severe hypothermia is defined as a core temperature less than 80°F and always represents an immediate threat to life. The typical indicators of clinical death cannot be relied upon in the setting of severe hypothermia; many patients have been resuscitated successfully from profound depressions in core temperature. Cardiovascular and respiratory deterioration are quite common in the setting of severe hypothermia.
7. The answer is E. Severe hypothermia must be treated aggressively because it is an immediate threat to life. The initial resuscitation goals are to stabilize airway, breathing, and circulation, and to restore core temperature to at least mild levels of hypothermia. The choice of rewarming techniques depends upon the level of hypothermia, the clinical status of the patient, and the availability of techniques at a given institution. In the setting of severe hypothermia, multiple rewarming techniques often are used simultaneously.

CHAPTER 32

JACLYN ROSENZWEIG, GREGORY J. ROSSINI, RAFIK SAMUEL, AND WISSAM CHATILA

Infections in the Intensive Care Unit

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the pathophysiology of specific infections in the ICU.
- Identify infectious complications in critically ill patients.
- Conduct appropriate diagnostic work-up for infections encountered in the ICU.
- Develop a systematic approach for managing ICU-related infections.
- Execute effective measures to prevent infectious complications in the ICU.
- Understand how to effectively work up and treat patients with sepsis.
- Choose the appropriate antimicrobial regimen for either empiric or culture-focused treatment of ICU infections.

COMMUNITY-ACQUIRED PNEUMONIA

Epidemiology

CAP is defined as pneumonia acquired outside of a hospital or long-term care facility.

Community-acquired pneumonia (CAP) is defined as pneumonia acquired outside of a hospital or long-term care facility. Estimates indicate that there are approximately 1 million hospitalizations annually in the United States for this serious illness,[1] with approximately 10% requiring ICU admission.[§] Many pathogens can cause CAP; some are related to specific epidemiologic conditions and/or risk factors. The patient's history is important when attempting to account for these potential etiologies. These include exposures (e.g., to animals and/

or their droppings), travel, time of year, presence of comorbid disease (underlying lung disease being most important), and immunosuppressive states. The emergence of drug-resistant pneumococcal isolates as well as community-associated, methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has led to differences in the ways physicians think about and manage CAP. Risk factors for β-lactam resistant *Streptococcus pneumoniae* infection include advanced age, recent β-lactam use, alcoholism, medical comorbidities, immunosuppressive illness or therapy, and exposure to children. Local antibiotic prescribing patterns may influence resistance patterns as well.

Risk factors for CAP caused by gram-negative rods include chronic steroid use, underlying pulmonary disease, and alcoholism.

Pathogenesis and Microbiology

CAP may be caused by many different pathogens, the most common of which are bacteria. The distribution of these pathogens varies with the clinical setting. *S. pneumoniae* is isolated most frequently as the etiologic cause of CAP requiring hospitalization (both ICU and non-ICU level of care). Other common causes of severe CAP treated in the ICU include *Legionella* spp., gram-negative bacilli (e.g., *Enterobacteriaceae* spp. and *Pseudomonas aeruginosa)*, and *S. aureus*.[2] Lower proportions of severe CAP (as compared with CAP not requiring ICU level of care) are caused by respiratory viruses and *Haemophilus influenzae*. The frequency of other potential etiologic agents, such as endemic fungi, will vary with the epidemiologic setting.

The three most common bacterial pathogens causing CAP are *S. pneumoniae, H. influenzae, and Moraxella catarrhalis.* In severe CAP, *S. pneumoniae* remains the most common pathogen, followed by *Legionella* spp. and gram-negative bacilli.

An increasing incidence of CAP due to CA-MRSA has been seen more recently. These strains are different from the hospital-acquired strains in both virulence and resistance patterns and can be associated with a necrotizing or cavitary pneumonia that often leads to shock and respiratory failure.[2] Most of these organisms contain the gene for Panton-Valentine leukocidin, a toxin that is associated with these clinical features.[2] CAP caused by gram-negative rods such as *Klebsiella pneumoniae* and *P. aeruginosa* is less common but may be encountered in patients with risk factors such as chronic steroid use, severe pulmonary disease, and alcoholism. These pathogens may cause a severe, necrotizing form of pneumonia requiring ICU management.

CAP caused by CA-MRSA may present as an aggressive necrotizing or cavitary pneumonia.

Clinical Features

Symptoms suggestive of pneumonia include respiratory complaints such as cough, sputum production, dyspnea, and pleuritic pain, as well as fever. Chest radiography should be performed on presentation and usually reveals pulmonary infiltrates. Lack of visible infiltrates may be secondary to dehydration, neutropenia, or early presentation. Computed tomography (CT) is more sensitive in determining the presence of pulmonary infiltrates and may be indicated if the presence of complications such as effusion, empyema, or adenopathy is suspected. Microbiologic data are used as supportive evidence for the diagnosis of CAP and may aid in the determination of appropriate treatment. Sputum Grams stain and culture have been traditionally viewed as low yield but can be quite helpful.[3] Identification of an organism along with sensitivity data can help physicians tailor antimicrobial therapy. In patients who require intubation, an endotracheal sample can be easily obtained. Inability to obtain an adequate sputum sample should not delay therapy. In addition to sputum cultures, blood cultures should be performed in patients with severe CAP. Blood cultures can reveal the infective organism even when sputum cultures are negative. Blood cultures are most helpful when drawn prior to initiation of antimicrobial therapy.

Diagnostic work-up of severe CAP should includee a sputum culture and blood cultures.

Cultures should be drawn prior to the initiation of antimicrobial therapy to increase their yield.

Severity of illness determinations can help physicians place patients in the appropriate treatment setting and may help define appropriate empiric therapy. Patients admitted with a diagnosis of CAP requiring ICU level of care will often present with respiratory failure and septic shock requiring intubation and subsequent mechanical ventilatory support. There are subsets of patients, however, who do not meet these "major" criteria and may still require treatment in an ICU. The 2007 joint IDSA/ATS consensus guidelines on the management of CAP in adults endorse the use of the CURB-65 or Pneumonia Severity Index (PSI) in conjunction with sound clinical judgment to guide site of care decisions.[§] Use of the CURB-65

criteria (confusion, uremia, respiratory rate, low blood pressure, age ≥65) will generate a severity of illness score. Patients with scores ≥2 require intensive therapy, likely in an ICU setting. The PSI consists of 20 different variables in an attempt to quantify illness severity that is then linked to an appropriate management setting (outpatient treatment, brief inpatient observation, or more traditional inpatient therapy). The benefit of the CURB-65 criteria is its ease of use; however, it is not as well validated as the PSI. The 2007 IDSA/ATS CAP guidelines outline consensus criteria to define severe CAP in an attempt to predict ICU admission needs.[§] The presence of septic shock requiring vasopressors and/or mechanical ventilation with endotracheal intubation are absolute indications for ICU admission. These are considered the major criteria in their model. Minor criteria were developed based on previous prediction models in an attempt to define those patients with an increased risk of death. The minor criteria consist of the CURB-65 criteria minus the age delineation. In addition, they also include several other indices: a PaO_2/FiO_2 ratio ≤250, the presence of multilobar infiltrates, the presence of leukopenia, and the presence of hypothermia. The threshold for ICU admission, using these criteria, is the presence of any one major criterion or at least three minor criteria.[§]

Treatment

When the patient's history suggests aspiration pneumonia, the empiric antimicrobial regimen used should cover anaerobic organisms.

The cornerstone of treatment of CAP is antimicrobials. In the ICU these medications are often used in conjunction with other treatment modalities for sepsis as well as ventilatory support for respiratory failure. In the presence of criteria of acute lung injury or acute respiratory distress syndrome (ARDS), ventilatory strategies using positive end expiratory pressure (PEEP) and low tidal volume are recommended. In critically ill patients with CAP, empiric therapy is broad and use of multiple antimicrobials is often necessary. Recommended standard empirical regimens should include coverage for the three most common bacterial pathogens, all of the atypical organisms, and most *Enterobacteriaceae* spp.[§] The patient's history will dictate whether other organisms need to be considered and, if so, what appropriate alterations to empiric therapy need to be made. It is at this point that a decision to cover for infection with MRSA or *Pseudomonas* spp. is made, as well as for other potential pathogens.

Empiric regimens for CAP should include coverage for the three most common bacterial pathogens, all of the atypical organisms, and most *Enterobacteriaceae* spp.

A β-lactam (cefotaxime or ceftriaxone) plus either azithromycin or a fluoroquinolone is the narrowest spectrum of antibiotics recommended for empiric treatment of CAP in the ICU.[§] In penicillin-allergic patients a respiratory fluoroquinolone and aztreonam is adequate initial coverage. The main alterations to these proposed regimens are when infection with MRSA or *Pseudomonas* is suspected. In the case of infection with *Pseudomonas*, an antipseudomonal β-lactam (piperacillin-tazobactam, cefepime, imipenem, or meropenem) plus either ciprofloxacin or levofloxacin (750 mg dose) can be used. If MRSA infection is suspected, vancomycin or linezolid should be added. Anaerobic coverage should be initiated in addition to above therapies when aspiration is suspected. Physicians should be aware of epidemiological considerations that may further alter empiric therapy and then adjust treatment as needed. Once the causative pathogen has been identified, antimicrobial therapy should be tailored (see Table 32-1). Should microbiologic testing prove to be unrevealing, empiric therapy may need to be continued for the full course.

ACUTE BACTERIAL MENINGITIS

Epidemiology

Acute bacterial meningitis (ABM) is a severe life-threatening infection involving the membranes of the central nervous system (CNS). ABM often presents in a fulminant fashion with multiple complications resulting in a high fatality rate despite the availability of potent antimicrobial therapy. The annual incidence of ABM is approximately 4–6 cases per 100,000 population in the United States.[4] Mortality rates vary and depend on the type of invading pathogen as well as the patient-specific risk factors (e.g., age and comorbid illness). Over

TABLE 32-1

COMMUNITY-ACQUIRED PNEUMONIA: ICU PATHOGENS AND THEIR TREATMENT

Common bacterial pathogens	*Streptococcus pneumoniae*	Penicillin or amoxicillin (if MIC <2) (otherwise choose agent based on susceptibility testing)
	Haemophilus influenzae	Amoxicillin or second or third-generation cephalosporin (β-lactamase producing)
Atypical organisms	*Legionella* spp.	Fluoroquinolone or azithromycin
Gram-negative bacteria	*Enterobacteriaceae* spp.	Third-generation cephalosporin or carbapenem
	Pseudomonas spp.	Antipseudomonal β-lactam plus ciprofloxacin or levofloxacin
MRSA		Vancomycin or linezolid
Anaerobes (aspiration)		Clindamycin or β-lactam/β-lactamase inhibitor
Influenza virus		Oseltamivir

time, the epidemiology of ABM has changed secondary to the introduction and widespread use of *H. influenzae* type b and *S. pneumoniae* vaccines as well as the emergence of multidrug-resistant *S. pneumoniae* as a new pathogen.

Pathogenesis and Microbiology

The pathogenesis of ABM depends on both host factors and the nature of the invading pathogens. Direct extension from adjacent structures (middle ear, paranasal sinuses, etc.) and hematogenous spread are the two routes of bacterial entry into the CNS; however, the exact mechanism of bacterial penetration through the blood–brain barrier (BBB) remains undetermined. Once the subarachnoid space has been penetrated, bacterial cell wall components stimulate the formation of various inflammatory cytokines, thereby activating the inflammatory cascade. This process further perpetuates disruption of the BBB. Inflammatory and cytokine responses have been reported to differ according to the invading organism, which may explain the variability in complication rates among various CNS pathogens.

N. meningitidis and *S. pneumoniae* are the most common causes of meningitis in adults.

In adults, *S. pneumoniae* and *Neisseria meningitidis* are the most common causes of meningitis (Table 32-2), accounting for 80% of all cases.[5] Risk factors for pneumococcal infections include otitis media, sinusitis, pneumonia, head trauma with cerebrospinal fluid (CSF) leak, immune deficiency, and asplenia. ABM caused by *S. pneumoniae* has a high fatality rate and may be associated with neurologic sequelae. The emergence of antibiotic-resistant strains of this organism limits its treatment and likely leads to higher complication and fatality rates.

N. meningitidis occurs more commonly in young adults and in college campus outbreaks. Nasopharyngeal carriage is believed to cause initiation of the meningitis with either organism.

On the other hand, *N. meningitidis* infections are more often found in children and young adults, and at times, occur in epidemics in schools and on college campuses. Individuals with complement deficiencies (C5–C8) are also known to be at far greater risk to develop neisserial infections. Following the widespread use of vaccines against *H. influenzae* capsular type b in the United States, there has been a steady decline in the incidence of meningitis

TABLE 32-2

BACTERIAL PATHOGENS CAUSING MENINGITIS IN ALL AGE GROUPS

0–3 Months	Group B streptococci
3 Months–18 years	
18–50 Years	*Streptococcus pneumonia* *Neisseria meningitidis*
>50 Years	*S. pneumonia* *Listeria monocytogenes*
Impaired immunity	*S. pneumonia* *L. monocytogenes*
Trauma/neurosurgery	*Staphylococci* Gram-negative rods

Listeria monocytogenes causes meningitis in elderly patients, neonates, and debilitated or immunosuppressed patients.

caused by this organism. *L. monocytogenes* is most commonly encountered in neonates and the elderly, as well as in debilitated patients including cancer patients, alcoholics, pregnant women, and immunosuppressed adults. Immunosuppressed adults and those who undergo neurosurgical procedures are also predisposed to develop meningitis resulting from aerobic gram-negative rods and *S. aureus*. *Staphylococcus epidermidis* infections are mostly observed in patients with cerebrospinal shunts.

Clinical Features

Fever, headache, and meningismus are typical manifestations of ABM; however, in the elderly or immunocompromised, the presentation may be subtler.

Kernig's sign is increased resistance to passive leg extension. Brudzinski's signs are associated flexion of the hips and knees with passive neck flexion.

Symptoms of ABM can be quite varied. The classic triad of fever, nuchal rigidity, and altered mental status is often not found, but most patients will have one or two of these symptoms along with additional findings, such as headache, rigors, vomiting, myalgias, and signs of cerebral dysfunction. Elderly, immunocompromised, and debilitated patients may have a less fulminant presentation in which these findings are subtler. Severe meningismus is sometimes accompanied by Kernig's sign (resistance to passive extension of the legs) and Brudzinski's sign (passive flexion of the neck causing flexion of the hips and knees). Uncommonly, patients may present with cranial nerve palsies, new-onset seizures, focal neurologic deficit, or signs of increased intracranial pressure such as severe hypertension, bradycardia, and coma. Meningococcal septicemia may also manifest with a hemorrhagic skin rash, acute adrenal insufficiency (Waterhouse–Friderichsen syndrome) caused by adrenal hemorrhage, and disseminated intravascular coagulation (DIC).

Treatment

Antibiotic therapy should be administered when clinical evaluation establishes suspicion of meningitis, and antibiotics should be given within 30 min from initial presentation.

Lumbar puncture is diagnostic of ABM in 60–90% of cases, and is associated with elevated CSF pressure and elevated CSF white blood cells.

Brain imaging with CT or MRI can exclude intracranial and parameningeal processes or complications related to meningitis.

Treatment of ABM is dependent on the timely recognition of this clinical syndrome. Patients with suspected ABM should have blood cultures drawn and undergo a lumbar puncture.† CSF sampling for protein, glucose, and Gram stain and culture should be performed. Patients suspected of having ABM should receive empiric antimicrobial therapy in combination with dexamethasone.† Delays in empiric therapy lead to increased morbidity and mortality. As such, if diagnostic tests are delayed or neuro-imaging tests are deemed necessary for further evaluation, empiric therapy should be administered as soon as possible (even if prior to the performance of diagnostic testing or CSF sampling).† Repeat CSF analysis should be performed in patients not clinically responding to appropriate antimicrobial therapy after 48 h in order to further guide treatment.

Selection of an empiric antibiotic regimen is based on the patient's age and risk factors (see Table 32-3). Large doses of bactericidal antibiotics with good CSF penetration are given to control this life-threatening infection. In adults, vancomycin plus a third-generation cephalosporin should be used.† In patients with any cellular immunodeficiency (whether disease- or drug-related), on hemodialysis, or if older than 55 years of age, ampicillin should be added to cover for *L. monocytogenes*.† Once the organism and its susceptibility is known, tailored antimicrobial therapy can be provided. Penicillin-susceptible strains of *S. pneumoniae* and *N. meningitidis* are treated with penicillin G.† *L. monocytogenes* is sensitive to ampicillin,

CHOICES AND DOSAGES OF EMPIRIC ANTIBIOTIC THERAPY FOR BACTERIAL MENINGITIS

Adult immunocompetent	Cefotaxime or	2 g q4h
	Ceftriaxone	2 g q12h
	+Vancomycin	1 g q12h
Over 50 years or with impaired immunity	Ampicillin	2 g q4h
	+Cefotaxime or Ceftriaxone	
	+Vancomycin	
Nosocomial or postneurosurgery	Vancomycin	1 g q12h
	+Cefepime	2 g q12h
	±Aminoglycoside[a]	

[a]Gentamicin, amikacin, or tobramycin if *Pseudomonas* is suspected; patients with gram-negative meningitis who fail systemic therapy should be considered for intrathecal or intraventricular aminoglycoside therapy

and usually an aminoglycoside is added for the first several days of therapy.† Methicillin-sensitive staphylococcal infections should be treated with nafcillin or oxacillin; vancomycin has poor CSF penetration compared to nafcillin and should be reserved for resistant infections. For infections caused by highly resistant *S. pneumoniae* (minimal inhibitory concentration (MIC) >2 g/mL), treatment with vancomycin and a third-generation cephalosporin is recommended.†

In cases of suspected pneumococcal meningitis, steroids should be administered before the first dose of antibiotics.

The need for adjunctive treatment with dexamethasone in patients with ABM is somewhat controversial. Published data on this topic do not provide a clear answer concerning the utility of steroids in this clinical setting. A study published in 2002 showed that adjunctive dexamethasone use in patients with pneumococcal meningitis improved outcomes by reducing both complications and mortality.[6] As such, current recommendations include the use of steroids as a treatment modality. Dexamethasone should be used empirically when there is suspicion for or a possibility of *S. pneumoniae* infection, and continued if confirmed with results from CSF Grams stain or blood cultures.† The beneficial effect of steroids is seen only when administered prior to or with the first dose of antibiotics. On the other hand, a 2007 randomized, double-blind, placebo-controlled trial in Sub-Saharan Africa did not support the routine adjunctive use of corticosteroids in the management of patients with suspected ABM.[7] In this area, pneumococcus is the primary pathogen, and an overwhelming proportion of patients included in the trial were HIV-positive.[7] The causal relationship for these findings is unclear, but could potentially have implications for HIV-positive patients in developed countries as well. Results from a similarly conducted study performed in patients with suspected bacterial meningitis in Vietnam illustrated a beneficial effect in those patients with microbiologically proven disease.[8] In this trial no difference in outcome was seen in the comparison of all patients with suspected bacterial meningitis.[8]

Postexposure prevention of ABM is directed toward individuals exposed to patients infected with *N. meningitidis.* One dose of ciprofloxacin (500 or 750 mg) or rifampin twice a day for 2 days (10 mg/kg; not exceeding 600 mg/day) is recommended and is effective in eradicating nasopharyngeal carriage of *N. meningitidis* for close contacts. Ceftriaxone (250 mg IM) has been administered as alternative meningococcal chemoprophylaxis for pregnant women and persons intolerant of ciprofloxacin.

SEPSIS

Epidemiology

Sepsis is a syndrome resulting from a cascade of deranged inflammatory events caused by serious infection. It is associated with nonspecific systemic manifestations that often lead to multiple organ system failure.

Sepsis is a syndrome whereby a serious infection induces a cascade of deranged inflammatory events causing nonspecific systemic manifestations that often lead to multiorgan dysfunction.[9] Clearly any infection can cause such a presentation, and the severity of illness may vary considerably in the presence of these nonspecific findings; hence the heterogeneity of the sepsis syndrome. The same presentation is observed in certain diseases without any evidence of infections, such as acute pancreatitis and major trauma. This noninfectious inflammatory pattern, which mimics sepsis, has been termed the systemic inflammatory response syndrome (SIRS).

Despite better understanding of the pathophysiology of sepsis, mortality approaches 30–40%.

Despite the availability of advanced life-supportive care and the introduction of newer antimicrobial therapy, sepsis is among the leading causes of ICU admissions and continues to be the most common complication seen in critically ill ICU patients. Moreover, sepsis remains associated with a mortality rate of 30–40% and is the most common cause of death in most ICUs in the United States and Europe.[10]

Pathogenesis and Microbiology

A more detailed discussion of the pathogenesis of sepsis is covered in Chap. 23. In brief, an infectious stimulus or one of its byproducts triggers the release of proinflammatory cytokine mediators (tumor necrosis factor-alpha, interleukin-1, interleukin-8), which

An infectious stimulus triggers the release of proinflammatory cytokines, such as tumor necrosis factor, interleukin-1, and interleukin-8.

initiates a systemic inflammatory response. Initial hypotheses regarding sepsis suggested that unimpeded proinflammatory responses contributed to the clinical features of this syndrome. Current evidence supports the hypothesis that sepsis results from derangements in the host immune response, i.e., an imbalance between proinflammatory and antiinflammatory cytokines (interleukin [IL]-1 receptor antagonist, IL-4, IL-10, tumor necrosis factor receptor antagonist).[9] In such an uncontrolled inflammatory milieu, other mechanisms such as redistribution of regional blood flow, reduction in oxygen supply, oxidant injury, and alterations in intermediary metabolism contribute to tissue ischemia and injury, resulting in organ dysfunction. The difference between sepsis and SIRS lies only in the precipitating stimulus; in SIRS, the initial insult is thought to be noninfectious.

The most common sites of infection associated with sepsis are the lung, abdominopelvic region, and urinary tract.

Any serious infection can lead to sepsis, and no single organism predominates. The spectrum of pathogens involved varies according to the host and the affected organ. The most common site of infection giving rise to severe sepsis is the lung (e.g., pneumonia), followed by the abdominal or pelvic region (e.g., cholecystitis), then the urinary tract (e.g., pyelonephritis). Staphylococcal infections and infections with enteric gram-negative organisms are frequently associated with nosocomial sepsis. Immunocompromised patients may develop sepsis from viruses and fungal pathogens, as well as from bacteria. The history, physical examination, and initial work-up often establish a suspected source of infection, although a proportion of patients will have no identifiable source of infection.

Clinical Features

Positive blood cultures are seen in 30% of patients and about 20–30% have no identifiable source of infection.

Sepsis can be confirmed by right heart catheterization. The usual findings include elevated cardiac output, low systemic vascular resistance, and low to normal pulmonary capillary wedge pressure.

Sepsis represents a continuum of clinical presentations (see Table 32-4). Systemic manifestations from infections define sepsis and the presence of organ dysfunction, or tissue hypoperfusion defines severe sepsis. The term septic shock is used when hypotension or hypoperfusion is refractory to fluid resuscitation. Sepsis is a clinical diagnosis in patients with suspected infection who present with fever or hypothermia, tachypnea, tachycardia, leukocytosis, or leukopenia. The diagnosis is confirmed by abnormalities in central hemodynamics. An elevated cardiac output, low systemic vascular resistance, and low to normal pulmonary artery occlusion pressure (wedge pressure) are characteristic of sepsis. During the early stages of sepsis, clinical features may be more specific and may vary according to the host and the affected organ; for example, hypoxemia and dyspnea would suggest pneumonia as the cause of sepsis. In elderly and immunocompromised patients or with the progression to severe sepsis, the site of infection tends to be less evident because of poor host response or multiple organ dysfunction. For instance, hypoxemia and dyspnea may reflect diaphragmatic dysfunction or ARDS in a patient who has abdominal sepsis.

A clinical picture suggesting sepsis should always prompt a diagnostic work-up that is directed toward identification of the source of infection and subsequent isolation of the responsible pathogen. A sepsis work-up is incomplete if it does not include a white blood cell count with a peripheral smear, chemistry profile, blood cultures, urine cultures, and a chest X-ray. Additional testing is usually guided by the history and physical examination. For example, a sputum Gram stain and culture are obtained when the clinical scenario is consistent with pneumonia. It is generally recommended to sample any fluid collection that

TABLE 32-4

CLINICAL FEATURES OF SEPSIS

CLINICAL PRESENTATION	LABORATORY
Fever or hypothermia	Leukocytosis or granulocytopenia
Tachypnea	Thrombocytopenia
Tachycardia with or without hypotension[a]	Respiratory alkalosis/hypoxemia
Oliguria	Hyperglycemia
Confusion or obtundation	Lactic acidosis

[a]Hypotension is usually defined as systolic blood pressure <90 mmHg or a drop of >40 mmHg from baseline. The term septic shock is used in the presence of sepsis-related hypotension refractory to fluid resuscitation

TABLE 32-5

UNUSUAL CAUSES OF SEPSIS OR SEPSIS-LIKE SYNDROME

Bacterial infections
Mycobacterial: tuberculosis, *Mycobacterium avium* complex
Rickettsial: Rocky Mountain spotted fever, ehrlichiosis
Nonbacterial infections
Viral: dengue, enteroviruses, hepatitis A or B, influenza, cytomegalovirus, herpes zoster viruses
Malaria
Fungal: *Candida*, *Aspergillus*
Noninfectious
Drug-related: anaphylaxis, neuroleptic malignant syndrome
Drug intoxication: cocaine, organophosphate
Drug withdrawal: alcohol
Anaphylaxis
Systemic vasculitis: polyarteritis nodosa, systemic lupus erythematosus
Acute pancreatitis
Acute hepatic failure
Heatstroke
Rhabdomyolysis

is found on diagnostic imaging because it may be the source of infection. Moreover, to optimize the microbiologic yield, all cultures should be obtained before administering antibiotics. Assessment of risk factors and comorbidities helps in the diagnostic work-up and the selection of antimicrobial therapy; however, if the primary site of infection is not readily identifiable, a systematic search for infection should cover the respiratory, gastrointestinal, biliary, and genitourinary tracts, along with the central nervous and cardiovascular systems.

With a high clinical suspicion for sepsis, conduct a diagnostic work-up directed at locating an infectious source and a specific pathogen.

Patients already in the hospital or in the ICU are vulnerable to developing secondary sepsis from either failure of their therapy or superimposed nosocomial infections. Specific nosocomial infections, which add significantly to the morbidity and mortality of patients, are discussed in more detail in this chapter. Often it becomes difficult to isolate the offending organism and ascertain whether the systemic inflammatory process is infectious or noninfectious in patients with prolonged hospitalization. These patients are typically colonized with numerous pathogenic organisms, particularly those receiving multiple antibiotics or systemic corticosteroids, making it more difficult for clinicians to identify an organism as pathogenic or as just a colonizer. Nonbacterial infectious pathogens such as fungi are less common causes of sepsis in most ICUs, but this may vary depending on geographic location and host susceptibility. These pathogens, along with the noninfectious causes of sepsis-like syndrome, should be considered in patients whose illness has no clear etiology (see Table 32-5).

Fluid collections found on imaging studies should be sampled before administration of antibiotics, if possible, to ensure the highest yield.

Sepsis is commonly encountered in hospitalized, debilitated patients, and those at risk to develop nosocomial infections.

Management

The strategy to manage sepsis and septic shock consists of two main approaches: (1) initial resuscitation and infection control, and (2) maintaining hemodynamics and adjunctive support. The first phase of sepsis management is relatively well defined and vital to having an improved outcome, whereas optimal supportive therapies remain to a certain extent debatable. Recent international guidelines for the management of severe sepsis and septic shock have been published, and an abridged summary of their recommendations is found in Tables 32-6 and 32-7.[‡]

Management of sepsis should focus on aggressive initial resuscitation and early institution of antimicrobial therapy and drainage of any abscesses.

Infection control involves the use of antimicrobials, drainage, or debridement (surgical or nonsurgical) of abscesses or necrotizing tissue when present, and surgery to repair any perforated viscous. Findings from the history, physical examination, and initial diagnostic work-up usually lead to a presumptive diagnosis and guide the initial choice of empiric antimicrobial therapy (Table 32-8). Any uncertainty about the cause of sepsis, site of infection, or type of pathogen justifies the use of aggressive broad-spectrum antibiotics, especially in the current era when resistant pathogens are a more common entity. As would

TABLE 32-6

MANAGEMENT OF SEPSIS: GOALS OF RESUSCITATION AND CONTROLLING INFECTION

GOALS	METHODS
Initial resuscitation	Maintain CVP 8–12 mmHg Maintain MAP ≥64 mmHg Maintain UOP ≥0.5 mL/kg/h
Diagnosis: identification of source of infection and its control	Obtain cultures prior to antimicrobial administration (two or more blood cultures and cultures of other sites as clinically indicated) Identify source of infection Apply source control methods as indicated (e.g., abscess drainage, tissue debridement, iv catheter removal)
Antibiotic therapy	Initiate antibiotic therapy early and initially use broad-spectrum antibiotics with likely activity and penetration based on presumed source Perform regular reassessment to optimize efficacy, prevent resistance, and avoid toxicity of antimicrobials Stop antibiotics if cause of sepsis deemed noninfectious

CVP, central versus pressure; MAP, mean arterial pressure; UOP, Urine output

Assessment of risk factors and comorbid conditions aid the diagnostic work-up and subsequent antimicrobial choice.

Despite the development of many investigational therapies, exceptional bedside care and optimal hemodynamic support remain vital for management of sepsis.

Low-dose steroid therapy should be avoided for the *routine* management of patients with sepsis. It is unclear if systemic steroids are beneficial for a subgroup of patients with refractory shock.

be suspected, an increase in mortality is observed in patients who receive delayed or inappropriate antimicrobial therapy. The ideal scenario is to start antibiotics very early in sepsis (immediately after obtaining all cultures) and then identify the cause of the infection and mechanically address the issue if necessary (drainage, surgery, etc). Unfortunately, not all patients present early in the course of their disease, and many progress to septic shock and require extensive supportive therapies despite adequate antimicrobial coverage. While vasopressor therapy, mechanical ventilation, and renal replacement interventions have a clear role in the management of severe sepsis, other interventions are still at question. The recent international guidelines suggest the use of corticosteroids in patients with refractory shock, treat hyperglycemia with intravenous insulin therapy, and possibly use colloids for resuscitation.[‡] However, findings from recent large multicenter trials demonstrated no consistent measurable benefit of these interventions on sepsis mortality[11,12] and that using pentastarch (a colloid) should even be avoided. Therefore, until clinical investigations demonstrate an effective approach to optimize adjunctive therapies and modulate the host inflammatory response, meticulous bedside care assuring optimal hemodynamic interventions to prevent secondary organ injury and complications offers the best hope for patient survival.

TABLE 32-7

MANAGEMENT OF SEPSIS: USE OF ADJUNCTIVE THERAPIES

THERAPY	RECOMMENDATIONS
Fluid replacement	Use crystalloids or colloids for fluid resuscitation Target CVP 8–12 mmHg Use fluid challenge technique with close monitoring
Vasopressor use	Target goal MAP ≥65 mmHg Use norepinephrine and dopamine as initial vasopressors of choice
Steroid use	Consider i.v. hydrocortisone therapy in adults with septic shock unresponsive to adequate fluid resuscitation and vasopressors
Recombinant human activated protein C	Consider use only in adult patients with sepsis-induced organ dysfunction and clinically determined high risk of death (APACHE II score ≥25) when no contraindications present

TABLE 32-8

EMPIRIC ANTIBIOTIC SELECTION FOR SEPSIS

Life-threatening sepsis	Aminoglycoside (gentamicin, tobramycin or amikacin) plus one of the following Cefepime Piperacillin-tazobactam Carbapenems Suspected MRSA: add vancomycin
Intraabdominal or pelvic infections	Piperacillin-tazobactam, ampicillin-sulbactam, imipenem or cefepime + metronidazole
Billiary tract sepsis	Third-generation cephalosporin (cefotaxime or ceftriaxone)
Urosepsis	Third-generation cephalosporin (cefotaxime or ceftriaxone) or Ciprofloxacin
Neutropenia	Cefepime Imipenem Piperacillin/tazobactam + aminoglycoside

NOSOCOMIAL INFECTIONS

Nosocomial Pneumonia

Epidemiology

Nosocomial (or hospital-acquired) pneumonia (HAP) is defined as a pneumonia that occurs in patients who have been hospitalized for more than 48 h. Ventilator-associated pneumonia (VAP) is a subset of HAP that occurs more than 48 h following endotracheal intubation. Health care associated pneumonia (HCAP) is pneumonia that occurs in patients with recent extensive health care contact (e.g., receipt of intravenous therapies, wound care, and/or hemodialysis clinic attendance within prior 30 days, residence in a nursing home or long-term care facility, or hospitalization within prior 90 days). These are common nosocomial infections carrying with them significant morbidity and mortality. The incidence of nosocomial pneumonia increases according to the patient's underlying severity of illness and is a common problem in the ICU, especially in mechanically ventilated patients. In addition, pneumonia is associated with the greatest mortality of any nosocomial infection: the attributable mortality is high and can range up to 24–50% in mechanically ventilated patients.[13]

Nosocomial pneumonia is associated with the highest mortality of all nosocomial infections in the ICU.

Time of onset of pneumonia is an important epidemiologic variable. Early-onset HAP and VAP occur within 4 days of hospitalization and carry a better prognosis due to increased likelihood of antibiotic-sensitive bacteria as causal organisms. In contrast, late-onset HAP and VAP are defined as occurring 5 days or more into a patient's hospitalization. As such, these tend to be associated with multidrug resistant (MDR) pathogens and carry an increased morbidity and mortality.[§§] Patients with early-onset HAP or VAP who have been recently hospitalized provide an exception and are at greater risk for infection with MDR pathogens; these patients should be approached in the same way as those with late-onset HAP and VAP.[§§]

Pathogenesis and Microbiology

The pathophysiology of nosocomial pneumonia is complex and varies among different hospital patient populations. Although risk factors can help identify patients with nosocomial pneumonia, management of such infections remains extremely challenging because of emerging resistant organisms, lack of a gold standard for diagnosis of pneumonia, and associated morbidities.

Risk factors for nosocomial pneumonia include severity of illness, comorbid conditions, malnutrition, advanced age, mechanical ventilation, and heavy sedation.

Risk factors for nosocomial pneumonia are either related to host factors or extrinsic factors. Host factors include severity of illness, associated comorbidities, malnutrition, and advanced age.[13] Extrinsic factors are related to interventions that interfere with the integrity of the host defense mechanisms such as nasogastric tubes, mechanical ventilation via endotracheal or nasotracheal intubation, and the use of heavy sedation or neuromuscular blockade. Most extrinsic risk factors impair swallowing and leave the upper airway unprotected from aspiration. Bacteria invade the lower respiratory tract via aspiration, inhalation of

TABLE 32-9

PREEXISTING CONDITIONS ASSOCIATED WITH PHARYNGEAL COLONIZATION BY GRAM-NEGATIVE BACTERIA

Prolonged hospitalization	Coma
Antibiotic exposure	Pulmonary disease
Major surgery	Renal disease
Diabetes mellitus	Neutropenia

contaminated aerosols, or hematogenous spread. Overt or covert aspiration (at times referred to as microaspiration) of oropharyngeal or gastric flora is thought to be the most common route of organism delivery to the lower respiratory tract. In critically ill patients, the oropharynx becomes colonized with gram-negative organisms a few days after admission to the hospital, especially if the patients have been exposed to antimicrobial therapy. Once an inoculum of pathogenic organisms reaches the lower respiratory tract, medical disease processes that reduce host immunity and violation of the host anatomic barriers make the ideal milieu for pneumonia to flourish.[13]

Since aspiration is a common route of pathogen entry into the lower respiratory tract and since critically ill patients have an altered oropharyngeal and gastrointestinal flora, one can understand the differences in responsible pathogens between nosocomial pneumonia and CAP. Nosocomial pneumonia may be caused by a wide variety of bacterial pathogens but has been most commonly associated with enteric gram-negative bacilli (see Table 32-9). Pneumonias caused by resistant gram-positive pathogens such as *S. aureus,* particularly the methicillin-resistant strains, are becoming more widespread in ICUs.[14] Prevalence of specific pathogens causing nosocomial pneumonia varies among ICUs because of variability in ICU microflora.

MDR bacteria have emerged as more frequent causes of nosocomial pneumonia, and the frequency of these infections varies in different ICUs.[14] Risk factors for pneumonia with MDR pathogens include recent antimicrobial therapy, prolonged hospitalization, specific ICU flora, and immunosuppressive disease or therapy.[14] They are more likely etiologic organisms in late-onset HAP and VAP. Knowledge of the local ICU microflora (*P. aeruginosa, Klebsiella* spp*., Enterobacter* spp*., Serratia* spp., *Acinetobacter* spp., and MRSA) with their local resistance patterns should guide the initial empiric treatment when these infections are suspected.

Clinical Features

Microbiologic evaluation via sputum or tracheal aspirate is nonspecific for diagnosing nosocomial pneumonia because a positive culture may reflect colonization.

The criteria for diagnosing pneumonia include clinical, radiographic, and laboratory evidence of infection. Classical signs and symptoms of pneumonia can be present and can include cough with new onset of purulent sputum or change in the character of sputum. Fever, tachypnea, dyspnea, tachycardia, hypoxemia, leukocytosis, crackles, or dullness to percussion are often present. In addition, one may find new or progressive infiltrates on chest radiographs and organisms isolated from sputum or blood cultures. Unfortunately, clinical evaluation is frequently limited in complicated and critically ill patients with a resultant decrease in the positive predictive value of many clinical findings normally associated with the diagnosis of pneumonia (see Table 32-10). Isolation of organisms from blood or pleural fluid cultures in the right setting is highly specific for pneumonia, but the prevalence of bacteremia in patients with nosocomial pneumonia is relatively low. On the other hand, the microbiology of sputum and tracheal aspirate is nonspecific for the diagnosis of nosocomial pneumonia because the majority of hospitalized patients are colonized with a number of potentially pathogenic organisms.

TABLE 32-10

RADIOGRAPHIC MIMICS OF PNEUMONIA

Atelectasis (most common)	Pulmonary infarct
Aspiration	Asymmetric pulmonary edema
Pleural effusions	Pulmonary hemorrhage
Acute respiratory distress syndrome	Bronchiolitis obliterans organizing pneumonia
Pulmonary contusion	

Many intensivists favor using invasive diagnostic techniques (fiberoptic bronchoscopy [FOB] to obtain bronchoalveolar lavage [BAL] fluid or protected specimen brushing [PSB]) because they are believed to be more accurate than clinical diagnosis. Published guidelines for the management of HAP suggest incorporating both the clinical and microbiologic data to guide the decision-making process regarding initiating and discontinuing antibiotic therapy.[§§] In this algorithm, physicians should obtain lower respiratory tract sample for microscopy and culture and initiate appropriate empirical antibiotic therapy when HAP, VAP, or HCAP is clinically suspected. Clinical response should be continually assessed in the days following therapy. If there is no evidence of clinical improvement 48–72 h following initiation of therapy and cultures are negative, a physician should search for other pathogens, complications, or sites of infection. If cultures are positive in the setting of a lack of clinical improvement at this time, antibiotics should be adjusted or other diagnoses and/or sites of infections sought. On the other hand, if clinical improvement occurs within that time period and cultures are positive, de-escalation of therapy should be performed based on culture data. If cultures are negative at 48–72 h and the patient is clinically improving, physicians should consider stopping antibiotics.

Tracheal aspirate Gram stains are often used to initiate empiric antibiotic therapy, and results from semiquantitative or quantitative cultures along with serial clinical evaluations after 2–3 days of empiric treatment guide the decision to maintain, change, or discontinue the initial empiric coverage.

Invasive testing is the accepted standard for the diagnosis of pneumonia in immunocompromised patients; BAL and PSB have a superior yield and a higher accuracy compared to noninvasive techniques in immunocompromised patients due to a higher prevalence of nonbacterial pathogens in these patients. Yield from the cultures is significantly reduced if the patient is already on antibiotic therapy; therefore, all cultures should be obtained before initiation of therapy, regardless of the diagnostic technique used to obtain respiratory secretion samples.

Poor bronchoscopic technique, early pneumonia, and use of antibiotics may reduce the sensitivity and specificity of bronchoscopic sampling.

Treatment and Prevention

It is obvious that accurate diagnosis is critical for optimal antimicrobial therapy. Hospital microflora, timing of the onset of the nosocomial pneumonia, types of risk factors, and severity of the patient's illness guide initial empiric antibiotic therapy (see Table 32-11). Supportive therapy, including ventilatory, hemodynamic, and nutritional support, together with the appropriate antimicrobial coverage are the cornerstones of successful treatment of nosocomial pneumonia. Inadequate initial antibiotic regimens, even if changed later in the course of the illness, are consistently found to be a significant risk factor for poor outcome in patients with nosocomial pneumonia.[§§]

Inappropriate antibiotic choice is a significant risk factor for mortality in nosocomial pneumonia.

The key decision in empiric treatment lies in the decision to cover for MDR pathogens based on the patient's clinical risk factors and the susceptibility patterns of one's ICU's flora. Initial therapy for patients diagnosed with early-onset HAP or VAP and without any risk factors for infection with MDR pathogens should include coverage for *S. pneumoniae*, *H. influenzae,* methicillin-sensitive *Staphylococcus aureus aureus* (MSSA), and antibiotic-sensitive

TABLE 32-11

ETIOLOGIC ORGANISMS OF NOSOCOMIAL PNEUMONIA AND INDICATED EMPIRIC THERAPY

CLINICAL SCENARIO	POTENTIAL PATHOGENS	EMPIRIC THERAPY
Early-onset HAP or VAP and no risk factors for MDR pathogens	*S. pneumoniae* *H. influenzae* MSSA Antibiotic-sensitive GNR *E. coli* *Klebsiella pneumoniae* Enterobacter spp. *Proteus* spp. *Serratia marcescens*	Ceftriaxone or levofloxacin, moxifloxacin, ciprofloxacin or ampicillin-sulbactam or ertapenem
Late-onset HAP or VAP or HCAP with risk factors for MDR pathogens	Etiologic pathogens causing early-onset disease plus *Pseudomonas aeruginosa* *Klebsiella pneumoniae* (ESBL) Acinetobacter MRSA	Antipseudomonal cephalosporin or antipseudomonal carbapenem or β-lactam/β-lactamase inhibitor plus antipseudomonal fluoroquinolone or aminoglycoside plus linezolid or vancomycin

enteric gram-negative bacilli (see Table 32-11).[§§] Antibiotics recommended for empiric therapy in this clinical situation include ceftriaxone, a respiratory fluoroquinolone, ampicillin-sulbactam, or ertapenem. Late-onset disease carries an increased risk of infection with MDR pathogens such as *P. aeruginosa,* ESBL *K. pneumoniae, Acinetobacter* spp., and MRSA. These patients who are at risk for pneumonia caused by MDR pathogens should be initially treated with broad-spectrum combination therapy until further culture data are known.[§§] The 2005 ATS/IDSA guidelines suggest the use of an antipseudomonal cephalosporin or a carbapenem or β-lactam/β-lactamase inhibitor plus an antipseudomonal fluoroquinolone or aminoglycoside plus linezolid or vancomycin as initial empiric therapy in late-onset HAP and VAP (Table 32-11).[§§] Choice of specific agents should be based on the presence of risk factors for MDR pathogens, as well as the local microbiology and antibiogram. Combination therapy is recommended, at least initially, to provide a broad-spectrum empiric regimen that is likely to provide at least one active drug against the MDR etiologic agent. Broad-spectrum empiric antimicrobial therapy should eventually be tailored to each individual patient based on clinical and microbiologic data. The optimal duration of therapy is not known; however, it has been shown that in patients with VAP, appropriate antimicrobial treatment for 8 days is as clinically effective as treatment for 15 days. In addition, shorter duration of treatment may reduce a patient's future risk for infection with increasingly resistant pathogens.[15] Unfortunately, even with the correct choice of antibiotics, overall mortality from nosocomial pneumonia remains substantial (25–50%)[13]; hence, prevention of such infection will have the greatest impact on the outcome of hospitalized patients.

Effective strategies for reducing the incidence of nosocomial pneumonia include strict infection control policies, reduction of the duration of mechanical ventilation, appropriate positioning of hospitalized patients, and limitation/early removal of invasive devices. Utilization of contact precautions for selected transmittable organisms (MRSA, group A Streptococci, *N. meningitidis,* penicillin-resistant *S. pneumoniae,* multiresistant gram-negative bacilli, *Mycobacterium tuberculosis,* and respiratory viruses) is the most important maneuver shown to be effective in reducing incidence of nosocomial pneumonia.

Semiupright position and contact precautions are the most effective maneuvers to prevent nosocomial pneumonia.

Intubation and subsequent mechanical ventilation markedly increase the risk for nosocomial pneumonia. It is recommended that intubation be avoided, possibly with the use of noninvasive positive pressure ventilation.[§§] Attempts at limiting the duration of mechanical ventilation should be made by the use of aggressive weaning protocols when applicable. Causality between acute sinusitis and nosocomial pneumonia has been suggested and, as such, the use of oral endotracheal and orogastric tubes, rather than nasotracheal and nasogastric tubes, can reduce the incidence of nosocomial sinusitis and possibly nosocomial pneumonia.[§§]Aspiration is thought to be the major mechanism leading to nosocomial pneumonia. The supine position facilitates aspiration and, thus, patients should be positioned in a semirecumbent position to help decrease its occurrence.[16] Enteral feeding is also associated with higher rates of aspiration and, thus, nosocomial pneumonia.[§§] The alternative, parenteral feeding, has associated potential risks such as line infections, and the risks/benefits of these two options must be weighed appropriately. It is uncertain whether the use of a specific ulcer prevention strategy (sucralfate vs. H2-blockers) has an impact on the development of nosocomial pneumonia; most of the evidence shows no significant differences between the two strategies.[17] Indiscriminate use of selective decontamination of the oropharynx and the digestive tract with topical antibiotics has not been found to be effective. In intubated patients, special endotracheal tubes have been introduced and shown to be effective in reducing VAP.

Intravascular Catheter-Related Infection

Epidemiology

Intravascular catheter-related infection is a serious complication of intravascular access. In current health care settings, intravascular devices are used frequently for administration of fluids and medications or for hemodynamic monitoring. These devices are most useful in the ICU setting, but they carry risk with their use. This inherent risk varies with the type of

catheter being used as well as the hospital epidemiology, anatomic catheter location, and duration of placement.[e]

Central venous catheters account for more than 90% of all catheter-related bacteremias; bacteremias secondary to peripheral venous catheter infections are rare. Before describing the pathogenesis and management of catheter-related infections, it is important to know the terminology used in this setting. First, the catheter is said to be colonized when a certain number of organisms grow from the culture of a removed catheter tip. Although colonization is thought to be a prerequisite for development of a line infection, it does not present with local or systemic signs of infection. Second, catheter-related infections may present as: (1) an exit site infection (local [<2 cm from catheter exit site] cellulitis and abscess formation), (2) a tunnel infection (local signs of inflammation or infection >2 cm from catheter exit site along tract of tunneled catheter), or (3) as a catheter-related bacteremia. Catheter-related bacteremia is correlated with significant colonization, even in the absence of local infection, and is defined as bacteremia originating from the catheter site; therefore, this diagnosis is based on isolation of the same organism from the catheter and the blood. Third, a blood culture is said to be contaminated because of improper sterilization technique while obtaining the blood sample and does not represent colonization or infection.

Central venous catheters cause 90% of catheter-related bacteremias.

Diagnosis of catheter-related bacteremia is based on the isolation of the same organism from the catheter and the blood.

Pathogenesis and Microbiology

Catheter-related infections are highly associated with colonization of the catheter, usually arising from skin colonization of the patient.[18] This is why attempts are made to avoid cannulation of the femoral veins as the inguinal region may be difficult to sterilize. Less commonly, the catheter tip is seeded hematogenously from a distant source following a transient bacteremia. Within 24–48 h of catheter insertion, a fibrin sheath forms around the intravascular surface of the catheter. During bacteremia, this fibrin sheath serves as a nidus for attachment and growth of organisms. Fibrin sheath formation and adherence of bacteria to catheters is related to the smoothness and thrombogenicity of the catheter, which varies among the different types of catheters. Contamination of the hub from inappropriate handling or blood draws and infection of the dermal tunnel from migration of organisms along the subcutaneous tunnel are common causes of catheter-related infections. Lastly, catheter-related infections can rarely be caused by contaminated infusates.

The most common cause of catheter-related bacteremia is dermal tunnel infection due to migration of organisms from contaminated or endogenous skin flora.

Skin colonization at the insertion site is strongly associated with catheter-related bacteremias.

Coagulase-negative staphylococci (*S. epidermidis*) and *S. aureus* bind easily to the surface of catheters and the fibrin sheath, and by far, are the most common causes of line infections.[e] The third most common organisms to cause catheter infections are *Enterococcus* spp. followed by Candida (*C. albicans*). Catheter-related infections caused by Candida spp. are more often seen in patients on multiple antimicrobials and receiving total parenteral nutrition.[e] Individuals who are on antimicrobials may also be more at risk to develop catheter-related infections with other organisms such as gram-negative enterics, (*Klebsiella* spp or *E. coli*), *Stenotrophomonas maltophilia, Flavobacterium* species, *Corynebacterium* species, or *Malassezia furfur.*

Clinical Features

The presentation of a catheter-related bacteremia is quite varied. Fever and leukocytosis with or without other signs of sepsis are common scenarios in ICUs. Complicated line infections often involve bacteremias with obvious sepsis, evidence of septic emboli, and even infected venous thrombi at the site of the catheter. As such, physicians should have a low threshold to search for the presence of catheter-related infections. Inspection of catheter sites should be part of the daily evaluation of hospitalized patients; paradoxically, an inflamed and erythematous site may be sterile, but a normal-appearing site may be significantly colonized. It should be remembered that signs of local inflammation at the insertion site are neither sensitive nor specific to detect catheter-related bacteremias or colonization. Clinical suspicion should be coupled with laboratory criteria to formally diagnose a catheter-related infection. Positive blood cultures in patients without an easily identifiable source of infection should raise the suspicion for a catheter-related bacteremia. Traditionally, blood cultures are

Inspection of the catheter site is important, but local inflammation at the insertion site is not very specific for colonization of the catheter.

obtained percutaneously from a distant site as well as from the catheter, which is then removed and sent for culture.

Catheter-related bacteremia is diagnosed when the same organism is isolated from blood cultures and catheter cultures in the absence of another active source of infection.[e] A positive culture from purulent exudate at the site of insertion is also accepted as a sign of catheter-related infection. Interpretation of blood cultures obtained from the same catheter that has raised concern for infection, rather than from a distant site, is always fraught with uncertainty; blood cultures may be positive because of contamination (poor technique obtaining the blood) or colonization, even in the absence of a true bacteremia.

Two accepted methods for culturing catheters yield meaningful information. The first and most frequently used method is the semiquantitative culture method (the Maki technique) in which a segment of the catheter is rolled on a culture medium, and colony-forming units (cfu) are counted following overnight incubation.[19] Because approximately 80% of catheter-related infections are caused by dermal tunnel infections, care should be taken to culture the intradermal segment (0.5 cm below the skin to 3 cm distally), not only the tip of the catheter. Catheter-related infection, by this method, is defined as the presence of 15 or more cfu; fewer than 15 cfu on semiquantitative cultures indicate insignificant colonization and is less likely to account for bacteremia.[18] The second method, the quantitative culture method (the Brun–Buisson technique), counts the number of organisms grown from catheter segment cultures after sonification of the catheter. Positive quantitative cultures are defined as more than 10^3 organisms in the broth and are associated with bacteremia.

Both the catheter tip and intradermal segment should be cultured. For the semiquantitative method, positive cultures are defined as growth of more than 15 cfu.

In contrast to semiquantitative and quantitative techniques used to establish the diagnosis of colonization and catheter-related infections, two other methods obviate removing the catheter. These methods can be especially useful as a method of detection in patients with limited vascular access. The first method consists of obtaining simultaneous blood samples from the catheter and from a peripheral vein for paired quantitative blood cultures. The finding of 5–10 times more colonies from blood drawn through the catheter compared to the peripheral site suggests catheter-related bacteremia and has been found to be most accurate in determining infections associated with tunneled catheters.[20] The second method relies on time required for blood cultures (also drawn concurrently from the catheter and a peripheral vein) to become positive. In catheter-related bacteremia, there is a positivity time differential between the two samples; blood cultures drawn through the catheter become positive at least 2 h earlier than the peripheral blood inoculum because of the higher organism count in the former.[21]

Treatment and Prevention

Often when a line infection is suspected in a seriously ill septic patient (those with hypotension, organ dysfunction, septic thrombosis, or persistent fever and bacteremia), blood cultures are obtained, the catheter is removed and sent for semiquantitative or quantitative cultures and empiric therapy with vancomycin, to cover *Staphylococcus* spp. and *Enterococcus* spp., is started. For critically ill patients and when gram-negative organisms are suspected, additional empiric gram-negative coverage should be included (third- or fourth-generation cephalosporins, fluoroquinolones, aminoglycosides, β-lactam-β-lactamase inhibitors, or carbapenems).[e] Antifungal therapy should be initiated also in patients suspected of having fungemia.[e] When the results from blood and catheter (or site) cultures become available, treatment can then be adjusted according to the results of the cultures and sensitivities. If the site is not colonized or the patient does not respond to therapy, another source for the infection should be sought and treated accordingly.

Local colonization without bacteremia usually responds to line removal (unless there is an expanding cellulitis) and antimicrobial therapy may not be required. The specific duration of therapy for catheter-related infection is variable. These infections can be subdivided into uncomplicated and complicated infections (e.g., those with septic thrombosis, endocarditis, or osteomyelitis). Catheter-related infection with bacteremia caused by organisms other than *S. aureus* is treated for 5–7 days after line removal; uncomplicated *S. aureus* catheter-related bacteremia is usually treated for 14 days.[e] Complicated catheter-related infections require a

longer duration of therapy and treatment must be individually tailored.[e] Unfortunately, some patients continue to have evidence of sepsis despite these measures, and under such circumstances, one should consider complications such as septic emboli, septic thrombophlebitis or cardiovascular infections. Patients with the risk factors such as antimicrobial therapy for more than 14 days, parenteral nutrition, growing *Candida* from two or more sites, complicated intraabdominal surgery, and neutropenia with persistent fever (>3 days despite empiric antibiotics) are at risk for candidemia. Such patients, if stable, should be started on fluconazole 400 mg/day and, if candidemia is confirmed, treatment should be continued for 14 days after line removal and clearance of cultures.[e] Unstable patients and those already on fluconazole who do not improve should be treated with an echinocandin.[e] Due to the associated risk of endophthalmitis, an ophthalmologic exam is recommended at the end of treatment.

Once catheter-related infection is documented, the catheter should be removed except in some instances of uncomplicated *S. epidermidis* line infections.[e] In contrast, infections of surgically implanted, long-term indwelling catheters (Broviac, Hickman, or Cook catheters) are commonly left in place unless the bacteremia is associated with a tunnel infection or if they are complicated by expanding cellulitis, septic thrombophlebitis, or resistant bacteremia despite appropriate antibiotics. Should this bacteremia recur following treatment, removal of the tunneled catheter is recommended.[e]

Treatment for catheter-related bacteremia involves removal of the central venous catheter in seriously ill patients and *S. aureus* infection. Removal of a surgically implanted catheter is not always required.

The most effective method for prevention of catheter-related infections is to limit the duration of the catheter. Other prevention strategies include appropriate selection of the catheter and insertion site, aseptic precautions during insertion of the catheter, and meticulous care of the catheter site and the delivery system. Cannulating the subclavian vein is associated with the lowest incidence of infection (but has a higher risk for other noninfectious complications), whereas use of the femoral vein site carries with it a higher infectious risk. Avoiding multilumen thrombogenic catheters and using cuffed or bonded catheters with antiseptics or antimicrobials will reduce, but not eliminate, the risk of catheter-related infections. Applying chlorhexidine at the insertion site reduces cutaneous bacterial colonization and thus dermal tunnel infections. Dry gauze or permeable dressings are more effective than transparent dressings for site care in decreasing the cutaneous flora. Changing the dressing daily and using topical antimicrobials also reduce the rate of skin colonization and catheter-related infections. Avoiding frequent interruptions to the delivery system, especially with total parenteral nutrition, minimizes risks of contamination. Changing catheters routinely over a guidewire does not prevent line infections; in the presence of dermal tunnel colonization or infection, this practice does not sterilize the tunnel. In addition, some clinicians advocate removal of high-risk catheters following an episode of bacteremia to prevent seeding of the catheter. Again, and most importantly, the central catheter should be removed when no longer required.

Catheter-related infections are preventable with strict aseptic techniques, proper choice of insertion site, and meticulous local care.

Clostridium difficile Colitis

Epidemiology

Clostridium difficile commonly causes antibiotic-associated colitis in hospitalized patients. The clinical presentation of *C. difficile* infections is variable, ranging from asymptomatic carriage or a simple self-limited watery diarrhea to a severe pseudomembranous colitis resulting in sepsis, toxic megacolon, and death. It is the most common cause of enteric infection in the hospital setting and its prevalence continues to rise. *C. difficile*-associated diarrhea often occurs in elderly, debilitated patients with a history of antimicrobial use in the hospital setting.[22] Additional potential risk factors include acid suppression, NSAID use, and enteral feeding.[22]

C. difficile colitis presentation ranges from self-limited diarrhea to severe toxic megacolon.

Pathogenesis and Microbiology

C. difficile is an anaerobic gram-positive bacterium that colonizes the gastrointestinal tract in some normal healthy adults and an increased proportion of hospitalized adults as well as neonates. It is hypothesized that antibiotics alter the colonic flora, facilitating

Antibiotics, by altering intestinal flora, allow overgrowth of anaerobic bacteria, including *C. difficile.*

Pseudomembranes, which are loosely adherent yellow–white exudative mucosal plaques, are found in about 25% of patients with mild disease and 87% of patients with severe disease.

the uncontrolled growth of anaerobic bacteria, including *C. difficile.* Antibiotic-associated colitis may result from any antimicrobial agent, but most frequently follows treatment with clindamycin and cephalosporins. Spores of this organism can be found widely in the patient's surrounding environment, a presence heightened in the hospital setting.[23] Patients generally acquire infection through the fecal-oral route, but *C. difficile* can also be transmitted after exposure to patients or staff who are infected or colonized with *C. difficile.*

Pathogenic strains of *C. difficile* elaborate two protein exotoxins, toxin A and toxin B, which can both cause colonic damage in humans. Strains that do not produce these toxins are not pathogenic. The presence of toxin A, in animal models, is associated with an inflammatory diarrhea and inflammatory cell infiltration of bowel wall mucosa. These toxins, when present, can also cause damage to the colonic mucosa, leading to ulcer formation. The expulsion of serum proteins and inflammatory cells from the mucosal defect can lead to the formation of pseudomembranes on the colonic mucosal surface. On direct inspection, pseudomembranous colitis is visualized as raised yellow plaques with associated edema and hyperemia of the bowel wall.

Recently, there have been reports of a more virulent strain of *C. difficile*. This toxin-gene variant strain has been associated with outbreaks of *C. difficile*-associated diarrhea in the U.S. health care facilities. There has been a change in this strain's toxin production, allowing significantly higher levels of toxin A and resulting in higher incidences of complications and death.[24] It has been postulated that increasing fluoroquinolone use in these facilities may select for infection with this aggressive strain.

Clinical Features

The clinical manifestations of *C. difficile* colitis usually include fever, leukocytosis, and watery diarrhea. Symptoms are usually temporally associated with the administration of antibiotics. More severe forms of this disease involve evidence of colitis with more severe diarrhea, as well as crampy abdominal pain. Pseudomembranous colitis is associated with these symptoms as well as the presence of pseudomembranes on sigmoidoscopic examination. Toxic megacolon is a severe complication that often results in acute peritonitis secondary to bowel perforation and even death. Patients with this severe form of disease often have a marked leukocytosis, high fever, and metabolic acidosis. Although diarrhea is the most common manifestation of *C. difficile* colitis, it is not invariably present, especially in the most critically ill.

C. difficile infection can be diagnosed by a variety of tests. Endoscopy demonstrating pseudomembranes and mucosal injury can establish the diagnosis of *C. difficile*-induced colitis most quickly and accurately. These pseudomembranes are more likely to be present in patients with more severe disease. Radiographic findings are often nondiagnostic and nonspecific; thickening or distension of the colon is suggestive of pseudomembranous colitis. Pneumatosis coli and intrahepatic portal venous air have been described in patients with severe *C. difficile* colitis. On the other hand, the laboratory diagnosis of *C. difficile* colitis has become more accurate and is based on the demonstration of bacterial toxins in stool samples.

The tissue culture cytotoxicity test is the gold standard for the laboratory diagnosis of *C. difficile* colitis; however, most hospitals use ELISA tests for both toxins A and B.

The gold standard for laboratory diagnosis is the tissue culture cytotoxicity assay; however, most hospitals use rapid enzyme immune assays (enzyme-linked immunosorbent assay, or ELISA). The ELISA methods rely on the use of monoclonal or polyclonal antibodies against both toxins A and B. ELISA testing has a lower sensitivity and specificity than the culture cytotoxicity test; therefore, a negative test does not exclude the diagnosis, and if the index of suspicion is high, colonoscopy should be performed. Colonoscopy is more useful than sigmoidoscopy because the disease may spare the rectum and the pseudomembranes may be found proximal to the sigmoid colon.

Treatment and Prevention

Management of *C. difficile* infections depends on the severity of illness. Mild diarrheal illness often responds to discontinuation of the offending antibiotic. In contrast, critically ill

patients require treatment with either vancomycin (125 mg p.o. q.i.d) or metronidazole (500 mg p.o. or intravenously q8h). Even in these patients , efforts should be made to discontinue any unnecessary antimicrobials.

Usually, when *C. difficile* colitis is suspected, empiric therapy with metronidazole or vancomycin is administered orally, pending results of diagnostic work-up. Either vancomycin or metronidazole for 10–14 days, when given via the enteral route, appears to be equally effective in the treatment of *C. difficile* colitis, but cost issues favor the use of metronidazole with initial infection.[25] Clinical improvement is usually noted within 3 days. For severe complicated *C. difficile* colitis, however, treatment with oral vancomycin may be associated with substantially higher cure rates.[26] When severe *C. difficile* colitis is suspected clinically, radiographic imaging should be performed and, if abnormal, surgical consultation obtained. Surgical intervention may be required to prevent a fatal outcome if medical management fails.

Intravenous vancomycin is not effective in C difficile colitis, but intravenous metronidazole is often used with adequate response rates. The parenteral route is used mostly in postoperative patients or those with an ileus, but with progression to toxic megacolon, vancomycin enemas are also administered together with intravenous metronidazole.

Infection control policies are imperative in prevention and control of *C. difficile* infection. These include contact isolation of infected patients, strict hand-washing techniques, and antibiotic restriction. Contact precautions should be used in patients with suspected or proven *C. difficile* infection, as it can be shed into the environment by these patients. Proper handwashing with soap and water is more effective than that with alcohol-based products as the bacterial spores are resistant to killing with alcohol. Due to the definite association between administration of antibiotics and both colonization and disease caused by *C. difficile,* limitation of unnecessary antibiotic use can serve to decrease rates of infection. Discontinuation of antibiotics, when possible, can help in the treatment of this infectious entity, although this is often not possible. At this time, treatment of asymptomatic carriers is not routinely recommended as an effort to decrease transmission of *C. difficile*.

Nosocomial Urinary Tract Infections

Epidemiology

Risk factors for nosocomial urinary tract infections include the presence of an indwelling catheter, female sex, diabetes mellitus, and poor catheter care.

Infections involving the urinary tract are commonly encountered in the ICU. These infections may involve the bladder, ureters, kidneys and, in men, the prostate. The most significant risk factor for these infections is the presence of an indwelling catheter. It is intuitive that the duration of catheterization influences the incidence of nosocomial urinary tract infections. Other risk factors for urinary tract infections include female sex, diabetes mellitus, and poor catheter care.[27]

Pathogenesis and Microbiology

Pathogens most commonly associated with nosocomial UTIs are enteric gram-negative rods. The presence of the catheter allows for organisms less commonly associated with urinary tract infections, such as staphylococci and yeast, to become pathogenic.

A catheter placed into the bladder serves as a path for bacteria and yeast to follow. The catheter surface may act as a site for bacterial adherence that allows the bacteria to move along the surface of the catheter and subsequently enter the bladder to cause infection. Urinary tract infections can be caused by a wide spectrum of organisms. The most frequently encountered organisms remain the gram-negative enteric bacteria (GNR). However, because of the exposure to antibiotics and direct entrance to the bladder by the catheter, other organisms such as nonenteric GNR, staphylococci, streptococci, enterococci, and yeast can become pathogens.

Clinical Features

Urinary tract infections can vary from a simple cystitis to more complicated infections such as pyelonephritis, pyelonephritis with bacteremia, and urosepsis. Cystitis can be missed because the patient may not be able to verbalize any symptoms. Pyelonephritis may present

with leukocytosis and fever. When bacteremia is associated with the UTI, full-blown severe sepsis can develop.

Since an indwelling catheter can be colonized by many bacteria, growing an organism from the urine does not mean there is an infection. The cornerstone to diagnosis of these infections includes not only the culture but also urinalysis with microscopy. A quantitative WBC on urine microscopy of greater than 10 WBC/mL often predicts an infection. Growth of cultured organisms greater than 10^5 cfu/mL is widely accepted as consistent with infection.

Findings on urinalysis with microscopy indicative of infection include quantitative WBC>10 WBC/mL and subsequent organism growth of $>10^5$ cfu/mL.

The urine specimen itself is easily obtained when a urinary catheter is in place. The specimen taken for urinalysis and culture should not be taken from the collection bag, but from the catheter itself.

Treatment and Prevention

Empiric therapy for nosocomial UTI will depend on individual patient and pathogens common to individual hospitals and ICUs. Patients with prior infections and use of antimicrobials are susceptible to infection with resistant organisms. If the urine Gram stain reveals GNR treatment can be initiated with a third-generation cephalosporin or a fluoroquinolone. If infection with *P. aeruginosa* is suspected, ceftazidime, cefepime, or ciprofloxacin can be utilized. Ampicillin or vancomycin can be used to treat Enterococcal infections. Treatment can then be tailored according to obtained culture data and sensitivities. When choosing an antimicrobial, one should also take into account the urine drug concentrations. For example, medications such as moxifloxacin, voriconazole, and the echinocandins do not get into the urinary tract in sufficient levels to be effective.

Urinary tract infections associated with indwelling catheters are considered complicated and, as such, require a longer duration of therapy as compared with treatment of simple cystitis. Complicated UTIs generally require treatment with antibiotics for 10–14 days depending on the severity of infection and the patient's clinical response.

Prevention of nosocomial UTI relies on avoiding unnecessary catheterization and timely removal of catheter when it is no longer needed.

Nosocomial UTIs are most often associated with the presence of urinary catheters and, as such, avoiding unnecessary catheterization and timely removal of the catheter are the mainstays of prevention. Short-term catheterization is acceptable in the ICU as most critically ill patients require accurate urine output measurement, but the catheter should be removed as soon as the patient's clinical status permits. Proper catheter care and management also aids in decreasing the incidence of catheter-associated UTI. This includes proper placement (using sterile technique), proper anchoring to limit traction on the urethra, and soap and water cleansing during bathing as maintenance care. Other postulated prevention methods including antimicrobial irrigation of the bladder, the use of antimicrobial-coated catheters, and/or the administration of prophylactic antibiotics have not been shown to be substantially beneficial in patients with indwelling bladder catheters.

SUMMARY

Infections are encountered routinely in the ICU. Nosocomial pneumonias along with intravascular catheter-related infections are the most common infections and account for most of the mortality associated with ICU infections. An understanding of the mechanisms involved in the development of infection in patients admitted to the ICU aids in the appropriate management of these patients and the subsequent prevention of devastating complications. More importantly, meticulous examination of each patient, assessment of risk factors, and knowledge of the types of organisms specific to the clinical scenario allow early and appropriate empiric therapy. Early institution of appropriate antimicrobials is important for the prevention of sepsis and its fatal sequelae. On the other hand, antibiotic therapy must be tempered by judicious use based on clinical information and on the severity of the patient's condition, thereby blunting the perpetuation of antibiotic resistance.

REVIEW QUESTIONS

1. **Which of the following is the most appropriate management plan for a 45-year-old man with hypotension, fever of 39.5°C, headache, nuchal rigidity, and somnolence?**
   - **A.** Computed tomography (CT) scan of the head
   - **B.** Lumbar puncture with Gram stain of the cerebrospinal fluid
   - **C.** Initiation of antibiotic therapy with ceftriaxone and vancomycin, concomitant lumbar puncture, and admission to the ICU
   - **D.** Admission to the ICU followed by performing lumbar puncture and starting dopamine

2. **A 65-year-old man with steroid-dependent chronic obstructive pulmonary disease and coronary artery disease is postcoronary artery bypass graft day 4. The patient has failed multiple attempts at weaning and continues to be on mechanical ventilatory support. The patient received cefazolin prophylaxis for 2 days postoperatively and treated with cefotaxime for a urinary tract infection. Over the next 24 h, he developed a fever of 39°C, progressive hypoxemia requiring increased oxygen supplementation, and progressive right lower lobe infiltrates on chest radiograph. Which management plan is best?**
   - **A.** Obtain blood and sputum cultures, continue cefotaxime, and wait for the culture and sensitivities before changing antibiotic therapy
   - **B.** Repeat urinalysis, remove the indwelling bladder catheter, and continue current antibiotic regimen
   - **C.** Start additional antibiotic therapy to include coverage of gram-negative organisms, including Pseudomonas species, and persistent gram-positive organisms, including MRSA, after obtaining sputum, blood, and urine cultures
   - **D.** Perform fiberoptic bronchoscopy with segmental right lower lobe lavage, obtain blood culture, continue cefotaxime, and wait for culture and sensitivity
   - **E.** Remove all central lines, send catheters for quantitative culture, and start vancomycin

3. **A 55-year-old man with a long history of alcoholism was admitted with hypotension, hypothermia, leukocytosis, left lower lobe consolidation, and right middle lobe consolidation on radiograph after being found stuporous in an alley behind a local cafe. The patient was admitted to the ICU for bilobar pneumonia where he was intubated because of poor gas exchange and progressive infiltrates on chest X-ray. At that point, he was started on clindamycin for suspected aspiration pneumonia. On day 5 in the ICU, he started having fever up to 39°C and profuse diarrhea, and on day 6, he became lethargic, hypotensive, and was noted to have bloody diarrhea. The appropriate management for this patient includes:**
   - **A.** Treat with immodium (an antidiarrheal) and dietary fiber supplementation
   - **B.** Obtain blood, sputum, urine cultures, and stool specimen for *Clostridium difficile* toxin assay and initiate empiric treatment with oral metronidazole and intravenous vancomycin for the remainder of the antibiotic course
   - **C.** Stop clindamycin and start broad coverage antibiotics to treat nosocomial-acquired pneumonia
   - **D.** Obtain CT scan of head and lumbar puncture, continue clindamycin if cerebrospinal fluid is negative for meningitis, and obtain transthoracic echocardiography to look for endocarditis

4. **A 40-year-old woman with gastroparesis receiving chronic outpatient TPN via a right upper extremity PICC line develops fever. Fever persists and she reports to the emergency department for evaluation. Shortly after arrival, she becomes tachycardic and hypotensive requiring ICU admission. The appropriate management plan for this patient is**
   - **A.** Initiation of antifungal therapy with fluconazole
   - **B.** Initiation of broad-spectrum antibiotic therapy as well as antifungal therapy and concomitant blood cultures, chest X-ray, and urinalysis with micro and culture to determine source of infection
   - **C.** Removal of PICC line
   - **D.** Admission to ICU and initiation of vasopressors

5. **A 45-year-old man presents with a chief complaint of dyspnea. He also describes productive cough and fever present for several days. He notes a recent hospitalization for an upper GI bleed. Radiographic imaging performed in the ED reveals a right middle and lower lobe infiltrate. Physical exam reveals an unkempt man with poor dentition, progressive respiratory distress, and rhonchi in the right lower lung field. His ETOH level on presentation is 200. He soon becomes increasingly hypoxic and hypotensive, and requires intubation for respiratory failure. Which of the following antibiotic combinations is most appropriate to give to this patient?**
   - **A.** Ceftriaxone and azithromycin
   - **B.** Clindamycin
   - **C.** Ceftriaxone, azithromycin, and clindamycin
   - **D.** Vancomycin and piperacillin-tazobactam

ANSWERS

1. The answer is C. Acute bacterial meningitis (ABM) is a fulminant fatal process, especially if recognition of the disease and institution of therapy are delayed. Often, there is concern about potential brain herniation if a lumbar puncture is performed in patients who have mental status changes and unsuspected brain masses; therefore, most clinicians obtain a CT scan before doing the lumbar puncture. However, CT scan of the brain is never considered a valid reason to delay antimicrobial treatment in patients suspected to have ABM. Lumbar puncture with fluid analysis is necessary in this scenario, but treatment with appropriate antibiotics should be instituted as soon as the diagnosis is suspected and after obtaining blood cultures. It may be true that this patient needs ICU care, but that should not delay the work up and treatment of ABM.

2. The answer is C. This patient has developed a ventilator-associated pneumonia that has led to clinical deterioration in the setting of antibiotic therapy for a urinary tract infection. Although the patient may have an inadequately treated urinary tract infection, he has worsening respiratory status and a chest radiographic finding suggesting a nosocomial ventilator-acquired pneumonia. The patient's new infection is likely due to a resistant organism; therefore, to continue his daily antibiotic regimen with cefotaxime while waiting for culture and sensitivity is inappropriate. Although some clinicians advocate the use of fiberoptic bronchoscopy to obtain quantitative bronchoalveolar lavage on protected specimen brush cultures, it is an accepted practice to obtain sputum and blood cultures while waiting for culture and sensitivity results and change to antimicrobial treatment to include treatment for MRSA and *Pseudomonas*.
3. The answer is B. The patient developed signs of sepsis and deteriorated, despite improvement of his pneumonia. His sepsis work-up should include *C. difficile* toxin assay because of the diarrhea. Other sources of infection may be his urinary tract, central indwelling catheter, spontaneous bacterial peritonitis, or meningitis. Endocarditis should be suspected if he has a new cardiac murmur or persistent bacteremia. The change in mental status in this patient is likely related to sepsis, and although CT scan of the brain and lumbar puncture may be required, other antibiotics should be added to clindamycin to treat his new sepsis. Indiscriminate use of antidiarrheals without first ruling out infection in a patient with fevers may lead to severe complications, including toxic megacolon. Intravenous fluids with potassium supplementation would be appropriate in this patient with profuse diarrhea. Flexible sigmoidoscopy may be helpful in diagnosing pseudomembranous colitis. In this patient with aspiration pneumonia, empiric metronidazole and stool analysis for *C. difficile* toxin are most appropriate.
4. The answer is B. At this early stage of presentation, the source of this patient's sepsis syndrome is unclear although catheter-related infection is likely. As such, a complete diagnostic work-up is warranted to search for the source of infection. Given her hemodynamic instability, broad-spectrum coverage should be initiated. Given her TPN dependence, she is at risk for associated fungemia and use of antifungals should be considered. Fluconazole alone would not be adequate as she should receive empiric coverage for bacterial pathogens. While she may require ICU admission and vasopressor agents, and possibly even PICC line removal, but most important should be empiric treatment for her sepsis syndrome and diagnostic work-up.
5. The answer is D. This man is presenting with pneumonia. His illness is severe enough to have led to respiratory failure. The presence of gingival disease and alcohol use raise the question of possible aspiration and, with it, possible anaerobic infection. Given this patient's recent hospitalization, he is at risk for infection with hospital-acquired pathogens. Clindamycin alone, while covering possible anaerobic infection, would not treat for a nosocomial infection. Vancomycin and piperacillin-tazobactam will cover anaerobes as well as common potential causative organisms of nosocomial pneumonia (including MRSA and *Pseudomonas*) and is the indicated treatment in this clinically unstable patient. Attempts should then be made to make a microbiologic diagnosis with blood and sputum cultures to tailor therapy.

CHAPTER 33

COLLEEN VELOSKI AND KATHLEEN J. BRENNAN

Critical Care Endocrinology

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Differentiate diabetic ketoacidosis from hyperglycemic hyperosmolar state and understand the management strategies for each disorder.
- Identify and treat thyroid disorders in the intensive care unit using clinical findings and laboratory data.
- Correctly determine the causes and treatments of the most common calcium disorders in the critical care unit.
- Know the clinical findings, diagnostic evaluations, and treatment of adrenocortical excess and insufficiency.
- Understand the pathogenesis and treatment of diabetes insipidus, and the syndrome of inappropriate antidiuretic hormone secretion.

Patients with type I diabetes mellitus have an overall lack of insulin.

DISORDERS OF GLUCOSE METABOLISM

Diabetic ketoacidosis and hyperglycemic hyperosmolar state are acute and life-threatening disorders of glucose metabolism. Both conditions may present with acute changes in mental status that can progress to coma.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) most commonly occurs in type I diabetes mellitus and results from lack of insulin combined with excess insulin counterregulatory hormone.

Diabetes mellitus type 1 occurs in patients with inadequate production of insulin as the result of an autoimmune destruction of pancreatic beta cells. DKA, a complication of type I diabetes mellitus, is associated with a profound insulin deficit with the presence of increased concentrations of glucagon and other insulin counterregulatory hormones. Anywhere from 8 to 29% of all hospital admissions for diabetes are due to DKA.[1] Triggers for DKA and insulin insufficiency include insulin noncompliance and conditions that may increase insulin requirements (Table 33-1).

INFECTION	ALCOHOL OR DRUG INGESTIONS
Injury	Insulin noncompliance
Emotional stress	Myocardial infarction

TABLE 33-1

TRIGGERS FOR DIABETIC KETOACIDOSIS (DKA)

Pathophysiology of DKA

The abnormalities in carbohydrate, protein, and lipid metabolism seen in DKA are the result of (1) decreases in circulating insulin levels and (2) excess counterregulatory hormones (glucagon, catecholamines, cortisol, and growth hormone). In DKA, serum glucose levels rise as insufficient circulating insulin reduces the peripheral tissue uptake of glucose into muscle and liver. At the same time, excessive amounts of counterregulatory hormones such as glucagon cause increased hepatic production of glucose through the stimulation of gluconeogenesis and glycogenolysis (Fig. 33-1).

Low insulin levels and increased cortisol result in decreased protein synthesis, and increased protein breakdown in the peripheral tissues provides amino acids for further glucose production by the liver. The combination of a lack of insulin with excessive circulating catecholamines causes lipolysis of adipose tissue, which results in the liberation of free fatty acids. In the liver, the free fatty acids are ultimately converted to ketone bodies, which include the strong organic ketoacids acetoacetic acid and β-hydroxybutyrate.

Ketone bodies, which include acetoacetic acid and β-hydroxybutyrate, are produced in the liver.

Elevated ketoacids causes a fall in serum pH that is initially tempered by the buffering effect of serum bicarbonate and an elevated anion gap. The anion gap $[NA^+ - (CL^- + HCO_3^-)]$ normally represents anions that are not usually measured, such as polyanionic plasma proteins (albumin), inorganic phosphates, sulfates, and organic acids. The elevation in ketoacids observed in DKA contributes to these unmeasured ions and elevates the anion gap, truly reflecting the severity of the episode. As continued ketoacids are produced, metabolic acidosis progresses, and the buffering capacity of available bicarbonate is exceeded. Compensation for metabolic acidosis occurs in the form of increased alveolar ventilation and CO_2 excretion, renal excretion of H^+, and increased renal HCO_3^- production. Eventually, ketoacid production exceeds this compensatory mechanism rapidly, leading to metabolic acidosis.

The anion gap represents unmeasured anions and is elevated in DKA as a result of ketoacid production: Anion gap $= [NA^+] - ([Cl^-] + [HCO_3^-])$.

Elevated serum glucose and ketones result in a significant osmotic diuresis causing dehydration. Sodium, phosphate, and potassium are lost in the urine as sequelae of the osmotic diuresis.

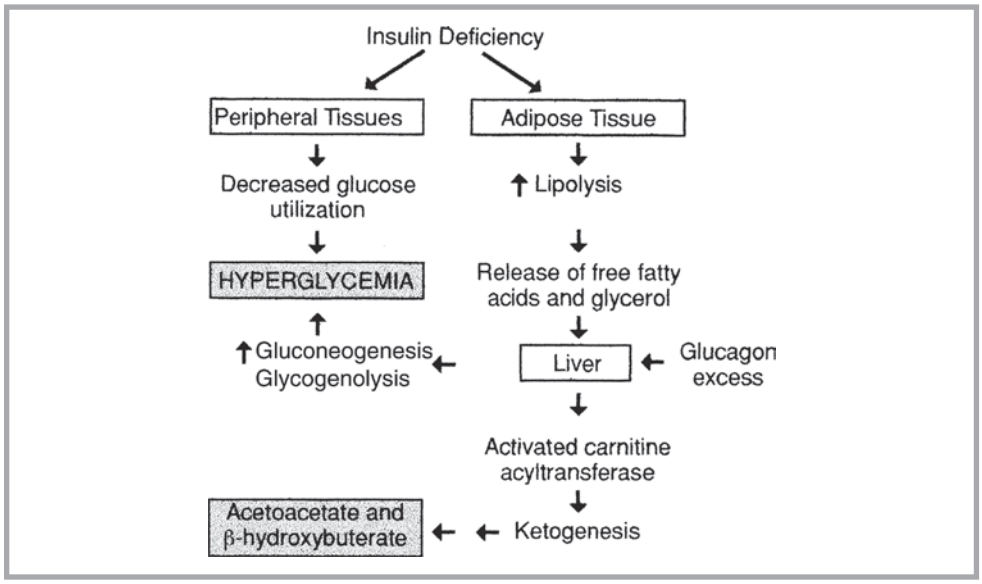

FIGURE 33-1

Pathogenesis of diabetic ketoacidosis (DKA). Insulin deficiency results in decreased uptake of glucose by peripheral tissues and subsequent hyperglycemia. The lack of insulin also leads to loss of inhibition of lipoprotein lipase in adipose tissue and increased release of free fatty acids (FFA) and glycerol. FFA and glycerol are taken up by the liver and synthesized into ketoacids (beta-hydroxybutyrate, acetoacetate, and acetone), which are released into the blood, resulting in an anion gap acidosis.

DKA is not common in type 2 diabetics since they usually continue to produce adequate amounts of insulin to prevent lipolysis. However, as type 2 diabetes progresses and beta cell function declines over time, some type 2 diabetics will not produce enough insulin to suppress lipolysis and DKA may develop. Similarly, severe hyperglycemia due to illness or glucocorticoids can also precipitate DKA in type 2 diabetics.

Clinical Findings

Patients can present after several hours or days of worsening diabetic control. The examination is notable for dehydration with poor skin turgor (tenting) and dry mucous membranes. Altered mental status is also common. The initial symptoms are polyuria, nausea, vomiting, and abdominal pain. The fruity odor of acetone, the breakdown product of ketoacids, may be detected on the patient's breath. Patients may also exhibit a pattern of rapid and deep breathing known as Kussmaul's respirations in an effort to maximize exhaled carbon dioxide.

Precipitating factors of DKA, such as infection, stroke, or myocardial infarction, should be considered during patient evaluation and appropriate studies done to confirm the diagnosis.

A complete neurological evaluation should be performed if changes in mental status are present. In about 10% of cases, no identifiable precipitating cause is found.[2]

Diagnosis

Serum glucose levels are usually elevated above 500 mg/dL with a concomitant elevation in serum ketones. A high anion gap metabolic acidosis is present as a result of increased ketoacids. Patients with renal insufficiency have higher anion gaps and serum ketoacids as a result of decreased urinary ketoacid excretion. In the insulin deficient state, β-hydroxybutyrate is the most common serum ketoacid; however, it is converted to acetoacetate as DKA is corrected. Most available laboratory tests for ketoacids utilize nitroprusside that measures acetoacetate only. Therefore, serum ketones are most useful in diagnosis rather than assessment of treatment efficacy. Acidosis causes an extravascular shift of potassium with initial high serum levels measured despite total body potassium deficit as a result of renal losses. Blood urea nitrogen and creatinine may be elevated as a result of severe dehydration. Urinalysis reveals concentrated urine with the presence of glucose and ketones.

β-Hydroxybutyrate is the most common ketoacid but is not measured; only acetoacetate is measured.

Management

The principle treatment for DKA consists of: (1) volume replacement, and (2) insulin repletion.

Volume resuscitation and insulin replacement are the principal treatments in DKA.

Volume replacement must be initiated before the administration of insulin to prevent hypotension. Fluid deficits in most patients presenting with DKA are approximately 5–10 L, and initial fluid resuscitation is necessary to restore intravascular volume and lower serum glucose levels through hemodilution. One liter of isotonic saline (0.9%) is administered in the first hour. Additional isotonic saline is administered until blood pressure is restored and/or with adequate renal perfusion as evidenced by urine production. Use caution in patients with underlying cardiac or renal disease. Once intravascular volume is restored, fluid repletion should continue with one half normal saline solution. In general, in patients with normal renal and cardiovascular status, the aim is to replace about one half of the estimated water deficit over 12–24 h.

Serum potassium may be initially elevated, but total body stores are low.

Patients with DKA often appear to have normal or even slightly elevated serum potassium due to low circulating insulin levels, causing potassium to shift out of the intracellular space and into the plasma. In fact, there is a total body potassium deficit in DKA, and serum potassium levels will decline with insulin therapy, volume repletion, and correction of the acidosis. Potassium chloride should be added to IV fluids when serum potassium levels go below 5.3 mEq/L. If serum potassium is between 4 and 5 mEq/L, 20 mEq/L of potassium should be added to each liter of replacement fluid. For serum potassium between 3 and

TABLE 33-2

CRITICAL CALCULATIONS IN DIAGNOSIS AND MANAGEMENT OF DKA AND HHS

$$\text{Anion gap} = [NA^+] - ([Cl^-] - [HCO_3^-])$$

$$[NA^+]_{\text{corrected}} = [NA^+] + 1.6\left(\frac{\text{Serum glucose} - 100\text{mg/dL}}{100}\right)$$

$$\text{Serum osmolality} = 2[NA^+] + \frac{\text{Serum glucose (mg/dL)}}{18} + \frac{\text{Blood urea nitrogen (mg/dL)}}{2.8}$$

$$\text{Free water deficit} = 0.6\ (\text{weight in kg}) \times \left(\frac{\text{Plasma } [Na^+]}{140} - 1\right)$$

4 mEq/L, 40 mEq/L potassium is added to each liter of replacement fluid. If serum potassium is less than 3.0 mEq/L, insulin should be held and 10–20 mEq of potassium per hour should be given until the serum potassium is greater than 3.3, at which time insulin can be restarted and 40 mEq/L potassium should be added to each additional liter of replacement fluid.[1]

Insulin therapy is initiated when potassium is greater than 3.3 mEq/L and isotonic saline has been infused. The administration of insulin increases the utilization of glucose in peripheral tissues, decreases fatty acid production, and inhibits glucose production by the liver. An initial bolus dose of intravenous insulin is given 0.1 U/kg followed by 0.1 U/kg/h maintenance therapy. With continuous intravenous insulin, serum glucose should decline at a rate of 50–70 mg/h. Serum glucose is measured hourly, and dextrose-containing fluids are added when glucose levels fall below 200 mg/dL to maintain glucose levels between 150 and 200 mg/dL. Electrolytes, blood urea nitrogen, creatinine, and the anion gap are measured every 2–4 h initially. Administration of insulin and dextrose-containing fluids should continue until the acidosis has reversed as indicated by decreasing anion gap and serum bicarbonate level greater than or equal to 18 mEq/L.[3]

Bicarbonate replacement in DKA is not well studied and remains controversial. Bicarbonate replacement is currently recommended when the arterial pH is less than 7.00, or in patients with decreased cardiac contractility and hypotension. Calculations used in the treatment of DKA are listed in Table 33-2. Normalization of the pH and resolution of the anion gap indicate the metabolism of ketoacids. Once the patient is stable and the anion gap is closed, the IV insulin may be discontinued 1–2 h after the administration of subcutaneous insulin. In known diabetics, the usual outpatient doses of subcutaneous insulin may be restarted if tolerating a diet. In newly diagnosed diabetics, insulin may be initiated using 0.5–0.8 U/kg/day with 50% given as basal insulin and the remaining 50% given as rapid-acting insulin divided among three meals.

Complications of DKA include cerebral edema, ARDS, and thrombosis.

DKA remains a life-threatening disorder with mortality as high as 50% in the elderly. Complications of DKA include cerebral edema as a result of hyperosmolarity that can cause progressive neurologic impairment. Acute respiratory distress syndrome (ARDS) has been rarely reported in cases of refractory DKA. Arterial and venous thrombosis is a recognized complication of DKA. Lactic acidosis may also be present with ketoacidosis due to shock, sepsis, or prior metformin use.

Hyperglycemic Hyperosmolar State

Hyperglycemic hyperosmolar state generally occurs in type 2 diabetes mellitus.

Hyperglycemic hyperosmolar state (HHS) is a metabolic derangement characterized by hyperosmolarity and hyperglycemia that occurs mainly in adults with type 2 diabetes. The number of patients admitted for HHS is much less than DKA and comprises about 1% of all diabetic admissions. Mortality exceeds that of DKA ranging from 10 to 50%, depending on the patient population.

Pathophysiology

Patients with type 2 diabetes mellitus have peripheral resistance to insulin.

HHS results from insulin resistance and relative insulin deficiency producing hyperglycemia. Hyperglycemia and the resulting hyperosmolarity cause an osmotic diuresis and shifts fluid to the extravascular space, thereby causing volume depletion and dehydration. Unlike DKA, ketoacidosis occurs less commonly.

Clinical Findings

Distinct clinical and laboratory findings distinguish HHS from DKA (Table 33-3). HHS develops more slowly than DKA, usually over days to weeks. Patients may complain of polydipsia, polyuria, and weight loss. By definition, all patients are severely dehydrated, hyperosmolar, and may have focal or global neurologic deficits. Although lethargy and obtundation are common, coma is present in less than 10% of cases.

Alterations in mental status are often the presenting symptoms of HHS.

Many HHS patients have a known history of type 2 diabetes; however, in at least one-third of patients, the development of HHS heralds the onset of diabetes mellitus. There is often a preceding illness that results in several days of increasing dehydration. The preceding event may be difficult to determine, but is frequently an infection, especially a pneumonia or urinary tract infection. A wide variety of other major illnesses may precipitate HHS, primarily through limiting mobility and access to water; these include an acute cerebral vascular event, acute myocardial infarction, and gastrointestinal (GI) bleeding. The stress response to any acute illness also tends to increase serum cortisol, catecholamines, glucagon, and other hormones that oppose the action of insulin. A variety of drugs that raise serum glucose, inhibit insulin, or cause dehydration may also cause HHS. Drugs and other iatrogenic causes of HHS include alcohol, corticosteroids, diuretics, dialysis, total parenteral nutrition, and dextrose-containing fluids. Noncompliance with oral hypoglycemic agents or insulin therapy can also result in HHS.

Severe dehydration caused by hyperglycemia and osmotic diuresis is the hallmark of HHS.

Diagnosis

Hyponatremia or hypernatremia may be present. The measured serum sodium should be corrected upwards by 1.6 mEq/L for every 100 mg/dL increase in serum glucose to determine the true sodium level (Table 33-2). Total body potassium is likely to be low regardless of its measurement; a low measured serum K^+ suggests profound total body losses as a result of osmotic diuresis. An elevated anion gap metabolic acidosis may be present but is usually less profound than that observed in DKA. Serum measurement of creatinine is elevated initially due to volume depletion, and, when possible, should be compared to previous values to determine true baseline creatinine. Serum glucose is usually dramatically elevated, often more than 800 mg/dL.

Serum effective osmolarity is nearly always greater than 320 mOsm/dL. If the calculated osmolarity is significantly lower than the measured value, toxic alcohol ingestion should be considered. Serum ketones may not be found in pure HHS, but may be present in cases of

TABLE 33-3

COMPARISON OF PRESENTATION OF DKA AND HYPERGLYCEMIC HYPEROSMOLAR STATE (HHS)

PARAMETER	DKA	HHS
Type of diabetes mellitus (DM)	Type 1	Type 2
Blood glucose	usually <600 mg/dL	usually >900 mg/dL
Primary therapy	Insulin	Volume repletion
Serum ketones	Extreme elevations	Normal to mildly elevated
Anion gap	Usually >20	Normal
Osmolarity	Mild elevation	Extreme elevations
Treatment	Insulin replacement	Fluid resuscitation

HHS where DKA or starvation ketosis concomitantly occurs. Urinalysis will reveal an elevated specific gravity, glucosuria, possible ketonuria, and possible evidence of urinary tract infection.

Creatinine phosphokinase (CPK) with isoenzymes should be measured to rule out rhabdomyolysis and acute myocardial infarction.

Management

Intravascular volume resuscitation is the principal treatment for HHS.

Intravenous access with crystalloid fluid resuscitation is the immediate goal of therapy. Fluid deficits in HHS are large, with fluid requirements often greater than 10 L. As in DKA, administration of one liter of normal saline in the first hour is appropriate. Isotonic saline may be infused at 15–20 m/kg body weight per hour with slower rates in patients with significant underlying cardiac or renal disease. Once vascular volume is restored, replacement fluid can be changed to one half isotonic (0.45%) saline at 4–14 mL/kg/h in patients with normal or elevated corrected sodium. Isotonic saline can be used at the same rate for hyponatremic patients.[4] Although many patients with HHS respond to fluids alone, intravenous insulin in dosages similar to those used in DKA can facilitate correction of hyperglycemia.

THYROID DISORDERS

Hypothyroidism and Myxedema Coma

Hypothyroidism is defined as a deficiency of circulating thyroid hormones that may be caused by failure of the thyroid gland to synthesize or secrete thyroid hormones (primary hypothyroidism) or by decreased release of thyroid-stimulating hormone (TSH) from the pituitary (secondary hypothyroidism) (Fig. 33-2). It is one of the most common diseases in the United States and affects approximately 8% of women and 2% of men over 50 years old.[5]

Chronic thyroiditis is the most common cause of spontaneous hypothyroidism in the United States. Other etiologies include idiopathic atrophy of the thyroid, thyroid ablation following treatment for Graves' disease, disruption of the hypothalamic pituitary axis, and iodine deficiency. Symptoms of hypothyroidism may be initially nonspecific and slowly progressive (Table 33-4). In general, hypothyroidism is not life-threatening and easily treated. However, severe, prolonged thyroid hormone deficiency can lead to myxedema coma.

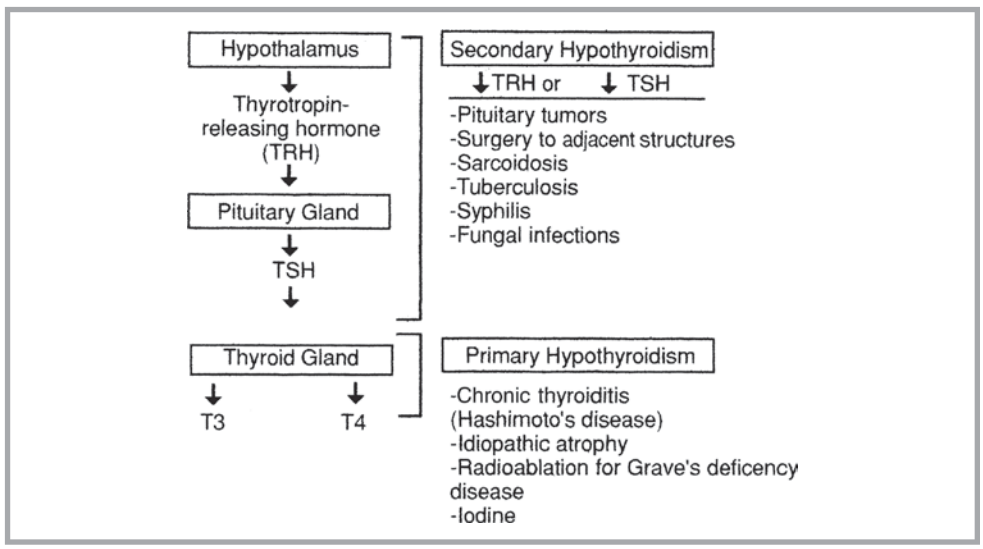

FIGURE 33-2

Etiology of hypothyroidism.

TABLE 33-4

CLINICAL FINDINGS OF SEVERE HYPOTHYROIDISM

SYMPTOMS	PHYSICAL EXAMINATION
Weakness, lethargy, and fatigue	Dry, yellow skin
Dry skin and coarse hair	Hypothermia
Puffy eyelids, face, and hands; swollen legs	Bradycardia
Cold intolerance	Nonpitting edema
Constipation	Slow, deep tendon reflexes
Weight gain	Loss of lateral eyebrow
Hoarseness	Hypoventilation
Menorrhagia	
Hearing loss	

TABLE 33-5

PRECIPITATING AND PREDISPOSING FACTORS FOR MYXEDEMA COMA

Untreated hypothyroidism	Medications
Prior thyroidectomy	Analgesics
Prior radiation therapy	Lithium
Autoimmune or congenital thyroid disease	Sedatives
Hypopituitarism	Amiodarone
Hypothermia	Tranquilizers
Infection	Narcotics
Cerebral vascular accidents	Anesthesia
Trauma	

Myxedema coma may present as hypothermia, hypoglycemia, shock, and hypoventilation.

Myxedema coma, an endocrine emergency, is a manifestation of severe hypothyroidism with findings that include hypothermia, hypoglycemia, shock, hypoventilation, or ileus. Precipitating factors for myxedema coma include cold exposure, illness, infection, trauma, and drugs that suppress the central nervous system (Table 33-5). The mortality rate in myxedema coma approaches 50–60%.[6]

Diagnosis

Initial laboratory evaluation includes serum TSH, free T4, and free T3.

The diagnosis of hypothyroidism is based on clinical findings and the results of thyroid function testing. The measurement of total thyroid hormone levels in the intensive care unit is not helpful since they are affected by low albumin levels and low levels of thyroid binding globulin (TBG). In suspected cases of thyroid dysfunction in critically ill patients, the initial laboratory evaluation includes serum TSH, free T4, and free T3. In primary hypothyroidism, TSH is elevated, and both free T4 and free T3 are low. In secondary hypothyroidism, TSH can be low or low normal with low free T4 and free T3 (Table 33-6).

Management

Patients with mild to moderate symptoms of hypothyroidism may be started on 0.05 mg of oral synthetic L-thyroxine with slow upward titration to a targeted maintenance dose over a 6–12-week period. Patients with moderate to severe hypothyroidism and those with underlying cardiovascular disease may be at higher risk for complications during initial therapy. Initial doses of thyroid replacement should be reduced to 0.025 mg in these patients, with appropriate monitoring for sequelae, including arrhythmias and angina.

In contrast, myxedema coma warrants immediate aggressive treatment due to the high mortality risk. The cornerstone of therapy is the administration of IV levothyroxine (parenteral T4) as a 200–300-µg bolus followed by 50 µg IV daily until the patient is able to tolerate oral replacement therapy. There is disagreement about the role of IV liothyronine (parenteral T3) in the treatment of myxedema coma. In severe cases, in addition to parenteral

TABLE 33-6

Nonthyroidal illness syndrome	↓/N	↓	N/↑/↓

N normal

T4, consider adding parenteral T3, 10 µg every 8 h depending on patients' age and cardiac status.[6]

After drawing a random cortisol level, stress doses of hydrocortisone (100 mg every 8 h) are recommended until adrenal failure can be ruled out. Supportive care may include intubation and mechanical ventilation for hypoventilation due to reduced hypoxic ventilatory drive[7] and respiratory muscle weakness. Slow external warming is indicated for associated severe hypothermia; however, excessive peripheral vasodilatation may lead to vascular collapse. Pulmonary artery catheterization may be required in patients with hemodynamic instability whose intravascular volume status is unclear or who may have a component of cardiogenic shock. Hyponatremia and hypoglycemia are often associated with myxedema coma, therefore, volume status and sodium must be carefully monitored.

Initial treatment of myxedema coma requires intravenous T4, hydrocortisone replacement therapy, consideration of intravenous T3, and supportive care.

Nonthyroidal Illness

Nonthyroidal illness commonly occurs in the critically ill patient. The thyroid function is normal but thyroid function studies show low values for T3/T4 and normal, low, or slightly elevated TSH levels (Table 33-6). In nonthyroidal illness, abnormalities in thyroid function studies are the result of the severe underlying systemic illness, decreased peripheral conversion of T4 to T3, and decreased binding of thyroid hormones to thyroid-binding globulin. Therapy is directed at treating the underlying illness.

Nonthyroidal illness is characterized by low T3/T4 and normal, low, or slightly elevated TSH with is normal thyroid function.

Thyrotoxicosis and Thyroid Storm

Levels of thyroid hormone that are greater than required for normal physiologic function may result in thyrotoxicosis. Severe hyperthyroidism commonly results from excessive stimulation of thyroid follicular cells in Graves' disease, an autoimmune disorder associated with the production of immunoglobulins that bind to and stimulate TSH receptors. Excessive ingestion of synthetic thyroid hormone may also produce similar findings (see levothyroxine overdose, later in this chapter). Conditions such as toxic nodular goiter or subacute thyroiditis can cause excessive thyroid hormone release, but rarely cause severe thyrotoxicosis. Less commonly, hyperthyroidism may result from excessive TSH production from the pituitary gland or from teratomas of the ovary (Table 33-7).

Elevated thyroid hormone levels increase adrenergic stimulation producing increased metabolic demand, O_2 consumption, and the work of breathing along with hyperdynamic circulation. Table 33-8 lists the clinical manifestations of hyperthyroidism in the critically ill patient. The presence of tachycardia, hyperpyrexia, tremor, agitation, should raise the suspicion of thyrotoxicosis, particularly in patients with exophthalmos and weight loss.

Thyroid storm is a rare and life-threatening complication of severe thyrotoxicosis that is associated with marked fever, tachycardia, and agitation that can lead to cardiovascular collapse. Thyroid hormone levels may be the same in both thyroid storm and uncomplicated thyrotoxicosis, Underlying factors that can precipitate thyroid storm include infection, surgery, acute psychiatric illness, DKA, pulmonary embolus, bowel infarction, parturition, trauma, withdrawal of antithyroid medication, radioactive iodine therapy, and iodine-containing contrast agents.

Thyroid storm is a life-threatening complication of thyrotoxicosis with tachycardia, fever, and altered mental status.

Altered mental status (agitation to coma)

Treatment

Treatment of thyroid storm consists of: (1) therapy to control the thyroid gland, (2) therapy to block the effects of thyroid hormone on peripheral tissues, (3) supportive care, and (4) treatment of the precipitating underlying cause of decompensation.[8]

Due to the hepatotoxicity associated with propylthiouracil (PTU), methimazole 30 mg PO every 6 h is now the preferred drug used to inhibit the synthesis of thyroid hormone. In patients unable to tolerate oral medications, methimazole may be administered rectally or intravenously.[9,10] Possible side effects of methimazole include rash, agranulocytosis, and hepatotoxicity.

Oral iodide is used to inhibit the release of formed thyroid hormone from the thyroid. Lugol's solution or a saturated solution of potassium iodide (SSKI) should be given 2 h after the first dose of methimazole to prevent the iodide from being used to synthesize new hormone.

Propranolol or other β-adrenergic antagonists are given to control heart rate. While all β-adrenergic antagonists are effective, propranolol is most frequently used to block the conversion of T4 to T3. Propranolol may be given intravenously 0.5–1.0 mg every 10–15 min, or 60–120 mg PO every 6 h. All β-adrenergic antagonists should be used with caution because they can precipitate cardiopulmonary instability in the elderly, patients with underlying CHF or other contraindications to beta blockade, asthmatics, and patients with cardiomyopathy. If necessary, verapamil or short-acting beta-blockers such as esmolol may be used instead.

Thyroid storm requires supportive care, which may include fluid resuscitation and cooling measures for hyperpyrexia. Glucocorticoids reduce the conversion of T4 to T3 and may benefit underlying autoimmune disease processes such as Graves', therefore; hydrocortisone 100 mg IV every 8 h is indicated for life-threatening thyroid storm. Cholestyramine can also be considered since it binds thyroid hormone in the GI tract, reducing circulating thyroid hormone levels.[11]

The treatment of thyroid storm includes methimazole, beta-blockers, oral iodide, and glucocorticoids.

Levothyroxine Overdose

Levothyroxine, a commonly prescribed medication, accounts for frequent accidental or intentional overdoses with as many as 5,000 cases reported annually. The symptoms begin approximately 24 h after ingestion with the conversion of T4 to T3. Immediate treatment is gastric lavage with administration of activated charcoal and sorbitol. The mainstay of therapy is beta blockade; however, in severe cases, plasmapheresis or dialysis may be necessary.

DISORDERS OF CALCIUM METABOLISM

Hypercalcemia

Parathyroid hormone (PTH) works in conjunction with vitamin D to maintain calcium homeostasis. PTH secreted in response to hypocalcemia stimulates renal tubular calcium resorption and phosphate excretion. PTH also stimulates the conversion of 25-hydroxyvitamin D to 1, 25-dihydroxyvitamin D, the active form of the vitamin that promotes calcium and phosphate absorption from the GI tract.

PTH-stimulates renal calcium reabsorption and phosphate excretion.

Hypercalcemia is defined as high serum levels of albumin-corrected total calcium or ionized calcium. In general, the most common causes of hypercalcemia are hyperparathyroidism (HPT) and malignancy. Primary HPT is the most common cause of hypercalcemia overall and is usually diagnosed in the outpatient setting. Primary HPT is a generalized disorder of calcium, phosphate, and bone metabolism caused by excessive, incompletely regulated secretion of PTH. Primary HPT is caused by single parathyroid adenoma in 80% of cases, multiple gland hyperplasia in 15–20% of cases, and, in exceedingly rare cases, parathyroid carcinoma.[12]

PTH-stimulated activation of vitamin D promotes calcium and phosphate absorption from the gut.

In hospitalized patients, malignancy is the most common cause of severe elevations in serum calcium. About 80% of cases of malignancy-related hypercalcemia are the result of secretion of PTH-related peptide (PTHrP) by a malignant neoplasm (humoral hypercalcemia of malignancy), while about 20% of cases are caused by direct induction of local osteolysis by bone metastases.[13] Although PTHrP activates PTH receptors, it is not detected by traditional PTH immunoassays. PTHrP can be measured directly in the serum by specific immunoassays.

Milk alkali syndrome is characterized by hypercalcemia, metabolic alkalosis, and impaired renal function and has become more prevalent in recent years. Calcium carbonate has been widely promoted as a supplement to prevent and treat osteoporosis, and as a therapy for dyspepsia. A diagnosis of milk-alkali syndrome should be considered when there is a history of using excessive amounts of calcium carbonate, and the laboratory evaluation demonstrates hypercalcemia, alkalemia, renal impairment, and a suppressed PTH.[14] Although relatively uncommon, vitamin D toxicity can also cause significant hypercalcemia.

Diagnosis

The concentration of ionized or free calcium in the extracellular fluid is tightly regulated. Since approximately 50% of total serum calcium is bound to albumin, decreased levels of albumin result in a lower total serum calcium level, though the free calcium levels may be normal. Total calcium levels can be adjusted for the effect of reduced serum albumin by

adding 0.8 mg/dL calcium for every 1 g/dL reduction in serum albumin below 4 g/dL as shown below:

Corrected total calcium = measured total calcium + 0.8 × (4 − serum albumin)

Ionized calcium should be measured directly to confirm the diagnosis of hypercalcemia whenever there is doubt about the validity of the total measured calcium, particularly in cases of severe derangements of albumin, dysproteinemic states (e.g., multiple myeloma), or borderline corrected total calcium.

Measurement of intact PTH is the first step in the evaluation to determine whether the cause of the hypercalcemia is PTH mediated or non-PTH mediated. In primary HPT, the PTH is high or inappropriately normal in the setting of hypercalcemia. In malignancy-related hypercalcemia and other causes of hypercalcemia such as milk-alkalai syndrome, hypervitaminosis D, etc., the PTH is low. PTHrP is detectable in the humoral hypercalcemia of malignancy, whereas bone metastases are present when hypercalcemia is due to osteolysis.

Clinical Findings

Significant symptoms are usually not present until the serum calcium is greater than 12 mg/dL, and severe symptoms usually result from rapid elevations in serum calcium. Clinical findings of primary HPT are related to both hypercalcemia and increased PTH. Symptoms include nephrolithiasis, polyuria, anorexia, nausea, vomiting, and constipation. Polyuria with decreased oral intake and vomiting can lead to marked dehydration and renal insufficiency. Neurologic manifestations may progress from weakness and fatigue to coma. The electrocardiogram may demonstrate a shortened QT interval.

Therapy

The general treatment strategy for moderate and severe hypercalcemia includes increasing urinary calcium excretion, inhibiting bone resorption, and decreasing intestinal calcium absorption. In patients with adequate renal and cardiovascular function, the initial management of symptomatic hypercalcemia includes aggressive volume repletion with isotonic saline (0.9%) to restore intravascular volume and promote calcium excretion via the kidneys. Normal saline is administered at an initial rate of 200–500 mL/h depending on the severity of the dehydration, hypercalcemia, and the overall clinical picture.[13] The rate of IV fluids is adjusted to maintain a urine output of about 100–150 mL/h. After adequate hydration is achieved, a loop diuretic may be used only if there are signs of fluid overload. Thiazide diuretics should be avoided since they stimulate renal calcium reabsorption.

For moderate to severe hypercalcemia, an IV bisphosphonate such as pamidronate 60–90 mg given over 4 h in isotonic saline infusion lowers calcium by inhibiting bone reabsorption.[15,16] Zoledronic acid 4 mg IV given over 15 min is approved for the treatment of malignancy-associated hypercalcemia and has been shown to normalize calcium faster than pamidrinoate with a longer duration.[17] Ibandronate is another bisphosphonate approved for treatment of the hypercalcemia of malignancy. Calcitonin, 4–8 IU/kg intramuscularly or subcutaneously inhibits bone reabsorption more rapidly and can lower serum calcium 1–2 mg/dL within several hours. Although tachyphylaxis usually occurs within 48 h, calcitonin can be used to lower calcium acutely until the intravenous bisphosphonate begins to take effect (usually 48–72 h). Gallium nitrate effectively lowers calcium in both PTHrP-mediated and non-PTHrP-mediated hypercalcemia of malignancy and is an alternative to bisphosphonate therapy.[18] However, the risk of nephrotoxicity and the need to administer by continuous infusion over 5 days limit its use.

Discontinuation of supplements containing calcium or vitamin D will lower the intestinal absorption of calcium. Medications that increase serum calcium, such as thiazide diuretics and lithium, should also be discontinued if possible. Glucocorticoid treatment is useful in lowering elevated 1, 25 dihydroxyvitamin D levels found in patients with hypercalcemia due to granulomatous diseases and certain lymphomas.

Dialysis is the treatment of last resort in severe life-threatening hypercalcemia. However, dialysis is the treatment of choice for severe life-threatening hypercalcemia in patients with

significant renal or cardiac disease who cannot tolerate hydration therapy. The only effective long-term treatment of symptomatic HPT remains parathyroidectomy. Calcimimetic agents such as cinacalcet that increase the sensitivity of the calcium-sensing receptor to calcium are not approved for the treatment of primary HPT but have been shown to be effective in lowering calcium in clinical trials.[19] Definitive therapy for malignancy-associated hypercalcemia requires treatment of the underlying malignancy.

Hypocalcemia

Hypocalcemia is defined as low serum levels of albumin-corrected total calcium or ionized calcium. Regulation of calcium is controlled by secretion of PTH by the parathyroid glands and activated vitamin D. PTH is secreted in response to low levels of ionized serum calcium. PTH decreases renal calcium excretion, stimulates the conversion of 25-hydroxyvitamin D to 1, 25-dihydroxyvitamin D (calcitriol) by the kidney, and, together with calcitriol, mobilizes calcium from bone. Hypocalcemia can be caused by inadequate PTH secretion or action, loss of calcium from the circulation due to sequestration, decreased vitamin D supply or action, abnormal magnesium metabolism, or critical illness such as sepsis, acute pancreatitis, or acute renal failure. Hypocalcemia is a common problem in the ICU due to the high prevalence of conditions that cause hypocalcemia (Table 33-9).

Hypoparathyroidism is often only diagnosed during the evaluation of unexplained hypocalcemia or following neck surgery, the most common cause of hypoparathyroidism (Table 33-10).

Hypoparathyroidism remains relatively uncommon in the general population of the United States, with an incidence of approximately 0.6%. Although hypoparathyroism is rare in the general population, it may be a more common finding in the intensive care unit patient due to the higher prevalence of infiltrative diseases, increased use of immunosuppressive and chemotherapeutic agents, and more frequent history of neck surgery in these patients. Transient mild hypocalcemia commonly occurs following parathyroidectomy for HPT, and sometimes after thyroidectomy. However, hungry bone syndrome causes severe, prolonged, symptomatic hypocalcemia due to the rapid influx of calcium into bones usually following parathyroidectomy for tertiary HPT due to chronic renal failure.

Vitamin D deficiency is a common problem in institutionalized patients and patients treated with anti-seizure medications such as phenytoin and phenobarbital that increase the

Drugs (cyclosporine, aluminum, L-asparaginase, doxorubicin, cytosine arabinoside, cimetidine)
Idiopathic

metabolism of vitamin D. In advanced chronic kidney disease, decreased activation of 25-hydroxyvitamin D to 1, 25-dihydroxyvitamin D (calcitriol) occurs, resulting in decreased calcium absorption from the gut and impaired mobilization of calcium from bone. Severe hypocalcemia has been reported in patients with underlying vitamin D deficiency who were treated with intravenous bisphosphonates.[20]

Clinical Findings

The duration, severity, and rate of onset of hypocalcemia determine the clinical manifestations. Mild hypocalcemia may be asymptomatic, but an abrupt mild lowering of ionized calcium can precipitate symptoms. In contrast, patients who develop hypocalcemia gradually may be surprisingly asymptomatic at very low calcium levels.

Neurologic symptoms predominate secondary to hyperexcitability of neuronal membranes. Symptoms of mild tetany include extremity and circumoral paresthesias, muscle cramping and twitching. Trousseau's and Chvostek's signs are classic physical findings in patients with neuromuscular irritability due to latent tetany. A positive Chvostek's sign is defined as twitching of the ipsilateral facial muscles in response to tapping the facial nerve just anterior to the ear (2 cm anterior to the earlobe below the zygomatic process).[21] Chvostek's sign is not very sensitive or specific as demonstrated in one study that found a positive Chvostek's sign in 25% of healthy individuals,[22] while another study found that 29% of patients with laboratory confirmed hypocalcemia had a negative Chvostek's sign.[23]

Trousseau's sign is characterized by the development of carpal spasm when a blood pressure cuff is inflated above systolic blood pressure at the level of the upper arm for more than 3 min. One study found Troussea's sign was positive in 94% of patients with hypocalcemia and only 1% of healthy patients.[24]

Symptoms of severe hypocalcemia include muscular tetany, altered mental status, and seizures.

Severe hypocalcemia causes overt tetany, altered mental status, and seizures. Laryngeal stridor and bronchospam may also occur in severe hypocalcemia. Serious cardiac effects are infrequent, perhaps because true cardiac tetany occurs at much lower calcium levels than those that precipitate the neurologic effects and ECG changes. The clinical manifestations of acute hypocalcemia are shown in Table 33-11.

TABLE 33-11

Papilledema
Altered mental status

Evaluation

Serum calcium levels should first be corrected for serum albumin levels as described previously in this section. Ideally, ionized calcium should be measured in critically ill patients since corrected calcium has been shown to be unreliable in critically ill patients[25] and is accurate when hypocalcemia is due to acute respiratory alkalosis or chelating agents that decrease ionized calcium but do not affect total calcium levels.

In addition to measuring total calcium and albumin or ionized calcium, magnesium, creatinine, intact PTH and 25-hydroxyvitamin D levels are essential to establish the diagnosis. Hypomagnesemia must be ruled out since it causes suppression of PTH resulting in an inappropriately low or normal PTH level while calcium levels are low. If hypocalcemia is due to hypoparathyroidism, PTH will be inappropriately normal or low in the setting of low serum calcium and high or high normal phosphorous, and normal magnesium. If hypocalcemia is due to vitamin D deficiency, 25-hydroxyvitamin D is very low, phosphorous may be low or low normal, and PTH is appropriately high. Patients with pseudohypoparathyroidism are hypocalcemic despite very high levels of serum PTH due to a genetic mutation that causes PTH resistance.

Treatment

Severe hypocalcemia is treated with intravenous calcium gluconate.

The treatment of hypocalcemia should be based upon the severity of the symptoms and the level of the serum calcium. Mild asymptomatic hypocalcemia need not be treated in the ICU. In contrast, if severe symptoms such as seizures, laryngospasm, tetany, QTc prolongation, or cardiac arrhythmia are present, treatment with intravenous calcium is warranted even if the serum calcium level is only mildly reduced (e.g., 7.0–8.0 mg/dL).[21] An initial dose of one or two 10 mL ampules of 10% calcium gluconate diluted in 50–100 mL of 5% dextrose solution given over 10 min (one ampule of 10% calcium gluconate provides 94 mg of elemental calcium) will raise the ionized calcium for 2–3 h. Following the initial dose, a continuous calcium infusion (10 ampules of 10% calcium gluconate diluted in one liter of 5% dextrose) given at an initial rate of 50 mL/h is administered with subsequent adjustments based on serial serum calcium measurements every 1–2 h initially to maintain corrected serum calcium at the lower end of the normal range. Oral calcium with calcium carbonate or calcium citrate and vitamin D supplementation with calcitriol can be started concurrently.[26]

Hypomagnesemia may also be present and must be treated to correct hypocalcemia. Chronic management of hypocalcemia consists of oral calcium (1–2 g of elemental calcium daily in divided doses) and vitamin D supplementation. If hypoparathyroidism or renal failure is present, calcitriol (1, 25-dihydroxyvitamin D) must be used rather than ergocalciferol

or cholecalciferol since both PTH and adequate renal function are required for conversion of 25-hydroxyvitamin D to 1, 25-dihydroxyvitamin D in vivo.

ADRENAL GLAND DISORDERS

The adrenal cortex produces glucocorticoids and mineralocorticoids.

The adrenal cortex produces several types of hormones that are synthesized from cholesterol, including glucocorticosteroids, mineralocorticosteroids, and androgens. Cortisol, the predominant glucocorticoid synthesized by the adrenal cortex, mainly influences carbohydrate and lipid metabolism but effects on other target organs such as the immune system are also significant. Under the control of the renin-angiotensin system, the mineralocorticoid aldosterone maintains potassium and volume balance via its effects on renal sodium and potassium excretion. Although aldosterone is the major adrenal hormone responsible for blood pressure, cortisol also plays a role by maintaining vascular responsiveness to catecholamines and angiotensin II.

The adrenal medulla produces dopamine, epinephrine, and norepinephrine.

The adrenal medulla synthesizes the catecholamines dopamine, norepinephrine, and epinephrine under the control of the sympathetic nervous system. In response to increased stress or physiologic demands, products of the adrenal medulla influence cardiac output and vascular tone.

Adrenocortical Insufficiency

Absolute adrenal insufficiency is caused by adrenal gland failure or inadequate or absent secretion of adrenocorticotropic hormone (ACTH).

Adrenocortical insufficiency is characterized by the deficiency of cortisol with or without a deficiency of aldosterone. Primary adrenal insufficiency (Addison's disease) is a result of intrinsic adrenal gland failure with deficiency of both cortisol and aldosterone. In response to low serum cortisol, secretion of adrenocorticotropic hormone (ACTH) by the anterior lobe of the pituitary gland is increased resulting in elevated serum ACTH levels. Secondary adrenal insufficiency results from inadequate or absent secretion of ACTH from the anterior lobe of the pituitary gland. The causes of primary and secondary adrenal insufficiency are listed in (Table 33-12). Autoimmune adrenalitis is the most common cause of primary adrenal insufficiency, while exogenous glucocorticoid therapy is the major cause of secondary adrenal insufficiency.

TABLE 33-12

ETIOLOGIES OF ADRENAL FAILURE

PRIMARY ADRENOCORTICAL INSUFFICIENCY	SECONDARY ADRENOCORTICAL INSUFFICIENCY
Autoimmune adrenalitis	Exogenous glucocorticoids

Congenital syndromes	Congenital conditions
	Isolated ACTH deficiency

While absolute adrenal insufficiency is relatively rare in the critically ill patient, relative adrenal insufficiency is now recognized as a cause of poor outcomes in certain patients. Relative adrenal insufficiency or critical illness-related corticosteroid insufficiency (CIRCI) is a term used to describe dysfunction of the hypothalamic-pituitary-adrenal axis in critically ill patients. CIRCI can cause persistent hypotension in critically ill patients that have already been volume resuscitated and placed on vasopressors. It denotes inadequate cellular corticosteroid activity for the severity of illness due to adrenal insufficiency and/or tissue corticosteroid resistance.[27]

Critical illness-related corticosteroid insufficiency (CIRCI) is caused by inadequate corticosteroid activity relative to the severity of illness.

Clinical Findings

The symptoms of absolute adrenal insufficiency depend upon whether the etiology is primary or secondary in (see Table 33-13), and whether the onset is acute or chronic. Acute adrenal crisis is a life-threatening emergency characterized by severe hypotension and shock that may be refractory to fluid resuscitation. Fever, hypoglycemia, and the other symptoms of adrenal insufficiency may also be present; however, severe hypotension is usually the predominant manifestation. Acute adrenal crisis can be precipitated by the acute onset of primary adrenal insufficiency or by lack of adequate exogeneous glucocorticoids in patients with primary adrenal insufficiency exposed to stress of infection, illness, or surgery. Less commonly, patients with secondary or tertiary adrenal insufficiency develop acute adrenal crisis in the setting of acute pituitary infarction or abrupt withdrawal from suppressive dose of glucocorticoids.

In the critically ill, adrenal insufficiency should be considered in patients who manifest hypotension that is unexplained or not responsive to therapy.

Generalized weakness and fatigue are common in both primary and secondary adrenal insufficiency. In primary adrenal failure, aldosterone insufficiency results in decreased potassium excretion and decreased sodium reabsorption in the distal renal tubules. Significant renal wasting of sodium and water may result in hypovolemia, azotemia, hyponatremia, and hyperkalemia. High levels of ACTH secreted in response to the deficient serum cortisol causes skin hyperpigmentation.

The symptoms of secondary adrenal insufficiency are similar except that hyperklalemia and dehydration do not occur since the mineralocorticoid function is intact, and GI symptoms are less common and less severe. Since ACTH is deficient rather than excessive, there is no hyperpigmentation of the skin. The hyponatremia is the result of inappropriate vasopressin secretion due to the lack of cortisol.

Adrenal crisis may result from a significant deficiency or inadequate response to acute stressors, including infection or surgery. Patients on chronic steroid therapy for adrenal insufficiency or other illnesses (e.g., chronic obstructive pulmonary disease, asthma, or connective tissue diseases) are at risk due to absent or diminished adrenal response to stress. Findings may include rapid clinical deterioration with marked hypotension, fever, abdominal pain, and altered mental status.

Diagnosis

Laboratory findings suggestive of primary adrenal insufficiency include hyponatremia, hyperkalemia, hypoglycemia, metabolic acidosis, eosinophilia, and azotemia. A reduced

TABLE 33-13

Salt craving	

random serum cortisol level does not confirm a diagnosis of adrenal insufficiency, but a low serum cortisol level in patients with a consistent clinical presentation may be suggestive. An 8 am cortisol less than 3 µg/dL in a patient with a normal diurnal rhythm is strongly suggestive of absolute adrenal insufficiency. In primary adrenal insufficiency, serum cortisol is low and serum ACTH levels are elevated. ACTH stimulation testing can establish the diagnosis of either primary or secondary adrenal insufficiency. For the rapid ACTH test, serum cortisol is measured before and 30 or 60 min after IV or IM injection of cosyntropin (synthetic ACTH) at 250 µg. A normal response is a rise in serum cortisol concentration after 30 or 60 min to a peak of 18–20 µg/dL.

The diagnosis of CIRCI differs from that of absolute adrenal insufficiency described above. Adrenal insufficiency is not usually the primary cause of the critical illness in these patients rather; the corticosteroid response is inadequate for the severity of illness. CIRCI may be diagnosed using the ACTH stimulation test or a random cortisol level. A random total cortisol of less than 10 µg/dL or an ACTH-stimulated change of less than 9 µg/dL in cortisol from baseline establishes the diagnosis of CIRCI.[27]

Treatment

Suspicion of adrenal crisis requires immediate glucocorticoid repletion. If the diagnosis is not established, 4 mg dexamethasone is administered intravenously followed by ACTH stimulation testing (dexamethasone does not interfere with serum cortisol assays). Following testing or in the case of known adrenal insufficiency, 100 mg hydrocortisone is administered every 8 h. Mineralocorticoids require several days for the effects to be clinically significant and are, therefore, not useful in the acute setting. Unless the acute illness fails to improve, glucocorticoids can be tapered over the next 1–3 days. In suspected cases of CIRCI, stress doses may be continued for longer periods depending on the response to therapy. Diagnostic testing to establish or confirm the diagnosis of adrenal insufficiency may be performed when the patient is stable to determine the need for chronic glucocorticoid therapy.

Acute adrenal crisis requires prompt glucocorticoid replacement therapy.

Chronic physiologic glucocorticoid replacement may be given as hydrocortisone in a twice-daily dose of 20 mg in the morning and 10 mg in the afternoon, or 5 mg of prednisone daily, or any other glucocorticoid at an equivalent dose. Although hydrocortisone has some mineralocorticoid effect, patients with primary adrenal failure will likely require additional mineralocorticoid replacement in the form of fludrocortisone 0.05–0.2 g daily for the clinical findings of persistent orthostatic hypotension, hyponatremia, and hyperkalemia. In all patients on chronic glucocorticoid replacement therapy, dosages must be increased before expected stressors such as surgery, or during illness.

Adrenocortical Excess

Exogenous glucocorticoid administration is the most common cause of adrenocortical excess.

In the general population, pituitary microadenomas that secrete excessive amounts of ACTH account for 80% of endogenous adrenocortical excess (Cushing's syndrome). Hypersecretion of glucocorticoids by adrenal tumors and ectopic ACTH production are less common. The most common of adrenocortical excess in the intensive care unit is iatrogenic, occurring in patients with exogenous glucocorticoid requirements.

Clinical Findings

Physical examination findings include truncal obesity, wide violaceous striae, and a rounded face in patients with chronic adrenocortical excess (Table 33-14). Mild to moderate hyperglycemia may also be present.

Diagnosis

Testing to establish the diagnosis of hypercortisolism (Cushing's syndrome) should be deferred until the acute illness has resolved.

The diagnosis of Cushing's syndrome in the critical care patient is usually precluded since physiologic stressors such as infection, illness, and hypotension appropriately stimulate the secretion of increased adrenal hormones including cortisol, catecholamines, and

TABLE 33-14

CLINICAL FINDINGS OF ADRENOCORTICAL EXCESS

Truncal obesity
Rounded face
Fat deposits in the supraclavicular fossae and over the posterior neck
Hirsutism
Amenorrhea
Psychiatric disorders/depression
Thin skin
Easy bruising
Purple striae
Proximal muscle weakness
Osteoporosis

mineralocorticoids. Standard tests such as the overnight dexamethasone suppression test or 24-h urinary free cortisol measurement are not useful or interpretable in the critically ill patient. The diagnostic testing for Cushing's syndrome should be deferred until the patient has recovered from the acute illness.

Therapy

In the intensive care unit, patients requiring prolonged glucocorticoid therapy should be monitored for the clinical consequences and frequently reassessed for possible dose reduction. As for other etiologies, such as an ACTH-secreting pituitary adenoma or hypersecreting adrenal adenoma, the primary goal of intensive care unit therapy is supportive until patient is stable enough for definitive diagnosis and treatment.

DIABETES INSIPIDUS AND SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Antidiuretic hormone (ADH) is produced by the supraoptic and paraventricular nuclei of the hypothalamus.

ADH promotes water reabsorption in the renal collecting ducts.

Arginine vasopressin or antidiuretic hormone (ADH) is produced in the supraoptic and paraventricular nuclei of the hypothalamus, travels down the pituitary stalk, and is stored in the posterior lobe of the pituitary gland. ADH promotes water reabsorption at the level of the renal collecting ducts. Disorders of the neurohypophysis or the kidneys can result in marked alteration of the body's ability to control urine concentration.

Diabetes Insipidus

Diabetes insipidus (DI) is characterized by the excretion of large quantities of dilute urine.

Central DI is caused by an absolute or relative deficiency of ADH.

Renal resistance to ADH causes nephrogenic DI.

Diabetes insipidus (DI) is a disorder characterized by excretion of large quantities of dilute urine due to an absolute or relative deficiency of ADH (central DI) or renal resistance to the effects of ADH (nephrogenic DI). Primary central DI is caused by an inherited or idiopathic reduction in the number of hypothalamic nuclei. Secondary central DI is more common and is caused by a variety of pathologic lesions of the neurohypophysis including tumor, trauma, pituitary surgery, hemorrhage, and infiltrative disorders. The renal resistance to ADH that causes nephrogenic DI may be due to an inherited disorder or an acquired disorder (e.g., drugs, hypercalcemia, hypokalemia, or damage to the kidney). DI may be a temporary or permanent condition depending on the etiology.

Clinical Findings

Patients present with polyuria (urine output exceeding 3 L/day) due to the inability to reabsorb water and concentrate urine. Patients complain of nocturia and thirst, and often crave ice-cold water. Most patients can maintain a normal or mildly elevated plasma sodium concentration due to the strong stimulation of the thirst mechanism. However, hypernatremia

and dehydration can develop rapidly in critically ill patients who do not have access to water or have impaired thirst.

Diagnosis

The diagnosis of DI is often made clinically based upon history and laboratory findings. The hallmarks of DI include polyuria (4–18 L/day) and dilute urine (osmolality less than 200 mOsm/kg H_2O, specific gravity <1.005).[28] A serum osmolarity >295 mOsm/kg H_2O or serum sodium greater than or equal to 145 mEq/L with continued diuresis of dilute urine in the absence of hyperglycemia, hypokalemia, hypercalcemia or significant renal insufficiency, is highly suggestive of diabetes insipidus. Since many critically ill patients do not have free access to oral fluids due to obtundation or sedation, the diagnosis of diabetes insipidus is usually fairly easy to establish since serum osmolality and serum sodium rise very quickly in response to urinary water losses. However, when the patient has access to water, the serum osmolality and serum sodium are usually normal or only very slightly elevated.

The water deprivation test is the principal test for establishing the diagnosis and underlying cause of DI. The purpose of the water deprivation is to elevate the serum osmolality above normal, allowing the urine concentrating function to be tested. Measurements of serum and urine osmolality and weight are taken at baseline. Water intake is withheld and urine output, urine osmolality, and weight are measured hourly, and serum osmolality and serum sodium every 2 h. Water deprivation is continued until one of the following conditions are met: (1) the serum osmolality exceeds 295 mOsm/kg H_2O, (2) urine osmolality reaches 600 mOsm/kg H_2O (normal concentrating function), (3) the urine osmolarity does not change over 3 h (impaired concentrating function), or (4) the patient develops hypotension, tachycardia, or body weight decreases by 3%. At the end of the dehydration period, obtain a plasma ADH level while the plasma osmolaltity is elevated. The diagnosis of DI is confirmed if the urine remains dilute (<200 mOsm/kg H_2O) despite serum hyperosmolality.

In diabetes insipidus, serum osmolality is elevated while urine osmolality remains <200 mOsm/kg H_2O.

The water deprivation test can establish diagnosis of DI.

To distinguish central from nephrogenic DI, 10 μg desmopressin (dDAVP) by nasal insufflation or 4 μg of DDAVP subcutaneously is administered. Urine osmolality and volume is then measured for an additional 2 h. An increase of >50% after dDAVP indicates central DI, whereas no increase or an increase <10% strongly suggests nephrogenic DI or primary polydipsia.[29] When the increase in urine osmolality is equivocal (e.g., 10–50%), the plasma ADH level drawn at the end of the dehydration period may help identify the underlying cause of DI.

Management

In the critical care unit, careful and frequent monitoring of urine output and specific gravity, serum sodium and serum osmolaltity is extremely important to avoid the development of severe hypernatremia in the unresponsive or obtunded patient with DI. Fluid losses should be replaced with hypotonic IV fluids if the patient is unable to drink or there is no enteral route available to administer free water.

Treatment of central DI, focuses on reversible causes and hormonal replacement therapy. Hormonal replacement therapy with desmopressin (dDAVP), 1–2 μg administered subcutaneously, is used for acute presentations of central DI in the intensive care unit. Treatment with dDAVP can cause water retention and hyponatremia if the dose is too high or too frequent, or if the DI resolves and therapy is continued. The lowest possible dose of dDAVP required to control polyuria should be used. Since DI is often transient following neurosurgery and can evolve into SIADH, dDAVP should be only be redosed in those patients when urine output is 200–250 mL for greater than or equal to 2 h with urine specific gravity <1.005 or urine osmolality <200 mOsm/kg H_2O.[28]

Patients with partial central DI may benefit from alternative therapies that include thiazide diuretics and ADH-releasing drugs. Thiazide diuretics paradoxically reduce urine volume by decreasing extracellular volume while increasing proximal tubule water reabsorption, with urine volumes falling 25–50%. Limiting salt intake in these patients reduces their solute load and urine output. ADH-releasing drugs, chlorpropamide, clofibrate, or carbamazepine

(100–400 mg PO b.i.d.), may be also used in patients with partial DI and in combination with thiazide diuretics.

Patients with complete nephrogenic DI may be treated with thiazide diuretics and by limiting salt intake. Indomethacin or other prostaglandin inhibitors may also be effective in reducing urine output by decreasing renal blood flow and glomerular filtration rate. Patients with partial nephrogenic DI may respond to higher doses of dDAVP.

Complete nephrogenic DI can be treated with thiazides, NSAIDS, and sodium restriction.

DDAVP may be used to treat acute and chronic DI.

Partial central DI may be treated with thiazide diuretics or sodium restriction alone.

An ADH-releasing drug may be used as an additional agent in partial central DI.

Syndrome of Inappropriate ADH Secretion

In contrast to DI, certain conditions cause an elevation in circulating ADH, resulting in increased renal water retention and concentrated urine. ADH may be elevated as a physiologic response to increased serum osmolality, true hypovolemia, or decreased effective intravascular volume as occurs in congestive heart failure, cirrhosis, and nephrotic syndrome. Patients with the syndrome of inappropriate ADH secretion (SIADH) have a pathologic excess of ADH that is not a physiologic response to excess serum sodium or hypovolemia. In these patients, excessive ADH release occurs in response to CNS injury or inflammation, drugs, pulmonary disorders, or ectopic production from malignant neoplasms.

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is characterized by water retention and concentrated urine.

Symptoms

ADH-mediated reabsorption of water by the kidney leads to the hyponatremia and decreased osmolality that is responsible for the symptoms exhibited by the patient. In mild SIADH, serum sodium levels are 130–135 mmol/L, usually with the absence of symptoms. As serum sodium levels fall with ongoing water reabsorption, cerebral edema may develop and precipitate alterations in mental status that range from confusion to coma. Patients with chronic hyponatremia may be asymptomatic even at very low sodium levels. Rapid development of severe hyponatremia (sodium <125 mmol/L) can have serious sequelae including seizures, coma, or respiratory failure.[30]

SIADH is caused by excess release of ADH by the neurohypophysis or ectopic production.

Diagnosis

The diagnosis of SIADH is a diagnosis of exclusion. Clinically, the patient must be euvolemic without signs of volume depletion or volume overload and without recent diuretic use. Other etiologies of euvolemic hyponatremia such as adrenal insufficiency and hypothyroidism must be excluded. Once these criteria are fulfilled, serum osmolality and urine osmolality are measured and effective osmolality (measured osmolality – BUN/2.8) is calculated. The diagnosis of SIADH is made when effective serum osmolality is <275 mOsm/kg H_2O while urine osmolality is >100 mOsm/kg H_2O.[30] Urine sodium >40 mmol/L with normal dietary intake also supports the diagnosis in the setting of hypoosmolality.

Treatment

Therapy is dependent upon the degree of absence of symptoms. Definitive treatment requires elimination of the underlying cause. Restriction of free water intake to a total of 500–1,000 mL/day remains the primary initial treatment in chronic asymptomatic SIADH and gradual correction of sodium is the goal. Increased dietary sodium intake should also be encouraged. For patients with chronic SIADH, treatment with demeclocycline may be useful in addition to water restriction. Demeclocycline 600–900 mg/day in divided doses is a potent inhibitor of ADH at the renal tubule. However, patients are at risk for renal failure, bacterial superinfections, and drug-induced water loss with hypernatremia and hypovolemia.

Acute hyponatremia (known to have developed within 48 h) with severe neurologic symptoms requires more aggressive treatment with 3% saline cautiously administered at 1–2 mL/kg body weight per hour. The goal is to raise the serum sodium level 1–2 mmol/L/h. Check serum sodium level every 2 h and adjust infusion rate.[30] An increase of less than

Central pontine myelinolysis (CPM) is a complication that may occur if serum sodium is corrected too rapidly in chronic hypernatremia.

Water restriction is the primary therapy for chronic asymptomatic SIADH.

Hypertonic saline is the treatment for acute symptomatic hyponatremia.

Oral and intravenous vasopressin-receptor antagonists are available for the treatment of SIADH.

10 mmol/L is usually sufficient to reduce symptoms.[31] Once symptoms have resolved, the correction rate should be reduced.[32] Furosemide may be used if volume overload occurs.

Unlike patients with acute hyponatremia, symptomatic patients with chronic hyponatremia are at known risk for central pontine myelinolysis (CPM) if the serum sodium level is corrected by more than 12 mmol/L over 24 h. CPM can cause quadriplegia and weakness of the lower face and tongue with permanent damage. Myelinosis may spread dorsally, compromising the sensory tracts and resulting in a "locked-in" syndrome. To avoid this complication of therapy, plasma sodium should not be increased more than 0.5–1 mmol/L/h and no greater than 8 mmol/L over 24 h.[30] As with treatment of acute hyponatremia, serum sodium levels must be checked every 2 h.

More recently, vasopressin-receptor antagonists have become available for the treatment of SIADH. This class of drugs binds to vasopressin (ADH) receptors, thereby blocking the antidiuretic effect at the level of the renal collecting tubules. Initially, intravenous conivaptan was the only vasopressin-receptor antagonist available; however, tolvaptan, an oral agent, was recently approved for the treatment of SIADH.

SUMMARY

Endocrine disorders remain a common finding in the intensive care unit patient. Clinical and laboratory findings help distinguish patients with DKA from those with HHS. Both disorders require specific and aggressive treatment. Thyroid, parathyroid, and adrenal gland disorders may have profound systemic effects, ranging from alteration in mental status to hemodynamic instability. Alterations in ADH secretion or renal response to ADH may result in DI or SIADH.

REVIEW QUESTIONS

A 40-year-old man with a history of type I diabetes presented to an emergency room with complaints of fatigue and progressive right flank pain. On physical examination, he had a temperature of 102.2°F with a heart rate of 120 beats/min, respiratory rate of 18/min, and blood pressure of 110/70 mmHg. His skin and mucous membranes were dry. The lung exam was clear, and the cardiac exam showed regular tachycardia without murmurs or rubs. His right flank was tender to percussion, and extremities were dry.

Laboratory tests showed a white count of $14.5 \times 10^3/\mu L$ with hemoglobin of 11.5 g/dL, hematocrit of 38%, and platelets of $336 \times 10^3/\mu L$. Chemistry total panel showed sodium of 150 mmol/l, potassium 3.4 mmol/L, chloride 110 mmol/L, bicarbonate 12 mmol/L, blood urea nitrogen (BUN) 60 mg/dL, creatinine 1.9 mg/dL, and glucose 400 mg/dL. Urinalysis showed 40 plus white blood cells per high-power field with white cell casts, glucose ++++, protein +, positive leukocyte esterase, and positive nitrates. Her arterial blood gas was pH 7.01; $PaCO_2$ 32 mmHg, and PaO_2 78 mmHg on room air.

1. **What would be the most appropriate primary therapy?**
   - **A.** Aggressive fluid resuscitation with normal saline, IV insulin 0.1 U/kg bolus followed by 0.1 U/kg/h continuous infusion and antibiotics
   - **B.** Correction of acidosis with one ampule of sodium bicarbonate given in 250 mL of normal saline followed by aggressive fluid rehydration with 3% saline
   - **C.** Subcutaneous insulin at the patient's usual outpatient dose along with IV saline at 100 mL/h
   - **D.** Potassium repletion with 40 mEq in 250 mL normal saline
   - **E.** Insulin bolus followed by continuous insulin infusion

2. **The patient's initial potassium was 3.4 mmol/L. Assuming good urine output, what would be the most appropriate initial medical therapy?**
   - **A.** Addition of 20 mEq/L potassium for each liter of replacement fluid
   - **B.** Addition of 40 mEq/L potassium for each liter of replacement fluid
   - **C.** Start IV fluids and IV insulin and repeat electrolyes in 1 h
   - **D.** Start 10 mEq/h potassium drip until serum potassium is 3.5 mmol/L

3. **After initial therapy, the patient exhibited a persistent elevated anion gap acidosis but her blood sugar had decreased to 100 mg/dL. The most appropriate response is to:**
   - **A.** Decrease the insulin infusion
   - **B.** Continue the insulin infusion and change IV fluids to 5 or 10% dextrose
   - **C.** Start enteral feeding
   - **D.** Discontinue insulin infusion and administer one ampule of dextrose intravenously. Repeat Accucheck in 1 h

4. A 32-year-old woman is found to have a nonsecreting pituitary macroadenoma after presenting with amenorrhea and headaches. Further evaluation of pituitary function reveal the following:

TSH = 0.5 mIU/L (0.46–5 mg/dL)
Free T4 = 0.4 ng/dL (0.8–1.8 ng/dL)
8 am serum cortisol = 2.0 (6–23 μg/dL)
ACTH = <2 pg/mL (6–76 pg/mL)

Which of the following is true?

A. Pituitary function is normal
B. Cortisol is low due to nonhyroidal illness
C. The patient has developed central hypothyroidism and central adrenal insufficiency
D. The patient has Cushing's syndrome

5. The patient above receives stress doses of hydrocortisone prior to transphenoidal resection of the pituitary tumor. A few hours after surgery, she starts to produce more than 600 mL of urine per hour. Serum sodium is 150 mEq/L (135–145 mEq/L) and urine specific gravity is 1.000 (1.010–1.030). Other electrolytes, serum glucose, and creatinine are normal.

Which of the following steps should be taken?

A. Perform a water deprivation test
B. Give desmopressin (dDAVP)
C. Reduce the hydrocortisone to a physiologic dose
D. Administer IV fluid according to hourly urine output and calculated fluid deficit
E. Both B and D

6. A 45-year-old man is transferred to the ICU following surgery to remove a large parathyroid adenoma. The PTH was 350 pg/mL (10–60 pg/mL) preoperatively and serum calcium was normal following the administration of IV bisphosphonates prior to surgery.

After the procedure, the patient felt well and was advanced to a normal diet. However, he quickly developed perioral numbness and carpal spasm, and was noted to have a positive Chvostek's sign. Serum total calcium was 6.9 with a normal albumin and ionized calcium was 4.0 mg/dL (4.7–5.2 mg/dL) when the patient had a seizure and was transferred to the ICU.

Which of the following steps should be taken?

A. Start activated vitamin D via IV infusion
B. Give 10% calcium gluconate diluted in 50–100 mL of 5% dextrose solution over 10 min followed by a continuous calcium infusion
C. Oral calcium and calcitriol should be administered every 4 h via nasogastric tube
D. Calcium and vitamin D replacement should be deferred until the patient is stabilized

7. A 79-year-old man with type 2 diabetes and chronic renal insufficiency was brought to the emergency room by his family complaining he was more confused and falling frequently. He awakens to voice but is somnolent and does not follow commands. His family reported that he had eaten little by mouth during the past 3 days. His temperature was 101°F with a heart rate of 110 beats/min and blood pressure of 100/70 mmHg. His skin and mucous membranes are dry. Laboratory values are notable for sodium 135 mmol/L, chloride 100 mmol/L, bicarbonate 21 mmol/L, potassium 5.3 mEq/L, and glucose 1,100 mg/dL. A urine dipstick indicated glucose, ketones, and concentrated urine. The most appropriate initial therapy would be:

A. Intravenous insulin bolus 0.1 U/kg bolus, then a continuous insulin infusion
B. Aggressive fluid resuscitation with 0.9% saline
C. Aggressive fluid resuscitation with 5% dextrose with 0.45 saline
D. Repletion of potassium

8. A 67-year-old female was brought to the emergency room by ambulance after she was found unresponsive by her family. According to her family, she seemed more confused lately. She has a history of hypertension and hypothyroidism. On admission, her temperature is 95°F, heart rate is 55, blood pressure is of 97/60 mmHg, and her SaO_2 is 82%. Examination shows she has no lateral eyebrows, and her skin is course, sallow, and puffy. Heart sounds are present and lungs have bilateral ronchi. Her abdomen is soft; bowel sounds decreased. Her deep tendon reflexes have a delayed relaxation phase. Hemoglobin is 13 mg/dL, and WBC count is 11,000/mm^3 with a normal differential. Sodium was 130 mEq/L, chloride 92 mEq/L, bicarbonate was 37 mEq/L. Her arterial blood gas showed a pH of 7.32, PCO_2 65 mmHg, and a PO_2 of 48. Chest X-ray showed a bilateral patchy infiltrates. She was intubated and placed on the ventilator. Antibiotics were started empirically to treat for community acquired pneumonia. What other therapy would be appropriate?

A. Intravenous IV liothyronine (T3) 300 μg IV bolus followed by 50 μg IV daily until symptoms improve
B. Intravenous levothyroxine (T4) 250 μg IV bolus followed by 50 μg IV bolus daily, and intravenous liothyronine (T3) 10 μg IV bolus followed by 2.5–10 μg IV every 8 h, and hydrocortisone 100 mg every 8 h
C. Methimazole 30 mg administered rectally every 6 h
D. Place a feeding tube and begin 0.05 mg of oral synthetic L-thyroxine

ANSWERS

1. The answer is A. In DKA, the main components of therapy include aggressive fluid resuscitation followed by parenteral insulin. Since the patient has evidence of a urinary tract infection, starting empiric antibiotics along with urine cultures would also be appropriate. Therefore, A is the best answer. Bicarbonate administration is still controversial, and current recommendations suggest its use only in cases of acidosis with pH <7.00 but with the risks of inducing alkalosis and hypokalemia. Potassium repletion will most likely be required as patients with DKA usually have a total body deficit, but it should not be the only therapy started. Subcutaneous insulin is not indicated in the acute management of DKA.

2. The answer is B. The initial serum potassium is 3.4 mmol/L. Current recommendations call for addition of 40 mEq/L potassium per liter replacement fluid in patients with adequate renal function.

If the serum potassium was between 4 and 5 mEq/L, then 20 mEq/L potassium would be added to each liter of replacement fluid. A potassium drip would only be indicated if serum potassium was less than 3 mmol/L. Patients with DKA usually have a total body potassium deficit, although usually they present with normal or slightly elevated potassium levels. In this case, the potassium is already low; therefore potassium replacement should be started now.

3. The answer is B. Decreasing or discontinuing the insulin infusion in the presence of a continued anion gap would lead to worsening of the acidosis. Continued insulin therapy is required to suppress ketogenesis and facilitate peripheral glucose uptake. Diet or enteral feeding should resume when acidosis and anion gap have resolved. In the presence of persistent anion gap acidosis, the insulin infusion is continued and dextrose-containing fluids are administered to keep the blood sugar between 150 and 200 mg/dL until the bicarbonate is greater than or equal to 18 mEq/L and the gap is closed.
4. The answer is C. The pituitary function is clearly abnormal given the low TSH in the setting of a low serum thyroxine (T4) level, and low ACTH while the 8 AM cortisol level is very low. If pituitary function were normal, both TSH and ACTH would be elevated in response to the low levels of circulating thyroxine and cortisol, respectively. Nonthyroidal illness is not likely the cause of the abnormal thyroid function tests since the patient is not yet sick, and nonthyroidal illness does not cause low cortisol. The patient has central hypothyroidism and central adrenal insufficiency. Cortisol and thyroxine are low because the tumor has damaged the pituitary resulting in inadequate secretion of the trophic hormones (TSH and ACTH) that stimulate target organ hormone secretion. Cushing's syndrome is a state of hypercortisolism.
5. The answer is E. The patient has developed central diabetes insipidus due to damage to the pituitary during surgery. A water deprivation test is not necessary because the diagnosis is not in question. The continued excretion of large amounts of dilute urine in the setting of hypernatremia following pituitary surgery is enough to make the diagnosis. The water deprivation test is used to make the diagnosis of DI when the serum sodium and serum osmolality are normal and large amounts of dilute urine are being excreted. The correct therapy is IV or subcutaneous administration of synthetic ADH (desmopressin/dDAVP) and IV fluids to replace urinary losses. The hourly urine output and calculated fluid deficit are used to determine the rate of the replacement. Stress doses of hydrocortisone are still required in this critically ill postoperative patient.
6. The answer is B. The patient has developed severe symptomatic hypocalcemia as a result of either damage to the reaming parathyroid glands, transient hypoparathyroidism due to chronic suppression of the remaining nonadenomatous parathyroids by hypercalcemia, or hungry bone syndrome. The patient requires urgent treatment to correct the hypocalcemia that is causing severe symptoms of tetany and seizure. Oral calcium and calcitriol will gradually raise the serum calcium and is indicated for mild asymptomatic hypocalcemia. Oral repletion of calcium and calcitriol should be started when the patient can tolerate oral medications and before the IV calcium infusion is discontinued.
7. The answer is B. Unlike DKA, patients with HHS do not have a marked requirement for insulin. HHS is associated with marked volume depletion and hyperosmolality. The initial therapy is volume resuscitationwith normal saline to restore intravascular volume. Serum potassium is elevated due to low circulating insulin levels, causing potassium to shift out of the intracellular space and into the plasma, but total body potassium is decreased due to renal losses. When the potassium falls below 5.3 mEq/L, potassium is added to the IV fluids. Potassium is not added to the initial IV isotonic saline since that will create a hypertonic fluid that will not correct the hyperosmolality.
8. The answer is B. The patient has community acquired pneumonia but also has signs of myxedema coma. Given the severity of her symptoms, intravenous therapy is indicated. In myxedema coma, IV levothyroxine (T4) is the preferred replacement. Liothyronine (T3) is not administered as the sole thyroid hormone replacement therapy. Treatment of myxedema coma requires intravenous levothyroxine with possible use of liothyronine replacement as well in appropriate situations. Hydrocortisone is given because of the possible coexistence of adrenal insufficiency. Oral thyroid replacement is not indicated in myxedema coma.

CHAPTER 34

FREDERIC H. KAUFFMAN AND KATHRYN GETZEWICH

Evaluation and Management of Toxicological Emergencies

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- List the methods available for decreasing toxin absorption in the gastrointestinal tract, with the indications, contraindications, and potential complications of each method.
- Describe toxin exposures for which enhancing toxin elimination is possible, with the specific means to do so.
- Describe the limitations of toxicologic drug screening, with indications for its use in specific clinical scenarios.
- Know those toxin exposures for which specific antidotes exist, with the indications and potential complications of their use.
- Identify the principles by which an exposure can be determined to be nontoxic and have a working knowledge of the many household items that are nontoxic.
- Describe mechanisms by which unknown compounds can be identified.

Treat the patient not the disease.

Develop an organized approach when treating overdose patients.

Despite the temptation to manage and treat the toxin-exposed patient from the perspective of the toxin ingested, the astute clinician understands that it is imperative to have a patient-centered approach to clinical management. The old adage, "treat the patient not the disease," is nowhere more relevant than in the field of toxicology. Identifying the specific toxin(s) ingested is, indeed, important to patient management, but most patients will not benefit from administration of a specific antidote. In fact, patients benefit most from an organized management-approach based upon sound toxicologic principles, guided by a working

CASE STUDY: PART 1

An 18-year-old male was noted to be quieter than usual at breakfast. Later that morning, after playing basketball, his sister noted that he was sweating profusely and complaining of abdominal pain. That same evening his mother found him lethargic and lying on the floor. He was rushed to the emergency room. Family members stated that before this episode, the patient was healthy, had no significant past medical or surgical history, and did not take illicit drugs. They denied the presence of prescription drugs in the household.

Physical examination revealed a lethargic, diaphoretic, disoriented male appearing his stated age. Temperature was 98°F, pulse 116/min and regular, BP 160/90 mmHg, respirations 60/min, and room air pulse oximetry 100%. There was no evidence of trauma. Pupils were 4 mm, equal, and reactive to light. Optic disks were sharp bilaterally. Neck was supple. Breath sounds were clear bilaterally. Cardiac exam was normal except for tachycardia. Decreased bowel sounds were noted, along with right lower quadrant tenderness without rebound. Rectal exam was normal except for heme-positive stool. Extremities were normal. Neurologic exam was significant for disorientation to person, place, and time but was otherwise nonfocal.

The patient was placed on a cardiac monitor (sinus tachycardia) and large-bore intravenous access was obtained. Intravenous naloxone resulted in no clinical change. Bedside glucose measurement was 40 mg/dL. Administration of one ampule of $D_{50}W$ resulted in the patient becoming intermittently agitated. Blood was sent for electrolytes, blood urea nitrogen, creatinine, complete blood count, and comprehensive drug screen; arterial blood gas on room air revealed PaO_2 121 mmHg, $PaCO_2$ 22 mmHg, and pH 7.39. A Foley catheter was placed and a urine sample sent to the laboratory.

knowledge of the ABCs, gastric decontamination, enhancement of drug elimination, and the recognition of nontoxic levels of exposure.

Rarely will a patient with a toxic exposure be managed initially by a physician trained and/or board certified in toxicology. More often, the treating physician and health care team are emergency or critical care specialists. It is essential that such individuals have sound knowledge regarding generic toxicologic principles, plus an understanding of what types of exposures require consultative input from a toxicologist, generally found via the regional poison control center. Knowing what you do not know is just as important as knowing what you do know. By selectively utilizing the expertise provided by regional poison control centers, the emergency or critical care specialist can provide optimal patient care based upon the latest scientific advances and at the same time facilitate ongoing toxicologic research.

Toxicology has become a highly specialized field with rigorous training and credentialing guidelines. It is impossible to duplicate a text of toxicology in this chapter. Rather, generic principles of poison management are emphasized, with detailed information on some of the more commonly required specific antidotes.

INITIAL TREATMENT OF THE PATIENT WITH ALTERED MENTAL STATUS AND SUSPECTED TOXIN EXPOSURE

ABC represents evaluation of a patient's airway, breathing, and circulation.

The management of all seriously ill patients, regardless of etiology, begins with addressing the ABCs. Evaluation for airway compromise, breathing difficulties, and circulatory problems should be done quickly, with attention to the possibility of head or cervical trauma in the patient in whom trauma cannot be immediately excluded. Adequacy of the frequency and depth of respirations must be assessed and if airway control and ventilatory support is necessary, this should be rapidly instituted. Once the airway is secured and oxygenation established, all vital signs should be obtained, including the often-neglected core temperature. A fingerstick blood glucose measurement should be considered a vital sign in these patients. Any life-threatening conditions identified by vital sign assessment (including pulse oximetry) should be treated, including hypotension, hypertension, significant bradycardia or tachycardia, dysrhythmias, hypoxemia, and profound hyperthermia or hypothermia. Establishment of large-bore intravenous access and cardiac monitoring is essential to clinical management. Blood samples should be sent for electrolytes, blood urea nitrogen, creatinine, glucose, and

Review vital signs including pulse oximetry.

Establish large-bore intravenous access.

TABLE 34-1

INITIAL TREATMENTS FOR THE PATIENT WITH ALTERED MENTAL STATUS AND SUSPECTED DRUG OVERDOSE

100% Oxygen
Hypertonic dextrose, 0.5–1.0 g/kg as $D_{50}W$ in the adult or $D_{10}W$ in the child
Thiamine 100 mg by slow IV administration
Naloxone 2 mg IV

Blood samples should be obtained after the ABCs are evaluated.

Inquire about co-ingestions such as acetaminophen and salicylates.

Initial evaluation of a patient with an altered mental status should include scanning for needle marks, bedside glucose testing, and examination of the pupils for miosis.

Repeat the ABCs frequently during the evaluation.

Interview family and friends for additional information.

complete blood count. Extra blood samples should be collected and held pending subsequent need for specialized laboratory studies. The role of drug screens in this setting is discussed later in this chapter, and their use should be guided by individual clinical assessment with the understanding that the results often do not influence early patient management. History and physical assessment should guide the need for specific drug levels, such as acetaminophen, salicylates, lithium, digoxin, and theophylline. Arterial blood gas analysis is indicated early to assess adequacy of oxygenation and ventilation, along with the possibility of certain toxic–metabolic etiologies for altered mental status (e.g., elevated anion gap metabolic acidosis secondary to volatile alcohol ingestion). A Foley catheter should be inserted, if clinically indicated, and urinalysis performed for potential clues as to the substance ingested (e.g., calcium oxalate crystals in ethylene glycol poisoning). Indications for naso-orogastric tube placement and gastric lavage are discussed later in the chapter.

In the initial management of patients with altered mental status, readily correctable causes must be entertained, including hypoxemia, hypoglycemia, thiamine deficiency, and opiate overdose. Administration of 100% oxygen is indicated initially, along with intravenous hypertonic dextrose solution, thiamine, and naloxone (Table 34-1).[1] There have been reports of adverse effects of hyperglycemia on patients with ischemic brain injury.[2-6] However, these effects had no impact on long-term survival or functional ability, and so empiric dextrose continues to be recommended.[7] Although uncommon, the presence of focal neurologic findings does not rule out hypoglycemia as a potential etiology.[8] If bedside glucose monitoring is utilized to assess serum glucose values, it is imperative that such instruments undergo regular quality-control calibration to ensure accuracy. Case reports of anaphylaxis associated with large, rapid intravenous boluses of thiamine do exist, but the likelihood of this complication is exceedingly rare and can be avoided by careful, slow administration with simultaneous vital sign monitoring.[9] Some authorities recommend naloxone be reserved for patients with clinical or historical evidence of opiate toxicity, such as miosis, respiratory/neurologic depression, or fresh cutaneous track marks.[10] The presence of any of these findings does, in fact, identify the overwhelming majority of opiate-intoxicated patients, but the margin of safety and potential clinical benefit of the drug mandate its liberal use in patients with decreased mental status when narcotic overdose is clinically feasible.

The remainder of the physical examination should be completed after the preceding antidotes have been administered, ABCs and vital signs have been reassessed, and life-threatening conditions have been treated. Specific attention should be paid to evidence for head, neck, trunk, or extremity trauma; focal neurologic findings; abnormal pupillary responses; unusual breath or skin odors; cardiorespiratory abnormalities; and specific toxicologic syndromes (Table 34-2). In addition, historical details that might provide clues as to specific toxins ingested should be aggressively sought. Family members, friends, and witnesses should be questioned concerning past medical history, social history, prescribed medications, toxic substances accessible to the patient, empty pill bottles, suicide notes, and past toxic ingestions.

DECREASING GASTROINTESTINAL ABSORPTION

Despite the long-term utilization of various techniques designed to decrease the absorption of orally ingested toxins, no other "dogma" of medical toxicology has been more controversial or more extensively challenged. For example, the once routine use of syrup of ipecac to induce emesis and thereby decrease toxin absorption has been relegated to a minimally used decontamination modality.[11] Clinical trials of various decontamination strategies have served to rigorously evaluate which therapeutic modalities make a significant difference in outcome

TABLE 34-2

TOXIC SYNDROMES AND THEIR PHYSICAL FINDINGS

TOXIN	MENTAL STATUS	BP	P	RR	T	PUPIL SIZE	BOWEL SOUNDS	DIAPHORESIS

for the patient. This scientific effort has led to a more rational basis for the management of such patients. No longer are simplistic guidelines that apply one strategy to all situations appropriate. Each patient must be considered individually, and therapy must be tailored to the individual circumstances (e.g., patient age, weight, and specific ingestion, time of ingestion, and clinical signs and symptoms) for clinical outcome to be maximized.

Gastric Emptying

The natural inclination of most clinicians when presented with a patient who has ingested a toxin is to want to remove the substance from the GI tract before it is metabolized. While this seems intuitive, studies show that gastric decontamination rarely affects the outcome of the poisoned patients. The decision to proceed with gastric emptying must be guided by several principles and questions (Table 34-3).

First, the clinician must evaluate the risk of the ingestion to the patient. What compound was ingested? Is the compound potentially lethal? When was the compound ingested? How much was ingested? Gastric emptying is not indicated for the ingestion of nontoxic compounds or nontoxic amounts of some potentially toxic compounds. The all-too-common practice of gastric emptying just to "teach the patient a lesson" has absolutely no place in clinical management. Gastric emptying is indicated when potentially toxic co-ingestions cannot be ruled out or when compounds with extreme clinical risk (e.g., cyanide) have been ingested. Obviously, such clinical decision making requires a careful clinical history and physical examination.

Gastric emptying is indicated when co-ingestions cannot be excluded out or when ingestion of highly toxic substances has occurred, which could be life-threatening.

Second, the clinician must decide if gastric emptying will remove enough compound(s) to produce clinically favorable results. Most drugs, other than those that delay gastric emptying (e.g., anticholinergics and sedative-hypnotics) or form pyloric concretions (e.g., iron and enteric-coated aspirin), are unlikely to be recoverable 2–4 h post ingestion.

Most ingestions are not recoverable by gastric lavage after 1 h.

Third, has gastric emptying been studied for the given ingestion, and have clinical benefits to gastric emptying been demonstrated? Clinical benefit to gastric emptying is maximized when the ingested compound is potentially very toxic and emptying takes place within 1 h of ingestion.[12,13]

Fourth, will gastric emptying itself pose a significant clinical risk to the patient? Although gastric emptying techniques are generally safe and carry little risk of complication when performed appropriately, some patients may be unsuitable for the procedure. Potential risks of gastric emptying include esophageal tears, pharyngeal injury, tracheal placement of lavage tubes, pneumothorax, and pulmonary aspiration.[14]

Potential complications of gastric lavage include esophageal tears, pharyngeal injury, tracheal placement of lavage tubes, pneumothorax, and pulmonary aspiration.

Fifth, are there alternatives to gastric emptying that carry less risk and greater potential clinical benefit to the patient? For example, many authorities have stated that in the setting of minimal benefit from gastric emptying and great potential benefit from a specific antidote (e.g., the patient presents to the emergency department 6 h post ingestion of a toxic dose of acetaminophen), gastric emptying simply delays the administration of effective therapy.[14]

Orogastric Lavage and Emesis

During the past two decades, considerable research has investigated the use of orogastric lavage and syrup of ipecac in overdose patients. Such analysis has refined the clinical principles that guide the treatment of patients. Annual rates of gastric lavage declined from 3.5% of all exposures in 1994 to 0.6% in 2004.[15] The limited randomized trials that evaluate the

TABLE 34-3

FACTORS THAT INCREASE THE LIKELIHOOD THAT GASTRIC EMPTYING WILL IMPROVE OUTCOME

Ingested compound has high risk of toxicity (e.g., salicylates, theophylline, cyclic antidepressants)
Clinical evidence of toxicity
Lack of effective antidote
Recent ingestion (less than 1–2 h)
Ingested compound not adsorbed by activated charcoal (e.g., heavy metals)
Ingestion of sustained release compound
Ingested compound delays gastric emptying (e.g., anticholinergics)

utility of gastric lavage have failed to demonstrate improved outcomes when gastric lavage is added to activated charcoal in the management of undifferentiated symptomatic poisoning.[15,16] The position articles from the American Academy of Clinical Toxicology and the EAPCCT state that "gastric lavage should not be employed routinely, if ever, in the management of poisoned patients."[17,18] It is generally accepted that unless the ingestion has occurred within an hour of presentation, and was of a potentially life-threatening amount, lavage should not be considered.[15]

Consider inducing emesis when the pill size is larger than the lavage tube.

If the decision is made to proceed with lavage, tube size is one variable to consider in addition to the size of the pill or compound ingested. In children, small diameter lavage tubes may limit therapy. However, in such situations even a small diameter tube may be efficacious in removing ingested particles.

Probably the most frequent risk affecting the decision to employ a gastric emptying technique is the risk of pulmonary aspiration. Any patient unable to protect their airway during the process of gastric emptying must be intubated before gastric lavage, and emesis is contraindicated. A patient who has ingested a substance with the potential to cause seizures or rapid CNS deterioration during lavage should be intubated first; included is ingestion of compounds such as cyclic antidepressants, isoniazid, propoxyphene, camphor, and beta-blockers. In addition, ingestion of materials likely to obstruct the airway in the setting of emesis is a contraindication.

Emesis carries a risk of aspiration and compromise of the airway.

The role and clinical importance of oral activated charcoal in the setting of drug ingestion has greatly expanded in recent years. Ipecac-induced emesis is not instantaneous and is often followed by a protracted course of nausea and vomiting, thereby delaying administration of activated charcoal. Orogastric lavage generally is a safe and rapid technique of emptying the stomach and can be followed immediately by the administration of activated charcoal via the lavage tube.

Ipecac-induced emesis plays little role in the management of the poisoned patient in the hospital setting. No studies demonstrate improved outcomes with the use of ipecac in the treatment of acute poisoning, and it may result in complications and a prolonged ED course. Despite its traditional role in prehospital home decontamination, the American Academy of Pediatrics no longer recommends home stocking of ipecac, and the US FDA has considered removing ipecac from over-the-counter status.[19]

Activated Charcoal

Activated charcoal has long been recognized as an effective adsorbent of many compounds. Carbonaceous material is first pyrolyzed and then oxidized at high temperature. This increases its surface area and adsorptive capacity via a maze of internal pores. Recent data from limited trials suggests there is no benefit to the use of activated charcoal in symptomatic or asymptomatic patients, except perhaps, in an acetaminophen overdose presenting within 2 h of ingestion. Furthermore, there is a high prevalence of vomiting, which increases the risk of aspiration.[16]

Activated charcoal works best when used in a 10:1 ratio (activated charcoal to drug).

Efficacy depends in large part on the timing of administration and the rate of drug absorption. If it is to be used, early administration of activated charcoal is essential. Charcoal is rarely effective beyond 60 min post ingestion, except perhaps with some sustained-release products and acetaminophen.[16,20] In the undifferentiated poisoned patient seen hours after ingestion, charcoal is unnecessary and should not be given.[13] Adsorptive capacity of activated charcoal is limited by the ratio of activated charcoal to drug, and in vitro and in vivo studies suggest that a ratio of 10 to 1 (activated charcoal to drug) maximizes effect.[14]

Multiple-dose activated charcoal (every 2–6 h) can be used with large-quantity ingestions or extended-release medications.

Multiple-dose activated charcoal, typically given every 2–6 h, enhances the total body clearance of many drugs in experimental animal and human studies.[14] Not only does the charcoal adsorb drug on first-pass through the gastrointestinal tract, but it also may enhance adsorption beyond that of single-dose charcoal when very large quantities of drug are ingested, drug absorption is delayed or release is prolonged (e.g., enteric-coated or sustained-release products). Additionally, drug reabsorption via enterohepatic circulation may be prevented, or enteroenteric circulation enhanced. This latter benefit clarifies the utility of multiple-dose charcoal in enhancing the elimination of intravenously administered drugs,

Multiple doses of activated charcoal can be given for drugs that remain in enterohepatic circulation (i.e., aminophylline).

When ingestion amount is unknown, 25–100 g of charcoal should be given in adults.

such as aminophylline. There is insufficient evidence to recommend the use of multiple-dose activated charcoal unless a life-threatening amount of substance has been ingested, and no controlled studies conclusively demonstrate it impacts the clinical course.[21]

Initial oral dosing of activated charcoal should take into account both patient size and amount of drug ingested (if known). An activated charcoal to drug ratio of 10 to 1 is ideal. If the amount of drug ingested is not known, current recommended adult dosing is 25–100 g. There is no universal standard for subsequent oral doses of activated charcoal; recommendations vary from 0.25 to 0.5 g/kg every 1–6 h. In settings where activated charcoal is poorly tolerated, slow continuous infusion via nasogastric tube may prove helpful.

Cathartics

Over the years, cathartics have been recommended in the management of poisoned patients. In theory, cathartics have been thought to hasten the elimination of orally ingested compounds, thereby limiting systemic toxin absorption. In adding cathartics to the use of activated charcoal, it also has been theorized that charcoal-induced constipation is minimized and elimination of charcoal-bound drug is enhanced. Unfortunately, despite the widespread use of cathartics, little evidence substantiates their clinical efficacy. In fact, significant adverse effects can occur with aggressive use of cathartics, including dehydration, hypokalemia, metabolic alkalosis, hypermagnesemia, hypocalcemia, and hyperphosphatemia. For these reasons, cathartics should not be used routinely in the management of the poisoned patient. Evacuation of sustained-release or insoluble toxins not adsorbed to activated charcoal is better and more safely accomplished through the use of whole bowel irrigation.

Whole Bowel Irrigation

Whole bowel irrigation should be used instead of cathartics for sustained-release or insoluble toxins.

Do not use whole bowel irrigation instead of charcoal.

Polyethylene glycol or equivalent should be given at 0.5–2.0 L/h (dependant on body size), and continued until clear rectal effluent is observed.

Contraindications for whole bowel irrigation include ileus, gastrointestinal perforation, or gastrointestinal obstruction.

Rapid bowel evacuation, a minimum of fluid and electrolyte shifts, and reduction in bioavailability of ingested toxin are the goals of whole bowel irrigation. Initial trials involved solutions that unfortunately caused dramatic fluid and electrolyte shifts, making the technique unacceptable in the management of most overdose patients. With the development of polyethylene glycol and electrolytes solution (PEG-ELS), a nonabsorbable solution that causes minimal fluid and electrolyte shifts, renewed interest arose in the toxicologic concept of whole bowel irrigation. The current clinical role for whole bowel irrigation in the poisoned patient remains to be rigorously tested. However, its use has become more prevalent in patients who have ingested sustained-release drugs (e.g., theophylline and verapamil), drugs that are not adsorbed to activated charcoal (e.g., heavy metals and sustained-release lithium), and drug packets (e.g., cocaine body packers).[22] It should be emphasized that whole bowel irrigation should not preclude administration of activated charcoal in patients who have co-ingested substances that are well adsorbed by activated charcoal. The oral or nasogastric dose of PEG-ELS is 0.5 L/h in small children and 2 L/h in adults, for 4–6 h or until the rectal effluent is clear. Contraindications to the use of whole bowel irrigation include the presence of ileus, gastrointestinal perforation, or gastrointestinal obstruction.

ENHANCING TOXIN ELIMINATION

In theory, once clinical strategies have been initiated to inhibit systemic toxin absorption, strategies to enhance toxin elimination from the body are sensible. However, such techniques are indicated in a minority of patients. Enhanced elimination techniques should be considered when patients fail to respond to appropriate and full supportive care; when renal or hepatic functions are compromised and normally would represent the major route of toxin elimination; when serum toxin levels indicate the potential for serious morbidity or mortality; or when scientific research suggests that significant toxin elimination can be achieved. Table 34-4 lists the more commonly utilized methods of toxin elimination. The first four methods listed (forced diuresis, alteration of urinary pH, multiple-dose activated charcoal, and whole bowel irrigation) are techniques that can be instituted quite readily in the Emergency Department when

CASE STUDY: PART 2

Pending laboratory results, the patient became intermittently lethargic and agitated, at one point punching a nurse in the face. Attempts at orogastric tube placement and administration of activated charcoal were unsuccessful. Because of increasing lethargy, the patient was intubated and gastric lavage performed, followed by administration of activated charcoal.

Laboratory results were significant for sodium 149 mmol/L, potassium 4.6 mmol/L, chloride 108 mmol/L, bicarbonate 18 mmol/L, blood urea nitrogen 14 mg/dL, creatinine 1.4 mg/dL, glucose 43 mg/dL (pre-D_{50}), hemoglobin 18 g/dL, white blood cell count 25,500 K/μL with left shift, and no coagulopathy. Follow-up arterial blood gas on 100% oxygen revealed PaO_2 468 mmHg, $PaCO_2$ 60 mmHg, and pH 7.13.

Shortly thereafter, the patient became febrile to 106°F. Initial supraventricular tachycardia rapidly deteriorated into bradyasystole unresponsive to advanced cardiac life support protocol and cardiopulmonary resuscitation. An autopsy was obtained.

TABLE 34-4

METHODS USED TO ENHANCE TOXIN ELIMINATION

Forced diuresis	Hemofiltration
Alteration of urinary pH	Exchange transfusion
Multiple-dose activated charcoal	Plasmapheresis
Whole bowel irrigation	Toxin-specific antibody fragments
Peritoneal/hemodialysis	Chelation therapy
Charcoal hemoperfusion	

appropriate. The remaining methods fall under the purview of intensivists and consultants, in which case the emergency physician provides initial supportive care, coupled with prompt identification of toxin exposure potentially amenable to these methods of elimination.

THE ROLE OF TOXICOLOGIC DRUG SCREENING

A question infrequently asked before ordering a toxicologic drug screen is, "How will this information help in the clinical management of the patient once results are available?" In reality, most clinical decisions are made before drug screen results are viewed by the clinician. Toxicologic drug screens rarely determine the additional need for specific therapeutic modalities. Appropriate decontamination procedures and supportive care is the cornerstone of successful clinical management in most poisoned patients. Finally, toxicologic drug screens are costly, especially when plotted against clinical utility when ordered routinely. As such, toxicologic drug testing should be undertaken only when diagnostic uncertainty persists or knowledge from the testing will affect clinical management (Table 34-5). In general, urine is the preferred specimen for qualitative, comprehensive assessment; serum is preferred when quantitative drug assessment correlates with clinical effect and management decisions or when serial levels will assist clinical monitoring. Although not universally accepted, some authorities argue that routine serum testing for acetaminophen and salicylate should be undertaken in all patients suspected of intoxication. This strategy incorporates the facts that such testing is inexpensive and readily available, these compounds are found frequently in combination with other over-the-counter preparations, and perhaps most importantly that missed identification of these agents risks significant morbidity and mortality.

- Toxic drug screens should be obtained if the results will change management.
- *N*-acetylcysteine is used in acetaminophen overdose.
- The acetaminophen toxicity nomogram is only used in acute ingestion.
- History of ingestion of more than 150 mg/kg of acetaminophen should prompt administration of *N*-acetylcysteine.
- Patients with liver disease require less acetaminophen to become toxic.

TABLE 34-5

CLASSES OF COMPOUNDS INCLUDED IN MOST COMPREHENSIVE DRUG SCREENS[a]

Alcohols	Antidepressants	Opioids
Barbiturates	Antihistamines	Nonopioid analgesics
Benzodiazepines	CNS stimulants	Antiarrhythmics
Anticonvulsants	Neuroleptics	

[a]Specific compounds tested vary from laboratory to laboratory; when requesting a comprehensive or drug-specific screen, it is essential to know exactly which drugs your laboratory is capable of testing for.

CASE STUDY: PART 3

The autopsy revealed no evidence of trauma or chronic medical conditions. Initial drug screen subsequently returned positive for salicylates; no other drugs were found. Quantitative analysis revealed a salicylate level of 125 mg% (therapeutic, 15–30 mg%). Cause of death was determined to be acute salicylate intoxication.

SPECIFIC ANTIDOTES FOR SPECIFIC TOXINS

Most poisoned patients benefit not from a specific antidote but rather from sound clinical management based upon general principles of poison management. However, in very specific settings where the toxin ingested is amenable to antidote therapy, the timely and knowledgeable use of a specific antidote may be lifesaving. Thus, a working knowledge of a select group of antidotes is an important part of the medical armamentarium for the emergency and critical care practitioner.

A list of commonly utilized antidotes follows. For each antidote, we discuss the toxin that it counteracts, its mechanism of action, clinical indications, dosing information, contraindications to use, and potential complications of treatment.

N-Acetylcysteine

Toxin

Acetaminophen.

Mechanism of Action

In acetaminophen ingestion, approximately 60% of the drug is metabolized to acetaminophen glucuronide and 30% to acetaminophen sulfate, both of which are nontoxic metabolites eliminated in the urine. Less than 5% of the drug is eliminated unchanged in the urine and is thought to be nontoxic. Between 5 and 15% of the drug is oxidized by the P-450 system to *N*-acetyl-*p*-benzoquinoneimine (NAPQI). In the presence of adequate stores of glutathione, NAPQI is complexed with glutathione and converted to nontoxic cysteine and mercaptate conjugates. In acetaminophen overdose, glutathione stores are depleted and free NAPQI binds to hepatic cellular proteins, with resultant cell death and hepatic necrosis. *N*-acetylcysteine (NAC) serves primarily as a glutathione precursor, thereby maintaining or replenishing stores of glutathione and allowing continued detoxification of NAPQI. NAC can serve as a substitute for glutathione, can increase sulfation of acetaminophen to nontoxic metabolites, and may limit the extent of hepatotoxicity.

Clinical Indications

History of acute acetaminophen ingestion greater than 150 mg/kg suggests a potentially toxic exposure, as does an acetaminophen level that falls on or above the toxicity line of the acetaminophen toxicity nomogram. NAC is most effective if given within 8 h of ingestion.[23] Chronic ingestion and ingestion of sustained-release products are more problematic, and the nomogram cannot be used in these settings. Hepatotoxicity is a concern in healthy adults ingesting more than 7 g/day (4 g/day in adults with chronic ETOH abuse or liver disease), or children ingesting more than 75 mg/kg/day. In such circumstances, signs or symptoms of hepatotoxicity, elevated hepatic enzymes, or acetaminophen levels greater than 10 µg/mL 4 h after the last dose should prompt NAC therapy.

Dosing Information

Intravenous NAC was FDA approved in 2004. To date, there is no evidence that either route is more effective than the other, and the mode of delivery should be tailored to the specific patient. Traditional oral dosing involves a loading dose of 140 mg/kg, administered by mouth or nasogastric tube, followed by a maintenance regimen of 70 mg/kg to be given every 4 h thereafter for an additional 17 doses. Current research is aimed at investigating shortened courses of treatment in certain lower-risk populations.[24-26] These studies suggest early discontinuation may be considered after a minimum of 20 h of treatment, when no further acetaminophen is detectable in the serum, and hepatic transaminases and PT times are normal.[27]

IV dosing calls for a loading dose of 140 mg/kg over 15 min, followed by a 50-mg/kg infusion over 4 h, concluding with a 16-h infusion of 100 mg/kg. If NAC is initiated beyond 8–10 h post ingestion, the infusion should continue beyond 20 h, and be discontinued when lab tests normalize.[27]

Loading dose of *N*-acetylcysteine is 140 mg/kg followed by 70 mg/kg given every 4 h for 17 doses.

Contraindications

No specific contraindications exist to the use of NAC in acetaminophen toxicity. Teratogenic data for NAC are not available, but the risk of not treating a potentially fatal overdose far exceeds the fetal risk of treatment.

Potential Complications

Oral NAC is quite foul tasting and may induce vomiting. NAC is rapidly absorbed but should be re-administered if vomited within 1 h of ingestion. Anaphylactoid reactions have not been reported with the use of oral NAC, but can be seen with the use of IV NAC. These reactions may occur as a dose-and rate-related effect, are generally minor (pruritis, vomiting), and usually respond to antihistamines and a slowing of the infusion rate.[28,29] Major adverse reactions and death are exceedingly rare and are most commonly related to rapid IV loading in patients with underlying airway disease or with dosing errors.[30,31]

Antivenin: Snakes

Toxin

Venom from rattlesnakes, water moccasins, copperheads, coral snakes, and some South American pit vipers and Asian snakes.

Mechanism of Action

Crotalidae Polyvalent Immune Fab (FabAV, Crofab), released in 2001, is the only currently manufactured snake antivenin in the US. It is a polyvalent IgG antibody created after ovine exposure to the cottonmouth, eastern and western diamondback, and Mojave rattlesnake, with cross-reactivity with other pit viper venom. Unlike the traditional crotalid and elapid antivenins, FabAV is manufactured by eliminating the Fc portion of the IgG molecule, creating a less immunogenic product. The antivenin acts by coating the offending antigen with IgG antibody. The systemic effects of the venom are thereby neutralized or blunted by this immunologic therapy. The lifesaving effectiveness of these antivenins has been proven in animal models, but the specific effect on human morbidity and mortality is unknown.

Clinical Indications

The ovine-derived serum is an impure solution containing not only venom-specific IgG but also other serum proteins that could induce allergic responses. The new Fab antivenin is less

Use antivenin to treat any local or systemic signs of envenomation.

immunogenic than others, but still can precipitate anaphylactoid reactions, serum sickness, and immediate or delayed hypersensitivity responses. The use of antivenin should be based upon symptomatology and snake type. Approximately 20% of snake bites are dry bites[32]; cottonmouth and copperhead bites are universally survived; and deaths from rattlesnake bites are rare.[33] Prophylactic administration is usually discouraged. Most snakebites cause pain and swelling over an area up to 6 in. in diameter. Symptoms warranting consideration of antivenin usage include tissue necrosis, anaphylaxis or shock, bleeding or coagulopathy, weakness, paralysis or paresthesias, dizziness, sweating, nausea, vomiting, hypothermia, or tachypnea.[27] Skin testing before administration of antivenin is not indicated for FabAV and no longer recommended before equine-derived IgG antivenins because the test is inaccurate and potentially dangerous.[34]

Skin testing before antivenin administration is not indicated.

Dosing Information

FabAV is indicated to treat any local or systemic signs of envenomation, including pain, swelling, fasciculation, paraesthesias, or hematologic abnormalities.[27] Initial dosing requirement is 4–8 vials depending on symptom severity. Each vial is reconstituted in 10 mL sterile water, then further diluted in 50 mL 0.9% normal saline, and administered within 4 h. The initial infusion of the antivenin solution should be 25–50 mL/h. The infusion rate may be increased to a rate of 250 mL/h if no allergic reactions are noted. Additional doses may be needed if symptoms persist or recur. The manufacturer recommends repeated 2-vial dosing every 6 h for three additional doses, but the added benefit is not well studied.[27]

Contraindications

Antivenin skin testing and prophylactic antivenin use should be discouraged, except in the case of a documented Mojave rattlesnake bite because the systemic effects may not be preceded by local symptoms. FabAV has not been studied with regard to bites from Mexican, Central American, or South American species. For bites from these, or other exotic snakes, other, less readily available antivenins may be indicated. In these circumstances, contact the Arizona Poison and Drug information Center, the American Zoo and Aquarium Association, or the American Association of Poison Control Centers.

Potential Complications

Use of the Fab-fragment antivenin has dramatically reduced the rate of adverse reactions, from 23 to 56% with older equine-derived IgG antivenins, to 14.3% with FabAV.[35] Similarly, the rate of serum sickness has dropped from 50% to 3–16%.[36,37]

Antivenin: Scorpion and Spider

Toxin

Venom from scorpion stings and spider bites. The only clinically important indigenous species of scorpion located in the United States are the *Centruroides* species of the southwestern desert. The most troublesome arachnoid venom comes from the black widow spider.

Mechanism of Action

As with snake antivenin, the antivenins for scorpion stings and arachnoid bites are produced by immunizing animals to the toxin and harvesting an IgG antibody, which can be intravenously administered to victims. The serum decreases symptomatology and aids in the treatment of patients who cannot be quickly transported to an appropriate healthcare facility. This scenario usually applies to small children geographically distant from an institution equipped for pediatric critical care. Antivenin to the *Centruroides* scorpion species is available through the Antivenin Production Laboratory at Arizona State University, Tempe (APL-ASU) and is

distributed throughout Arizona despite lack of FDA approval. Its use is restricted to the state of Arizona, and transport across state lines is prohibited. The use of antivenin to black widow spider bites is usually not necessary and is again limited to patients who are symptomatic or have the potential for systemic complications.

Clinical Indications

Bites from the *Centruroides* scorpion species and the black widow spider warrant consideration of antivenin if systemic symptoms are present.

These antivenins should only be used in patients who develop serious systemic symptoms. Proper usage of the antivenins requires a working knowledge of the venoms and their clinical expressions. The venom from *Centruroides* scorpion species is predominantly a neurotoxin, but other proteins in the inoculum can cause hemolysis, local tissue destruction, or hemorrhage. The sting causes local pain, numbness, swelling, and possibly tactile hyperesthesia. It should be noted that the local symptoms seen after a scorpion sting do not correlate well with systemic toxicity. Systemic symptoms may include anxiety, restlessness, muscle spasms, nausea, vomiting, excessive salivation, sweating, pruritis, hyperthermia, blurred vision, pseudoseizures, hypertension, hemiplegia, syncope, cardiac dysrhythmias, or respiratory arrest. As with most intoxications, children and the elderly are at a greater risk of severe reactions.

The black widow spider has venom composed of both protein and nonprotein compounds that paralyze prey and liquefy tissues for subsequent ingestion by the arachnid. The paralyzing protein in the spider's venom produces its toxic effect by destabilizing neuronal membranes and causing depletion of acetylcholine from presynapic nerve terminals. Usually, the patient initially notes a pinprick sensation followed by local swelling and erythema. The clinician may notice two small fang marks in the area of redness. A dull crampy pain, usually perceived at the bite site, spreads to a generalized cramping that predominates in the abdomen. Other symptoms may include dizziness, restlessness, ptosis, nausea, vomiting, headache, pruritis, dyspnea, conjunctivitis, profuse sweating, weakness, dysarthria, anxiety, and cramping pain in all muscle groups. The patient is usually hypertensive, and cerebrospinal fluid pressure may be elevated. There may be electrocardiographic changes similar to those produced by digitalis. The symptoms are usually more severe in children or small adults because the inoculum to volume of distribution is greater.

Dosing Information

Increasing infusion rate and cumulative dose of antivenin positively correlate with the likelihood of developing serum sickness.

Scorpion antivenin is shipped from APL-ASU to the hospital as fresh immune serum. The 5-mL vials are usually instilled over 15–30 min. Black widow antivenin is dispensed in 2.5-mL vials and should be diluted in 50 mL of saline for intravenous use. The infusion rate and the cumulative dose administered correlate directly with the likelihood of developing toxic side effects. In other words, an increase in dose amount and a faster infusion rate are associated with more adverse side effects.

Contraindications

There are no absolute contraindications to usage of antivenin to scorpions or black widow spiders. Any administration of these products should be preceded by serious consideration of the benefit-to-risk ratio, and toxicologic consultation is advisable to those unfamiliar with their administration.

Potential Complications

Since these antivenins are also animal-derived IgG preparations, the same potential complications associated with classic snake antivenins exist, including anaphylactic reactions and serum sickness. However, the amounts administered for scorpion and spider envenomations are much less, and carry proportionally lower risk. There is little interest in producing a Fab-fragment antivenin for these bites due to limited profitability.

Calcium

Toxin

Calcium channel blockers, fluoride, ethylene glycol, magnesium, and potassium.

Mechanism of Action

Normal calcium balance is needed for proper muscle and nerve function. The aforementioned toxins create an absolute or relative imbalance of calcium in different ways. Calcium channel blockers create a relative intracellular hypocalcemia. Infusing calcium can attenuate over blockade of calcium channels in a calcium channel overdose. Calcium infusion increases its extracellular concentration, thereby augmenting its transcellular gradient and facilitating its movement intracellularly. In fluoride and ethylene glycol overdoses, calcium complexes with the toxin to create a salt. Eventually, an absolute hypocalcemia ensues, and a calcium infusion is needed to maintain and restore homeostatic levels. High serum levels of potassium or magnesium can destabilize cardiac membrane potentials with resultant arrhythmias. The added positively charged ions outside the cell membranes create a less negative and more excitable membrane potential. Calcium infusion counteracts this destabilization of membrane potentials by providing extra intracellular cations that drive the membrane potential in a negative direction toward a more secure resting potential.

Obtain serial serum calcium levels in ethylene glycol or fluoride ingestions.

Clinical Indications

Calcium infusion during calcium channel overdose is indicated for bradycardia, any atrioventricular blockade, altered mental status, or idioventricular rhythm. Calcium infusion can also be given if hypotension ensues, but its clinical efficacy in this situation is unproven.[38] In the presence of hypocalcemia, calcium infusion can aid in the effectiveness of atropine administration. Intravenous calcium salts should also be administered with symptomatic hypocalcemia as a result of ethylene glycol or fluoride intoxication. The clinical manifestations of hypocalcemia include perioral paresthesias, tingling of the fingers and toes, seizures, laryngeal spasm, and spontaneous or latent tetany. Other manifestations of hypocalcemia include Chvostek's sign, Trousseau's sign, prolongation of the Q-T interval, and changes in the QRS complex and ST segments that may mimic alterations seen in an acute myocardial infarction. Hypermagnesemia and hyperkalemia should be treated with calcium infusion if any signs of cardiac arrhythmias are noted.

After a calcium channel blocker overdose, calcium infusion should be started for bradycardia, atrioventricular blockade, altered mental status, or idioventricular rhythm.

Consider calcium infusion in patients with hypermagnesemia or hyperkalemia and any cardiac conduction disturbance.

Dosing Information

The optimal dose of calcium in calcium channel overdose is unknown.[38] A reasonable approach is to give a 0.6-mL/kg bolus of 10% calcium gluconate (0.2 mL/kg 10% calcium chloride) over 5–10 min. After the bolus, initiate a continuous calcium gluconate infusion at 0.6–1.5 mL/kg/h (0.2–0.5 mL/kg/h 10% calcium chloride).[39] Infusion should be titrated to affect. Monitoring patients for iatrogenic hypercalcemia is prudent in those without life-threatening complications, and levels should probably not exceed twice-normal.[38] The acutely administered cumulative dose should not exceed 45 mEq because of the dangerous possibility of hypercalcemia. Skin exposure to hydrogen fluoride in concentrations greater than 20% usually requires an intradermal injection of 10% calcium gluconate. Exposures to hydrofluoride with a concentration less than 20% respond to coverage with calcium carbonate tablets mixed with a water-soluble jelly. In fluoride burns of the digits, an intraarterial calcium infusion can be attempted. Intravenous calcium, in the form of calcium chloride or calcium gluconate, should be given in doses sufficient to reverse EKG abnormalities (QT or QRS prolongation) associated with ethylene glycol overdose, hypermagnesemia, or hyperkalemia. Intravenous calcium should not exceed a rate of 1.8 mEq/min unless the patient is in a life-threatening situation.

Contraindications

The development of hypercalcemic toxicity. If digitalis toxicity exists, or the patient is currently taking digoxin, extreme caution should be taken. In cases of concomitant hyperphosphatemia, the serum calcium times phosphate product should not exceed 66 mg/dL.

Potential Complications

Hypercalcemia. Symptoms include nausea, vomiting, constipation, hypertension, shortening of the Q-T interval, polyuria, altered mental status, hyporeflexia, and coma.

Cyanide Antidotes

Toxin

Cyanide.

Lilly Cyanide Kit

Mechanism of Action

A cyanide kit contains all the antidotes needed in a cyanide overdose.

Cyanide has a high affinity for the ferric ion. The binding of cyanide to the ferric ion disrupts intracellular aerobic metabolism by removing it from the cytochrome oxidase complex; this results in hypoxemia. The most commonly used antidote in the United States, the Lilly Cyanide Kit, contains amyl nitrate pearls, 3% sodium nitrite, and 25% sodium thiosulfate. The exact mechanism by which nitrites work is not known, but the use of cyanide induces methemoglobinemia. Methemoglobin converts to cyanomethemoglobin under normal physiologic conditions. Cyanomethemoglobin then reacts with thiosulfate and the enzyme rhodenase to form thiocyanate, which is excreted in the urine.

Clinical Indications

In cases of moderate to severe overdose associated with clinical deterioration not amenable to supportive care.

Dosing Information

Ideally, a methemoglobin level of 30% should be attained before giving thiosulfate.

Amyl nitrite pearls should be broken into a gauze sponge and placed so the patient can inhale the fumes for at least 30 s of each minute if sodium nitrite solution is not immediately available. Three percent sodium nitrite solution can be diluted in approximately 100 mL solute and infused intravenously over 2–4 min. The goal is to produce a methemoglobin level close to 30%. Subsequently, 50 mL of 25% thiosulfate solution can be given intravenously. Follow methemoglobin levels and re-dose if symptoms reappear within 1 h of initial dosing. If symptoms reappear, the aforementioned procedure should be reinstituted with pharmacologic doses at 50% of the original amount.

Contraindications

Caution should be used in patients with cardiovascular disease.

Potential Complications

Nitrites may worsen hypoxemia in patients with concomitant elevated carboxyhemoglobin levels. Thiocyanate can cause nausea, vomiting, arthralgias, muscle cramps, and psychosis.

Multiple-wavelength co-oximeters measure light absorption of blood at numerous ultraviolet wavelengths; the percentage of methemoglobin will be listed on the arterial blood gas report.

Nitrites can produce hypotension and methemoglobinemia. Methemoglobin levels greater than 30% can produce symptomatic cyanosis, whereas levels greater than 70% can be lethal.[40]

Hydroxocobalmin

Recently, Hydroxocobalmin (Cyanokit) was FDA-approved for the treatment of CN poisoning. Hydroxocobalmin is a natural form of vitamin B12 that detoxifies CN through the irreversible formation of cyanocobalamin, which is subsequently excreted in the urine. Unlike the nitrite kit, hydroxocobalmin is well tolerated, has minimal side effects, and can be safely used in the prehospital setting in patients with smoke inhalation and suspected CN poisoning.[41] Recommended dosing is 5 g diluted in 100 mL of 0.9% NS infused over 15 min.

Deferoxamine

Toxin

Iron, aluminum.

Mechanism of Action

Deferoxamine binds aluminum and iron.

Deferoxamine has a high binding affinity for iron and aluminum and therefore it complexes with the metals. The deferoxamine complex is then excreted from the body.

Clinical Indication

All symptomatic patients with a serum iron level greater than 500 μg/dL should receive deferoxamine.[42] Symptoms include lethargy, significant abdominal pain, hypovolemia, acidosis, having more than one episode of emesis or multiple soft stools.[43] Intravenous deferoxamine therapy should be given to all these aforementioned presentations. Patients with mild toxicity can receive intramuscular injections. Deferoxamine can also be used to treat aluminum-associated dialysis encephalopathy and osteomalacia.

Dosing Information

Initial intravenous infusion rates have been recommended at 15 mg/kg/h, and may be increased to 35 mg/kg/h; duration of therapy should not exceed 24 h because of the risk of pulmonary toxicity. Two grams of deferoxamine can be given during the last half hour of dialysis to aid in aluminum detoxification.[43,44]

Contraindications

Deferoxamine should not be given to patients with anuria or end-stage renal disease.

Severe renal disease or anuria in patients not receiving dialysis, because most of the chelate is excreted in the urine.

Potential Complications

Hypotension, pulmonary toxicity (ARDS), ocular and ototoxicity, and infection.

Digoxin-Specific Antibody Fragments

Toxin

Digoxin, digitoxin, oleander, squill toad venom.

Mechanism of Action

Digoxin-immune antigen-binding fragment (Fab) (digibind) is composed of specific anti-digoxin sheep-derived antibodies. Digibind is administered intravenously and binds free

digoxin intravascularly and in the interstitial space. The Fab–digoxin complex is predominantly removed from the body via the kidneys. Digibind's half-life is approximately 15 h, and clinical improvement is seen within 30 min of administration. It is unclear what effect renal impairment has on Fab–digoxin removal.

Digibind half-life is 15–20 h in patients with normal renal function.

Clinical Indications

The indications for using digoxin-specific antibody fragments are predicated upon the signs and symptoms of digoxin toxicity. Digoxin serum levels may not correlate well with impending life-threatening toxicity because the drug concentrates in tissues before equilibrating in the serum. The time of distribution of digoxin is approximately 6–8 h. Serum concentrations of digoxin greater than 15 ng/mL usually require digoxin-specific antibody fragments regardless of clinical signs of toxicity. Signs of digoxin toxicity include first-, second-, or third-degree heart block as well as ventricular tachycardia and fibrillation. Other indications for digibind usage include patients with known digoxin ingestions greater than 10 mg or an elevated potassium level greater than 5.0.

Dosing Information

Each vial of digibind contains 38 mg of digoxin-specific Fab fragments, which can bind approximately 0.5 mg of digoxin or digitoxin. The dose of digibind given to neutralize digoxin is based on either the amount ingested, if a reliable history is given or the serum concentration, if the serum level was drawn at least 4 h after the ingestion. An accurate history allows the clinician to calculate the needed digibind dose. The amount of digoxin ingested is multiplied by 0.8, which is the bioavailability of the drug. Doubling this product generates the number of digibind vials needed. If basing digibind dosing on serum levels of digoxin, the clinician multiplies the serum concentration of digoxin by the patient's weight in kilograms and divides that product by 100 to calculate the dose.

If neither an accurate history nor a serum level is available, the recommended empiric dose is 10 vials over 30 min for acute intoxications, or 4–6 vials for chronic ingestions.[38] Signs of reversal should be seen within 30 min. If toxicity persists, an additional dose of digibind should be administered. Digibind is primarily excreted in the urine, and its half-life appears to be 15–20 h in patients with normal renal function. The half-life of digoxin is 1.5–2 days; therefore, a rebound in serum digoxin levels can occur 12 h after digibind administration. Readministration of digibind should be based on signs of digoxin toxicity. It should be noted that digoxin serum levels, drawn after administration of digibind, may not be accurate or clinically relevant. Most laboratories are not equipped to measure free digoxin levels and therefore report the total amount, which includes both free and digibind-bound digoxin.

Re-dosing of digibind should be considered if signs of digoxin toxicity have not reversed within 30 min.

Serum levels of digoxin are probably inaccurate after the initial dosing of digibind.

Contraindications

There are no contraindications for digoxin-specific antibody fragments.

Potential Complications

Serum potassium levels must be closely monitored when digibind is administered. Digoxin acts on the Na-K-ATPase pump, which increases intracellular levels of Ca^{2+} and Na^{+}, and extracellular levels of K^{+}. Hyperkalemia is the usual electrolyte abnormality precipitated by acute digoxin toxicity; however, increased serum potassium may not accurately assess total body potassium due to the higher than normal proportion of extracellular potassium. The high serum potassium eventually leads to an increase in renal clearance, which could result in lowering of total potassium body stores. The administration of digibind, and a re-shifting of potassium intracellularly, could then result in the development of hypokalemia and its associated complications. Digibind may also exacerbate congestive heart failure.[38]

Hyperkalemia is the usual electrolyte abnormality precipitated by acute digoxin toxicity.

Hypokalemia can occur after digibind dosing.

Ethanol and Fomepizole

Toxin

Methanol, ethylene glycol.

Mechanism of Action

Both ethanol and fomepizole competitively inhibit methanol and ethylene glycol conversion to toxic metabolites by antagonism of the enzyme alcohol dehydrogenase. Fomepizole has an affinity 500× that of ethanol and 5,000–10,000× that of methanol or ethylene glycol. Inhibiting conversion of ethylene glycol and methanol allows passage of the unchanged substrate into the urine.

Clinical Indications

Ethylene glycol is found in antifreeze.

Ethanol or fomepizole should be administered immediately if the patient history suggests ingestion of either methanol or ethylene glycol. Ethanol administered in doses sufficient to produce intoxication has served as standard treatment for both toxin ingestions; prospective evaluation of this therapy is not available. Treatment is based upon an understanding of the mechanism of drug toxicity and the competitive antagonism of alcohol dehydrogenase by ethanol, in addition to anecdotal and case report experience(s). Ethanol therapy requires frequent blood concentration monitoring and dose adjustment, and is fraught with potential complications such as hepatotoxicity, pancreatitis, hypoglycemia, and aspiration. Fomepizole also acts by inhibiting alcohol dehydrogenase but has none of the above adverse effects. Small clinical studies in patients with methanol or ethylene glycol poisoning have found fomepizole to be safe and effective.[45,46] Studies comparing ethanol to fomepizole in the treatment of methanol and ethylene glycol poisoning are not available.

Methanol can be found in de-icing solutions, shellac, and paint thinners.

Ethylene glycol is most commonly found in antifreeze, whereas methanol can be found in de-icing solutions, windshield washing fluid, carburetor cleaners, shellac, and paint removers or paint thinners. An inebriated patient with a normal ethanol level should also raise suspicion of methanol or ethylene glycol intoxication and should result in treatment. Other situations suggesting methanol or ethylene glycol overdose include an unexplained metabolic acidosis or a high anion gap. Note that a normal anion gap does not rule out ethylene glycol or methanol overdose because it is the metabolites of these substances that induce the acidosis. In other words, the time between the exposure and measurement of arterial pH and serum electrolytes may be insufficient to produce a high anion gap acidosis. With this in mind, it should also be noted that despite treatment with an ADH-inhibitor, dialysis may be needed for clearance of metabolites already formed. Ethylene glycol or methanol overdose will cause an elevated osmolar gap. Serum levels of the toxins may also be used to help guide therapy. Any serum level of methanol or ethylene glycol above a trivial amount should result in ethanol or fomepizole administration.[45,47] Serum levels of methanol or ethylene glycol greater than 25–50 mg/dL are indications for the use of either antidote in addition to immediate dialysis.[48,49]

A normal anion gap does not rule out ethylene glycol or methanol overdose.

Serum levels of ethylene glycol or methanol >25 mg/dL require dialysis.

Dosing Information

Ethanol can be given in oral or intravenous form. Oral ethanol delivery is preferred, but patient noncompliance or incapacity to safely ingest the alcohol often results in the need to administer the treatment intravenously. Obtaining a blood ethanol level of 100–150 mg/dL provides sufficient competitive blockade of alcohol dehydrogenase to allow methanol and ethylene glycol to pass in the urine relatively unchanged.[50]A loading dose of 0.6–0.7 g/kg IV given in 10% ethanol solution usually results in a rapid attainment of appropriate serum ethanol levels. A pretreatment serum ethanol level greater than 100 mg/dL obviates the need for a loading dose.[51] An IV maintenance dose of 66 mg/kg/h of ethanol in the nondrinker (154 mg/kg/h for chronic drinkers) should keep serum levels at an acceptable range. Differences in the metabolism of ethanol necessitate periodic monitoring of serum levels.

Because of increased ethanol clearance, patients undergoing hemodialysis require a maintenance dose of 250–350 mg/kg/h to maintain appropriate serum ethanol levels.[51]

Fomepizole is given via a loading dose of 15 mg/kg, followed by 10 mg/kg every 12 h for four doses, then increases to 15 mg/kg every 12 h until the ethylene glycol or methanol level is undetectable or the patient is asymptomatic with a normal arterial pH. In patients with a significant metabolic acidosis, renal clearance of toxins is improved by adding bicarbonate. In addition, thiamine and pyridoxine should be given to patients with ethylene glycol ingestion and folic acid should be given to those with methanol ingestion.

Contraindications

There are no absolute contraindications to ethanol or fomepizole usage in severe ethylene glycol or methanol overdose.

Potential Complications

The administration of ethanol could cause worsening CNS depression, hypoglycemia, pancreatitis, and dehydration. Patients receiving ethanol orally have the added risk of aspiration and therefore require close monitoring in an ICU setting. Intravenous infusion of ethanol can cause venous irritation at the infusion site; consequently, it should be diluted with solute to at least a 10% solution. A 5–10% ethanol solution is hyperosmolar and can cause undesirable fluid shifts in a patient.[45,47] Fomepizole has a more favorable side effect profile, predictable pharmacokinetics that allow for a less complicated dosing regimen, does not require frequent blood sample monitoring, and does not cause CNS depression. It is significantly more costly.[52]

Flumazenil

Toxin

Benzodiazepine.

Mechanism of Action

Flumazenil competitively inhibits the effects of benzodiazepines at the benzodiazepine binding site on the $GABA_A$ receptor.

Clinical Indication

There are no absolute indications for the use of flumazenil. It can be used to reverse oversedation created by benzodiazepines. Its use in benzodiazepine overdose has not been shown to consistently alter outcome or hospital length of stay.[53]

Dosing Information

Flumazenil can usually be given safely at a rate of 0.1 mg/min and the total dose rarely needs to exceed 2–3 mg. The onset of action occurs within a few minutes and the duration of action is approximately 1 h. The patient should be closely observed as the half-life of flumazenil is considerably shorter than that of the long-acting benzodiazepines and subsequent doses may be required.

Contraindications

Flumazenil can induce seizures in patients who have a history of seizures, those who are currently being treated for seizures with benzodiazepines, and in patients using tricyclic antidepressants.[54] Caution should also be used in giving flumazenil to patients with any long-term usage or dependency on benzodiazepines.[55]

Flumazenil use can cause seizures in patients taking TCAs.

Potential Complications

Flumazenil can potentially cause seizures in patients with a known seizure disorder. The possibility of cardiac arrhythmias also exists.[56] Reversal of the benzodiazepine effect may result in confusion, restlessness, and agitation. Since benzodiazepine overdose usually requires only supportive care, the potential risks associated with flumazenil administration should be considered. It is most useful in highly selected cases, such as small children with accidental poisoning.[55]

Naloxone

Toxin

Opioid intoxication.

Mechanism of Action

Naloxone is a narcotic antagonist that competitively binds opiate receptor sites.

Clinical Indications

Opiate overdose resulting in clinically significant respiratory depression, hypotension, or potential loss of airway protection by the patient.

Dosing Information

The usual initial dose of naloxone is 0.2 mg in a nonopioid-dependent patient. The first dose can be as high as 2 mg if the opioid overdose is known to be substantial. The starting dose for opioid-dependent patients should probably be 0.1 mg because higher doses can potentially induce withdrawal. Naloxone can be given intravenously, intramuscularly, or subcutaneously. Oral administration is not effective because of substantial first-pass metabolism by the liver. The onset of action occurs within 2 min of administration when given intravenously. The onset of action via intramuscular or subcutaneous injection is only slightly longer in a patient with a normal integument and muscle mass. The half-life after parenteral administration is 30–81 min. Repeated dosing or continuous infusion may be needed if the half-life of the narcotic is substantially longer than that of naloxone. The maintenance dose of naloxone is two-thirds of the initial effective dose, which should be given on an hourly basis. This may be administered as hourly scheduled injections of naloxone or by diluting naloxone in saline and infusing continuously.

Contraindications

Known hypersensitivity to naloxone.

Potential Complications

Caution should be used when administering naloxone to long-term users of narcotics because of the possibility of inducing withdraw symptoms. Patients may awaken confused, disoriented, or angry. Naloxone has also been associated with hypertension, cardiac arrhythmias, pulmonary edema, and seizures.[57]

Naloxone can be given IV, IM, or SC.

Initial dosing of naloxone is 0.2–2 mg.

Initial dosing of physostigmine is 1–2 mg.

The half-life of physostigmine is approximately 18 min.

Physostigmine

Toxin

Anticholinergics, including atropine, and phenothiazines.

Mechanism of Action

Physostigmine reversibly inhibits central and peripheral cholinesterases, resulting in higher acetylcholine concentrations at the postsynaptic nerve terminal.

Clinical Indications

Physostigmine is used to reverse the life-threatening clinical effects of an anticholinergic overdose. Symptoms of anticholinergic toxicity include lack of salivation and perspiration, mydriasis, confusion, hallucinations, restlessness, and tachycardia. Other sequelae of anticholinergic overdose include coma, severe hypertension, or seizures.

Dosing Information

Physostigmine can be administered intravenously or intramuscularly. The dose to reverse a cholinergic intoxication is 1–2 mg. Physostigmine should be given over several minutes under close monitoring. The onset of action is within minutes and the half-life is approximately 18 min, but pharmacokinetics vary widely between patients. Repeat dosing of physostigmine may be necessary if the half-life of physostigmine is shorter than that of the ingested anticholinergic.

Contraindications

Physostigmine is contraindicated in patients with asthma, diabetes, cardiovascular disease, obstruction of urinary or gastrointestinal tract, and those receiving a depolarizing neuromuscular blocking agent. Overdose or too rapid administration of physostigmine can cause hypotension, bradycardia, hypersalivation, seizures, nausea, vomiting, defecation, and urination. Asystole has been reported in patients with tricyclic overdose, so patients with a QRS >0.10 s or suspected of TCA ingestion should not be given physostigmine.[58-60]

Potential Complications

Physostigmine augments acetylcholine levels and therefore can increase vagal tone, cause hypersalivation, diarrhea, bradycardia, and seizure. The possibility of physostigmine overdose and its potential for lethal effects creates a high cost-to-benefit profile and should caution its use.

Physostigmine should be given with extreme caution.

Sodium Bicarbonate

Toxin

Tricyclic antidepressant, salicylates, rhabdomyolysis, ethylene, and methanol intoxication.

Method of Action

Sodium bicarbonate may decrease the affinity of tricyclic binding to the cardiac myocyte sodium ion channels, ultimately resulting in less dangerous cardiac arrhythmias. Salicylate toxicity is altered by alkalinization with sodium bicarbonate by shifting a larger proportion of the salicylate into the ionized form and thereby lessening its ability to cross the blood–brain barrier and cause neurotoxicity. Alkalinization also helps increase renal excretion of salicylates. Myoglobin dissociates into globin and ferrihemate, which is toxic to renal tubules at a urine pH below 5.6. Preventing a urinary pH below 5.6 permits the safe passage of myogloblin into the urine without significant release of the toxic ferrihemate.[61] Sodium bicarbonate administration in methanol intoxication may decrease ocular toxicity by changing the distribution of the offending metabolite, formic acid.[62] Animals poisoned with ethylene glycol showed a fourfold increase in the lethal dose by using sodium bicarbonate alone.[63]

Bicarbonate should be considered in cyclic antidepressant overdose with a QRS complex >0.10 s in duration.

Salicylate overdose patients showing neurologic toxicity should receive a bicarbonate infusion.

Clinical Indications

Some authors advocate starting bicarbonate in tricyclic overdoses when the QRS complex duration is greater than 0.10 s.[64] Sodium bicarbonate should be given as soon as patients show signs of systemic toxicity during salicylate overdoses and when the urinary pH falls below 6.0 in a patient with rhabdomyolysis. Sodium bicarbonate should be administered to an ethylene glycol or methanol overdose patient whose acidosis results in a serum pH below 7.30.[65]

Dosing Information

Urinary pH should be maintained above 6 in rhabdomyolysis.

In tricyclic overdose, the goal is to narrow the QRS complex while keeping the blood pH between 7.5 and 7.55; this can be accomplished by rapidly infusing 1–2 mEq/kg sodium bicarbonate as a bolus and then initiating a maintenance infusion. In salicylate overdose, the bicarbonate is titrated until the urinary pH approaches 7.5, whereas in rhabdomyolysis, the goal should be a urinary pH of 6.5. During toxic alcohol poisonings, the blood pH should be titrated upward to a pH greater than 7.3.

Contraindications

Sodium bicarbonate loading and maintenance dosing requires the infusion of large amounts of volume into the vascular space. Patients who have heart failure, renal failure, or currently have pulmonary edema with respiratory compromise should be given bicarbonate with caution. Bicarbonate can also increase the carbon dioxide load on the respiratory system; therefore, caution and close monitoring are warranted for patients unable to increase their minute ventilation.

Potential Complications

As previously stated, the patient could have respiratory failure from a large volume load or an increased demand on minute ventilation. A blood pH alkalinized to greater than 7.55 could cause seizures or arrhythmias. Hypocalcemia can occur with sodium bicarbonate administration in ethylene glycol intoxication; therefore, calcium should be monitored. Hypokalemia can occur by shifting of potassium ions from the extracellular to the intracellular compartment with changes in serum pH.

Vitamin K

Toxin

Coumarins and indandiones. The coumarins include warfarin and the super-warfarins present in some rodenticides.

Mechanism of Action

Coumarin depletes the reduced form of vitamin K, which is essential in the activation of coagulation factors 2, 7, 9, and 10. Infusing vitamin K overwhelms this coumarin-induced depletion of coagulation factors.

Clinical Indications

Bleeding resulting from or complicated by a prolonged prothrombin time. Vitamin K can also be used in patients with substantially elevated prothrombin times who are currently not bleeding but who are at high risk of bleeding. Characteristics associated with an increased risk of bleeding during warfarin therapy include age above 65; a history of cerebrovascular

disease, stroke, or gastrointestinal bleeding; heart disease; concurrent aspirin therapy; and hypertension.[66]

Dosing Information

The amount of vitamin K needed to reverse the effects of a coumarin or an indandione overdose is dependent on the cumulative dose of poison ingested and the half-life of the toxin preparation. The initial prothrombin time and the degree of normalization of the prothrombin time should also influence the dosing and route of administration. Vitamin K can be administered intravenously, intramuscularly, orally, or subcutaneously. Oral administration is preferred in patients without active bleeding.[67,68] Its absorption time from the gastrointestinal tract is 2–3 h and its peak onset of action is approximately 12 h. The absorption of oral vitamin K depends on the availability and competence of the hepatobiliary circulation; therefore, patients with biliary obstruction, pancreatitis, steatorrhea, or cholestasis may have decreased absorption and efficacy. Starting doses can range from 1 to 50 mg, and the greatest pharmacokinetic activity is obtained with administration of the vitamin every 6 h. The number of doses needed to reverse the toxin depends on the half-life of the poison and the efficacy of previous doses. The duration of action of warfarin can be as long as 2–5 days, whereas some super-warfarins present in rodenticides can have a duration of action lasting several months. Therefore, ingestion of a super-warfarin may require several months of vitamin K therapy. Subcutaneous administration of vitamin K has similar pharmacokinetics as the oral preparation, except there is a slightly faster onset of action.[68] Aqueous solutions are dispensed in 2 mg/mL and 10 mg/mL preparations. Subcutaneous injections of vitamin K are limited to 5 mL per injection site (or 50 mg). Injections greater than 5 mL have variable absorption. Intramuscular injections of vitamin K should be avoided because of the potential for intramuscular bleeding. Intravenous injections of vitamin K have resulted in the death of several patients. Although the onset of action of intravenous administration is slightly better than the subcutaneous route, its risk-to-benefit ratio preclude its use in most situations.[69] In the case of severe life-threatening hemorrhage, intravenous vitamin K has been shown to increase the activity of coagulation factors 2, 7, 9, and 10 to only 50% of normal levels after 4 h.[70] This slow improvement in coagulation factors provides reason for treating hemorrhage in the acute setting with blood products such as fresh-frozen plasma. If a situation arises that requires the administration of vitamin K intravenously, steps should be taken to minimize potential complications. The solution should be diluted in normal saline or a preservative-free dextrose solution and administered slowly at a rate that does not exceed 1 mg/min in adults.

Efficacy of oral vitamin K is dependent on an intact hepatobiliary circulation.

Maximum pharmacologic activity of vitamin K is obtained with q 6 h dosing.

Contraindications

Vitamin K_1 has no contraindications.

Potential Complications

Overcorrection of the prothrombin time can present a problem for patients at high risk of developing thrombi. Vitamin K administered intravenously has resulted in several reported deaths; therefore, its use should always be questioned. Rapid intravenous administration may be associated with facial flushing, diaphoresis, chest pain, hypotension, or dyspnea with or without an anaphylactoid reaction. Subcutaneous injections of vitamin K can result in a local skin reaction. Intramuscular injections in patients with a propensity to bleed can cause development of a hematoma.

IV administration of vitamin K should be avoided.

Protamine

Toxin

Heparin.

Method of Action

Protamine complexes with heparin, creating a neutralized compound.

Heparin is an acidic compound that induces its anticoagulant effect by binding and complexing with antithrombin III. Protamine, a stronger base compound than antithrombin III, has a greater electrochemical affinity to complex with heparin than antithrombin III. As such, protamine removes heparin from the heparin–antithrombin III complex and creates a neutralized protamine–heparin complex.

Clinical Indications

Protamine is most often used during cardiac surgery to reverse the effects of heparin following separation from the cardiopulmonary bypass pump. Its use in the intensive care unit setting should be limited.

Dosing Information

Heparin diffuses quickly from the circulation; therefore, the protamine dose needed to reverse heparin-induced anticoagulation relates to both the time of administration and the dose of heparin. One hundred units of heparin, administered within the previous 15 min, will be neutralized by 1–1.3 mg of protamine. Approximately 0.5 mg and 0.25 mg of protamine can be given per 100 units of heparin administered within the previous 1 and 2 h, respectively. Many cardiac surgery centers administer a fixed dose (based on patient body weight) of 3–4 mg/kg of protamine, at the conclusion of cardiopulmonary bypass. Protamine should be infused slowly; the rate of protamine administration should not exceed 50 mg over 10 min. Repeat dosing can be based on partial thrombin times or activated clotting times (ACT) drawn 5–15 min after completion of the protamine infusion. Administering a larger dose of protamine than required should be avoided as protamine has been shown to have anticoagulant effects, through its action on platelet function, when given in excess.[71,72]

Contraindications

Any patient with a known or suspected allergy to protamine should be given protamine with extreme caution. Because protamine should only be administered in life-threatening heparin-induced bleeding, the use of protamine in an allergic patient should be based on clinical judgment. Because protamine is derived from salmon sperm, there is believed to be an increased risk of adverse reactions in patients with fish allergies. Patients previously exposed to protamine have an increased risk of anaphylactic reactions.[73] Patients at risk for severe reactions include those who underwent any type of procedure or surgery that required heparin administration and reversal. Diabetic patients who have used protamine-containing insulin preparations, which include NPH Iletin I-II, Lispro, and Umuline Protamine Isophane, are also considered to be at increased risk.

Potential Complications

Documented adverse reactions include bradycardia, labile systemic blood pressure, pulmonary hypertension and RV dysfunction, thrombocytopenia, leukopenia, anticoagulant effects, and anaphylactoid and anaphylactic reactions. The systemic hypotension and bradycardic

TABLE 34-6

COMMONLY ENCOUNTERED NONTOXIC ITEMS

Bath oils	Ballpoint pen ink	Most antibiotics
Body conditioners/shampoos	Crayons	Corticosteroids
Cosmetics	White glue/paste	Candles
Shaving cream	Play-doh	Cigarettes
Toothpaste	Silly Putty	Latex paint
Laundry detergent	Clay	Motor oil
Chalk	Antacids	

TABLE 34-7

SUMMARY OF TOXINS AND ANTIDOTES

TOXIN	ANTIDOTE	DOSAGE	CLINICAL INDICATION	CONTRAINDICATIONS
Aluminum	Deferoxamine	2 g 0.5 h during dialysis	Encephalopathy, osteomalacia	None
Atropine	Physostigmine	1–2 mg/5 mm	Overdose not responsive to supportive care	Asthma, GI/GU obstruction, diabetes, cardiovascular disease history of seizures, cyclic antidepressants, benzodiazepine dependency
Benzodiazepines	Flumazenil	0.1 mg/min starting dose	No absolute indications	
Calcium channel blocker	Calcium	1 g CaCl or 3 g Ca gluconate	Hypotension, conduction abnormalities	Hyperphosphatemia, hypercalcemia
Coral snake venom	Elapid	5 vials in 250 mL NS	Tissue necrosis, systemic symptoms	Horse serum sensitivity
Coumarins	Vitamin K	Based on INR	Bleeding	None
Cyanide	Lilly cyanide kit	Amyl nitrite pearls and/or 3% sodium nitrite, then 25% sodium thiosulfate	Moderate to severe overdose not amenable to supportive care	See text
Digitoxin	Digibind	1 vial/0.5 mg digoxin	See digoxin	None
Digoxin	Digibind	1 vial/0.5 mg digoxin	Digoxin level >15 ng/mL, AV blockade, K^+ >5.0, digoxin ingestion >10 mg	None
Ethylene glycol	Calcium	CaCl or Ca gluconate	Hypocalcemia	Hyperphoshatemia, hypercalcemia
	Ethanol	0.8 g/kg bolus, then 130 μg/kg/h	See text	None
	Sodium bicarbonate	1–2 mEq/kg bolus then 1 amp in D_5W	Blood pH <7.30	Volume overload
	Fomepizole	15 mg/kg bolus, then 10 mg/kg q12 × 4, then 15 mg/kg q12	See text	None
Fluoride	Calcium	10% Ca gluconate injection or $CaCO_3$ mixed with jelly	Tissue necrosis, systemic hypocalcemia	Hyperphosphatemia, hypercalcemia

(*continued*)

TABLE 34-7

(CONTINUED)

Heparin	Protamine	0.5 mg within 1 h of heparin 0.25 mg within 2 h of heparin	Bleeding	Protamine sensitivity
Hyperkalemia	Calcium	CaCl/Ca gluconate	Hypocalcemia	Hypercalcemia
Hypermagnesemia	Calcium	CaCl/Ca gluconate	Hypocalcemia	Hypercalcemia
Indandiones	Vitamin K	Based on INR	Bleeding	None
Iron	Deferoxamine	<15 mg/kg/h not to exceed 24 h	Serum Fe >300 μg/dL	Anuria, renal insufficiency
Methanol	Ethanol	See ethylene glycol	See text	None
	Sodium bicarbonate	1–2 mEq/kg bolus then 1 amp in D_5W	Serum pH <7.30	Renal or heart failure
	Fomepizole	See ethylene glycol	See text	None
Myoglobin	Sodium bicarbonate	1–2 mEq/kg bolus then 1 amp in D_5W until urinary pH>6.5	Urinary pH <6.0	Volume overload
Oleander	Digibind	1 vial/0.5 mg digoxin	See digoxin	None
Opioids	Naloxone	0.4–2.0 mg starting dose	Hypotension, respiratory depression	Known naloxone hypersensitivity
Phenothiazines	Physostigmine	1–2 mg/5 min	Life threatening signs and symptoms of anticholinergic OD	See above
Pit viper venom	Crotalidae Polyvalent Immune Fab	4–8 vials diluted in NS	Rattlesnake bites, tissue necrosis, systemic symptoms	See text
Salicylates	Sodium bicarbonate	1–2 mEq/kg bolus then 1 amp in D_5W	CNS symptoms	Volume overload
Scorpion venom	APL-ASU antivenin	5-mL vials over 15–30 min	Systemic symptoms	Serum sensitivity
Spider venom	IGG spider antivenin	2.5 mL vials diluted in 50 mL NS	Systemic symptoms	Serum sensitivity
Squill toad venom	Digibind	1 vial/0.5 mg digoxin	See digoxin	None
Cyclic antidepressants	Sodium bicarbonate	1–2 mEq/kg bolus then 1 amp in D_5W	QRS complex >0.10	Volume overload

INR international normalization ratio

events are believed to be infusion rate-related complications; therefore, protamine should not be given at a rate greater than 50 mg over 10 min. Supportive care for a possible anaphylactic or anaphylactoid reaction should be readily available before administration.

NONTOXIC EXPOSURES

A surprisingly large and varied number of products commonly encountered in everyday life are either nontoxic in any amount or route of exposure or are nontoxic in limited amounts. Patient and parental anxiety, along with overall health care cost, can be limited when identification of a nontoxic exposure can be made. When absolute product identification of a single, nontoxic ingestant can be made, a reliable estimate of amount and route of exposure is available, the patient is symptom free, and reliable patient observation and follow-up are assured, the exposure can be classified as nontoxic. If any of these factors is deemed unreliable, the patient should be instructed to seek immediate medical evaluation. Table 34-6 provides a partial list of commonly encountered items that are nontoxic.

SUMMARY

Sound principles of supportive care are the foundation for the clinical management of the poisoned patient. Establishment of an adequate airway, ensuring breathing and oxygenation, and maintaining adequate circulation are the first and foremost therapeutic priorities. A thoughtful approach to gastric decontamination and toxin elimination will supplement care and improve clinical outcome. A working knowledge of some of the more commonly used antidotes is helpful (and mandatory in the case of oxygen, naloxone, glucose, and thiamine), and can always be supplemented by communication with the nearest poison control center (Table 34-7). A careful history may identify nontoxic exposures, thereby eliminating the need for potentially noxious treatment.

REVIEW QUESTIONS

1. Which overdose may not benefit from a bicarbonate infusion?
- **A.** Cyclic antidepressant overdose
- **B.** Salicylate overdose
- **C.** Methanol ingestion
- **D.** Ethylene glycol ingestion
- **E.** Digoxin overdose

2. Which of the following choices is not an indication for giving digibind?
- **A.** Serum potassium level >5.0 mEg/L
- **B.** Serum calcium <7.0 mg/dL
- **C.** A known ingestion >10 mg
- **D.** Any degree of heart block
- **E.** Digoxin serum concentration >15 ng/dL

3. Re-dosing of digibind should be based on which of the following criteria?
- **A.** A digoxin level of 20 ng/dL after initial dosing of digibind
- **B.** A digoxin level of 30 ng/dL after initial dosing of digibind
- **C.** Second-degree heart block
- **D.** Atrial fibrillation
- **E.** Fifteen hours after the initial dose (the half-life of digibind) of digibind and a normal sinus rhythm

4. Which of the following choices is not a contraindication for flumazenil usage?
- **A.** Diazepam dependency
- **B.** A patient receiving gabapentin for neuralgia
- **C.** Concomitant tricyclic antidepressant overdose
- **D.** A patient currently taking doxepin for depression
- **E.** A patient receiving diazepam for a seizure disorder

5. In which patient scenario is an ethanol infusion not absolutely necessary?
- **A.** A patient receiving dialysis for a methanol overdose
- **B.** A patient who admits to taking only a small amount of paint thinner
- **C.** An unconscious patient with an unexplained osmolar gap and a blood pH without any metabolic derangements
- **D.** An inebriated patient who is found unconscious at home
- **E.** A child found unconscious near an empty container of antifreeze

6. In acetaminophen overdose
- **A.** Acetaminophen glucuronide and acetaminophen sulfate are toxic metabolites
- **B.** The majority of the drug is excreted unchanged in the urine

C. *N*-acetylcysteine decreases sulfation of acetaminophen
D. Glutathione stores are depleted allowing free NAPQI, the toxic oxidation product, to bind to hepatic cellular proteins

7. In the initial management of a patient with altered mental status
A. A full toxicologic screen should be sent immediately
B. A CT scan of the brain is required to rule out a structural lesion
C. Readily correctable causes should be entertained, such as hypoxemia and hypoglycemia
D. A rapid intravenous bolus of thiamine should be administered

8. Ethanol withdrawal
A. May mimic sedative/hypnotic withdrawal
B. Results in an increase in blood pressure and pulse, and a decrease in respiratory rate and temperature
C. May mimic opioid withdrawal
D. Does not mimic any toxic ingestion syndromes

ANSWERS

1. The answer is E. It is generally recommended that a person being treated for a cyclic antidepressant overdose be given a bicarbonate infusion when their QRS complex exceeds 0.10 s. The bicarbonate infusion should be continued until the QRS complex narrows or the blood pH attains a level between 7.50 and 7.55. Salicylate intoxication with systemic toxicity (i.e., confusion, etc.) should prompt a bicarbonate infusion. The goal is a urinary pH approaching 7.50. Alkalinization to a blood pH greater than 7.30 may also help patient outcome in a methanol or ethylene glycol poisoning. An overdose with digoxin would not benefit from a bicarbonate infusion and therefore would be considered the correct answer.

2. The answer is B. Indications for digibind dosing in a digoxin overdose include a potassium level greater than 5.0, a known ingestion of greater than 10 mg, any first-, second-, or third-degree heart block, ventricular tachycardia and fibrillation, or a digoxin concentration greater than 15 ng/dL. There is no clear benefit in supplementing calcium in a patient with a digoxin overdose.

3. The answer is C. Re-dosing of digibind should be based on signs of toxicity such as cardiac conduction delays, ventricular tachycardias, or fibrillations. Therefore, the reemergence of a second-degree heart block should prompt re-dosing of digibind. The serum concentration level of digoxin is usually not useful after the initiation of digibind because most serum assays are unable to discriminate between digibind and digoxin. Consequently, digibind re-dosing based on digoxin concentration levels received after the initial antidote dose is incorrect. Although the half-life of digibind is considerably shorter than digoxin, re-dosing of digibind should be based on clinical signs and symptoms.

4. The answer is B. Patients who have a seizure disorder, who receive benzodiazepines for control of their disorder, as well as those patients who are on benzodiazepines long term, should only be given flumazenil with extreme caution, and some authors would argue that the benefits might not outweigh the potential harm. Patients who are receiving tricyclic antidepressants chronically or concomitantly in an overdose should not receive flumazenil. Gabapentin is occasionally used to treat seizures, but the drug itself does not preclude the usage of flumazenil.

5. The answer is D. Ethanol should be used in any patient with suspected methanol or ethylene glycol ingestion. Ethylene glycol is found in antifreeze, whereas methanol can be found in de-icing solutions, shellac, paint removers and thinners, windshield washer fluid, and carburetor cleaners. Serum methanol or ethylene glycol levels greater than 25 mg/dL should result in immediate dialysis along with the administration of ethanol. Patients with methanol or ethylene glycol ingestion may not have a metabolic acidosis, but they will have an osmolar gap. The anion gap and metabolic acidosis created by an ethylene glycol or methanol overdose may not be evident at presentation because it is the active metabolites that create these metabolic derangements. Therefore, a patient with an unexplained osmolar gap and a history or physical exam compatible with an ethylene glycol or methanol overdose should probably receive an ethanol infusion until the serum levels of these toxins return and confirm or refute the preliminary diagnosis of an ethylene glycol or methanol overdose. Any child with a suspected ingestion of antifreeze should receive an ethanol infusion until the potential threat of an overdose can be ruled out. A patient without suggestion of methanol or ethylene glycol ingestion should not receive a prophylactic ethanol infusion.

6. The answer is D. Acetaminophen glucuronide and acetaminophen sulfate are nontoxic metabolites of acetaminophen that are eliminated in the urine. Less than 5% of ingested acetaminophen is excreted unchanged in the urine. Normally, glutathione stores complex with NAPQI, an oxidation product of acetaminophen, which is toxic to hepatocytes. Nontoxic conjugates of cysteine and mercaptate are the end result. In an overdose situation, glutathione stores become depleted allowing free NAPQI to bind to hepatic cellular proteins, resulting in cell death and hepatic necrosis. *N*-acetylcysteine serves as a glutathione precursor, resulting in continued detoxification of NAPQI and increasing sulfation of acetaminophen to nontoxic metabolites.

7. The answer is C. Toxicologic screens rarely determine the need for additional therapeutic measures and do not replace the need for appropriate decontamination procedures and supportive care. They are costly and should be reserved for cases of diagnostic uncertainty or when knowledge of test results will affect patient management. Readily correctable causes of altered mental status should be considered and treated. Such examples include hypoxemia, hypoglycemia, thiamine deficiency, and opiate overdose. CT scan of the brain is not part of the initial management, but may become necessary in the absence of readily diagnosable / correctable causes of altered mental status and in the patient with focal neurologic findings. Thiamine should not be administered by rapid intravenous bolus due to the uncommon but known potential for anaphylaxis. The drug should be administered slowly and with simultaneous vital sign monitoring.

8. The answer is A. Both ethanol and sedative / hypnotic withdrawal present with very similar toxic syndromes, which include an increase in blood pressure, pulse, respiratory rate, temperature, pupil size, and diaphoresis in the setting of abnormal mental status. Opioid withdrawal usually does not result in changes in respiratory rate or temperature, and mental status remains normal. Adrenergic agonist overdose can mimic ethanol withdrawal due to excess sympathetic nervous system stimulation.

CHAPTER 35

JESSE GOLDMAN AND GAUTAM S. CHOURE

Metabolic Disturbances of Acid–Base and Electrolytes

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Use a systematic approach to identify the types of acid–base disorders.
- Be proficient in calculating the anion gap (AG) and the delta:delta equations.
- Differentiate among common causes of elevated AG and non-AG acidoses.
- Identify common causes of metabolic alkalosis.
- List the common causes, clinical symptoms, and physical examination signs of:
  - Hyponatremia
  - Hypernatremia
  - Hypokalemia
  - Hyperkalemia
  - Hypocalcemia
  - Hypercalcemia
  - Hypomagnesemia
  - Hypermagnesemia
  - Hypophosphatemia
  - Hyperphosphatemia
- Determine the treatment options for the electrolyte disorders listed.

A wide range of acid–base and electrolyte disorders are encountered daily by clinicians caring for critically ill patients. The aim of this chapter is to supply the reader with a systematic strategy that can be used when confronted with abnormal serum chemistry and blood gas data to arrive at a correct assessment, diagnosis, and therapeutic plan. Several case studies illustrate and help guide this discussion. This chapter does not dwell on the basic pathophysiology of each disorder, but we encourage the reader to refer to the Suggested Reading list at the end of the chapter to learn more about specific areas.

METABOLIC DISORDERS OF ACID–BASE METABOLISM

Terminology

Blood pH is, a dimensionless quantity, defined as the negative log of the serum hydrogen ion concentration.

Clinical disorders of acid–base balance may be classified according to how two variables, $PaCO_2$ and serum bicarbonate concentration ($[HCO_3^-]$), are altered by underlying causal pathologic processes. A primary change in the $PaCO_2$ resulting in a pH change is referred to as (depending upon direction) either a respiratory acidosis or respiratory alkalosis. Metabolic disorders of pH are the result of primary changes in the serum concentration of bicarbonate. A primary decrease in the serum bicarbonate (accompanied by low pH) is referred to as metabolic acidosis; a primary increase in the serum concentration of bicarbonate (accompanied by an elevated pH) is referred to as metabolic alkalosis. Acidemia means that the blood pH is less than 7.38 (lower limit normal), and alkalemia means that the blood pH is greater than 7.42 (upper limit normal). "Acidosis" signifies that the patient has a pathophysiologic process contributing to excess blood acidity even if the measured pH is normal or even above 7.42. So, it is possible for a patient, for example, to be suffering from the process of diabetic ketoacidosis (DKA) but actually have alkalemia from, for instance, extreme hyperventilation.

A mixed acid–base disorder is present in a patient when two (or more) independent pathophysiologic processes are present, resulting in an alteration in serum bicarbonate concentration, $PaCO_2$ or both not explainable as a simple acid–base disorder.

Primary alterations of the serum bicarbonate result in both metabolic events, such as buffering, that attempt to restore acid–base equilibrium and thereby restore normal pH. A "simple" acid–base disturbance is present when a single pathologic process results in alteration of the HCO_3^- (or $PaCO_2$) accompanied by an appropriate compensatory change of the reciprocal variable.[1] A mixed acid–base disorder is said to occur when two (or more) independent pathophysiological processes can be detected to result in alterations of the serum bicarbonate concentration or $PaCO_2$, or both.[2]

Systematic Approach

A stepwise approach to the analysis of acid–base chemistries is mandatory since even experienced clinicians may not perceive by crude inspection that two or more disorders exist in a particular patient simultaneously. Neglecting one may lead to suboptimal patient outcomes. This approach should be used every time one confronts an abnormal set of electrolytes and blood gases.

Step 1: Identify the Most Obvious Disorder and Check for Internal Consistency

There exists a physico-chemical relationship between H^+ concentration, serum bicarbonate concentration, and $PaCO_2$ based upon their concentrations in aqueous solution. Knowing this relationship (a modified Henderson–Hasselbach equation) can allow the clinician to quickly identify uninterpretable data. For example, the pH and $PaCO_2$ of the arterial blood gas (ABG) are directly measured but the bicarbonate concentration on the blood gas is only calculated. Therefore, only the bicarbonate concentration from the serum electrolyte panel should be considered since this is the true bicarbonate. Said another way, a difference in the calculated and measured serum bicarbonate greater than 2–3 mEq/L should raise suspicion that clinical conditions have changed between these two measurements. Taking a moment to examine the internal consistency of these lab values will save time and effort.

$$[H^+] = 24 \times PaCO_2/\text{measured } [HCO_3^-] \quad (35\text{-}1)$$

CASE STUDY 1: PART 1

A 19-year-old girl is brought to the emergency department by her mother for complaints of persistent vomiting for several days duration. She has a history of insulin-dependent diabetes mellitus and chronic depression with a prior attempted suicide and alcohol abuse. Physical examination showed her to be lethargic, with a temperature of 98.2°F. Respirations equal 35/min; blood pressure and heart rate are supine: BP 120/80 mmHg and HR 120/min, sitting: BP 100/70 mmHg and HR 160/min. Laboratory values reveal Na^+, 136 mEq/L; Cl^-, 70 mEq/L; K^+, 3.6 mEq/L; HCO_3^-, 19 mEq/L; BUN (blood urea nitrogen), 21 mEq/L; serum blood glucose, 580 mg/dL; serum osmolarity, 315 Osm; and ABG: pH, 7.58; PaO_2, 104 mmHg; $PaCO_2$, 21 mmHg.

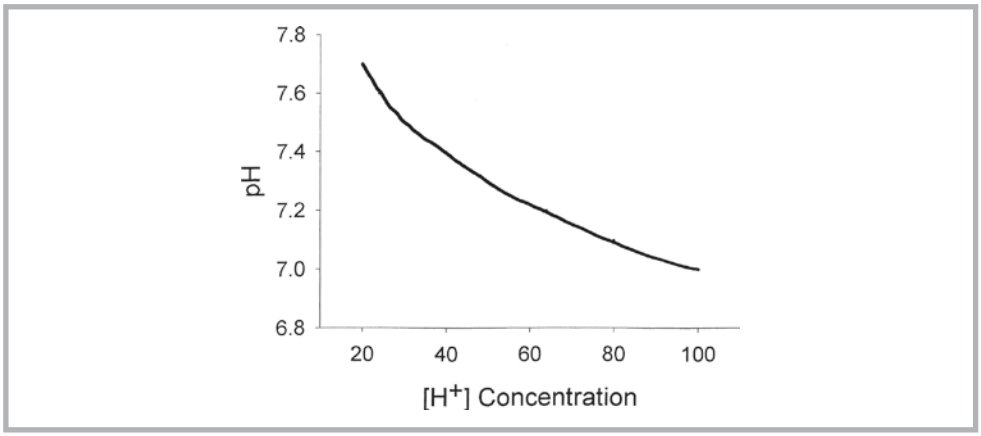

FIGURE 35-1

Relationship of pH to $[H^+]$. The relationship is nearly linear from pH 7.1–7.5, values normally clinically encountered. At pH extremes, the relationship becomes more curvilinear.

pH is the negative log of the serum hydrogen ion concentration ($[H^+]$). A normal arterial blood pH ranges from 7.38 to 7.42. The population mean value of 7.4 corresponds exactly to a blood hydrogen ion concentration ($[H^+]$) of 40 nanoequivalents per liter. Though pH decreases as $[H^+]$ increases, the relationship overall is nonlinear (Fig. 35-1). However, it approximates linearity over the narrow range of physiologic pH values normally encountered clinically (7.2–7.6). Within these limits, the pH can be calculated by estimating that the pH will change by 0.08 U (up or down) for every 10 nEq/L change in $[H^+]$ (above or below 40 nEq/L). A more accurate estimate of $[H^+]$ is required for more extreme ranges of pH because the slope of the relationship of pH and $[H^+]$ steepens below 7.2 and above 7.6. The pH can then be calculated by knowing that the pH will change by more than 0.08 U for every 10 nEq/L change in the $[H^+]$ above 60 nEq/L, and that the pH will change by more than 0.125 U for every 10 nEq/L change in the $[H^+]$ below 20 nEq/L. If the calculated $[H^+]$ (from the modified Hendelson–Hasselbach) does not agree with the measured pH, (within 5) then an accurate assessment of the patient's acid–base status cannot be determined. Most commonly, the serum bicarbonate and blood gas were obtained at different times reflecting temporal changes in the patient from, for example, preintubation and postintubation. Another cause of confounding data is simple laboratory error. Here again, the calculated $[H^+]$ does not equal $24 \times PaCO_2$/measured $[HCO_3^-]$. In all other "correct" clinical conditions, this relationship holds true.

Step 2: Assess the Compensatory Response

The body's homeostatic mechanisms are designed to protect serum pH. That is, to adjust the serum bicarbonate and/or $PaCO_2$ to normalize the pH. As a result of understanding these mechanisms, clinical rules have been developed to classify acid–base disturbance. When examining an ABG (and serum bicarbonate), first examine the pH, decide the primary disturbance, and what the compensatory laboratory change is. The compensatory response (when present) always creates a second "laboratory" abnormality. Remember, the compensatory mechanism never overcorrects or even fully returns the serum pH completely to normal. The single exception is chronic respiratory alkalosis in which the pH may occasionally correct

CASE STUDY 1: PART 2

The pH from the ABG informs us that our patient is alkalemic. The rapid respiratory rate and low $PaCO_2$ completely support respiratory alkalosis. Calculation of the $[H^+]$ using the modified Henderson–Hasselbach equation ($[H^+] = 24 \times (PaCO_2/HCO_3^-)$, or $24 \times 21/19 = 26$ mEq. The pH can be calculated by assuming that the pH will change by 0.0125 U for every 1 nEq/L change in the $[H^+]$ below 40 nEq/L. In this case, $0.0125 \times 14 = 0.18$, giving a calculated pH of $7.40 + 0.18 = 7.58$. Therefore, the calculated and the measured pH agree, which confirms the internal consistency of our data. This is as one expects, since the ABG and serum electrolytes were drawn simultaneously.

Compensatory mechanisms never overcorrect or fully return pH to normal. Occasionally, chronic respiratory alkalosis may correct to normal pH.

all the way into the normal range; but still never overcorrects. Regardless, the primary disturbance is first determined by examining the pH and fitting either the $PaCO_2$ or bicarbonate concentration to a metabolic or respiratory cause. When interpreting an ABG, the clinician then determines if the compensation is appropriate or inappropriate. An inappropriate compensation means that there is actually a second (or potentially even a third) separate acid–base abnormality. Occasionally, the absence of compensation can either result from insufficient time for compensatory mechanisms to manifest or to coexisting dysfunction within the renal or respiratory systems.

The expected respiratory compensation for either a metabolic acidosis or alkalosis can be predicted by the following formulas: a $PaCO_2$ that lies outside the *predicted* limits from the equations below defines a coexisting respiratory disorder.

$$\text{Metabolic acidosis : } PaCO_2 = 1.5\ ([HCO_3^-]) + 8 \pm 2 \text{ (Winter's formula)} \quad (35\text{-}2)$$

$$\text{Metabolic alkalosis : } PaCO_2 = 40 + 0.6\ (\Delta[HCO_3^-]) \quad (35\text{-}3)$$

Thus far, in our patient case, the patient demonstrates respiratory alkalosis. The casual clinician will be aware that the serum bicarbonate is low, and assume that it is entirely compensation for a respiratory alkalosis. It is subsequently demonstrated that an additional phenomenon is present.

Step 3: Determine the Serum Bicarbonate Concentration and the AG Metabolic Acidosis (Low Serum Bicarbonate)

Metabolic acidosis is characterized by low serum bicarbonate and low PCO_2. The low bicarbonate results from either (1) accumulation of nonvolatile acids or (2) loss of bicarbonate through the gastrointestinal tract or (3) failure to excrete acid by the kidney. The most important step in assessing a metabolic acidosis is to calculate the AG. This maneuver should become routine when assessing all serum electrolytes as it quickly helps the clinician categorize the type of metabolic acidosis present. Checking the AG routinely will sometimes even reveal an unmeasured anion (disease state) in patients with a normal serum bicarbonate concentration. The AG equation is used to calculate the AG:

Determination of the anion gap (AG) is a crucial step in assessing any metabolic acidosis.

$$AG = [Na^+] - ([Cl^-] + [HCO_3^-]) \quad (35\text{-}4)$$

The net total body concentrations of anions always equal the total concentration of cations in the body. Otherwise, an individual's body would simulate a battery thereby holding a net electric charge. The AG equation accounts only for those serum electrolytes present in the greatest concentration, and assumes that all other ions have negligible contribution. Most physiologic substances not captured in the Winter's equation are anions so that unmeasured anions exceed unmeasured cations; the difference is the AG. In the healthy state, the normal AG is 12(±2).[3] Originally, a value of 17 was described, but improvements in electrodes detection of chloride have led to a lowering of the normal AG. Low AG occur rarely in critically ill patients, but, when present, the most common etiologies are hypoalbuminemia,

An AG acidosis can be caused by either exogenous or endogenous compounds.

multiple myeloma, or, very rarely, bromide intoxication. Since albumin is the dominant component of the normal physiology AG, it is important to consider significant changes in the serum albumin level when calculating an individual AG. As a rule of thumb, the normal AG is corrected down by 2–3 for every 1 g/dL reduction in the normal serum albumin concentration. This is recommended to accurately assess the presence or absence of another unmeasured anion or to categorize the types of metabolic acidosis.[4]

Metabolic Acidosis

Elevated AG Acidosis

In a high AG acidosis, the rise in serum [H^+] is due to an accumulation of an unmeasured anion, which is often an organic acid (Table 35-1).[3] This rise may be the result of either endogenous acid production (ketoacids and lactate) or of certain exogenous compounds (ethylene glycol, salicylates, and methanol). The identification of an "osmolar gap" is required to identify the presence of an unmeasured toxic substance without charge since an uncharged substance will not influence the AG. The osmolar gap is the difference between the calculated and measured serum osmolarity, which should normally be less than 10 mOsmol. The calculation for serum osmolality is

$$\text{Serum osmolality} = 2(Na^+) + \text{glucose}/18 + \text{BUN}/2.8 \quad (35\text{-}5)$$

Normal AG Acidosis

The two most common causes of normal AG acidosis are gastrointestinal bicarbonate loss and inappropriate renal acid retention (RTA [renal tubular acidosis]).

In normal AG acidosis, the fall in bicarbonate is usually matched by a proportional rise in the serum chloride, often referred to as a hyperchloremic metabolic acidosis. The causes of this form of metabolic acidosis are listed in Table 35-2. This form of acidosis most often specifically results from gastrointestinal [HCO_3^-] losses or of renal origin. A normal AG acidosis may also result from rapid dilution of the plasma HCO_3^- by rapid administration of large volumes of isotonic saline i.e., a dilutional acidosis. The addition of acid equivalents to the body fluids as excessive amino acids may also lead to the development of normal AG acidosis.

The approach to a patient with non-AG metabolic acidosis (Fig. 35-2) begins with the history and physical examination as well as determination of the serum potassium concentration ([K^+]). The most common cause of normal AG acidosis is diarrheal illness, which directly leads to loss of both [HCO_3^-] and [K^+]. Also, through a renin mediated pathway, effective

TABLE 35-1

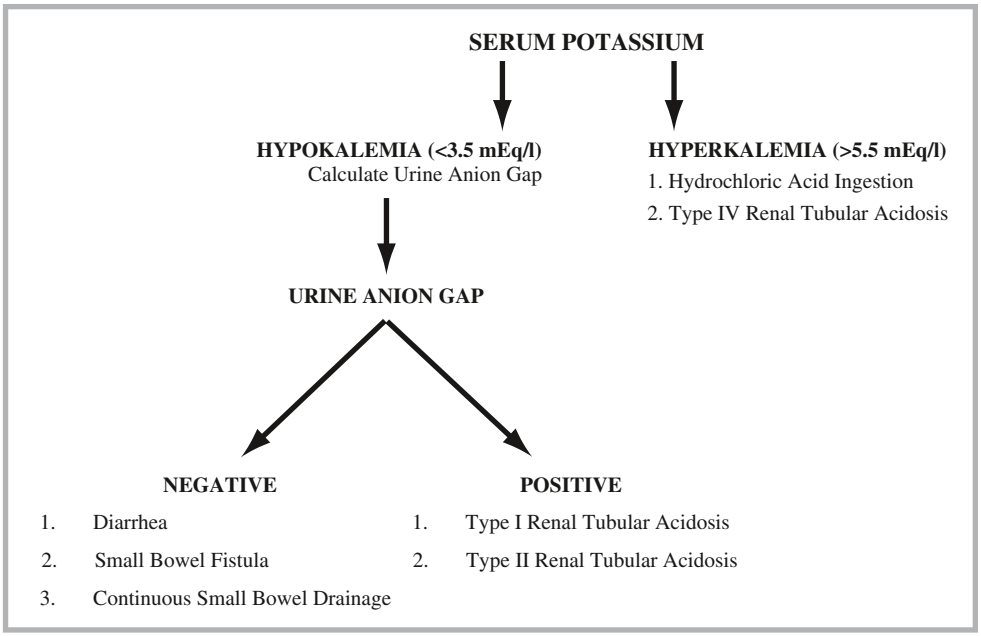
Hydrochloric acid addition

FIGURE 35-2

Algorithm for normal anion gap (AG) acidosis. Most causes of normal AG acidosis are associated with hypokalemia, but two conditions that occur in the setting of hyperkalemia are hydrochloric acid ingestion and type IV renal tubular acidosis (RTA). Calculating the urine anion gap (UAG) estimates the urinary ammonium (NH_4^+) excretion and is used to differentiate type I and II RTA (positive UAG) from the remaining causes of normal AG acidosis with hypokalemia (negative UAG).



volume depletion from diarrhea also results in increased aldosterone levels. Hyperaldosteronism enhances renal [K^+] secretion and further worsening of hypokalemia. Hypokalemia is also found in non-AG acidosis caused by both proximal (type II) and most types of distal (type I) RTA. Patients with type IV RTA are usually hyperkalemic. Nevertheless, metabolic acidosis caused by gastrointestinal losses can correctly be differentiated from RTA by the determination of urinary ammonium ([NH_4^+]) excretion, which is low in RTA and high in patients with diarrhea. Urinary ammonium cannot be directly measured, but its "electrical shadow" can be estimated by calculating the urine anion gap (UAG), as follows[5]:

$$\text{Urine } [K^+] + \text{urine } [Na^+] - \text{urine}[Cl^-] = \text{urine anion gap (UAG)} \qquad (35\text{-}6)$$

If the sum of the major urinary cations ([Na^+] + [K^+]) is less than the major urinary anion ([Cl^-]), then [NH_4^+] makes up the charge difference and therefore is adequately present in urine (i.e., a negative UAG). A positive UAG indicates an RTA with an acidification defect in the form of inadequate [NH_4^+] excretion. A negative UAG indicates adequate ammoniagenesis and therein an extra-renal cause of the hyperchloremic acidosis (see Fig. 35-2). One caveat, this equation is only valid if the urine sodium concentration is less than 20 mEq/L. Additionally, the urine pH is valuable in differentiating a proximal (type II) from a distal (type I) RTA. In distal RTA, the urine pH is always greater than 5.3. Of course, most patients with elevated urine pH do not have proximal RTA (or a distal RTA). In contrast, the metabolic acidosis found in renal insufficiency and RTA type IV is accompanied by an elevation in plasma [K^+]. RTA type IV results from generalized distal nephron dysfunction with hypoaldosteronism and is most commonly seen in diabetics. Hyperkalemia decreases renal ammoniagenesis responsible for the metabolic acidosis. That hyperkalemia sustains acidosis in these patients is supported by the observation that treating hyperkalemia corrects their acidosis.

Metabolic Alkalosis (High Serum Bicarbonate)

Metabolic alkalosis is the state of elevated serum bicarbonate ([HCO_3^-]) with expected compensatory decrease in $PaCO_2$. This disorder occurs as the result of either the loss of excess [H^+] or the gain of [HCO_3^-]. The kidney normally excretes all [HCO_3^-] excess (ex: baking soda ingestion). Therefore, to maintain the state of metabolic alkalosis, there must also be a sustaining defect impairing the renal excretion of [HCO_3^-]. The causes of metabolic alkalosis can be divided into those associated with a high urine chloride ([Cl^-]) and those associated with a low urine [Cl^-] (Table 35-3).[6] The most common cause of metabolic alkalosis is

CASE STUDY 1: PART 3

The measured serum bicarbonate in our patient was low (19 mEq/L), which might have (if viewed in isolation) incorrectly led us to predict a low pH given her history of insulin requiring diabetes. In a simple acid–base disorder, we expect the serum [HCO_3^-] and $PaCO_2$ to move in opposite directions. Here, in the setting of a high serum pH, both the [HCO_3^-] and $PaCO_2$ were low, which can occur only if the patient has a mixed acid–base disturbance. Calculation of the AG revealed a significant gap acidosis of 47 ([Na^+] – ([Cl^-] + [HCO_3^-]), or 136 – (70 + 19)). Clues to the etiology of the AG acidosis can be found in the history and physical exam. The history of diabetes mellitus, elevated blood sugar, and noncompliance suggested DKA. Another possibility is alcoholic ketoacidosis. Both diagnoses can be confirmed by measuring the urine and serum ketones and a serum ethanol level. A toxic ingestion is always possible. However, in this case, there is no evidence of an osmolar gap. The calculated serum osmolality is 2(Na^+) + glucose/18 + BUN/2.8, or 2(136) + 580/18 + 21/2.8 = 312 Osm, the same as the measured serum osmolality. Finally, an elevated serum lactate may result from severe dehydration and volume depletion leading to decreased tissue perfusion. Thus far, in our patient, two acid–base disorders have been identified: respiratory alkalosis and an AG metabolic acidosis.

TABLE 35-3

CAUSES OF METABOLIC ALKALOSIS

Associated with low urinary chloride	Associated with high urinary chloride
Vomiting	Mineralocorticoid excess
Volume contraction	Exogenous $NaHCO_3^-$ therapy
Nasogastric suction	Corticosteroid abuse

loss of HCl from the stomach either as vomiting or nasogastric suctioning. This extracellular volume depletion, with urine [Cl^-] is low, and the alkalosis resolves after volume replacement. If the urine [Cl^-] is high (>40 mEq/L), then mineralocorticoid excess, diuretics, or recovery from sodium bicarbonate loading are common culprits.

The most common causes of metabolic alkalosis are related to extracellular volume depletion.

Step 4: Determine the Delta Anion Gap and the Delta:Delta

This step is useful to identify additional or hidden metabolic disorders by comparing the change in the AG with the change in serum [HCO_3^-]. In a simple metabolic acidosis, the decrease in the serum bicarbonate (normal [HCO_3^-] – measured [HCO_3^-]) and the increase in the AG (measured AG – 12) should be proportional. This relationship has become known as the delta:delta (ΔAG: Δ[HCO_3^-]). Another approach is to add the ΔAG to the measured serum [HCO_3^-] value; a resultant value less than the normal serum [HCO_3^-] is a clue that a hidden non-AG acidosis is present. Similarly, a resultant value that is higher than the normal serum [HCO_3^-] suggests that a hidden metabolic alkalosis is present.

The delta:delta equation may identify the presence of additional metabolic disorders if present.

ELECTROLYTE DISORDERS

Disorders of Water and Sodium Metabolism

Of all electrolyte disorders, by far the most common is hyponatremia. The number of etiologies and specific disorders that cause hyponatremia is vast and ever growing. However, despite the apparent complexity of the problem, the etiology of most cases of hyponatremia can be determined with a few readily accessible tests, including plasma osmolality, volume status, urine osmolality (UOsm), and urine sodium.

Hyponatremia is initially classified by osmolality into hypotonic, isotonic, or hypertonic types.[7] Some texts refer to isotonic and hypertonic hyponatremia as pseudohyponatremia. However, this chapter addresses all three osmolality states.

Hypotonic hyponatremia represents the largest group and usually the most critically ill. Hypotonicity can cause many adverse effects as a result of inevitable intracellular swelling. Among the adverse effects are seizures, neuromuscular excitability, and coma. Usually, these effects are not seen early in disease. Some of the common causes of hypotonic

CASE STUDY 1: PART 4

The calculations for determining the delta:delta in our case yielded the following information:

Determination of the Delta AG:
AG=[(Na^+)−(Cl^- + HCO_3^-)]
AG=[(136)−(70+19)]=47
Normal AG=12
Delta AG=47−12=35

Determination of the Delta [HCO_3^-]:
Normal HCO_3^-=24 mEq/L
Measured HCO_3^- in this patient=19 mEq/L
Delta HCO_3^-=24−19=5 mEq/L

The normal value for serum bicarbonate is 24 mEq/L. Adding the measured serum bicarbonate (19) to the delta AG (35) gives a value of 54. This value, obviously, is higher than the normal serum bicarbonate, indicating that this patient also has a severe metabolic alkalosis. Therefore, this patient was found to have a triple acid–base disorder: (1) respiratory alkalosis from hyperventilation, (2) AG metabolic acidosis from DKA, and (3) a metabolic alkalosis from vomiting and dehydration. She was treated with IV fluids and insulin. Her serum electrolytes and blood gases were normal by the end of 1 week.

TABLE 35-4

CAUSES OF HYPONATREMIA AND HYPOOSMOLALITY

Disorders of impaired renal water excretion
Depleted intravascular volume
Gastrointestinal losses
Renal losses
Skin losses: burns, cystic fibrosis
Edematous states
CHF (congestive heart failure)
Cirrhosis
Nephrotic syndrome
Hypoalbuminemia
Diuretics
States of ADH excess
Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
Cortisol deficiency
Decreased solute intake
Normal renal water excretion
Primary polydipsia
Pregnancy
Malnutrition

hyponatremia, as shown in Table 35-4, can be subdivided into disorders in which renal water excretion is impaired and those in which it is normal. Once it is determined that the patient is hypotonic, the next step is determining the patient's volume status.

Hypotonic Hyponatremia

Hyponatremia can be hypotonic, isotonic, or hypertonic.

Low-volume hypotonic hyponatremia, by definition, is a loss of both sodium and water but obviously more sodium. Common causes are diuretics, GI losses, and adrenal insufficiency. A clue for adrenal insufficiency would be high potassium in conjunction with low sodium, a result of decreased aldosterone secretion. High-volume states include congestive heart failure (CHF), cirrhosis, and other hypoalbuminemic states. Normal volume states are usually divided into the syndrome of inappropriate antidiuretic hormone secretion (SIADH) or psychogenic polydipsia.[8]

Antidiuretic hormone (ADH) and the thirst mechanism are the main by-products of stimulation of osmoreceptors, which are located in the hypothalamus. ADH has its greatest effect on the collecting duct to increase water permeability back into the bloodstream. Therefore, ADH secretion should increase water reabsorption and lead to an increased urine concentration.

Checking UOsm is useful to determine whether water excretion is normal or impaired. A UOsm less than or equal to 100 mOsmol/kg indicates ADH suppression. Primary polydipsia is an example of hyponatremia with a UOsm of less than 100 mOsmol/kg. Conversely,

CASE STUDY 2: PART 1

A 50-year-old man presented to his primary medical doctor with the complaint of weakness. He stated that for the last 6 months, he had felt extremely fatigued at his job as a construction worker. On review of systems, patient also noted that he had lost 15 lbs. in the past year, had a slight amount of lightheadedness, and had three episodes of hemoptysis in the last month. The physical exam showed normal vital signs and no abnormalities. Basic metabolic panel reveals sodium of 120 mEq/L, BUN of 3 mEq/L, and osmolality of 250 mOsmol/kg.

values greater than 100 mOsmol/kg indicate water excretion is impaired (Table 35-4), and include effective circulating volume depletion, the syndrome of inappropriate SIADH, adrenal insufficiency, and hypothyroidism.

In patients with hyponatremia, UOsm indicates whether water excretion is normal or impaired.

Various simple blood tests and a reliable history will lead the physician to the correct diagnosis from this point. One last confirmatory test is the Una, where a low (less than 25 mEq/L) value clinches the diagnosis of a depleted effective circulating volume.

Hyponatremia with a Normal or High Plasma Osmolality

Hyponatremia in these two categories is often referred to as pseudohyponatremia. Clinically, the distinction between hypoosmotic and nonhypoosmotic hyponatremia is critical because therapy in nonhypoosmotic hyponatremia is not directed toward correcting the sodium. Isotonic hyponatremia is often seen when a preponderance of either lipids or proteins displace sodium in the serum. Common examples are multiple myeloma and uncontrolled diabetes mellitus. Hypertonic hyponatremia is caused by infusions of glucose or mannitol. Again, the measured sodium in these cases does not represent the true sodium. For example, for each 100 mg/dL glucose increase, the serum sodium decreases by 1.6 mEq/L.

Treatment of Hyponatremia

Central pontine myelinolysis is a fatal complication of too aggressive correction of hyponatremia.

Treatment of hyponatremia is directed at two pathways: raising the low sodium itself while at the same time treating the underlying cause. Normal saline is usually sufficient in cases of hypovolemic hypotonic hyponatremia, and water restriction works well in normovolemic or edematous cases. However, in symptoms of seizure, coma, or extreme hyponatremia (<110 mEq/L), the use of hypertonic saline (3%) is indicated.

Central pontine myelinolysis is a rare but often fatal complication of too rapid sodium repletion. If sodium is replenished too quickly, the cells will shrink (from free water shifts), causing central pontine myelinolysis. There is no established rate of sodium correction, but most authors suggest the sodium correction should not exceed 1–2 mmol/h.[9]

Hypernatremia

The major difference in the diagnostic considerations between hyponatremia and hypernatremia is that all patients with hypernatremia are, by definition, hyperosmolar. Therefore, the first step in the evaluation of these patients is the determination of volume status. Regardless of the volume status of these patients, they are always free water depleted. Total body water is roughly estimated to be 60% of total weight in kilograms. The equation for free water deficit is as follows:

$$\text{Free water deficit} = (\text{total body water})\,(\text{measured serum } Na^+ - 145)/145 \quad (35\text{-}7)$$

or

$$\text{Free water deficit} = (0.6)\,(\text{body weight in kg})\,(\text{measured serum } Na^+ - 145)/145 \quad (35\text{-}8)$$

CASE STUDY 2: PART 2

An extensive workup of this patient's hyponatremia was begun. The patient denied any recent nausea, vomiting, or surreptitious use of diuretics. The patient had no history of heart or liver disease and no contradictory evidence on physical examination. Serum transaminases, albumin, bilirubin, and alkaline phosphatase were normal. A chest X-ray, ordered because of the patient's symptom of hemoptysis, revealed a 3 × 3-cm mass-like lesion in the right middle lobe. Urine tests were also done; osmolality was 680 mOsmol/kg and urine sodium was 50 mEq/L.

CASE STUDY 2: PART 3

The patient was sent for a CT-guided needle biopsy of the lung mass. Pathology returned as small cell lung cancer. Urine chemistry tests were consistent for SIADH secondary to lung cancer causing hyponatremia. The patient began chemotherapy and water restriction to treat his lung cancer and SIADH, respectively.

Hypernatremia requires at least one of the following: water loss, decreased water ingestion, or sodium overingestion.

Table 35-5 shows the main etiologies of hypernatremia. One of three circumstances must occur for hypernatremia: decreased water ingestion, water loss, or overingestion of sodium. The major categories of water loss include insensible losses (sweating, burns, fever, etc.), renal losses (including central and nephrogenic diabetes insipidus [NDI]), gastrointestinal losses, hypothalamic disorders, and water loss into cells. The major cause of increased sodium ingestion is usually iatrogenic, as occurs during the often indiscriminate use of $NaHCO_3^-$ during cardiopulmonary resuscitation. This problem commonly occurs also in the administration of high-Na^+ feeding to infants.

The body has two basic defense mechanisms to combat the development of hypernatremia: ADH and thirst sensation, which is sensed by hypothalamic osmoreceptors. An interesting dynamic between the two is that, although it is generally accepted that ADH release is the first response of the body, occurring when POsm exceeds 275–285 mOsmol/kg, thirst is the more important regulator. Severe hypernatremia will not occur unless for some reason the patient is unable to ingest water or has a nonfunctional thirst reflex. Hypernatremia is very rarely observed in young alert people, and neurologic compromise is often present in patients with severe hypernatremia. Patients at risk include the physically and mentally handicapped, the elderly, or any condition wherein normal ingestion of water does not occur.

TABLE 35-5

CAUSES OF HYPERNATREMIA

- Water loss
  - Insensible loss
    - Sweating
    - Burns
    - Infection, fevers
  - Renal loss
    - CDI
    - NDI
    - Osmotic diuresis
  - GI losses
  - Primary hypodypsia
  - Water loss into cells
- Sodium retention
  - Iatrogenic NaCl or $NaHCO_3^-$ administration
  - Sodium ingestion

CASE STUDY 3: PART 1

A 65-year-old man with a history of hypertension, diabetes, and ischemic heart disease was brought to the ER complaining of a sudden onset of crushing chest pain. His EKG was consistent with an acute anterior wall myocardial infarction (MI). On the way to the catheterization lab, the patient went into cardiac arrest. Resuscitation efforts were successful, but only after 15 min. Despite the restoration of sinus rhythm and adequate BP, the patient remained comatose. Basic chemistries on the second ICU day showed Na 164 mEq/L, K 3.9 mEq/L, BUN 36 mEq/L, Cr 0.8 mEq/L, glucose 140 mg/dL, and POsm 332 mOsmol/kg.

Central and Nephrogenic Diabetes Insipidus

Central and NDI are two of the commonest etiologies of hypernatremia in hospitalized patients in general and in ICU patients in particular. The two conditions, however, differ greatly with respect to their causes and treatments. A basic appreciation of ADH function and origin is imperative to understanding these disorders.

ADH is produced in the hypothalamus by the supraoptic and paraventricular nuclei (Fig. 35-3). It is then stored in the posterior lobe of the pituitary gland. Intravascular volume depletion is the strongest stimulus for ADH release. ADH action occurs at the collecting duct of the nephron, where it increases water permeability; this increases urine concentration.

CDI is defined as those conditions where the production and secretion of ADH is either completely or partially impaired. Table 35-6 lists the most common etiologies of CDI, which include head trauma, neurosurgery, hypoxic/ischemic insult, neoplasm, or other miscellaneous insults. All these disorders are characterized by a lack of endogenous ADH, not kidney responsiveness to it. Exogenous ADH will correct the problem in these circumstances.

Nephrogenic diabetes insipidus (NDI), on the other hand, is a disorder in which the production and secretion of ADH are normal but renal unresponsiveness to ADH causes water

Central diabetes insipidus (CDI) is caused by complete or partial impairment of ADH secretion, whereas Nephrogenic diabetes insipidus (NDI) is caused by renal unresponsiveness to ADH.

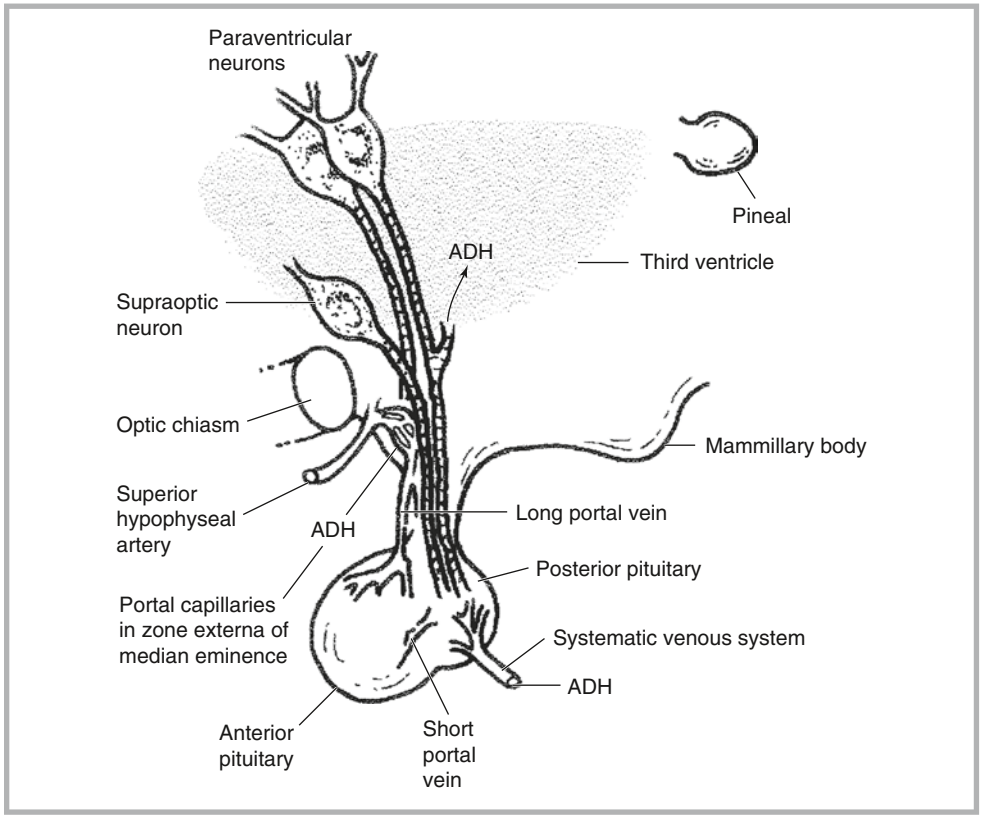


FIGURE 35-3

Production and secretion of antidiuretic hormone (ADH). ADH is produced by the paraventricular and supraoptic nuclei in the hypothalamus, transported down their axons, and secreted at three sites: the posterior pituitary gland, the portal capillaries of the median eminence, and the third ventricular CSF (adapted from Rose.[25] With permission).

CASE STUDY 3: PART 2

Throughout the second and third ICU days, the patient's POsm remained 285–290 mOsmol/kg and urine output exceeded 300 mL/h. Urine studies revealed a UOsm of 130 mOsmol/kg and a urine sodium <10 mEq/L. Additionally, the patient's fractional excretion of sodium was <1%. A water restriction test was begun.

loss and therefore unconcentrated urine. There are multiple causes of NDI, ranging from congenital to acquired (Table 35-7). The most common causes of NDI in adults are lithium toxicity, osmotic diuresis (seen in uncontrolled diabetes mellitus or hyperosmolar hyperglycemic nonketotic coma, HHNK, and hypercalcemia.

NDI-associated hypercalcemia is often seen in two subsets of patients, those with primary or secondary hyperparathyroidism, and those whose hypercalcemia is due to cancer. Usually, calcium levels greater than 11 mg/dL are needed before NDI is apparent. The mechanism is not understood, although some investigators believe that calcium deposition in the medulla with resultant tubulointerstitial injury is the cause. The resolution of NDI follows the restoration of normal calcium, although sometimes it takes as long as 12 weeks after normal calcium is restored. Osmotic diuresis as a result of uncontrolled diabetes mellitus is another common cause of NDI. Glucosuria must be present to establish this diagnosis. Other causes of osmotic diuresis observed in the ICU include long-term high-protein enteral tube feedings and mannitol infusions (e.g., as used in cases of increased intracranial pressure).

Lithium is the medication most often implicated in causing NDI. Toxic levels usually must be present for NDI, but this is not universally the case. Lithium causes NDI by directly accumulating within the collecting tubule cells, therefore decreasing the generation of cyclic AMP, which is needed for water reabsorption. This condition should be suspected in all patients with diminished mental status in whom hypernatremia is seen, particularly in young patients or those who have a psychiatric history.

Lithium is the drug most often implicated in NDI.

The distinction between central and nephrogenic DI is not often successfully made at the time of presentation. Few hospitals have the laboratory means to measure endogenous ADH, and complicated clinical scenarios can blur the picture. The easiest and most readily available test to differentiate between CDI and NDI is the water restriction test. Reduced water intake will cause an increased plasma osmolality, which should increase ADH secretion and hence increase urine concentration. In CDI, regardless of the increase in plasma osmolality

The water restriction test is used to differentiate between CDI and NDI.

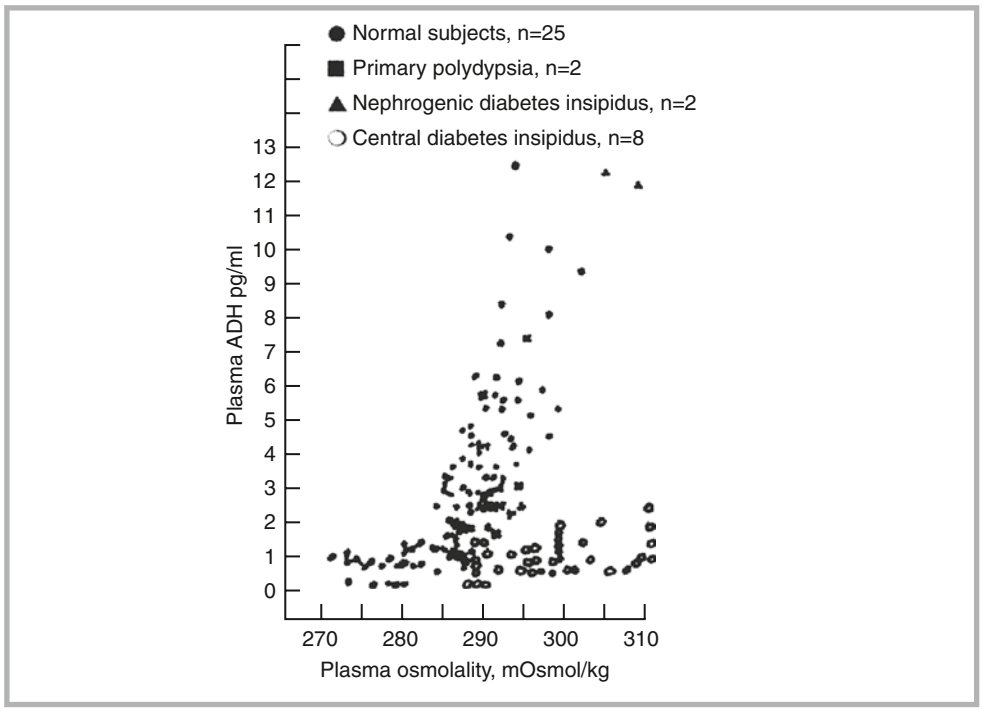

FIGURE 35-4

Response of plasma ADH to plasma osmolality. The water restriction raises plasma osmolality. In normal subjects and those with primary polydipsia and nephrogenic diabetes insipidus (NDI), plasma ADH rises in an attempt to reabsorb water. Central diabetes insipidus (CDI) is defined as partial or complete impairment of ADH secretion, despite increasing plasma osmolality (adapted from Rose.[25] With permission).

caused by water restriction, the ADH level will never increase and the urine will remain very dilute (Fig. 35-4). In NDI, as the POsm rises, the urine will remain dilute, but unlike CDI, the level of ADH will appropriately rise. The distinction between CDI and NDI is confirmed by a trial of ADH (vasopressin, or 1-deamino-D-Arg-8 vasopressin, DDAVP). Giving exogenous ADH will increase UOsm for CDI only, as illustrated with the patient in our case.

Symptoms of Hypernatremia

Regardless of the etiology of hypernatremia, the symptoms are quite similar and predominately neurologic in nature. It is thought that these symptoms result from the constant shifting of water in and out of brain cells because of the osmotic gradient. Headache, weakness, dizziness, irritability, and, in severe cases, even seizures and coma can be observed.[10] Other symptoms of hypernatremia include those related to a patient's particular volume status, whether volume depleted (e.g., jugular venous distension (JVD) <5 cm H_2O, poor skin turgor, orthostatic hypotension) or volume overloaded (e.g., pulmonary or peripheral edema). Patients with diabetes insipidus with an intact mental status rarely have signs or symptoms or volume loss. Common symptoms in patients with either CDI or NDI include polyuria, nocturia, and polydypsia; this allows another use of the water restriction test, differentiating primary polydipsia for CDI or NDI. Last, patients with CDI or NDI are prone to develop hydroureter, or hydronephrosis, as a result of conscious efforts to minimize repeated urination.

Diagnosis and Treatment

Diagnosing hypernatremia depends on an increased serum Na^+ level and the appropriate clinical setting. There are some key diagnostic points to remember. First, thirst provides the main protection from hypernatremia, and so long as one has an intact thirst mechanism and access to water, hypernatremia will not develop. The second diagnostic point is the importance of checking a patient's volume status. Very few disorders cause either hypervolemic (primary hyperaldosteronism, iatrogenic $NaHCO_3^-$), or euvolemic (CDI, NDI) hypernatremia. The third and fourth diagnostic points are the utility of UOsm and the water restriction test in differentiating among various disorders.

CASE STUDY 3: PART 3

A water restriction test was begun for this patient. After 12 h, his urine output was still 300–400 mL/h. A trial of 5 U of vasopressin was begun. After 3 h, his urine output was 35 mL/h and his measured UOsm was 450 mOsmol/kg. A diagnosis of CDI was made, secondary to anoxic encephalopathy suffered during cardiac arrest. A standing dose of 2 U vasopressin subcutaneously was started, with correction of his serum sodium to 142 mEq/L by the fifth hospital day. However, the patient's mental status never improved; he was placed on comfort care 1 week later, and later expired.

CASE STUDY 4

A 21-year-old collegiate athlete on a gymnastics scholarship complained of dizziness and leg weakness. She had had increased fatigue in both lower extremities (proximal and distal) since the athletic season started 1 month ago. She has had no recent trauma or previous episodes of lightheadedness or syncope. Physical examination revealed frequent ectopy on heart exam. Neurologic exam was unremarkable, including negative Chvostek's sign. EKG revealed frequent premature ventricular beats. Sodium, 138 mEq/L; potassium, 2.0 mEq/L.

Treatment of hypernatremia is directed toward treating both the high sodium and the underlying disorder.

Treatment of hypernatremia is directed toward treating both the high sodium and the underlying disease. Specific treatments for specific etiologies are not discussed here; most are obvious (e.g., DDAVP for CDI, discontinuation of lithium for NDI, fluid repletion for insensible losses). Rather, the general principles of free water repletion are discussed.

When hypernatremia is corrected too rapidly, severe fluid shifts can result in cerebral cells, causing cerebral edema, brain damage, and even death. Therefore, it is advised to correct Na^+ slowly unless the patient has significant symptoms. Lowering sodium by 0.5 mEq/h, or 12 mEq/day, has been suggested. Additionally, after calculating the free water deficit, the rate of free water repletion should be half the total projected deficit in the first 12–24 h, with slow correction thereafter. Finally, in cases of hypovolemic hypernatremia, normal saline should be used first to correct volume status before more hypotonic fluids are used to further correct the sodium concentration.

Serum Potassium Disorders

Hypokalemia

About 98% of total body potassium is intracellular.

Potassium differs widely from sodium in terms of body distribution. About 98% of body potassium is intracellular. The balance between sodium and potassium is maintained by the sodium–potassium ATPase pump in the cell membrane.[11,12]

Hypokalemia has significance in critical care and is caused by a multitude of etiologies (Table 35-8). Hypokalemia can be seen with decreased net intake, increased entry into cells, increased gastrointestinal losses, increased urinary losses, increased sweat losses, and dialysis.

Diuretic use is the most common cause of hypokalemia.

Diuretic use, loop, or thiazide is the most common cause of hypokalemia. High levels of both urinary chloride and potassium verify this diagnosis. Other causes of urinary potassium loss include type 1 RTA (hypokalemic, hyperchloremic acidosis), amphotericin B administration, and hypomagnesemia. Diarrhea, intestinal fistulas, tube drainage, and chronic laxative abuse are examples of gastrointestinal losses. Many conditions cause increased entry of potassium into cells, such as alkalosis, insulin, beta-agonists, and aldosterone.

Symptoms and Treatment

Hypokalemia is associated with a wide range of complications, the most serious of which are cardiovascular.

Muscle weakness and paralysis, rhabdomyolysis, hyperglycemia, renal dysfunction, and cardiac arrhythmias are signs of hypokalemia (Table 35-9). Cardiac complications include a number of reported arrhythmias, such as premature atrial and ventricular beats, sinus bradycardia, atrioventricular block, and v-tach/v-fib. Various clinical scenarios increase the risk of

TABLE 35-8

Rhabdomyolysis
Renal dysfunction

arrhythmias from hypokalemia, including cardiac ischemia, left ventricular hypertrophy (LVH), and digitalis use. Potassium is essential for ventricular repolarization, and with hypokalemia, many EKG changes are seen. Some are ST segment depression, appearance of "u" waves, PR interval prolongation, and widening of the QRS complex.

If left untreated, low serum potassium can have multiple deleterious effects on kidney function. Rhabdomyolysis is usually not seen unless the serum potassium level is below 2.5 mEq/L.

The main principle in the treatment of hypokalemia is that rapid administration of potassium is potentially harmful and should be used only in life-threatening situations. Intravenous potassium should be given at no more than 10–20 mEq/L/h. Oral potassium supplements are usually adequate to replete deficits in most patients. Patients with DKA who actually have low rather than high serum potassium represent a marked deviation from this principle.

Hyperkalemia

The three major categories of hyperkalemia are increased intake, movement from cells into extracellular fluid, and decreased urinary excretion (Table 35-10). Examples of intraextracellular shifts are DKA, acidosis, beta-adrenergic blockade, digitalis overdose, and succinylcholine administration.

DKA and digitalis overdose are two very frequent causes of hyperkalemia in the critically ill.

TABLE 35-10

MAJOR CAUSES OF HYPERKALEMIA

Shift into extracellular fluid
Acidosis
Insulin deficiency
Beta blockade

General anesthesia (succinylcholine)
Decreased excretion
Renal failure
Hypoaldosteronism
Type I RTA
Increased intake, either oral or intravenous

CASE STUDY 5: PART 1

A 25-year-old Caucasian man with no known medical history came into the emergency room complaining of nausea and vomiting for 2 days. The patient also complained of fever and rusty-colored sputum. Physical exam revealed bronchial breath sounds over the right middle lung field. Chest X-ray revealed a right middle lung infiltrate. Laboratory values were WBC, 16,000/mm^3 (84 segs, 8 bands); sodium, 130 mEq/L; potassium, 6.7 mEq/L; chloride, 103 mEq/L; HCO_3^-, 5 mEq/L; glucose, 700 mg/dL. EKG showed global peaked T waves. The patient was immediately volume resuscitated with 2 L normal saline, and an insulin drip at 10-U/h was started.

Case studies illustrates that, although the patient's acidosis and hyperglycemia led to a high level of extracellular potassium, in reality his total body potassium was depleted at the time of presentation. The insulin, by reversing his acidosis and the potassium shift out of cells, made his extracellular potassium dangerously low, precipitating the fatal arrhythmia. A critical mistake was made in not following through on the serum chemistries to guard against potassium depletion.

Symptoms, Diagnosis, and Treatment

Besides muscle weakness and cardiac arrhythmias, no other symptoms are directly related to hyperkalemia. However, these patients present with many other complaints, related to the underlying disease that originally caused hyperkalemia. Cardiac changes are common and usually directly related to the level of extracellular measured potassium (Fig. 35-5). Peaked T wave and a shortened QT interval are among the first changes and are thought to represent rapid repolarization; these changes are seen when the serum concentration is below 7 mEq/L. Above 7 mEq/L, changes are seen that reflect delayed depolarization, including widening of the QRS complex, and, finally, the sine wave pattern, as the QRS complex merges with the T wave.[13] Ventricular fibrillation can soon follow. These changes are not uniformly seen at these levels in all patients, mostly because of other factors (calcium, sodium, acid–base status) that influence electrical cardiac activity. Frequent EKG monitoring is a must.

A large variety of electrocardiographic changes are observed with hyperkalemia; the most serious occur when serum potassium is >7 mEq/L.

The evaluation and diagnosis of hyperkalemia begins with the history, especially information concerning kidney disease, medications (i.e., potassium-sparing diuretics, angiotensin-converting enzyme inhibitors), and muscle weakness. After physical exam, EKG, serum chemistries, and ABG are done.

The main principle of treatment of hyperkalemia is determining the severity of hyperkalemia according to the clinical scenario (Table 35-11). Life-threatening situations call for the use of IV calcium, which has been shown in various studies to have cardioprotective effects within 5 min.[14] Other therapies, such as beta-agonists, insulin, and glucose, can be used next (although their effect is, of course, temporary). Binding resins are used for final excretion from the body.[15] Antagonism of membrane actions, increased potassium entry into

Intravenous calcium is the first step in the treatment of life-threatening hyperkalemia.

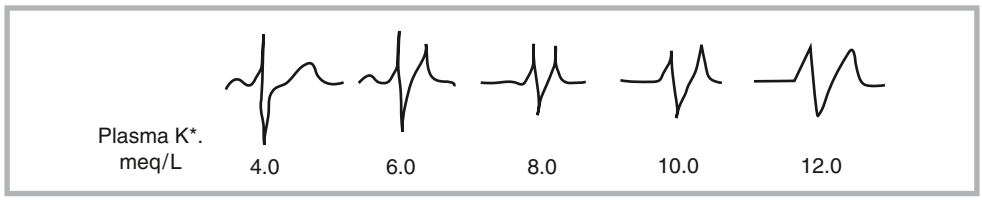

FIGURE 35-5

Electrocardiographic changes in hyperkalemia. The initial changes observed are peaking and narrowing of the T wave with a short QT interval. As hyperkalemia worsens, QRS widening, decreased amplitude, loss of the P wave, and the sine wave pattern (QRS-T wave merging) appear. These changes are observed at the approximate potassium levels illustrated, but there is substantial individual variability (adapted from Rose.[25] With permission).

CASE STUDY 5: PART 2

The patient was given IV azithromycin in addition to the volume resuscitation and continuous intravenous insulin. The patient had no further nausea or vomiting. A recent finger stick revealed a blood sugar of 250 mg/dL, so the patient's fluids were changed to D_5 0.5 normal saline at 150-mL/h, and the insulin drip was changed to 5 U/h. At the time, the resident in charge asked the third-year medical student to obtain more serum chemistries. The patient refused blood testing, and no further changes were made in his management for the next 4 h. While in the elevator, being transported to his hospital room, the patient developed ventricular fibrillation and expired.

TABLE 35-11

TREATMENT OF HYPERKALEMIA

Acute/life-threatening scenarios	Nonlife-threatening

Intravenous insulin and glucose	Insulin/glucose
Dialysis	Binding resins

cells, and removal of excess potassium are the three major mechanisms of the therapies. In a patient with merely high potassium but without signs of muscle weakness or EKG abnormalities, a binding resin can be used as first-line therapy, with frequent EKG monitoring.

An appreciation of total body potassium in addition to extracellular potassium is crucial to understanding the causes and treatments of both hypokalemia and hyperkalemia. Cardiac arrhythmias are the major complications. Treatment principles for both hypokalemia and hyperkalemia are determined by the severity of clinical signs and symptoms. Frequent cardiac monitoring is implemented because a clear correlation between measured potassium and cardiac abnormalities is not always demonstrated.

Serum Calcium, Magnesium, and Phosphate Disorders

Calcium

No electrolyte is under such complicated and multifactorial regulation than calcium. Calcium abnormalities are often found incidentally on routine blood screens in the outpatient setting and can have disastrous consequences. The three main regulatory hormones in calcium homeostasis are PTH, calcitonin, and vitamin D (Table 35-12). These three hormones have

Parathyroid hormone (PTH), calcitonin, and vitamin D are the three main regulatory hormones in calcium homeostasis.

TABLE 35-12

ACTIONS OF MAJOR CALCIUM-REGULATING HORMONES

	BONE	KIDNEY	INTESTINE
Parathyroid hormone (PTH)	Increases resorption of calcium and phosphate	Increases reabsorption of calcium; decreases reabsorption of phosphate; increases conversion of 25-OHD_3 to 1,25-$(OH)_2D_3$; decreases reabsorption of bicarbonate	No direct effects
Calcitonin (CT)	Decreases resorption of calcium and phosphate	Decreases reabsorption of calcium and phosphate; questionable effect on vitamin D metabolism	No direct effects
Vitamin D	Maintains Ca^{2+} transport system	Decreases reabsorption of calcium	Increases absorption of calcium and phosphate

SOURCE: adapted from Greenspan.[26] With permission

as their major sites of action, bone, intestine, and the kidneys, respectively. One of the sterol hormones, vitamin D is synthesized in the skin by means of ultraviolet radiation. It then undergoes 25-hydroxylation in the liver and 1-alpha hydroxylation in the kidneys. The final product ($1,25(OH)_2D_3$) increases absorption of calcium and phosphate in the intestine and kidney and increases calcium resorption from bone. PTH increases resorption of both calcium and phosphate from bone, while increasing calcium resorption and decreasing phosphate resorption in the kidney. PTH also stimulates conversion of $25\text{-}D_3$ to its final product. Calcitonin has antagonistic effects toward PTH in both bone and kidney.

Hypercalcemia

Etiologies of hypercalcemia include parathyroid related, malignancy related, vitamin D related, endocrine disorders, and renal failure (Table 35-13).[16]

Primary hyperparathyroidism and malignancy are the two most common causes of hypercalcemia.

Primary parahyperthyroidism is the most common cause of hypercalcemia.[17] The diagnosis is made by both high calcium and a high PTH level. About 80% of cases of primary parahyperthyroidism are caused by solitary adenomas; the remainder is caused by four-gland parathyroid hyperplasia. Hypercalcemia secondary to parahyperthyroidism is often found on routine laboratory checks in asymptomatic patients. Hypercalcemia secondary to malignancy often presents as a medical emergency. Organ systems involved include CNS (confusion, loss of memory, depression, somnolence, coma), neuromuscular (weakness), rheumatologic (joint pain, calcium pyrophosphate crystals, chondrocalcinosis), dermatologic (rash and pruritus), GI (nausea, vomiting, dyspepsia, constipation), renal (nephrolithiasis, polyuria, renal colic), and cardiovascular (hypertension, potentiation of cardiac effects of digoxin, and various EKG changes such as PR prolongation, QRS widening, QT segment shortening, and T-wave flattening).

Malignancies causing hypercalcemia include both solid tumors (lung, breast, and kidney) and hematologic malignancies (multiple myeloma). These tumors secrete a PTH-like hormone, with a negative feedback effect on PTH secretion. These patients have high calcium in the presence of a low PTH. Other causes of hypercalcemia include granulomatous diseases such as sarcoidosis (increased vitamin D_3 production in macrophages), renal failure (e.g., diabetic nephropathy), and lithium toxicity (increased PTH threshold for negative feedback).

The standard of care for hypercalcemia starts with intravenous fluid repletion.

Treatment for hypercalcemia begins with aggressive IV repletion, usually normal saline (Table 35-14).[18] A loop diuretic is employed once the patient is determined to be in a euvolemic state. More long-term maintenance therapies, especially in the case of malignancy-related hypercalcemia, include bisphosphonates such as pamidronate. These agents reduce bone turnover of calcium. The dose of pamidronate is 60–90 mg IV infused over 1–3 h. Other principles in the treatment of hypercalcemia include a low calcium diet and, if the patient is taking digitalis, awareness that hypercalcemia lowers the threshold for the adverse effects of digitalis.

CASE STUDY 6

A 63-year-old man with a history of nonsmall cell lung cancer stage II IA presented to the ER with a change in mental status during the preceding 2 days. His wife reported poor oral intake and weight loss over the past 2 weeks. The patient was afebrile, with evidence of volume depletion indicated by significant orthostatic changes in both heart rate and blood pressure. The measured calcium was 13 mEq/L and the measured albumin was 1.8 mEq/L.

TABLE 35-14

TREATMENT OF HYPERCALCEMIA

Emergent treatment
Normal saline (2–3 L over 3–6 h)
Lasix (40–100 mg every 2–4 h)
Calcitonin
Bisphosphonates (60–90 mg infused over 1–3 h)
Dialysis
Nonemergent treatment
Adequate fluid intake
Bisphosphonates
Oral calcium restriction
Knowledge of outpatient medication regimen (especially digitalis)

Hypocalcemia

Hypocalcemia is defined by ionized calcium less than 1 mmol/L or total serum calcium less than 8.5 mg/dL in the presence of a normal serum albumin level. The major etiologies of hypocalcemia include PTH related (insufficiency or suppression), vitamin D shortage, hyperphosphotemia (chelates calcium), hypoalbuminemia, hypomagnesemia, and pancreatitis.

Clinical findings predominately involve the neuromuscular system (muscle weakness, fatigue, and neuromuscular irritability in the form of spasms or seizures), cardiac manifestations (prolongation of the QT interval, resistance to digitalis, hypotension, CHF), and laryngospasm and respiratory arrest from neuromuscular weakness.[19]

Laryngospasm with subsequent loss of airway protection is the gravest consequence of hypocalcemia.

Two common clinical signs used to diagnose hypocalcemia and differentiate it from other forms of neuromuscular weakness are Chvostek's sign and Troussea's sign. Chvostek's sign is elicited by tapping the facial nerve anterior to the ear lobe, slightly below the zygomatic arch. A positive response is defined by twitching of the facial muscles innervated by the facial nerve on the stimulated side. Troussea's sign involves inflating an upper extremity sphygmomanometer cuff above systolic blood pressure for a period of no less than 2 min; a positive response is defined by development of a carpal spasm.

Chvostek´s and Troussea´s signs are two common clinical maneuvers that can identify hypocalcemia.

Treatment of hypocalcemia is stratified into management for severe symptomatic vs. asymptomatic patients (Table 35-15). The largest worry in patients with hypocalcemia and clinical signs of tetany (positive Chvostek's or Troussea's sign) is the development of laryngeal spasm, stridor, and loss of airway protection. Treatment options always include IV calcium in the form of calcium gluconate, correction of magnesium and phosphate abnormalities, frequent EKG monitoring, and establishment of a safe airway. Anticonvulsants

TABLE 35-15

TREATMENT OF HYPOCALCEMIA

Severe life-threatening
Calcium gluconate (10 mL 10% solution over 10 min) or calcium chloride (10 mL 10% solution in 50 mL D_5W over 30 min
1–2 mg/kg/h of elemental calcium if symptoms persist
Correct magnesium, potassium, and phosphorus abnormalities
Asymptomatic
Calcium gluconate 2–4 g/day, divided into doses q6 h
Vitamin D preparation

may be needed in severe cases before calcium repletion is complete. Patients who are hypocalcemic secondary to excision of hyperfunctioning parathyroid glands may be vitamin D resistant and have hypocalcemia refractory to a standard level of repletion. This condition is often termed the hungry bones syndrome. These patients require increased levels of IV calcium repletion and more frequent monitoring of levels.

Complications are sometimes observed with too aggressive repletion of calcium, such as hypercalcemia and hypercalciuria. Stone formation is a frequent problem. Thiazide diuretics are used in these cases.

Magnesium

Magnesium is an important cofactor for multiple enzymatic reactions involving energy utilization. Primarily an intracellular cation, with less than 1% found in the serum, magnesium is important for multiple processes, including Na–K ATPase channels, stability of membranes, mitosis/meiosis, and muscle contraction. Various states in which higher levels of magnesium are needed include critical illness, pregnancy, diarrhea, or diuresis. Magnesium is absorbed in the small intestine and excreted via the kidney. In times of extreme magnesium depletion, the kidney is able to severely restrict excretion (<1 mmol/day). Hence, urinary magnesium levels are very useful in determining etiologies of hypomagnesemia.

Hypomagnesemia

Hypomagnesemia is very common in the critical care setting.

Hypomagnesemia is quite common in the ICU, with various studies reporting prevalence at 10–65%.[20] The three most common main categories of hypomagnesemia are (1) intracellular serum shifts, (2) GI losses, and (3) renal losses. Common causes of intracellular shifts include chelation by tissues during pancreatitis and rhabdomyolysis or shifts from insulin therapy. Excess GI wasting can result from malabsorption, diarrhea, nasogastric suction, or fistulas. High urinary magnesium levels in the face of hypomagnesemia suggest a primary renal cause. The most common cause of renal wasting of magnesium is drug toxicity. Cyclosporine, amphotericin B, digitalis, aminoglycosides, and diuretics (loop and thiazide) are frequent culprits.

Hypomagnesemia affects multiple organ systems, including the cardiovascular (arrhythmias, vasospasm, angina), neuromuscular (weakness, spasms, seizures, tetany), and gastrointestinal systems (anorexia, dysphagia, nausea).[21]

Cardiac arrhythmias are seen with deficient stores of magnesium, even with normal magnesium serum levels.

Treatment of hypomagnesemia depends on the acuteness or chronicity of the disorder. Acute hypomagnesemia requires IV repletion, in the form of magnesium sulfate. Often low potassium is present, and this should be treated. One dangerous aspect of magnesium deficiency is that cardiac arrhythmias are seen with deficient stores of magnesium not reflected in the serum levels. In life-threatening situations, 8–16 mmol should be given over 5 min; this rate is changed to over 3 h in severe depletion without cardiac arrhythmias. Chronic magnesium depletion is most commonly treated with oral magnesium.

Hypermagnesemia

Hypermagnesemia is extremely uncommon in patients with normal renal function. Hypermagnesemia is often seen after ingestion of antacids or laxatives containing magnesium in patients with renal failure. Lithium intoxication, hypothyroidism, and adrenal insufficiency are other causes.

Clinical effects are not closely related to serum measurements of magnesium. CNS (change in mental status, confusion, coma), cardiovascular (prolonged PR, QRS, ST, heart block), and neuromuscular (depressed deep tendon reflexes, paralysis, respiratory muscle paralysis) changes are a few of the major consequences.[22] Treatment modality chosen

depends on the severity of organ system damage. In life-threatening cases, IV calcium is given to stabilize neuromuscular and cardiac membrane instability while magnesium is removed via dialysis. In less acute cases, IV fluids (saline) and loop diuretics are given to increase elimination.

Treatment of life-threatening hypermagnesemia involves intravenous calcium (for stabilization of cardiac membranes) and dialysis.

Phosphorus

Serum phosphate is under the control of both the parathyroid gland and the kidney. Clinically significant hypophosphatemia is usually less than 2 mg/dL. The kidney is quite adept at phosphate retention in states of phosphate depletion. A 24-h urine phosphate greater than 100 mg when the serum phosphate is less than 2 mg/dL suggests renal disease. Etiologies of hypophosphatemia include intracellular shifts, sepsis, alkalosis, alcoholism, DKA, and salicylate poisoning.[23]

Similar to magnesium and calcium, low levels of phosphorus can have disastrous neuromuscular complications, including respiratory muscle paralysis, CNS changes, and skeletal myopathy. Less commonly seen are hematologic manifestations (hemolysis and impaired platelet function.

Hypophosphatemia often has disastrous neuromuscular complications.

Treatment includes IV potassium phosphate (2.5–5.0 mg/kg/q6h) for acute circumstances. Serum phosphorus, potassium, calcium, and magnesium levels should be checked every 12 h. When phosphorus levels are above 2 mg/dL, an oral sodium phosphate is used. The most important principle in treating hypophosphatemia is monitoring calcium and magnesium levels as well. In a patient with hypercalcemia, correcting the phosphate first will lead to the formation of calcium phosphate crystals, which can deposit anywhere with disastrous consequences, including irreversible joint dysfunction.

Hyperphosphatemia (serum phosphate level >4.5 mg/dL) can be caused by increased intestinal absorption, parenteral administration, renal dysfunction, frank renal failure, hyperthyroidism, or massive extracellular shifts, such as seen in sepsis, hypothermia or hyperthermia, rhabdomyolysis, or tumor lysis syndromes, such as after chemotherapy for various lymphomas. The most common causes of hyperphosphatemia seen in the ICU are sepsis, rhabdomyolysis, hypothermia, and tumor lysis syndrome. Clinical manifestations are few. Rather, symptoms of the underlying cause (i.e., tumor lysis syndrome) predominate. First-line therapy includes calcium-containing antacids, which bind phosphorus in the gut. High rates of IV fluids and acetazolamide are effective at increasing urine phosphate excretion. Attempts are also made to restrict the patient's phosphorus intake to less than 200 mg/day. Dialysis (either hemodialysis or peritoneal dialysis) is used in cases of renal failure.[24]

Sepsis, rhabdomyolysis, hypothermia, and tumor lysis syndrome are the most common etiologies of hyperphosphatemia encountered in the ICU.

SUMMARY

Disturbances of acid–base balance and electrolytes are common in critical care. Acid–base disorders can be simple or complex, acute or chronic, incidental or life-threatening. As demonstrated by the clinical cases presented, a systematic approach is used to identify the nature of acid–base disorders, with particular emphasis given to AG metabolic acidosis, non-AG metabolic acidosis, and metabolic alkalosis.

Electrolyte abnormalities have the potential for severe clinical sequelae, and treatment for all abnormalities is based on the severity of clinical findings. Through reading this chapter, you should gain a broad appreciation of the diversity and clinical relevance of acid–base and electrolyte disorders in the critically ill patient.

REVIEW QUESTIONS

1. **Identify the acid–base disturbance in the following patients:**
   - **A.** A 25-year-old asthmatic presents acutely short of breath and episodes of vomiting to the ER with pH 7.56, $PaCO_2$ 30 mmHg, HCO_3^- 32 mEq/L, and O_2 saturation 96%
   - **B.** A 30-year-old-woman with a history of eating disorder comes into the ER with a change in mental status and vomiting. An empty bottle of aspirin is found in the patient's bedroom. Chemistries are Na^+ 134 mEq/L, K^+ 4.3 mEq/L, Cl^- 90 mEq/L, HCO_3^- 10 mEq/L, BUN 20 mEq/L, creatinine 0.7 mEq/L, glucose 110 mg/dL; ABG: pH 7.52, $PaCO_2$ 28 mmHg, PaO_2 73 mmHg, O_2 saturation 96%

2. **All the following are causes of AG metabolic acidoses except:**
   - **A.** Salicylate poisoning
   - **B.** Lorazepam infusion
   - **C.** Ethylene glycol
   - **D.** Vomiting
   - **E.** Mangosteen juice use

3. **All the following cause hypotonic hyponatremia except:**
   - **A.** Vomiting
   - **B.** Syndrome of inappropriate SIADH
   - **C.** Mannitol ingestion
   - **D.** Primary polydipsia
   - **E.** Congestive heart failure

4. **By accumulating in the renal collecting tubule cells, this is the drug most commonly implicated in causing NDI:**
   - **A.** Lasix
   - **B.** Lithium
   - **C.** Beta-blockers
   - **D.** Thiazide diuretics
   - **E.** Haldol

5. **DKA is a clinical scenario in which, despite initial laboratory results, the patient is actually**
   - **A.** Total body hypokalemic
   - **B.** Total body hyperkalemic
   - **C.** Total body normokalemic

6. **Why do patients with hypercalcemia secondary to malignancy have low PTH levels?**

7. **Describe the following maneuvers:**
   - **A.** Chvostek's sign
   - **B.** Trousseu's sign

8. **The first step that should be taken in the management of life-threatening hypermagnesemia is:**
   - **A.** Normal saline
   - **B.** Loop diuretic
   - **C.** IV calcium
   - **D.** Dialysis

ANSWERS

1. **A.** The answer is A. Acute respiratory and metabolic alkalosis. The patient is hyperventilating, as can be observed by the fall in PaCO2 and rise in pH. The serum bicarbonate level has increased secondary to loss of H+ ion during vomiting. Normally, during respiratory alkalosis, serum bicarbonate should decrease as a part of compensatory changes.
   B. The answer is B. Triple acid–base disorder. The high pH combined with a low $PaCO_2$ reveals respiratory alkalosis. However, the patient had a low serum HCO_3^-, consistent with an acidosis. The AG ($[Na^+] - (Cl^- + HCO_3^-]$) is elevated at 34, so the patient also has an AG metabolic acidosis, probably from salicylate ingestion. The patient has a delta AG (34–12) of 22, and if this value is added to the patient's measured HCO_3^- of 10, we get a value of 32, which is a higher than normal serum bicarbonate level of 24. Therefore, the patient also has a metabolic alkalosis, probably from vomiting after ingestion.
2. The answer is D. Salicylate poisoning, lorazepam infusion, ethylene glycol, and Mangosteen juice use can cause AG metabolic acidosis. Lorazepam infusion uses propylene glycol as solvent, prolonged infusion of lorazepam infusion can lead to lactic acidosis. Mangosteen juice is a tropical fruit from Southeast Asia that is available for US importation. The fruit contains mangostin, which is a known potent inhibitor of mitochondrial function. Daily ingestion of mangosteen juice was implicated in the development of severe lactic acidosis. Some other rare causes of lactic acidosis include propofol infusion, metformin toxicity, and caffeine intoxication. Excessive vomiting almost always results in a metabolic alkalosis secondary to volume contraction.
3. The answer is C. All the choices listed cause hyponatremia. However, mannitol ingestion causes hypertonic hyponatremia. This condition is a common iatrogenic cause of hyponatremia seen, for example, in cases in which mannitol is employed to treat instances of increased intracerebral hemorrhage.
4. The answer is B. Lithium is the only medication that causes NDI by accumulating in renal collecting tubule cells and is the drug most commonly implicated. Lithium treatment showed impaired urine concentrating ability and reduced urinary AQP2 and cAMP excretion correlatedwith the duration of lithium therapy.
5. The answer is A. Patients with DKA are total body potassium depleted, despite the high serum potassium levels. A failure to replete potassium while correcting the ketoacidosis can result in serum hypokalemia (from intracellular shift of potassium) and fatal cardiac arrhythmias.
6. Production of PTH-like hormone from the malignancy, which exerts negative feedback on PTH. In some malignancies, PTH-related peptide may be elevated.

7. **A.** Tapping the facial nerve anterior to the ear lobe, slightly below the zygomatic arch. A positive response is defined by twitching of the facial muscles innervated by the facial nerve on the innervated side.
B. Inflating an upper extremity sphygmomanometer cuff above systolic blood pressure for a period of no less than 2 min. A positive response is defined by development of carpal spasm.

8. The answer is C. In cases of life-threatening hypermagnesemia, IV calcium is given immediately to stabilize cardiac membranes and prevent fatal arrhythmias.

CHAPTER 36

AMY J. GOLDBERG AND ABHIJIT S. PATHAK

Special Problems in the Critically Ill Trauma Patient

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Identify the etiologies of traumatic shock.
- Describe the compensatory mechanisms in shock.
- Describe the measures for determining the adequacy of resuscitation during traumatic shock.
- Define the global and regional endpoints of resuscitation in trauma.
- Appreciate the utilization of trauma damage control.
- Discuss abdominal compartment syndrome and its pathophysiology.
- Appreciate the significance of the early recognition of limb compartment syndrome.
- Discuss the various complications associated with massive blood products transfusion in the trauma patient.
- Discuss the importance of recognizing and treating inhalation thermal burns and toxic inhalation injuries.
- Recognize carbon monoxide toxicity and institute proper treatment.
- Recognize the importance of venous thromboemolism as a complication in the trauma patient.

Shock is best defined as an abnormal physiological state in which oxygen delivery is inadequate to meet normal metabolic needs.

TRAUMATIC SHOCK AND RESUSCITATION

Definitions

Shock is best defined as an abnormal physiological state in which oxygen delivery is inadequate to meet normal metabolic needs. It has been classified as hypovolemic, cardiogenic, and distributive. Indeed, traumatized patients usually present with hypovolemic shock secondary to acute blood loss from bleeding; however, they can also present with cardiogenic

CASE STUDY: PART 1

A 35-year-old male helmeted motorcyclist struck by a car and thrown 30 feet. On EMS arrival in field, patient noted to be unresponsive. He was intubated and transported with spinal precautions. On arrival to the ED, VS are blood pressure (BP) 80/60mmHg, heart rate (HR) 150 beats/min, and respirations controlled with Ambubag. On examination, there are abrasions across his upper abdomen, equal breath sounds, and no extremity or pelvic deformity. There is abdominal distension and the patient grimaces to pain. Working d*x* is hypovolemic shock most likely from intraabdominal hemorrhage.

or distributive shock. In particular, cardiogenic or rather cardiac compressive shock in the trauma victim may be secondary to tension pneumothorax or cardiac tamponade and are clinical diagnoses, which should be promptly treated with decompression of the affected hemithorax or pericardium, respectively. Distributive shock is usually neurogenic secondary to a cervical spine injury resulting in loss of sympathetic tone and, unlike in the hypovolemic patient, it clinically presents with bradycardia, hypotension, and warm, pink skin on exam.

Although resuscitation of the injured patient is usually accomplished in the Emergency Department (ED), or during emergent operative procedures, it is not uncommon for a trauma patient to arrive in the intensive care unit (ICU) in an under-resuscitated condition. Most often, this is a result of inadequate volume replacement during the initial resuscitative period; however, the presence of continued blood loss from undiagnosed injuries must always be a consideration.

The physiologic status of the trauma patient must be carefully determined on arrival to the ICU. For severely injured patients, or those who undergo prolonged diagnostic or therapeutic operative procedures, it is advisable to check on the condition of the patient prior to actual ICU arrival. Evidence of under-resuscitation must be meticulously pursued. The initial patient evaluation should include, at a minimum, a thorough physical examination, a complete assessment of all available hemodynamic parameters, hemoglobin and arterial blood gas analysis, and a chest radiograph. Additionally, a careful summary of all resuscitative efforts must be compiled, including a tabulation of all injuries and the estimated extent of the blood loss and an accounting of total amounts of infused crystalloid and blood products. This summary should include a review of the actual emergency room and anesthesia records for documentation of hypotensive episodes, acidosis, oliguria, or the intraoperative use of vasoactive medications, clues that indicate a shock state persists despite the appearance of normal hemodynamics.

For severely injured patients, or those who undergo prolonged diagnostic or therapeutic operative procedures, it is advisable to check on the condition of the patient prior to actual ICU arrival. Evidence of under-resuscitation must be meticulously pursued.

Compensatory Mechanisms

Traditionally, the markers of a successful resuscitation have been the restoration of BP, HR, and urine output (UOP). If these parameters remain abnormal, then the need for further resuscitation is quite obvious and a state of uncompensated shock exists. However, patients can have sustained tissue hypoperfusion and inadequate oxygen delivery even after normalization of these parameters. Indeed, up to 85% of severely injured trauma patients have been shown to have inadequate tissue oxygenation. This condition has been termed compensated shock and can lead to multiorgan system dysfunction or even death if not appropriately addressed.

The reliance on gross measures of resuscitation such as HR, BP, and even urine output (UOP) can be misleading and often prevents the early detection and reversal of occult shock.

Management/Fluid Resuscitation

The tenets of management of traumatic shock are making the correct diagnosis, the treatment of the problems and/or injuries that caused shock to develop, and fluid resuscitation. The main goals of fluid resuscitation are to restore effective blood volume, optimize tissue perfusion, and prevent and/or limit ischemic-reperfusion injury. Global ischemic-reperfusion injury after shock is responsible for the development of the systemic inflammatory response (SIRS) and the multiorgan system dysfunction syndrome (MODS).

The main goals of fluid resuscitation are to restore effective blood volume, optimize tissue perfusion, and prevent and/or limit ischemic-reperfusion injury.

CASE STUDY: PART 2

Patient underwent laparotomy and splenectomy and then underwent postop CT scans of the brain, c-spine, chest, and T/L spine, which were negative for any injury. The patient required six units of blood and went to the surgical ICU postop. A central venous pressure (CVP) was transduced and was noted to be 2 mmHg, the patient exhibited a sinus tachycardia in the low 100′s with BP of 130/80 mmHg with UOP of 30 mL/h. A lactate level was noted to be elevated and the central venous O_2 saturation was 60% with a hemoglobin of 9 g/dL. The patient underwent additional IV boluses of LR with a rise in the CVP to 10 mmHg along with a decline in the HR to 80 beats/min. The patient was in compensated shock upon arrival to the SICU and after adequate evaluation and management, corrected his shock state.

The reliance on gross measures of resuscitation such as HR, BP, and even UOP can be misleading and often prevents the early detection and reversal of occult shock. Tachycardia has historically been shown to be neither a sensitive nor specific indicator of shock. Furthermore, BP may be restored in the severely injured trauma patient by vasoconstriction and does not ensure that there is adequate perfusion. Indeed, the arterial base deficit and serum lactate have been shown to be better global markers or indicators of the adequacy of tissue perfusion. Severely injured patients or those who exhibit overt signs of under-resuscitation should undergo central hemodynamic monitoring (i.e., CVP line or pulmonary artery catheter) to assess intravascular volume status and guide further fluid resuscitative therapy.

Crystalloid solutions have been traditionally used for initial resuscitation of shock in the trauma patient, in particular, lactated Ringer's solution. Increasing data suggests that that lactated Ringer's is proinflammatory and may exacerbate SIRS, thereby contributing to MODS.[1] Another concern with large-volume crystalloid solution resuscitation has been the development of the abdominal compartment syndrome (ACS).[1] Because of these issues, there has been a recent flurry of investigation that attempts to address the role of hypertonic saline in the initial resuscitation of the trauma victim. Many investigators have shown that at low volumes (4 mL/kg) 7.5% saline is more effective at restoring the extracellular fluid (ECF) compartment, cardiac output, and organ perfusion than large-volume resuscitation with lactated Ringer's.[2] At the present time, hypertonic saline resuscitation cannot be recommended over standard crystalloid resuscitation in the initial resuscitation of the trauma patient.

Endpoints of Resuscitation

Base Deficit/Acidosis

Inadequate tissue perfusion and oxygen delivery causes a shift from aerobic to anaerobic metabolism with the resultant production of pyruvate and hydrogen ions, leading to metabolic acidosis. The degree of metabolic acidosis is quantified by the base deficit and is used as an estimate of oxygen debt in the trauma victim. It is defined as the amount of base in millimoles that is needed to titrate a liter of arterial blood to a normal pH in the presence of normal oxygenation, carbon dioxide, and body temperature. The base deficit can predict mortality with patients having a base deficit >15 mmol having a 25–50% mortality. Furthermore, patients with progressive base deficit despite seemingly adequate resuscitation should be suspected of having continuing blood loss.

The primary and initial treatment of metabolic acidosis should be the restoration of oxygen delivery by fluid administration or inotropic support, not pharmacologic correction of pH with bicarbonate.

The primary and initial treatment of metabolic acidosis should be the restoration of oxygen delivery by fluid administration or inotropic support, not pharmacologic correction of pH with bicarbonate. Only at pH levels less than 7.2 should consideration be given to the use of intravenous sodium bicarbonate. Experimental evidence suggests that below this degree of acidosis, myocardial contractility is reduced. Thus, making serial determinations of the base deficit and pH, based on arterial blood gas sampling, is a simple and reliable tool to assess the adequacy of resuscitation.

Serum Lactate

Serum lactate may be a useful marker for judging the adequacy of resuscitation following trauma.

A shift from aerobic to anaerobic metabolism with the production of pyruvate and H+ ions occurs when there is inadequate tissue perfusion and oxygen delivery. Pyruvate is converted

to lactate during anaerobic metabolism and is measured as an indirect global marker of oxygen debt after shock. Admission lactate, highest serum lactate, and the time required to normalize blood lactate level have been shown to correlate with mortality in trauma patients. One study using multiple logistic and linear regression analyzes found that lactate and base deficit were independent predictors of mortality, ICU and hospital length of stay.[3] Additionally, it has been suggested that the correlation of blood lactate level with survival is time-dependent, that is, early (within 24 h) normalization of lactate levels (less than 2 mEq/L) improves the chance of survival. By contrast, persistent (greater than 48 h) elevations in serum lactate are associated with a high (greater than 75%) mortality. Thus, serum lactate may be a useful marker for judging the adequacy of resuscitation following trauma.

Oxygen Delivery and Consumption

There is considerable controversy concerning the utility of measuring oxygen transport variables in the care of the critically ill trauma patient. Specifically, the controversy has centered around whether attempts to achieve normal or supranormal oxygen delivery affect outcome. Theoretically, the concept involves matching a patient's oxygen needs to oxygen delivery. This debate has persisted for over 20 years and, although initial studies demonstrated an improvement in survival among patients in whom oxygen delivery was increased above normal (>600 mL/min/m^2), subsequent studies have failed to demonstrate any benefit.[4] Indeed, it is more likely that patients who are able to attain supranormal oxygen delivery goals have a better chance of survival than those patients who cannot, and that this is a marker of their physiologic reserve. Because shock is a state in which oxygen delivery to the tissues is inadequate for normal aerobic metabolism, achieving oxygen delivery that is sufficient for an adequate level of oxygen consumption should be the ultimate goal of resuscitation.

Oxygen delivery that is sufficient for an adequate level of oxygen consumption should be the ultimate goal of resuscitation.

Hemodynamic Monitoring

Because measures of HR and BP are often unreliable in guiding resuscitation, the ICU physician may utilize a pulmonary artery catheter to evaluate crucial hemodynamic parameters. CVP and pulmonary capillary wedge pressure (PCWP), as well as measured or calculated indices of cardiac performance, such as cardiac index and left ventricular stroke volume, can provide important information. Normal hemodynamics must be known; many variables affecting the trauma patient can impact these values independent of intravascular volume status (Appendix B). Temperature, acute respiratory failure, sepsis, and direct cardiac injury can make these data difficult to interpret. Furthermore, CVP and the PCWP may have limitations in the critically ill trauma patient due to changes in ventricular compliance (injury, edema, etc.) or intrathoracic pressure (mechanical ventilation, etc.). Right ventricular end diastolic volume index (RVEDVI) may more accurately reflect left ventricular preload than CVP or PCWP because of these limitations. Nonetheless, every effort should be made to normalize venous filling pressures and maintain a normal cardiac output.

Often, the young trauma patient will be resuscitated rapidly with volume restoration, but the elderly patient and those who have experienced prolonged periods of profound hypotension or cardiac arrest may require vasoactive therapy to support and maintain an acceptable hemodynamic profile. However, the first-line therapy for a trauma patient in shock should never be administration of vasopressor therapy unless all other causes of under-perfusion, most importantly, volume depletion, have been excluded.

Gastric Tonometry

Gastric tonometry is a technique that has been used as a tissue-specific endpoint and assesses the adequacy of GI tract perfusion. The splanchnic circulation and bowel are very sensitive to changes in blood flow, and the GI tract is the first organ system to manifest signs of ischemia during low-flow states. In particular, the intestinal mucosa is metabolically active and does not receive adequate blood flow during shock. In low-flow states, the flow of oxygenated

blood to the mesenteric circulation may be shunted to critical organs such as the brain and heart. Because CO_2 is readily diffusible across the intestinal mucosa, intraluminal pCO_2 approximates intramucosal pCO_2. Gastric tonometry involves a technique whereby a probe is inserted into the stomach and intraluminal pCO_2 is measured and an estimate of intramucosal pH is obtained using the Henderson–Hasselbach equation. Several studies have demonstrated that aggressive resuscitation to restore an intramucosal gastric pH ≥7.35 can improve patient outcome, especially when this correction occurs within the first 12 h after the injury.

Tissue Oxygen and Carbon Dioxide

The measurement of transcutaneous O_2 and CO_2 are additional regional markers of perfusion, which have been used in the trauma patient. Essentially, an optical sensor is placed into the subcutaneous tissue to examine peripheral perfusion. By the same principles of gastric tonometry, flow of oxygenated blood in low-flow states may be shunted to more immediately critical organs such as the brain and heart. Limited data suggests that transcutaneous and muscle pO_2 and pCO_2 may predict the risk of death in trauma patients.[4]

Near Infrared Spectroscopy (NIRS)

NIRS is a noninvasive technique that evaluates skeletal muscle oxygenation utilizing the differential absorption properties of hemoglobin. In particular, a probe/sensor emits light in the near-infrared spectrum (650–1,000 nm) and photons from multiple wavelengths are either absorbed or reflected back to the probe and measure tissue oxyhemoglobin levels. Preliminary studies suggest that NIRS measurement of pO_2, pCO_2, and pH may predict the risk of developing MODS and death after trauma.[4]

TRAUMA DAMAGE CONTROL

Definition/Stages

Severely injured patients with profound hemorrhagic shock who require operation and develop metabolic failure are managed by abbreviated procedures, which control bleeding and contamination. After undergoing further resuscitation in the SICU and correction of their metabolic failure and shock, they return to the OR for definitive repairs.

There has been a paradigm shift over the past 10–15 years in the management of trauma patients. In those patients with intraoperative metabolic failure (defined as acidosis, hypothermia, and coagulopathy), conservative operative techniques to control hemorrhage and contamination without performing definitive repairs have led to shorter operative times and increased patient survival.[5] In essence, severely injured patients with profound hemorrhagic shock who require operation and develop metabolic failure are managed by abbreviated procedures, which control bleeding and contamination and defer complex definitive repairs to a later time when the patient is more stable. After undergoing further resuscitation in the SICU and correction of their metabolic failure and shock, they return to the OR for definitive repairs. This concept can be applied to any severely injured body region; however, it is most commonly encountered in patients undergoing laparotomy or thoracotomy. There are three stages of damage control.

1. *Control of hemorrhage and contamination*: The primary goal is to control hemorrhage from major organs and blood vessels by packing certain organs/spaces, resecting major GI tract injuries to control contamination (without necessarily restoring GI continuity), and utilizing a temporary incisional wound closure. The patient returns to the OR for definitive repairs after resuscitation is completed.
2. *Resuscitative phase in the SICU*: Involves correction of metabolic failure and reversal of shock. This usually requires invasive hemodynamic monitoring. Monitoring of the intraabdominal pressure (IAP) may be required to identify intraabdominal hypertension (IAH) in those patients who progress to develop the ACS.
3. *Reoperative phase/definitive repair*: Involves returning patients back to the OR for removal of packs, completion of definitive repairs, restoration of GI continuity, and final closure of the incision if possible.

Abdominal Compartment Syndrome

Definition/Clinical Sequalae

ACS is a clinical situation, which occurs when the IAP rises with resultant cardiopulmonary and renal compromise. It is characterized by a tense, distended abdomen with the triad of elevated peak inspiratory pressures and inadequate ventilation, hemodynamic compromise secondary to poor venous return, and decreased renal function with oliguria. These derangements usually correct after abdominal decompression. IAH can occur as a result of the accumulation of ascites, blood and/or clot, bowel edema or distension, and reduction of bowel from a large chronic hernia, resulting in loss of domain (displacement of abdominal contents into hernia). In the trauma patient, IAP can rise secondary to the accumulation of blood and/or clot, bowel edema, or congestion from resuscitation or injury, and additionally from intraadominal packing for diffuse nonsurgical bleeding. Closure of a noncompliant abdominal wall under tension may further increase IAP.

Pathophysiology

In several animal models, IAP above 20 mmHg has been shown to have a negative effect on both cardiovascular and pulmonary performance. Clinical studies have demonstrated a significant improvement in cardiovascular indices once IAH has been therapeutically reduced by decompressive laparotomy. Specifically, surgical decompression has been shown to increase cardiac index, oxygen delivery, and gastric mucosal pH and UOP, while reducing CVP. Often, a variety of measures of pulmonary gas exchange improve and the patient requires less supplemental oxygen or positive end-expiratory pressure (PEEP).

Management

In the appropriate clinical scenario, the IAP can be monitored. This is most commonly performed via the indirect method of measuring the bladder pressure. This is accomplished by instilling 100 mL of NSS into the bladder via a Foley catheter. The tubing on the collecting bag is clamped and a needle (18 G or larger) is inserted into the specimen-collecting port of the tubing proximally and attached to a pressure transducer, which is then trended on the ICU monitor. The zero point is at the level of the symphysis pubis. Elevation of bladder pressure may proceed to ACS and abdominal decompression will need to be considered; a bladder pressure greater than 20 mmHg is significant. However, it is important to remember that IAH can be present without ACS, which is a clinical diagnosis as noted above.

Elevation of bladder pressure may proceed to ACS and abdominal decompression will need to be considered; a bladder pressure greater than 20 mmHg is significant.

Decompressive laparotomy can be performed at the bedside or in the operating room. Before decompression is carried out, optimization of volume and oxygen delivery status should be achieved along with correction of any coagulopathy. Several techniques are popular, but all include release of fascial closure, irrigation of the abdomen to remove blood clots, removal of any abdominal packs, and, if practical, reclosure of the abdomen with some type of synthetic material that allows replacement of the bowel into the abdomen without undue pressure. A marker of how much tension can be tolerated is provided by the respiratory parameters of tidal volume and peak airway pressure; these should be observed during the closure. This procedure may need to be repeated on several occasions. Alternatively, once bowel edema subsides and IAH reverses, final anatomic closure of the abdomen may take place.

COMPARTMENT SYNDROME

Definition/Pathophysiology

Compartment syndrome is a potentially catastrophic complication that can follow crush or vascular injury of an extremity. Because this complication usually occurs several hours after injury or revascularization surgery of an extremity, it is often diagnosed in the ICU. Diagnosis

and treatment must be accomplished rapidly to avoid loss of limb. Therefore, careful monitoring of patients at risk and a clear understanding of the clinical presentation of this syndrome are necessary.

A high level of clinical suspicion is needed to diagnose extremity compartment syndrome early.

Following a crush injury of an extremity, or revascularization surgery, edema caused by direct or reperfusion injury can produce extensive amounts of third-space tissue fluid. Although any extremity can be at risk, this syndrome is most common in the leg. The muscles of the extremities, which are encased in tough, nonelastic fascial compartments, are the areas where the process actually occurs. These noncompliant compartments will not stretch when edema develops acutely in and around the musculature. Thus, increasing edema formation progressively elevates hydrostatic pressures within the muscle compartment. This pressure can ultimately rise to exceed not only venous pressure, but also arterial pressure. The end result is a compromise of capillary blood flow within the muscle compartment, with resultant ischemia and eventual necrosis of not only the muscle but of the nerve tissue as well.

Diagnosis

Classic signs of compartment syndrome are pain, paresthesias, pulselessness, pallor, poikilothermia, and paralysis.

In the awake patient, several classic signs of compartment syndrome have been recognized. These signs are often referred to as the six P's: pain, paresthesias, pulselessness, pallor, poikilothermia, and paralysis. Progression to the last four P's carries significant morbidity and suggests failure to diagnose the syndrome at its earliest and most treatable stages. Any patient at risk who complains of pain out of proportion to their injury or the beginning of paresthesias should be carefully examined for this syndrome. On examination, compartments should be palpated. Generally, they are tense, firm, and very tender as a result of the extremity edema. Stretching of the affected muscle compartment will exacerbate pain. The foot and great toe should be flexed and extended passively to elicit pain in the involved compartment. Exacerbation of pain should prompt the immediate measurement of actual pressures in each of the compartments of the extremity. The leg, for example, has a total of four compartments.

In an unconscious patient, the early signs of compartment syndrome cannot be easily determined. Thus, the diagnosis is often made late when marked tenseness in the extremity or a change in the quality of the pulse is appreciated. An absent arterial pulse is generally considered to be a very bad prognostic sign.

Compartment pressures can be obtained with handheld monitoring devices or needles attached to pressure transducers. Some debate exists as to the exact pressure reading that establishes the diagnosis. In a normotensive patient, a compartment pressure greater than 30 mmHg is considered by most to be pathologic (some have suggested mean arterial pressure – compartment pressure differences >40 mmHg). Measurements must be made in each compartment of the extremity, keeping in mind that the leg has four separate fascial compartments: anterior, lateral, deep, and superficial posterior.

Management

Once established, the compartment syndrome must be treated by immediate surgical fasciotomy of all compartments in the affected extremity. In the leg, this entails decompression of all four fascial compartments; necrotic muscle should be debrided.

Immediate surgical fasciotomy is the treatment of choice for compartment syndrome.

Should muscle ischemia result from the compartment syndrome, systemic complications of hyperkalemia and myoglobinuria can occur. Following myocyte death, intracellular potassium and the oxygen transport protein myoglobin are released. Hyperkalemia can initially be treated with conventional measures. Myoglobin is toxic to the renal tubular epithelial cells and can cause tubular necrosis of the kidney with the potential for progression to acute renal failure. Once myoglobinuria is confirmed, the goals are to stop additional myocyte death in the affected limb and prevent renal failure. All dead muscle tissue in the affected extremity must be removed; at times, this may require limb amputation. Muscles of questionable viability can be followed by serial clinical examination, including intraoperative inspection and serial serum creatinine kinase measurements. Volume loading and vigorous diuresis,

preferably with an osmotic diuretic, are required to keep UOP brisk so that precipitation of myoglobin in the renal tubules can be prevented. Alkalinization of the urine is commonly recommended and performed to prevent precipitation of soluble myoglobin; however, this therapeutic intervention lacks convincing evidence of human clinical efficacy. (See discussion in Chap. 22).

MASSIVE TRANSFUSION AND ITS COMPLICATIONS

Massive Transfusion Protocol

Trauma patients often require transfusion of large quantities of blood products during resuscitation and operation. Many institutions with a busy trauma service have created and utilize a massive transfusion protocol (MTP), in order to rapidly respond to patient needs (See Chap. 55). Consistent use of a MTP that directs the aggressive and timely transfusion of RBCs, FFP, platelets, and possibly cryoprecipitate, has been shown to improve survival in trauma patients with hypovolemic shock secondary to blood loss. There is recent literature regarding what is the appropriate ratio of component transfusion such as FFP and platelets to PRBCs. Many centers have MTPs, which attempt to achieve a 1:1:1 ratio of PRBC:FFP:PLT during massive transfusion.[6]

Massive blood transfusion is the complete replacement of a patient's blood volume within a 24-h period. In an adult, this usually requires up to ten units of packed red blood cells (PRBCs). Mortality in this population approaches 50%. The clinical sequelae of massive transfusion commonly observed in the ICU are hypothermia, hypocalcemia, hyperkalemia, hypokalemia, coagulopathy, and respiratory failure.

Massive blood transfusion is the complete replacement of a patient´s blood volume within a 24-h period.

Clinical Sequelae of Massive Transfusion

Hypocalcemia

Banked blood is anticoagulated with citrate, which chelates ionized calcium. Transfusions of large quantities of blood lead to a large citrate load that can result in hypocalcemia. Furthermore, hypocalcemia is exacerbated by hypothermia and acidosis and can lead to cardiac dysfunction or disturbances in coagulation. Therefore, careful attention to serum calcium levels and correction of hypocalcemia are imperative. Most modern operating rooms suites have an on-site laboratory with the capability of providing electrolyte and arterial blood gas measurements within several minutes.

Hyperkalemia

During the storage of banked blood, hemolysis occurs, thus releasing potassium from the red blood cells. During massive blood transfusion, as much as 8 mEq/L potassium can be infused with each unit of transfused cells. Therefore, hyperkalemia can be observed following massive transfusion and frequent measurements of serum potassium are recommended during resuscitation.

Hypothermia

As a consequence of rapid infusion of blood and crystalloid, trauma patients are at risk for the development of hypothermia. Platelet function is directly impaired by hypothermia, probably via alterations at the level of the cell membrane. Platelet dysfunction can become clinically significant despite a normal platelet count. The presence of dilutional thrombocytopenia in massively transfused patients can further limit platelet function. Depletion of clotting factors is often underestimated in the hypothermic trauma patient.

Hypothermia is a consequence of rapid massive volume resuscitation.

Treatment is aimed at correction of hypothermia present on arrival to the emergency room and prevention of further temperature loss during resuscitation, operation, and recovery.

Blood and fluid-warming devices should be used during trauma resuscitation. High ambient temperatures should be maintained in the emergency department and operating rooms. Every effort should be made to utilize active rewarming devices such as warming blankets, convective air re-warmers, and radiant heat lamps. Although simple, active core re-warming by gastric and urinary bladder irrigation is somewhat inefficient. The use of extracorporeal and continuous arteriovenous re-warming may be needed in the severely hypothermic patient.

Coagulopathy

The etiology of coagulopathy is usually multifactorial. The most common cause is likely to be a dilutional coagulopathy as a result of massive infusions of crystalloid and PRBCs; contributing factors include hypothermia and acidosis. It is often difficult to exclude DIC as a cause of coagulopathy in the setting of severe trauma and subsequent massive transfusion. In this type of clinical situation, the diagnosis and treatment of coagulopathy is, of necessity, often presumptive. Though there may be time to send blood samples to the laboratory for analysis, therapy must be initiated immediately and will initially include aggressive transfusion of PRBC, FFP, and platelets. Cryoprecipitate should be considered if DIC is a possibility.

Massive transfusion can lead to severe coagulopathy.

The major hemostatic defects in the massively transfused patient appear to be related to thrombocytopenia, secondary to dilution and consumption at the sites of injury, and platelet dysfunction secondary to hypothermia. Although considerable controversy exists, platelet transfusions do not appear to be justified simply because a patient has required a single blood volume replacement; the patient who has undergone a previous splenectomy may be an exception to this rule. Platelet counts of 20,000/μL are usually adequate in nonbleeding patients; however, even if the platelet count is as high as 100,000/μL, transfusion may be appropriate in a trauma patient with evidence of ongoing bleeding. In patients who have received more than 10–15 units of blood and who continue to have nonmechanical bleeding, or experience a significant drop in platelet count, platelet transfusion should be considered. Likewise, clotting factor deficiency should not occur following a single blood volume replacement. However, patients who are transfused with more than 15 units of blood and who have significant ongoing nonmechanical blood loss, and a presumed coagulopathy, should have blood coagulation factor replacement with the administration of fresh-frozen plasma; as noted above, cryoprecipitate should be considered.

Recombinant Factor VII (rFVIIa)

The only FDA-approved indication for rFVIIa is bleeding associated with hemophilia. However, there has been off-label use in trauma and a recent clinical trial revealed a decrease in RBC transfusion requirements in blunt trauma victims when compared to placebo; however, there was no difference in outcome.[7]

Transfusion Related Acute Lung Injury (TRALI)

TRALI presents as noncardiogenic pulmonary edema during or within hours of transfusion. It can occur in 1 out of 5,000 transfusions.[8] The pathway to injury is not fully understood; two mechanisms have been proposed, one immune-mediated and the other nonimmune-mediated (see Chap. 55). It has been observed to occur soon, within 4 h of blood product administration. Clinically, it is indistinguishable from ALI/ARDS and the diagnosis is one of exclusion; treatment is supportive.

CARE OF THE BURN PATIENT

Although modern care of the burn patient is routinely accomplished in a regional burn center, it may be necessary for trauma centers to temporarily manage an acute burn patient prior to transfer. Control of the airway and evaluation for the possibility of inhalation/burn airway

injury are most often accomplished in the emergency room during initial resuscitation. Following airway evaluation and management, the major consideration in the next 24 h is continuation of fluid resuscitation. (See also Chap. 40).

Inhalation Injury

Inhalational injury may involve direct thermal injury to the airways and lung tissue and additional risk of toxic gas exposure.

Inhalation injury can be separated into the two distinct pathophysiologic components that differ as to the nature of the injury, timing of manifestations, and treatment. Direct thermal injury or the inhalation of toxic gases can injure the airway. Patients at increased risk for inhalation injuries are those burned in a closed-space fire or exposed to petroleum-based fires.

Transfer of heat from hot gases to the airway mucosa produces direct thermal injury. Because the upper airway is a very efficient heat exchanger, direct thermal injury to the airway below the level of the larynx is uncommon. Because this injury occurs at the time of fire exposure, these patients usually exhibit signs of inhalation injury early, often in the emergency room. Signs of possible inhalation injury include carbonaceous sputum and carbonaceous deposits about the nose and mouth, burnt facial and nasal hairs, and hoarseness or stridor. For such patients, fiberoptic laryngotracheoscopy should be performed to evaluate the airway. The presence of edema, blisters, ulcerations, or hemorrhage indicates the need for intubation as these lesions may progress over time and produce airway obstruction. When these findings are absent, the patient should be administered high-humidity oxygen and admitted to the ICU for monitoring of arterial oxygen saturation; periodic blood gases are required to evaluate for progressive hypercapnia and resolution of CO saturation. The use of systemic steroids in these patients remains controversial.

Signs of inhalation injury are carbonaceous sputum, singed facial hairs, hoarseness, stridor.

Airway edema, blisters, ulcers, and hemorrhage indicate a need for intubation.

Inhalation of nonheated toxic gases can also produce a delayed injury to the lower airway and lung. These patients may have stigmata of inhalation injury. Treatment is the same as previously outlined; however, these patients must be followed closely in the ICU for up to 72 h as a worsening chest X-ray or PaO_2/FiO_2 ratio may signal the development of lung injury or a superimposed pneumonia.

Carbon Monoxide Poisoning

Carbon monoxide (CO) intoxication occurs in closed-space fires.

Patients exposed to a closed-space fire are at risk for the development of CO poisoning. Because CO binds more avidly to hemoglobin than oxygen, once exposed, patients require treatment with 100% oxygen. CO toxicity may manifest as subtle to severe neurologic or cardiovascular changes; thus, a high index of suspicion for poisoning must be maintained when initially treating burn patients.

All patients at risk should have measurement of serum CO saturation levels (normally less than 3%). Smokers may have baseline CO levels of 3–5% and firefighters on duty may have levels as high as 8%. Treatment is dependent on symptomatology. Patients with mild elevations of CO should be treated with 100% humidified oxygen and serial monitoring of blood CO saturation. Patients with mild neurologic symptoms are likewise treated with high-concentration oxygen and closely monitored. Patients presenting with high CO levels and severe neurologic symptoms, such as obtundation, coma, or hemodynamic instability, are best treated with hyperbaric oxygen therapy. The treatment of patients with mild neuropsychologic dysfunction is controversial. Obviously, when in doubt, high concentrations of inspired oxygen should be utilized initially in all patients at risk.

CO toxicity is treated with high-concentration oxygen and occasionally with hyperbaric oxygen.

Fluid Resuscitation

Calculations of fluid requirements for a burn patient are made with reference to several standard formulas and take into account the percentage of body surface burned and the patient's ideal weight. During the first 24 h, fluid resuscitation is accomplished with a crystalloid

TABLE 36-1

RECOMMENDED CALCULATIONS FOR BURN FLUID THERAPY

First 24 h
Lactated Ringers, 2–4 mL/kg body weight/% burn
Half given during the first 8 h, half during the following 16 h
Second 24 h
Colloid as
30–50% burn, 0.3 mL/kg body weight/% burn
50–70% burn, 0.4 mL/kg body weight/% burn
>70% burn, 0.5 mL/kg body weight/% burn
D5W to maintain urine output >1 mL/kg/h

preparation, generally lactated Ringer's solution. During the next 24 h, both crystalloid and colloid infusions are utilized (Table 36-1).

The percent of total body surface (TBS) area burned can be estimated by referring to the so-called rule-of-nines diagram (Fig. 36-1). The anterior thorax and abdomen, the back, and each lower extremity contribute 18% each to the TBS; the head and the upper extremities, 9%; and the genitalia, 1%. A more rapid estimate can also be made with the realization that the surface area of a patient's palm is equal to approximately 1% of TBS.

UOP is a reliable guide to the burn patient's intravascular volume status; however, invasive central monitoring is desirable for patients with extensive burns (greater than 70%) and in the elderly with confounding underlying diseases. Additionally, hematocrit levels should be maintained at 30–35%.

The amount of initial fluid resuscitation is determined by the extent of TBS burns.

A unique complication observed in patients with circumferential burns of the extremities is vascular compromise secondary to compartment syndrome. Burn eschar is fibrotic, or nonelastic, in character. When edema develops in the affected extremity, a physiologic

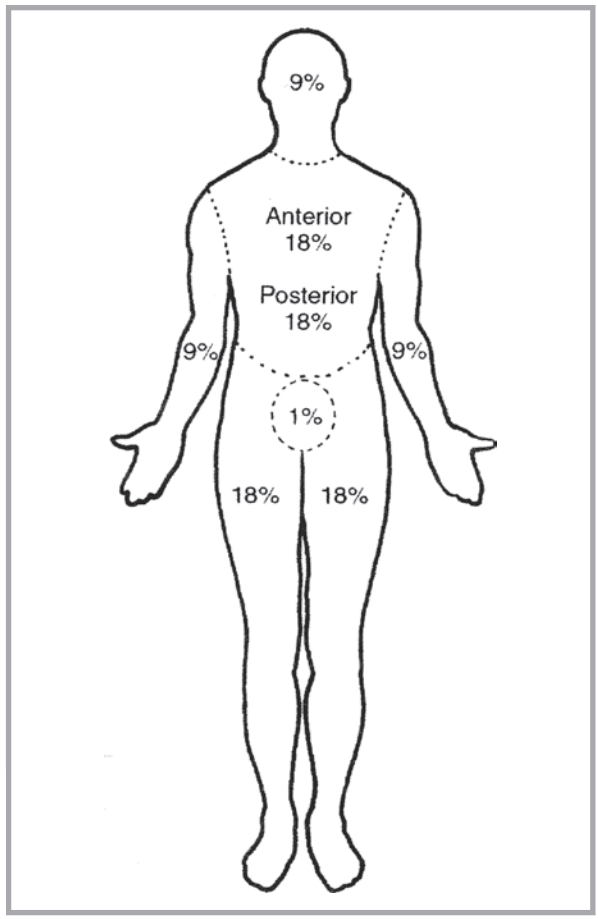

FIGURE 36-1

The rule-of-nines is used to calculate burned area to characterize magnitude of burn involvement.

situation comparable to compartment syndrome can develop. The most useful tool to monitor the status of blood flow to an extremity with circumferential burns is a Doppler-flow probe and, if needed, compartment pressure measurements. Serial examinations are warranted, and loss of pulsatile blood flow is an absolute indication for urgent surgical escharotomy. It is important to remember that extremity compartment syndrome can occur well before the loss of an arterial pulse, so a keen level of awareness for the need for surgical compartment release must be maintained.

VENOUS THROMBOEMBOLISM (VTE) IN TRAUMA

Trauma patients are at increased risk for deep venous thrombosis (DVT) and pulmonary embolus (PE) with the incidence as high as 20 and 6%, respectively. However, identifying the trauma patient who is at high risk for VTE can be challenging. Not only does the trauma victim have the usual risks of the hospitalized patient for VTE, but the nature of their injury can place them at increased risk. The American College of Chest Physicians guidelines[9] discusses risk stratification for identifying those patients who are at low, moderate, and high risk for VTE. The trauma victim may also have a hypercoagulable state secondary to their inflammatory response, further increasing coagulability. Factors that are independently associated with an increased risk of VTE in trauma patients include spinal cord injury (SCI), lower extremity or pelvic fracture, need for surgical procedure, increasing age, insertion of a femoral venous line, major venous repair, prolonged immobility, and longer duration of hospital stay (Table 36-2).[10]

Prophylaxis

Pharmacologic Prophylaxis

There is little evidence to support low-dose heparin (LDH) (5,000 U subcutaneous every 8–12 h) as a sole agent for prophylaxis in the trauma patient at high risk for VTE. Studies on the use of LDH in trauma patients are inconclusive; many are single institutional nonrandomized studies with small sample size. Low-molecular-weight heparin (LMWH) has been shown to be more efficacious with the same or less bleeding risk than LDH prophylaxi.[10] This may be because LMWH has superior bioavailability compared to unfractionated heparin.

Mechanical Prophylaxis

Pneumatic compression devices (PCD) are effective in reducing the risk of DVT in the general surgery population and offer the distinctive advantage of not being associated with bleeding complications; they have become the standard prophylaxis method for low-to-moderate risk

PCDs used in conjunction with LMWH are first-line prophylaxis for DVT in many trauma patients.

TABLE 36-2

RISK FACTORS FOR DEEP VENOUS THROMBOSIS (DVT) IN THE TRAUMA PATIENT

Age >40 years
Obesity
Major surgery
Venous injury
Immobilization
Pelvic fractures
Glasgow score <8
Massive transfusion
Spinal cord injury
Lower extremity fracture
Femoral central venous pressure (CVP) >16 mmHg

TABLE 36-3

EAST GUIDELINES: INDICATIONS FOR VENA CAVA FILTER PLACEMENT IN THE VERY HIGH RISK TRAUMA PATIENT

Those patients who cannot receive anticoagulation because of increased bleeding risk, and have an injury pattern rendering them immobilized for a prolonged period of time, including the following:
Severe closed head injury(GCS<8)
Incomplete spinal cord injury with paraplegia or quadriplegia
Complex pelvic fractures with associated long bone fractures
Multiple long bone fractures

SOURCE: Data from Rogers et al.[10]

trauma patients. Arteriovenous (A-V) foot pumps may be used as a substitute for PCDs in certain patients who cannot wear PCDs because of their injuries. However, A-V foot pumps have not been shown to be as efficacious as PCDs.

Vena Cava Filters

Many trauma patients have contraindications for pharmacologic prophylaxis due to the nature of their injury and the risk for continued bleeding. Insertion of a "prophylactic" vena cava filter for the prevention of pulmonary embolism may be considered in very high-risk trauma patients (listed in Table 36-3). Retrievable filters have been increasingly utilized over the past 5 years, and many centers exclusively use these filters.

SUMMARY

Several unique situations are associated with the patient who has experienced blunt and/or penetrating trauma. It is paramount in critical care to carefully attend to the resuscitation process and to be observant for the numerous complications associated with the trauma itself or the resuscitation efforts. Surgeons and intensivists play a significant and collaborative role in minimizing these complications and ultimately improving patient survival.

REVIEW QUESTIONS

1. Appropriate shock resuscitation includes all the following, except:
- **A.** Intravenous infusion of crystalloids
- **B.** Blood transfusion
- **C.** Vasopressor therapy
- **D.** Intravenous infusion of sodium bicarbonate
- **E.** All the above

2. All the following statements are correct concerning limb compartment syndrome, except:
- **A.** Crush injury or limb revascularization surgery are often the causal event
- **B.** Limb edema is due to reperfusion
- **C.** The limb is always pulseless
- **D.** Pain and paresthesias of the limb are common
- **E.** Common complications include hyperkalemia and renal failure

3. Concerning carbon monoxide (CO) intoxication, which statement is false?
- **A.** It is a common complication of inhalation injury
- **B.** CO binds more avidly than O_2 to the hemoglobin molecule
- **C.** Neurologic sequelae are common
- **D.** O_2 therapy should be used
- **E.** All patients should be placed in a hyperbaric chamber

4. All the following are considered a complication of massive blood transfusion therapy, except:
- **A.** Hyperkalemia
- **B.** Hypocalcemia
- **C.** Hypokalemia
- **D.** Hypothermia
- **E.** Hypercoagulability

ANSWERS

1. The answer is C. Primary therapy does not include sodium bicarbonate solution. Sodium bicarbonate should only be used during extreme metabolic acidosis.
2. The answer is C. Compartment syndrome can be present in a limb with arterial pulses. Muscle necrosis can occur due to small vessel ischemia secondary to fascial compartment tense edema.
3. The answer is E. Hyperbaric O_2 should only be used for patients with severe neurologic symptoms or cardiovascular instability.
4. The answer is E. Patients are likely to be hypercoagulable secondary to depleted or diluted clotting factors and low or dysfunctional platelets.

CHAPTER 37

JOHN M. TRAVALINE, FRIEDRICH KUEPPERS, AND JACQUELINE S. URTECHO

Ethics in Critical Care

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Know the four fundamental principles of medical ethics.
- Understand the importance of obtaining informed consent.
- Know when an order for no resuscitation is appropriate.
- Understand the issues regarding withholding and withdrawing life-sustaining therapy, organ donation, and the concept of medical futility.
- Understand the role of ethics consultation in the critical care setting.

GENERAL PRINCIPLES

Ethical issues are common in critical care. The high degree of urgency present in managing extremely ill patients, the often sudden onset of their illness, the frequent lack of decision-making capacity of patients who are critically ill, and, for many critically ill patients, the status of being near death all contribute to ethical questions about the appropriateness of therapy.

An approach to ethics in critical care can begin with consideration and understanding of four fundamental principles of biomedical ethics: (1) to do good (beneficence), (2) to do no harm (nonmaleficience), (3) to respect the patient's wishes (autonomy), and (4) to be fair (justice).[1] Nearly all issues that arise in patient care in the critical care setting can be approached initially with one or more of these principles in mind. It is important to recognize, however, that although these principles are useful in forming arguments for debate, they remain abstract. Nonetheless, they are a foundation for ethical debate and serve as important guideposts for clinical decision-making.

The four fundamental principles of biomedical ethics are beneficence, nonmaleficience, autonomy, and justice.

In this chapter, we discuss four areas of medical ethics in the context of critical care. These areas – informed consent and the use of advance directives, the do not resuscitate order (DNR), medical futility, and the withholding and withdrawing of life-sustaining medical therapy – are commonly encountered subjects of ethical discourse in this setting. In the last section of this chapter, we discuss some practical matters concerning the role of ethics consultation in critical care units.

CASE STUDY

J.M. was a 79-year-old man with long-standing hypertension and chronic renal failure receiving outpatient dialysis. He had been doing well, able to live independently and drive himself regularly to the dialysis center 3 times per week. During one dialysis treatment, however, he was noted to have fever and his blood pressure dropped lower than expected and could not be maintained without the use of vasopressor medication. He was transferred to the medical intensive care unit where the diagnosis of sepsis with shock was established. Appropriate and aggressive medical therapy was continued, but despite this, the patient deteriorated and needed to be intubated and placed on mechanical ventilation.

After 3 days, there was still no response to medical therapy. Moreover, routine physical examination revealed that J.M. was no longer moving any part of his right side in response to stimulation although he had been able to do so when he was admitted. Computerized tomography of the brain confirmed the suspicion that J.M. had suffered an extensive left-sided, dominant hemispheric stroke. Neurologic consultation revealed that it was extremely unlikely that J.M. would be able to speak again, understand what is spoken, or move the right side of his body. There was concern that given the size of the infarct, he would be at risk for bleeding and significant swelling of the brain. His attending physician was also concerned that, from the sepsis alone, despite continued therapy, J.M. was not going to survive. Other consultant physicians involved with the case concurred.

By the fifth day of hospitalization, the attending physician was beginning to consider the withdrawal of therapy. It became clearer to her that all the medical efforts were now serving to prolong an inevitable dying process (and signs of cerebral edema were now noted on physical exam). It was obvious to her that J.M. was unable to make any decisions regarding his ongoing medical care, but she knew that he had completed an advance directive shortly after his wife died a few years earlier. This advance directive was obtained from his son; it clearly expressed J.M.'s wishes not to undergo continued life-sustaining therapy such as hemodialysis, mechanical ventilation, and vasopressor medication when his physician and other consultant physicians agreed that there was no reasonable chance for regaining mental capacity and functioning. In accordance with this directive, J.M. was withdrawn from mechanical ventilation and vasopressors that had been supporting him and within several minutes he died as he had wished. His son and other family members were present, as J.M. would have liked.

INFORMED CONSENT AND ADVANCE DIRECTIVES IN THE INTENSIVE CARE UNIT

One of the most important aspects of the physician–patient relationship concerns a patient's autonomy and a physician's duty to preserve it. Obtaining informed consent and acknowledgment and complying with a patient's advance directive are two major ways by which autonomy is respected.

An advance directive, in the context of health care, refers to the patient's expression of wishes with respect to what they would want regarding medical care if they have lost the capacity to make decisions about such matters.[2] Such expressions, which are generally written documents, may be very specific. For example, a patient may state that, in the event of irreversible coma and the development of cardiac arrest, "I do not want cardiopulmonary resuscitation (CPR) to be performed." Other directives may simply authorize a surrogate individual to make decisions for the patient regarding medical care in the event of decisional incapacity. The appendix to this chapter shows an example of a standard advance directive that can be completed by a patient. Although this example includes commonly encountered situations and prompts an individual to select specific options, there is no absolute standard that must be followed. A patient may simply compose a letter expressing their wishes. Such a document can carry the same degree of empowerment as a lengthier standardized document. The key element, from an ethics perspective, is to uphold the patient's autonomy by adhering to previously expressed wishes when they are known.

Another important component of the interactions between physician and patient is the matter of informed consent. Informed consent is intended to uphold the principle of respect for a person's private space and self-determination.[3] Certain procedures or interventions must be discussed with the patient, particularly when some risk is involved. The patient's consent must be documented with a form signed by the patient and the physician. Examples of some of the more common invasive procedures in the critical care setting include insertion of central venous and intra-arterial catheters, thoracentesis, various types of endoscopies, and surgical procedures. Implied consent is usually present in medical emergencies when

Informed consent is generally needed before performing any invasive procedure.

TABLE 37-1

ORDER OF PRIORITY FOR HEALTH CARE REPRESENTATIVE (ADAPTED FROM THE PENNSYLVANIA LAW CONCERNING LIVING WILLS AND HEALTH CARE POWERS OF ATTORNEY, 29 JAN 2007)

Spouse
Adult child
Parent
Adult brother or sister
Adult grandchild
Adult with knowledge of patient's values and wishes

patient is not able to provide consent, and time does not permit obtaining consent from a patient surrogate. Noninvasive medical therapies and procedures generally do not require a specific written consent.

The informed consent document should contain certain elements: a description of the procedure and the reason(s) for doing it and a discussion of the risks, benefits, and possible alternatives. A valid consent must ensure that the patient or surrogate providing consent is competent (legally and operationally, i.e., de jure and de facto), does so voluntarily, and is informed, comprehending the relevant items for which consent is being requested.

In the critical care setting, because of critical illness, a patient often lacks decision-making capacity. In such cases, physicians turn to a surrogate decision maker for the patient. The President's Commission for the Study of Ethical Problems in Medicine and Biomedical Research states that decision-making capacity requires (1) the possession of a set of values and goals, (2) the ability to understand and communicate relevant information, and (3) the ability to reason and deliberate about one's choices.[4] It is the responsibility of the physician to determine whether these conditions are met. If the patient lacks capacity to give informed consent, the next of kin, usually the spouse may do so. If there is no spouse, or the spouse also lacks capacity, then the following relatives in order of precedence may give informed consent: an adult child, a parent, an adult brother or sister, an adult grandchild.[5] Individual states, however, may have different requirements (Table 37-1). The basis for surrogate decision making is that the surrogate is generally in a position to best understand a patient's medical situation and act accordingly with the patient's best interest in mind.

DO NOT RESUSCITATE ORDERS

In 1960, closed-chest cardiac massage was introduced to restore circulation in patients who suffered from cardiac arrest.[6] This technique in combination with assisted ventilation was formalized as a method of CPR for salvable victims of cardiopulmonary arrest. With the near contemporaneous emergence of coronary care and postsurgical units, the prototypes of intensive care units as we recognize them today, the use of CPR to restore spontaneous cardiac function became a standard practice in the care of critically ill patients. As technology advanced and other resuscitative therapies became available, CPR, along with other resuscitative efforts, was routinely applied.

Over time, however, there came increasing awareness that despite these advances in technology to prolong life and the apparent success of such resuscitative maneuvers, there were circumstances in which disease processes, regardless of interventions, led to an inexorable decline in a patient's condition and eventually death. With this realization, the application of CPR became more limited in such circumstances. Physician orders for "DNR" began to appear, followed by a flurry of investigations. These studies analyzed when DNRs were written, how they were used, their implications, and whether patients desired their application. Table 37-2 lists selected studies of the DNR order in critical care.

Sometimes referred to as a "no code" order, DNR specifically requires health care providers to refrain from resuscitation of a patient in the event of cardiopulmonary arrest. It is generally not considered a limitation of other therapies, even if they are also potentially life-sustaining. Generally, DNR is established when a patient's condition is such that performing resuscitation would not likely benefit the patient, an example being terminal illness in which resuscitation will not favorably affect the course of the disease. Another circumstance is a

TABLE 37-2

STUDIES CONCERNING THE DNR (DO NOT RESUSCITATE) ORDER IN CRITICAL CARE

FOCUS	DESIGN	CONCLUSION	REFERENCE
Impediments to writing DNR orders	Chart selection and panel review	Limited physician–patient relationship is major impediment	15
Overview characteristics of DNR patients in the ICU	Prospective inception cohort	DNRs occur earlier and more frequently than in past in patients with poor outcomes	16
Nursing care requirements of DNR patients in the ICU	Prospective chart review	DNR patients required more nursing care	17
ICU deaths With respect to the frequency of CPR and variability in withdrawal of life support	Prospective survey, multicenter	Wide variability in end-of-life care	18
Variation in frequency of DNR orders and relationship between guidelines and qualitative observations regarding terminal care	Prospective inception cohort	DNR orders associated with patient's severity of physiologic abnormalities, age, admission diagnosis, and prior health status	19
Incidence and implications of DNR orders in medical ICU	Retrospective chart review	DNR orders occurred in older, more severely ill patients with worse prior health and poorer prognosis on ICU admission; DNR not influenced by race or socioeconomic status	20
General description of DNR orders in ICU	Multiple hospitals; retrospective chart review	DNR ordered earlier in some patients with worse prognosis; short time interval between DNR order and death or ICU discharge	21
Compared physicians' and nurses' opinions regarding DNR	Prospective opinion survey in a single hospital	Physicians and nurses agree regarding timing of DNR orders; when they disagree, physicians more likely to recommend DNR	22
Relationship between age and DNR in ICU	Large multicenter database sets	Older patients more likely to have DNR orders written independent of severity of illness	23
Patient preferences for resuscitation and the frequency and timing of DNR orders	Prospective cohort; multicentered	Frequency and timing of DNR orders is associated with patient preferences and short-term prognoses; DNR underutilization suggested	24
Review of the DNR order since its inception around 1976	Review article	DNR remains useful and may serve as a means to patients' wishes regarding end-of-life treatments	25
Determine whether illness severity correlated with the presence of DNR order	Single center surgical ICU comparison between deaths in patients with and without DNR	Only past medical history was positively associated with DNR order	26
Better understand physician confidence regarding DNR discussions	Survey internal medicine attendings and residents	Physician confidence regarding DNR discussions is low compared to confidence in discussing other medical discussions	27

patient who is permanently unconscious and has no meaningful interaction with others or their environment; resuscitation to restore the patient to that state is unacceptable. In critical care, DNR may be appropriate when death is inevitable even when all other life-sustaining therapies are continued; interventions aimed at restoring cardiopulmonary function in this circumstance may be considered as a mere prolongation of a dying process.

Ambiguity continues to exist in some settings with respect to "code status." To avoid confusion, it is necessary to specify clearly the goals of care for a patient and to designate the treatment level that explicitly states therapies that are to be employed or withheld. Table 37-3 lists some of the various terms regarding orders for no resuscitation.

DNR may be appropriate when death is inevitable despite continuance of all other life-sustaining therapy.

DNR is commonly viewed as the initial step in the limitation of medical therapies. Once the order is established, physicians may use this specific limitation of not performing CPR as a step toward limiting other therapies. A patient and their surrogate may also view this limitation as the first step in defining the limits of other therapies deemed inappropriate. It is important to recognize that such a limitation to therapy may be reversed by the patient or the surrogate at any time.

If a patient is considered to be a candidate for DNR status, the physician should discuss with the patient, or their surrogate in cases of decisional incapacity, what DNR status means and why it may be appropriate. The physician leading this discussion should be experienced in such matters, and in settings where there may be physicians in training, generally the attending physician should lead the discussion, modeling the skill for the junior physicians. First, sufficient time should be provided so that interruptions are minimized. It is important that both the patient and the surrogate have enough time to comprehend DNR status and to ask questions. Also, it is important to have enough time to explore the patient's wishes and thoughts regarding their condition, their expectations about their care and treatment, and the relevant values that influence the decision to forgo resuscitation. Second, the physician or health care provider must be sensitive in listening to and eliciting the patient's concerns, fears, and anxieties concerning their illness and the implications for the future. The patient also needs an accurate description of their medical condition, in understandable terms, so that any decision can be based upon the best information possible. The physician must also take care that his or her own values do not present a strong bias that could affect the patient's ability to come to a personal decision. Further, the patient must be reassured that DNR does not mean that either other therapies or their care will be lessened. Because patients might view the limitation of no resuscitation as involving some degree of abandonment (which may cause a patient to resist DNR), the physician must ensure that the explicit as well as implicit meaning of DNR is clearly articulated and understood by the patient. Last, in discussions concerning DNR, the patient's decision must be respected. Health care providers in critical care especially need to respect a patient's autonomy and not appear disrespectful if a patient's decision differs from that which they themselves would have made.

DNR does not mean do not treat.

DNR is compatible with aggressive, intensive care.

DNR orders should be clearly documented.

In sum, the proper establishment of DNR should ensure a sound decision by the patient or surrogate, clear understanding of DNR status by the patient, and a complete discussion of all the patient's/surrogate's questions. Written documentation of the DNR status in the medical record and communication to the physician and other health care staff must be clear to avoid miscommunication and confusion.

TABLE 37-3

CODE STATUS DESIGNATIONS

Code: refers to the initiation of an emergency response team to attend the patient with cardiopulmonary arrest
No code: refers to a patient's status when, even in the event of cardiopulmonary arrest, there is no call for an emergency response team to initiate resuscitation
Slow code: refers commonly to a status where it is predetermined that a patient in cardiopulmonary arrest be provided with less than maximal effort during a resuscitative attempt. This status is quite controversial and continues to be debated
Chemical code: refers to a resuscitative effort performed by using only drugs in the resuscitation and not initiating mechanical devices such as mechanical ventilation, pacemakers, electrocardioversion, or defibrillation

WITHHOLDING AND WITHDRAWING LIFE-SUSTAINING THERAPY

Withholding or withdrawing medical therapies when implementation or continuance of such therapies is determined to be of no benefit to the patient may be seen as extending a DNR order. Sometimes, despite the addition of therapy or the continuation of some therapy, a patient will continue to progress in a disease process until death. Under these circumstances, it may be appropriate to limit interventions or perhaps even withdraw previously initiated therapy that is no longer of any benefit to the patient.

Frequently, the issues surrounding withholding or withdrawing medical therapy are complex and involve ethical concerns. A patient may, by the way of an advance directive, wish no further therapy if it is of no benefit. Here the principle of autonomy is relevant. Sometimes the principle of nonmaleficience is evident in not continuing therapy that produces undue burden for a patient with no anticipated benefit. Occasionally, there are issues of justice in withholding or withdrawing therapy, particularly with scarce resources. All these factors should be carefully considered when deciding to limit life-sustaining therapy in a critically ill patient. As with the decision for DNR orders, withholding or withdrawing life-sustaining therapy requires a discussion that informs the patient or surrogate of the patient's condition and the medical appropriateness of limiting some therapy while providing assurance that the patient's best interests are the goal. These discussions frequently occur over a period of time. It is important at each time that the patient and their surrogate understand any plans for withholding or withdrawing therapy.

Discussion is of paramount importance in issues of withholding and withdrawing life-sustaining therapy.

To facilitate these decisions in critical care, professional societies have published guidelines[7] for appropriate withdrawing and withholding of medical therapy. These guidelines underscore some important points (Table 37-4).

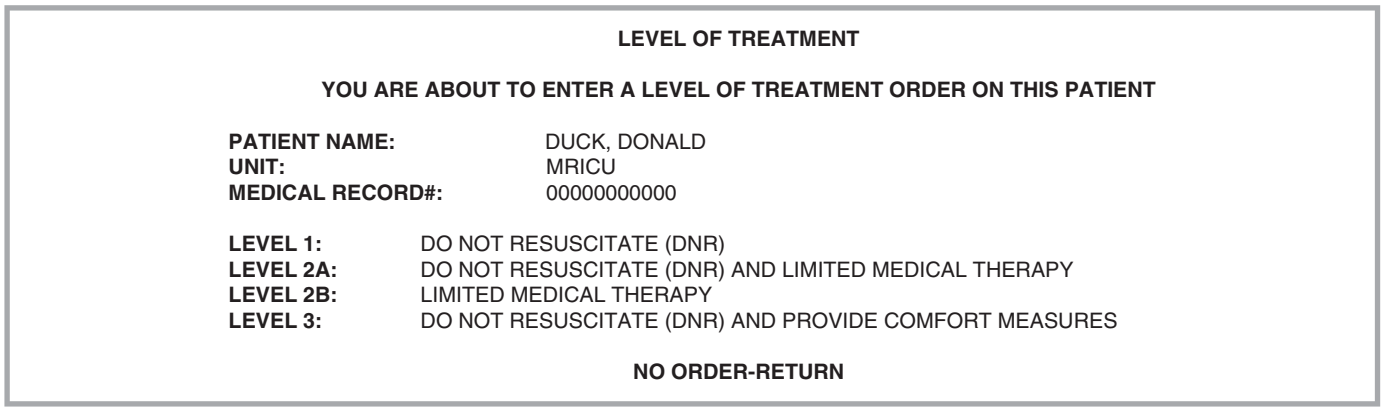
In clinical practice, mechanisms exist to facilitate the implementation of orders to withhold or withdraw life-sustaining therapy. Although generally not as uniform as orders for no resuscitation, they share many similarities. Many institutions have a standard form listing a number of therapies that are often withheld. After establishing with the patient or surrogate the appropriateness of limiting therapy, the physician can check off the therapies to withhold. Such therapies include transfusion of blood products and initiation of mechanical ventilation or vasopressors. At our institution, a paperless computer order entry system allows the physician to enter a pathway for the level of therapy, leading to successive screens on which a selection of specific therapies, grouped by category, can be made (Fig. 37-1). Once selected, these limits of therapy appear on a daily patient summary sheet that is placed in the patient's medical record so that all caregivers may see and acknowledge the particular limits. This system procedure has facilitated patient care, promoted patient autonomy, and minimized the number of ethics consultations for clarification of clinical care issues regarding appropriate therapy. Moreover, it has eliminated most of the ambiguity formerly associated with a patient who wished to be resuscitated in the evident of cardiopulmonary arrest but did not wish intubation and mechanical ventilation. In these situations, the ability to more precisely define the limits of therapy and hold the necessary discussions with the patient has provided important advances in the management of critically ill patients.

Another important aspect of withdrawing and withholding medical therapy concerns variability in patients and their family's views about life-sustaining therapy and end-of-life care. It is very important for the critical care team to be respectful of cultural and religious views in this area.

TABLE 37-4

KEY POINTS REGARDING WITHDRAWING AND WITHHOLDING MEDICAL THERAPY

No moral difference between withholding and withdrawing medical therapy
Respect for patient autonomy
The importance of acting on the patient's behalf to do good and to avoid harm
Communication with the patient and patient's family is a critical element
Physicians are not bound to provide therapy that they deem futile



LEVEL OF TREATMENT

YOU ARE ABOUT TO ENTER A LEVEL OF TREATMENT ORDER ON THIS PATIENT

PATIENT NAME: DUCK, DONALD
UNIT: MRICU
MEDICAL RECORD#: 00000000000

LEVEL 1: DO NOT RESUSCITATE (DNR)
LEVEL 2A: DO NOT RESUSCITATE (DNR) AND LIMITED MEDICAL THERAPY
LEVEL 2B: LIMITED MEDICAL THERAPY
LEVEL 3: DO NOT RESUSCITATE (DNR) AND PROVIDE COMFORT MEASURES

NO ORDER-RETURN

FIGURE 37-1

Computer screen that appears when a physician selects "level of treatment" pathway. An appropriate level of treatment can then be selected by the attending physician.

ORGAN DONATION AND DEFINITIONS OF DEATH

Until the Uniform Determination of Death Act[8] was approved in the United States in 1981, there was no comprehensive legal basis for determining death. Its conception arose from technologic advancement in the medical field creating a potential disparity between the law and medical practice. According to the Uniform Determination of Death Act, "an individual who has sustained either (1) irreversible cessation of circulatory and respiratory function or (2) irreversible cessation of all functions of the entire brain including the brain stem is dead." Around the same time in 1981, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published *Defining Death, A Report on the Medical, Legal, and Ethical Issues in the Determination of Death.*[9] Most hospitals have a policy detailing the criteria that must be met in order to declare brain death, though details concerning the criteria may vary among institutions. An essential feature of all brain death determination protocols is to ensure that neurologic states that can mimic brain death, e.g., hypothermia, certain drug overdoses, are excluded diagnoses. One of the major criteria for brain death includes the loss of brain stem reflexes. This includes an absence of pupillary light reflex, corneal reflex, oculocephalic, oculovestibular, and oropharyngeal reflexes. In addition, the absence of respiratory efforts to breathe with documented hypercarbia (e.g., $PaCO_2$ 60 mmHg or 20 mmHg above normal value) is another clinical criteria used in the determination of brain death. In addition to these clinical examination tests, confirmatory testing is also part of the determination process. Currently, electroencephalography, cerebral blood flow scanning, four vessel cerebral angiography, and brainstem auditory evoked potential testing are the tools used for brain death confirmation.[10]

The concept of brain death remains an important precondition for organs such as heart, liver, lungs, and kidneys, to be harvested for transplantation. Organ procurement from patients who are pronounced dead by cardiopulmonary criteria is increasing and is commonly referred to as donation after cardiac death. This method of organ procurement continues to pose important ethical challenges.[11] Among those challenges are issues of informed consent, avoiding conflicts of interest, organ preservation techniques which do not contribute to or hasten death, and care for the body during organ procurement.

MEDICAL FUTILITY

Medical futility is frequently an elusive concept.

The concept of medical futility is quite controversial. Although it may appear to be a rather simple and straightforward concept that can be easily applied in medical practice, it is surrounded by considerable ambiguity.[12] This ambiguity begins with its definition. Because

TABLE 37-5

ETHICS COMMITTEE CONSENSUS STATEMENT FROM THE SOCIETY OF CRITICAL CARE MEDICINE REGARDING MEDICAL FUTILITY

Treatments that have no beneficial physiologic effect
Treatments that are extremely unlikely to be beneficial
Treatments that are beneficial but are extremely costly
Treatments that are of uncertain or controversial benefit

there is no generally accepted definition of futility that answers important clinical questions that occur every day in critical care practice, many discussions concerning medical futility are frustrating and disappointing. Nonetheless, much has been written concerning the area of medical futility and many have attempted to achieve consensus on this matter. For example, a consensus statement from the Society of Critical Care Medicine's ethics committee[13] elucidates the concept of medical futility by defining four categories for various treatments that may be considered futile (Table 37-5). In the strictest sense of the definition, only those treatments that have no beneficial physiologic effect should be considered futile, while those in the other three categories are considered inappropriate and therefore inadvisable.

Discussion about futile therapy almost always involves issues of values, and the conflicts that arise as to when therapy is "futile" involve differences in values. The often-discussed example of performing CPR in a patient with metastatic lung cancer illustrates a few of the problems. Generally, a physician would not recommend performing resuscitative maneuvers in such a patient because such intervention would only prolong the inevitable process of dying. In contrast, the patient may value the prolongation of life even if for only 1 more day. In this case, resuscitation in the event of cardiopulmonary arrest may indeed be successful in restoring cardiopulmonary function; however, it may incur extreme cost and in fact be of uncertain benefit or may even lead to greater harm. These are the types of scenarios that are encountered in critical care medicine and create the need for frank discussion and counseling for patients and often their families so that appropriate therapy is provided. At many times, communication with a patient or surrogate allows the exploration of values in the context of risks and benefits for any proposed treatment so that an informed decision can be reached and the goals of therapy achieved accordingly.

In the context of debate surrounding medical futility, the physician must always first ascertain the goal of any particular circumstance and ask whether the implementation of such a therapy will help achieve that goal. Communication that promotes accurate understanding of the medical facts and facilitates an affirmation of particular values will help minimize potential conflicts that arise in cases of medical futility.

Futility often engenders much emotion among health care staff. Some of these reactions are anger, frustration, sadness, and helplessness. Typically, futility cases involve a patient or family/surrogate who wishes everything to be done and a physician or health care team who deems it inappropriate to continue or provide additional therapy considered to have no benefit. The feelings of the patient or surrogate may include a sense of false optimism, distrust of health care providers to act in the best interest of the patient, religious beliefs, poor understanding, sense of entitlement, or psychologic factors such as guilt or denial. Management of such cases requires the health care team to demonstrate empathy with patients and their families, initiate and maintain effective communication, and establish clear goals of therapy, explaining these goals clearly to the patient and surrogate.

THE ROLE OF ETHICS CONSULTATION IN CRITICAL CARE

Most hospitals have an ethics committee that can respond to a request for consultation when a conflict arises in the clinical realm. Consultations may be sought concerning an institution's policy. The mechanism by which an ethics committee is available for consultation varies, but in each case, the consultation should assist the persons requesting their service. This assistance includes clarification of issues, retrieval of additional information, mediation

Ethics consultation may facilitate resolution of difficult ethical problems in the ICU.

of conflict, safeguarding a patient's interest, particularly in cases of decisional incapacity and the absence of a surrogate, and assurance for the appropriateness of a particular action.[14]

SUMMARY

Conduct in the critical care setting must follow the generally accepted principles of medical ethics. These principles protect the dignity of the human being and allow the application of medical science in a manner aimed at preserving life and, inasmuch as possible, ensuring a reasonable quality of living for the patient. The apparent conflicts that arise concerning the ethics of patient care in the critical care setting frequently can be minimized by explicit statement of the goals of therapy, open and honest communication among patients, families, and health care staff, and commitment to care. At times, ethics consultation may be necessary to facilitate patient management in the critical care setting and to ensure appropriate patient care.

REVIEW QUESTIONS

1. **Which of the following is not a fundamental principle bioethics?**
   - **A.** Justice
   - **B.** Rationing
   - **C.** Beneficence
   - **D.** Autonomy

2. **Concerning an order for no resuscitation, which of the following is true?**
   - **A.** A DNR order implies no treatment
   - **B.** DNR is incompatible with aggressive, intensive care
   - **C.** Orders for DNR must be documented in the medical record
   - **D.** An order for no resuscitation cannot be changed once established

3. **Of the following, which is important to consider in approaching an ethical problem in the critical care setting?**
   - **A.** The patient's medical insurance plan
   - **B.** Duration of critical illness
   - **C.** Presence of an advance directive
   - **D.** Whether a particular therapy is futile

4. **Elements of informed consent should include at least all the following except:**
   - **A.** Assurance of a successful outcome from the proposed procedure
   - **B.** Detailed risks and benefits of the proposed procedure
   - **C.** Indication for doing the proposed procedure
   - **D.** Explanation of alternative options

5. **A patient lacks decision-making capacity for health care decisions; however, all of the patient surrogates have decision-making capacity. Which of the following is true?**
   - **A.** Adult children have priority over the patient's spouse
   - **B.** The patient's adult grandchild does not have priority over the patient's minor child
   - **C.** The patient's spouse has priority over the patient's mother
   - **D.** All of the above are true regarding surrogate priority

6. **Ethics consultation may be useful in a clinical situation because:**
   - **A.** Ethics issues may be clarified
   - **B.** Conflict mediation may occur
   - **C.** Patient's interests are protected
   - **D.** All of the above

ANSWERS

1. The answer is B. The four fundamental principles of biomedical ethics are beneficence, nonmaleficience, autonomy, and justice.
2. The answer is C. Documentation of an order for no resuscitation must be present in the medical record of the patient. Further, the discussion(s) concerning issues of resuscitation and leading to a decision for DNR should also be clearly documented in the medical record of the patient.
3. The answer is C. An approach to an ethical problem in any setting involves many aspects. A patient's insurance plan or duration of illness is seldom an important matter to consider. Similarly, determining whether a particular therapy is futile is usually not relevant. Although many cases in critical care appear to involve a question of futility, at most times, this question is superficial, and deeper issues, usually having to do with effective communication with patients and their families, are key. There is no consensus about medical futility and, when it can be recognized, it is thought to occur rather infrequently. A crucial aspect of many ethical problems in critical care is the existence of an advance directive.

4. The answer is A. A physician proposing to perform a procedure for a patient must obtain informed consent. At minimum, this consent must include a discussion of the risks and benefits of the proposed procedure in detail, the reason for performing the procedure, and an explanation of the potential alternatives. A physician may convey an opinion regarding the likelihood of success for a proposed procedure, but there cannot be any assurance of a successful outcome. Risks and potential complications almost always prevent giving such assurance.
5. The answer is C. Regarding decision-making for priority for a patient who lacks decision-making capacity; a spouse has priority over the parent of the patient. Similarly, an adult grandchild has priority over a patient's minor child. A patient's adult children, however, do not have priority over a patient's spouse.
6. The answer is D. All of the listed choices are reasons why clinical ethics consultations may be useful.

APPENDIX: THE MEDICAL DIRECTIVE

Introduction. As part of a person's right to self-determination, every adult may accept or refuse any recommended medical treatment. This is relatively easy when people are well and can speak. Unfortunately, during serious illness, they are often unconscious or otherwise unable to communicate their wishes – at the very time when many critical decisions need to be made.

The Medical Directive allows you to record your wishes regarding various types of medical treatments in several representative situations so that your desires can be respected. It also lets you appoint a proxy, someone to make medical decisions in your place if you should become unable to make them on your own.

The Medical Directive comes into effect only if you become incompetent (unable to make decisions and too sick to have wishes). You can change it at any time until then. As long as you are competent, you should discuss your care directly with your physician.

Completing the form. You should, if possible complete the form in the context of a discussion with your physician. Ideally, this should occur in the presence of your proxy. This lets your physician and your proxy know how you think about these decisions, and it provides you and your physician the opportunity to give or clarify relevant personal or medical information. You may also wish to discuss the issues with your family, friends, or religious mentor.

The Medical Directive contains six illness situations that include incompetence. For each one, you should consider the possible interventions and goals of medical care. Situation A is permanent coma; B is near death; C is with weeks to live in and out of consciousness; D is extreme dementia; E is a situation you describe; and F is temporary inability to make decisions.

For each scenario, you should identify your general goals for care and specific intervention choices. The interventions are divided into six groups: (1) CPR or major surgery, (2) mechanical breathing or dialysis, (3) blood transfusions or blood products, (4) artificial nutrition and hydration; (5) simple diagnostic tests or antibiotics, and (6) pain medications, even if they dull consciousness and indirectly shorten life. Most of these treatments are described briefly. If you have further questions, consult your physician.

Your wishes for treatment options (I want this treatment; I want this treatment tried, but stopped if there is no clear improvement; I am undecided; I do not want this treatment) should be indicated. If you choose a trial of treatment, you should understand that this indicates that you want the treatment *withdrawn* if your physician and proxy believe that it has become futile.

The Personal Statement section allows you to explain your choices, and say anything you wish to those who may make decisions for you concerning the limits of your life and the goals of intervention. For example, in situation B, if you wish to define "uncertain chance" with numerical probability, you may do so here (Fig. 37-2).

An earlier version of this form was originally published as part of an article by Emanuel and Emanuel.[2] It does not reflect the official policy of the American Medical Association.

Next you may express your preferences concerning organ donation. Do you wish to donate your body or some or all of your organs after your death? If so, for what purpose(s) and to which physician or institution? If not, this should also be indicated in the appropriate box.

In the final section, you may designate one or more proxies, who would be asked to make choices under circumstances in which your wishes are unclear. You can indicate whether or not the decisions of the proxy should override your wishes if there are differences. And, should you name more than one proxy, you can state who is to have the final say if there is disagreement. Your proxy must understand that this role usually involves making judgments that you would have made for yourself, had you been able – and making them by the criteria you have outlined. Proxy decisions should ideally be made in discussion with your family, friends, and physician.

What to do with the form. Once you have completed the form, you and two adult witnesses (other than your proxy) who have no interest in your estate need to sign and date it.

Many states have legislation covering documents of this sort. To determine the laws in your state, you should call the state attorney general's office or consult a lawyer. If your state has a statutory document, you may wish to use the Medical Directive and append it to this form.

You should give a copy of the completed document to your physician. His or her signature is desirable but not mandatory. The Directive should be placed in your medical records and flagged so that anyone who might be involved in your care can be aware of its presence. Your proxy, a family member, and/or a friend should also have a copy. In addition, you may want to carry a wallet card noting that you have such a document and where it can be found.

FIGURE 37-2

The form on the following pages 739–743 is an example of an advance directive. This particular directive is quite detailed and specific. It also prompts a person to provide a personal statement that can be helpful for guiding appropriate care for a person in the event of decisional incapacity.

MY MEDICAL DIRECTIVE

This Medical Directive shall stand as a guide to my wishes regarding medical treatments in the event that illness should make me unable to communicate them directly. I make this Directive, being 18 years or more of age, of sound mind, and appreciating the consequences of my decisions.

SITUATION A

If I am in a coma or a persistent vegetative state and, in the opinion of my physician and two consultants, have no known hope of regaining awareness and higher mental functions no matter what is done, then my goals and specific wishes—if medically reasonable—for this and any additional illness would be:

- ☐ prolong life; treat everything
- ☐ attempt to cure, but reevaluate often
- ☐ limit to less invasive and less burdensome interventions
- ☐ provide comfort care only
- ☐ other *(please specify):* _____

_____

Please check appropriate boxes:

	I want	I want treatment tried. If no clear improvement, stop	I am undecided	I do not want
1. **Cardiopulmonary resuscitation** (chest compressions, drugs, electric shocks, and artificial breathing aimed at reviving a person who is on the point of dying).		*Not applicable*		
2. **Major surgery** (for example, removing the gallbladder or part of the colon).		*Not applicable*		
3. **Mechanical breathing** (respiration by machine, through a tube in the throat).				
4. **Dialysis** (cleaning the blood by machine or by fluid passed through the belly).				
5. **Blood transfusions or blood products.**		*Not applicable*		
6. **Artificial nutrition and hydration** (given through a tube in a vein or in the stomach).				
7. **Simple diagnostic tests** (for example, blood tests or x-rays).		*Not applicable*		
8. **Antibiotics** (drugs used to fight infection).		*Not applicable*		
9. **Pain medications, even if they dull consciousness and indirectly shorten my life.**		*Not applicable*		

SITUATION B

If I am near death and in a coma and, in the opinion of my physician and two consultants, have a small but uncertain chance of regaining higher mental functions, a somewhat greater chance of surviving with permanent mental and physical disability, and a much greater chance of not recovering at all, then my goals and specific wishes—if medically reasonable—for this and any additional illness would be:

☐ prolong life; treat everything
☐ attempt to cure, but reevaluate often
☐ limit to less invasive and less burdensome interventions
☐ provide comfort care only
☐ other *(please specify):* _____

_____

I want	I want treatment tried. If no clear improvement, stop	I am undecided	I do not want
	Not applicable

	Not applicable		

SITUATION C

If I have a terminal illness with weeks to live, and my mind is not working well enough to make decisions for myself, but I am sometimes awake and seem to have feelings, then my goals and specific wishes—if medically reasonable—for this and any additional illness would be:

* In this state, prior wishes need to be balanced with a best guess about your current feelings. The proxy and physician have to make this judgment for you.

☐ prolong life; treat everything
☐ attempt to cure, but reevaluate often
☐ limit to less invasive and less burdensome interventions
☐ provide comfort care only
☐ other *(please specify):* _____

SITUATION D

If I have brain damage or some brain disease that in the opinion of my physician and two consultants cannot be reversed and that makes me unable to think or have feelings, *but I have no terminal illness*, then my goals and specific wishes—if medically reasonable—for this and any additional illness would be:

☐ prolong life; treat everything
☐ attempt to cure, but reevaluate often
☐ limit to less invasive and less burdensome interventions
☐ provide comfort care only
☐ other *(please specify):* _____

_____

_____

SITUATION E

If I . . .
(describe a situation that is important to you and/or your doctor believes you should consider in view of your current medical situation):

☐ prolong life; treat everything
☐ attempt to cure, but reevaluate often
☐ limit to less invasive and less burdensome interventions
☐ provide comfort care only
☐ other *(please specify):* _____

_____

_____

I want	I want treatment tried. If no clear improvement, stop	I am undecided	I do not want

_____

MY PERSONAL STATEMENT

(Use back page if necessary)

Please mention anything that would be important for your physician and your proxy to know. In particular, try to answer the following questions: 1) What medical conditions, if any, would make living so unpleasant that you would want life-sustaining treatment *withheld*? (Intractable pain? Irreversible mental damage? Inability to share love? Dependence on others? Another condition you would regard as intolerable?) 2) Under what medical circumstances would you want to stop interventions that might already have been started? 3) Why do you choose what you choose?

If there is any difference between my preferences detailed in the illness situations and those understood from my goals or from my personal statement, I wish my treatment selections/my goals/my personal statement *(please delete as appropriate)* to be given greater weight.

When I am dying, I would like—if my proxy and my health-care team think it is reasonable—to be cared for:

- ☐ at home or in a hospice
- ☐ in a nursing home
- ☐ in a hospital
- ☐ other *(please specify):*_____

CHAPTER 38

YAROSLAV LANDO AND GERARD J. CRINER

Psychological Dysfunction in the Intensive Care Unit Patient

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Define the types of psychological dysfunction found in ICU patients.
- Know the medical and psychological problems that contribute to psychological dysfunction in the ICU patient.
- Be aware of environmental factors contributing to psychological impairment in the ICU patient.
- Define delirium and its assessment and treatment.

An intensive care unit (ICU) patient can develop various psychiatric disorders that can manifest either during the ICU stay or after discharge. Several factors play a role in the development of psychiatric disorders (Table 38-1). The first is the effect of the severe medical illness or its treatment on cognitive function. The second is the patient's psychological response to their severe illness (e.g., feeling that any worthwhile life is over). Trauma patients admitted to the ICU have unique features that may even further predispose them to psychological dysfunction.[1] Trauma patients may also suffer from a sense of guilt if they were somehow responsible for the event that caused trauma which injured another individual and concern about body image, if disfiguration or limb loss has occurred. A patient's worry and preoccupation about the symptoms frequently results in failure to eat or to participate in rehabilitative efforts (i.e., weaning from mechanical ventilation) and may worsen his or her clinical condition. Finally, the patient's interaction with the surrounding ICU environment can result in behavior, thought, or mood disturbances.[2] The necessary constraints imposed by an ICU environment care for critically ill patients (continually lighted environment, medical personnel talking, multiple beeping alarms, around-the-clock interventions) can cause sleep and sensory deprivation.[3]

In most cases, the physical complications of the patient's medical or surgical illness are the most important factors contributing to the patient's psychiatric disorder, notably delirium.[4] Some cases result from the emotional impact of the illness; others may have already been present, especially in those patients admitted after accidents or self-inflicted injuries. In another subset of patients, environmental factors that are imposed by the ICU environment may play a significant role.

Several factors contribute to the development of psychiatric disorders in ICU patients: the severity and nature of the underlying medical illness, the patient's psychological response to the illness, and the patient's interaction with the surrounding ICU environment.

TABLE 38-1

GENERAL CAUSES OF PSYCHIATRIC DISORDERS IN CRITICALLY ILL PATIENTS

CNS dysfunction
CNS hypoperfusion states
Hypoxemia
Metabolic derangements
Medication side effects
Alcohol or drug withdrawal
Infections
Subjective interpretation of the meaning of the illness
Feeling that life is over
Loss of libido
Sense of personal failure
Personal worry and preoccupation
Catatonia
Major depression
Withdrawal
Hypochondrial preoccupation with symptoms
Exaggerated or denied pain experience
Family and environmental interactions
Feeling that one is a burden to the family
Response to loss of control over activities of daily living
Clingy, needy response to caregivers or family
Response resulting in threats to leave the hospital against medical advice

TABLE 38-2

PSYCHIATRIC DISORDERS OBSERVED IN THE INTENSIVE CARE UNIT

Anxiety
Depression
Behavioral problems
Hostility
Delirium/psychosis

The ICU environment may promote psychological dysfunction in the ICU patient: noise, sleep and sensory deprivation, lack of orienting clues, and frequent medical interventions all may help precipitate disorientation and delirium.

Newer-generation ICUs have been redesigned with careful attention to help maintain normal patient circadian cycles.

Initial studies suggested that the physical environment of the ICU plays a large role in precipitating psychological disturbances in the ICU patient. The unique ICU environment, including constant noise, sleep deprivation, monitoring equipment, monotonous sensory input, and lack of orienting clues, may contribute to psychological dysfunction in some patients.[5] Although the independent influence of environmental factors has not been totally clarified, these early observations have influenced the design of modern ICUs to avoid some of these environmental factors that may negatively impact psychological dysfunction. The newer-generation ICUs have been redesigned with careful attention to help maintain normal patient psyche, including efforts to reduce noise, encourage more human contact, and provide visible clocks and calendars and windows that provide a view to the external environment to ensure adequate sleep and maintain normal circadian rhythm.

Recent literature provides insight into the long-term outcome of psychological problems that arise in the ICU. Studies of patients recovering from catastrophic or exceptionally life-threatening situations have shown that such patients are prone to prolonged psychological reactions, particularly posttraumatic stress disorder and other phobic anxiety syndromes.

The most common psychiatric disorders that arise in an ICU patient include delirium, depression, anxiety, and behavioral problems.

The most common psychiatric disorders that arise during a patient's ICU stay include delirium, depression, anxiety, and behavioral problems (Table 38-2). The purpose of this chapter is to succinctly review the definitions, etiologic factors, clinical signs and symptoms, pathogenesis, and management of the various psychological disturbances that arise in the critically ill patient.

DELIRIUM

Delirium is by far the most common psychiatric disorder that occurs in the ICU. It is defined as "a transient organic mental syndrome of acute onset, characterized by global impairment of cognitive function, a reduced level of consciousness, attention abnormalities, increased or decreased

CASE STUDY

J.C. is a 45-year-old man who underwent successful kidney-pancreas transplantation 6 months ago. Following the transplant, he was started on an appropriate immunosuppressive medical regimen. He is now readmitted with a fungal infection of his left orbit. After multiple debridements were unsuccessful in eradicating the disease, J.C. underwent an anterior skull base resection in an effort to contain the infection. Postoperatively, he was placed in the ICU and received aggressive antifungal therapy, broad-spectrum antibiotics, systemic steroids, prophylactic peptic ulcer and gastric motility agents, strong pain relievers, and several antihypertensive drugs. He developed mild renal insufficiency, a variety of electrolyte disturbances, and cytomegalovirus hepatitis. On admission to the ICU, he was awake and alert, responded to simple questions with appropriate answers, and was completely oriented to person, place, date, and time.

In the ICU 48 h postoperatively, J.C. became fidgety. He started tugging on his bladder catheter and attempted to remove his intravenous lines. He was unable to sleep for any significant length of time. His behavior alternated within several minutes from sleeping, to agitation and climbing out of bed. He was unable to separate dreams from reality. J.C. would make inappropriate statements (e.g., "Since someone stole my car battery, I think I can take this IV out."). Afterward, he would usually realize he had said something inappropriate. He frequently described how his room changed colors at night and how he felt he was in a cage surrounded by stuffed animals. During neurologic assessments, however, he remained oriented and occasionally became easily frustrated with the staff's questioning his awareness of date, time, and place.

psychomotor activities, and a disordered sleep–wake cycle." A classification of mental disorders uses the term delirium as the only official designation for this syndrome (Table 38-3).

Many patients experience delirium during their hospitalization, and its presentation can be extremely variable. Although the exact incidence is unknown, it is believed that 10–15% of hospitalized medical-surgical patients and 30–40% of ICU patients suffer from delirium at some point during their hospitalization.[4] The incidence of delirium, however, may be as high as 60% in the elderly ICU patient.[6] Up to 80% of patients receiving mechanical ventilation in the ICU may develop delirium.[7] Patients with delirium tend to have significantly longer ICU and total hospital length of stays, increased healthcare costs and have been shown to have higher mortality rates (up to 20%) compared with similar patients without delirium.[8,9] Besides the underlying disease process contributing to the development of delirium, this tendency may be related to potentially dangerous behavior that leads to complications such as self-extubation, removal of lines and catheters, and cardiovascular stress.

Recognizing the development of delirium and knowing which patients are at risk can be challenging. It is important to remember that the onset of delirium is acute, generally transient, and rarely lasts longer than 1 month. It is manifested by a state of impaired consciousness or

Delirium is a transient organic mental syndrome of acute onset characterized by a global impairment of cognitive function.

Delirium may affect 30–40% of ICU patients. Delirium may present in clinically diverse forms.

TABLE 38-3

DSM-III DIAGNOSTIC CRITERIA FOR DELIRIUM

Reduced ability to maintain attention to external stimuli (e.g., questions must be repeated because attention wanders) and to appropriate shift attention to new external stimuli (e.g., perseverates answer to previous question)
Disorganized thinking, as indicated by rambling, irrelevant, or incoherent speech
At least two of the following:
Reduced level of consciousness, e.g., difficulty keeping awake during examination
Perceptual disturbances: misinterpretations, illusions, or hallucinations
Disturbance of sleep–wake cycle with insomnia or daytime sleepiness
Increased or decreased psychomotor activity
Disorientation to person, place, or time
Memory impairment, e.g., inability to learn new material, such as the names of several unrelated objects after 5 min, or to remember past events, such as history of current episode of illness
Clinical features develop over a short period of time (usually hours to days) and tend to fluctuate over the course of a day
Either (1) or (2)
1. Evidence from the history, physical examination, or laboratory tests of a specific organic factor (or factors) judged to be etiologically related to the disturbance
2. In the absence of such evidence, an etiologic organic factor can be presumed if the disturbance cannot be accounted for by any nonorganic mental disorder, e.g., manic episode accounting for agitation and sleep disturbance

alertness, indicating the patient's inability to be fully aware of their environment. Delirium may present with clinically diverse scenarios due to its varied symptoms. The most common presentation variant is described as hyperactive-hyperalert. These patients tend to be restless, agitated, and even combative. Acute withdrawal from alcohol (delirium tremens) is a classic example of this variant. Less common and often overlooked is a hypoactive-hypoalert variant of delirium. These patients are sleepy, quiet, and slow to respond, and describe decreased psychomotor activity. Because they have vivid hallucinations and are absorbed in a dreamlike state, they sometimes mumble to themselves or make inappropriate gestures. Patients may also manifest a mixed delirium variant, a presentation that includes features of both these variants. Irregularly and unpredictably, mixed delirium patients alternate between the two forms, sometimes during a single day. J.C., from our case presentation, was an example of this form of delirium. He alternated between a variety of different states: awake and agitated, to sleep with bizarre dreams, to awake and hallucinating, and back again to awake and appropriate.

Delirium has multiple etiologies: age, psychosocial stress, the nature and severity of underlying medical or surgical disorder, sensory overload or under-load, immobilization, and sleep deprivation all contribute to the development of delirium.

Multiple etiologies of ICU delirium have been identified (Tables 38-4 and 38-5). It is not difficult to understand why J.C. became delirious. He had a severe fungal infection, acidosis, renal insufficiency, electrolyte disturbance, and hepatitis. He was treated with many of the medications listed in Table 38-5. In his case, as in most others, determining the exact cause of delirium is sometimes very difficult and withdrawing potential causative agents means risking improper management of the underlying medical conditions.

Although any patient in the ICU can become delirious, certain underlying factors tend to predispose patients to this condition: age 60 years or older, presence of brain damage, and presence of chronic brain disease (e.g., Alzheimer's). Of these predisposing factors, age is the most predictive. Elderly patients tend to develop significant signs of delirium with only minor physiologic derangements. Patients who are elderly and demented appear to be those most prone to the development of delirium.

TABLE 38-4

ORGANIC CAUSES OF DELIRIUM

Drug or poison intoxication
- Prescribed drugs
- Alcohol
- Illicit drugs
- Industrial poisons
- Poisons of animal, plant, and mushroom origin

Withdrawal syndromes
- Alcohol
- Sedatives and hypnotics
- Amphetamines

Metabolic encephalopathies
- Hypoxemia
- Hypoglycemia
- Hepatic, pancreatic, pulmonary, or renal insufficiency
- Avitaminosis
- Hypervitaminosis
- Endocrinopathies
- Fluid and electrolyte disturbances
- Errors of metabolism

Infections
- Intracranial
- Systemic

Head trauma

Epilepsy

Neoplasm

Vascular disorders
- Cerebrovascular
- Cardiovascular

CNS space-occupying lesions

Hematopoietic system disorders

Hypersensitivity disorders

Injury by physical agents

TABLE 38-5

DRUGS COMMONLY USED IN THE ICU THAT ARE REPORTED TO CAUSE PSYCHOSIS AND DELIRIUM

Acyclovir
Aminocaproic acid
Amphotericin B
Anticonvulsants
Anticholinergic agents
Antihistamines
Benzodiazepines
Captopril
Cephalosporins
Cimetidine
Ciprofloxacin
Clonidine
Corticosteroids
Digitalis
Imipenem
Ketamine
Ketoconazole
Lidocaine
Methyldopa
Metoclopramide
Metronidazole
Narcotics
Nifedipine
Nitroprusside
NSAIDs
Penicillin
Procainamide
Propranolol
Quinidine
Ranitidine
Theophylline
Trimethoprim-sulfamethoxazole

Other factors that can contribute to formation of delirium are psychosocial stress, sensory overload or under-load, immobilization, and sleep deprivation. One study of postoperative ICU delirium found that many episodes of organic delirium occurred in patients located in rooms without windows. Also, experimental sleep deprivation in normal subjects can reproduce the same mental status changes that are observed with ICU delirium. In the surgical ICU patient, respiratory diseases, infections, anemia, hypotension, hypocalcemia, hyponatremia, elevated liver enzymes, azotemia, hyperbilirubinemia, hyperamylasemia, and metabolic acidosis,[10] all have been demonstrated to facilitate the onset of delirium and may worsen and prolong its course. Unfortunately, most ICU patients are exposed to all of these factors. A list of risk factors predisposing to delirium is shown in Table 38-4.

Recent attention has been directed toward evaluating patients in the ICU for the presence of delirium, even those receiving mechanical ventilation. The Confusion Assessment Method (CAM) is a simple, validated tool used for the detection of delirium in both the clinical and research settings.[6,11,12] CAM uses a cognitive assessment that is usually performed using a mini-Mental State Examination that assesses orientation, registration, language, recall, visual perception, and the performance of multistep tasks and attention task tests (digit span). During the assessment, observations are made to evaluate four key delirium criteria: (1) acute change in mental status, (2) inattention, (3) disordered thinking, and (4) an altered level of consciousness. The CAM has been shown to be a reliable, reproducible measurement of the presence of delirium when compared to assessments made by psychiatrists, with reported sensitivities and specificities of 94–100% and 90–95%, respectively.

In order to be able to perform the CAM in the ICU patients, a brief assessment that includes a nonverbal assessment is preferred. The CAM for ICU (CAM-ICU) has been recently developed for the detection of delirium for the ICU patients, even those requiring mechanical ventilation.[12] The CAM-ICU uses the same four key delirium criteria to determine the presence of delirium but uses nonverbal tasks such as picture recognition and nonverbal responses to simple commands to rate the features of the CAM assessment. Picture recognition and vigilance random letter tests are nonverbal tools used to assess attention in the ICU patient unable to speak because of endotracheal intubation or for other reasons that impair the ability of the patient to verbally communicate with the assessor. The CAM-ICU has been validated to be a useful and reproducible assessment for the detection of delirium in both ventilated and nonventilated ICU patients.[11,12] Elements and questions used for assessment of the CAM-ICU are shown in Table 38-6.

Management of delirious patients includes recognizing the syndrome in patients at risk, observing and assessing mental function, and identifying and treating the underlying cause when treating patient symptoms.

Management of delirious patients requires recognizing the syndrome and the patients at risk, accurately observing and assessing mental function, treating the symptoms, and identifying and treating underlying causes. This can be difficult and though the active participation

TABLE 38-6

CONFUSION ASSESSMENT METHOD FOR THE INTENSIVE CARE UNIT (CAM-ICU)

Feature I: Acute onset of mental status change or fluctuating course
Is there a change in mental status from baseline?
Did the behavior fluctuate in the first 24 h?
Feature 2: Inattention
Does the patient have trouble focusing their attention?
Is there an inability to shift or maintain attention?
Feature 3: Disorganized thought
Is the patient coherent, or have disorganized thought?
Is the patient able to follow simple commands?
Feature 4: Does the patient have an altered level of consciousness
Any level of consciousness other than alert?
Alert-normal, fully aware of environment, and reacts to simple commands appropriately
Vigilant-hyperalert
Lethargic-drowsy but easily aroused
Stupor-difficult to arouse, unaware of some elements in the environment
Coma-unarousable, unaware of the environment, no interaction with interviewer

SOURCE: modified from Soja et al.[12] with permission

of physicians, nurses, and ancillary staff is required, the responsibility usually falls disproportionately upon the nursing staff; they have the greatest degree of contact with critically ill patients and are ultimately responsible for overseeing their safety and emotional support.

When a patient shows hyperactive and agitated behavior, the nursing staff usually recognizes these symptoms as signs of delirium. However, if the patient lies in bed, rarely talks, has decreased motor activity, and responds slowly, delirium may go unrecognized, because the patient does not present nursing staff management problems. This patient may be experiencing confusion or hallucinations. Once delirium is recognized, simple nonpharmacologic interventions should be implemented. Timing medical and nursing interventions to allow for periods of sleep can be extremely beneficial to the patient. Other nocturnal comfort measures are the avoidance of loud noises and bright lights while the patient tries to sleep. Keeping a patient awake all day so he or she can sleep all night is not recommended; this practice may worsen the problem and can contribute to more sleep deprivation.

Sensory overload is a very common phenomenon in ICU patients.

Sensory overload is very common in the ICU. Noise should be limited as much as possible, by adjusting alarm limits on monitoring devices, keeping intercom levels down, avoiding loud staff conversations near patients, and shielding patients from viewing traumatic events in the ICU. During patient interactions, the patient should be addressed by name and every procedure should be explained as it is performed, even if the patient is sedated and paralyzed. This practice lessens the chance of startling the patient and perhaps causing them to become more confused. ICU lighting can contribute to a patient's delirium. Natural and artificial lighting should simulate day–night cycles, and bright overhead fluorescent lights should not be flickered on-and-off without warning the patient or protecting them from the light. Continuous bright lighting promotes further anxiety and circadian rhythm asynchrony. Finally, delirium can be further exacerbated by sensory deprivation. Keeping the patient informed regarding his or her surroundings and providing clocks and calendars can be very helpful. Allowing frequent visits by family and significant others can further decrease this sensory under-load.

After nonpharmacologic interventions are implemented for the treatment of delirium, the patient should be reassessed for persistent signs of delirium.

After the above-described nonpharmacologic interventions, the patient should be carefully reassessed for persistent signs of delirium. The agitated and hyperactive patient requires sedation to minimize the risk of personal injury and allow appropriate care. Of the many choices of medications available to treat delirium, some have been demonstrated to have greater benefit. Psychotropic drugs (neuroleptics) used to control the signs and symptoms of certain neurotic and personality disorders have been recommended to treat agitation. Although several neuroleptic agents can be utilized, haloperidol is considered by many to be the drug of choice for the treatment of delirium in the critically ill patient. It is safe, efficacious, nonaddicting, and has few cardiovascular and pulmonary side effects. Haloperidol can be administered in various doses every 20–30 min until agitation subsides. The return of agitation indicates the need for additional haloperidol.

Psychotropic drugs may be used to control the signs and symptoms of agitation.

Haloperidol is considered by many to be a drug of choice for the treatment of delirium in critically ill patients.

Atypical antipsychotics are also being introduced into clinical practice for the treatment of ICU delirium. The "atypical" antipsychotics (e.g., risperidol, olanzapine, aripipraole, ziprasidone, and quetiapine) are only available in oral formulations but have fewer side effects than haloperidol, although weight gain, hypotension, and increased glucose intolerance may occur.

The pharmacological benefits of both haloperidol and the atypical antipsychotics in the treatment of delirium are thought to derive from the normalization of cerebral function by blocking dopamine receptors, activating serotonin receptors, and facilitating the effects of acetylcholine. Moreover, anti-inflammatory effects have also been attributed to the use of haloperidol in the treatment of delirium.[13]

Benzodiazepines are another class of medications frequently used for sedation in critically ill patients.

Benzodiazepines are another class of medications frequently used for sedation in the critical care setting. They must be used with caution due to their depressive effects on respiratory and cardiac function (especially in the elderly or severely ill patients). An efficacious "pharmacologic cocktail" to treat agitation in the critically ill patient contains haloperidol and a short-acting benzodiazepine. The combination of these two classes of agents creates synergism and allows for smaller doses of each to be used with greater efficacy and fewer side effects. Benzodiazepines are also considered agents of choice to treat alcohol and illicit drug withdrawal.

If the patient's agitation is secondary to pain, narcotics can be successfully used to treat those symptoms as well as delirium. Unfortunately, this class of agents may actually cause or exacerbate delirium and has profound cardiac and respiratory effects. Barbiturates have been utilized in the past for treatment of delirium, but their role has been significantly reduced because of the high incidence of side effects and their long half-life. Finally, in cases of severe agitation/delirium in which concerns for personal injury exist, neuromuscular blockers may have a therapeutic role. Use of these drugs should be judicious, and should be accompanied by appropriate sedation and analgesia. Because neuromuscular blockers have no ability to alter consciousness, cognition, or pain they should never be used without sufficient patient sedation.

If the patient's agitation is secondary to pain, narcotics can be successfully used to treat these symptoms as well as delirium.

ANXIETY

When patients suffer life-threatening medical illnesses requiring an ICU admission, they may develop acute anxiety and fear. Fear commonly emanates from concerns regarding the possibility of death or permanent infirmity.[2,14] Once this fear subsides, patients tend to become preoccupied with their illness and its treatment(s). The complexity of human personality frequently is revealed in the ICU setting by the numerous manifestations that fear and anxiety can take. Some examples include paranoia, frequent calls for the nurse, silent withdrawal, outbursts of anger and impatience, and threats to leave the hospital against medical advice.

The best treatment for anxiety in the ICU patient is a combination of medication and quiet reassurance. If anxiety is apparent when evaluating the patient, anxiolytic treatment should be considered, and the desired end point should be negotiated with a cooperative patient. Benzodiazopines are the best drugs for treating the initial stages of anxiety and fear. Which agent to use depends on the desired clinical effect. For example, physicians must choose between preparations that are oral or intravenous, have shorter or longer onsets of action and duration, and between those agents that have or do not have active metabolites. Geriatric patients are particularly vulnerable to the accumulation of the longer-acting metabolites of benzodiazepines.

The best treatment for anxiety in the ICU patient is a combination of medication and quiet reassurance.

A recent study from University of Iowa tested the effects of music therapy on relaxation and anxiety reduction for critically ill patients receiving ventilatory assistance. Compared to a control group, these investigators demonstrated that a single music therapy session was effective in decreasing anxiety and promoting relaxation.

BEHAVIORAL PROBLEMS

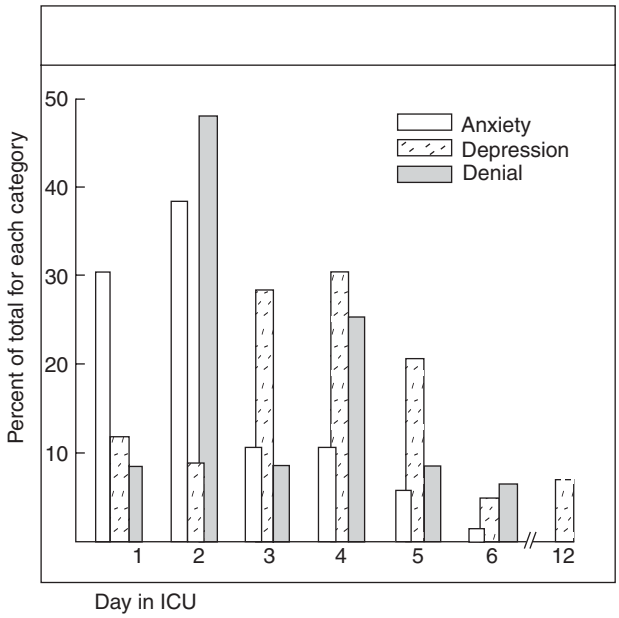
For almost 30 years, it has been known that patients demonstrate a specific chain of emotional and behavioral reactions during their ICU stay (Fig. 38-1). Initially, anxiety is prominent. It is followed by increasing denial of the significance and prognosis of the illness and the stay in the ICU, as part of a reaction against the development of anxiety.[3] Several days into the ICU admission, denial subsides and depression appears, as the impact of the patient's clinical status becomes clearer. Premorbid character traits emerge, as patients adjust to the initial shock of the crisis that resulted in their ICU admission.[15] During this time (about 3–5 days after ICU admission), patients tend to become more passive-aggressive, irritable, and demanding. If their normal personality has a hostile edge, it will certainly manifest as their ICU stay continues. This type of behavior often leads to disruptions in their care. Members of the medical and nursing staff may begin to avoid the patient or misperceive their medical needs.

Management of the delirium patient may be complicated and require consultation with a psychiatrist.

Managing these behavioral problems can be complicated, and consultation with a psychiatrist may be necessary to develop therapeutic strategies. Ideally, these strategies enable the caregivers to work with the patient and provide the best possible ICU care. Treatment strategies should be individualized to each patient's psychological makeup (e.g., firm limit setting). Physicians must clearly communicate with the nursing and ancillary staff about

FIGURE 38-1

Typical onset of emotional and behavioral reactions of an intensive care unit patient.



specific helpful interventions that will best serve the goal of rapid recovery and successful discharge of the patient from the ICU.

TREATMENT WITH SPECIFIC PHARMACOLOGIC AGENTS

Commonly medications used to treat psychiatric disorders in the ICU include the benzodiazepines, sedative-hypnotics, antipsychotics, narcotics, anticholinergics, and antihistamines.

The use of specific medications to decrease patient recall of unpleasant events during the critical phases of their illness is extremely important. The medications commonly used to treat psychiatric disorders arising in the ICU include benzodiazepines, sedative-hypnotics, antipsychotics, narcotics, anticholinergics, and antihistamines. We briefly review here the more commonly used agents in each class. These agents are described in greater detail in Chap. 57.

Benzodiazepines

The main effect of the benzodiazepines is to produce antegrade amnesia without impairing the recall of previously stored information.

Benzodiazepines are the prototype drugs for amnesia. They also have anxiolytic, sedative-hypnotic, anticonvulsant, and muscle relaxant effects. The main effect of benzodiazepines is to produce anterograde amnesia (impairing the acquisition and storage of new information) but not to impair recall of information previously stored. This effect is ideal for ICU patients because the goal is to prevent awareness and recall of unpleasant events while leaving the patient's prior memories unaffected.

The benzodiazepines more commonly utilized in the ICU are listed in Table 38-7. Diazepam, considered a long-acting benzodiazepine because of its metabolites, is used because of its rapid absorption and onset of effect in the central nervous system. Its half-life is approximately 30 h. Midazolam has a very short onset of action (5 min) and is considered a short-acting agent (half-life, 2.4 h), although it may have prolonged effects, especially in critically ill patients. Unlike diazepam, it seems to cause greater anterograde amnesia. A recent trial comparing midazolam vs. dexmedetomidine (a α_2 receptor agonist) to sedate critically ill patients has shown that dexmedetomidine-treated patients spent less time on mechanical ventilation, had less delirium, and developed less tachycardia and hypertension.[16]

TABLE 38-7

BENZODIAZEPINES USED IN THE INTENSIVE CARE UNIT

	ONSET OF ACTION	ACTIVE METABOLITE	HALF-LIFE (H)	DEGREE OF SEDATION
Midazolam (Versed)	Fast	Yes	2–5	+++
Diazepam (Valium)	Fast	Yes	20–70	+++
Chlorezapate (Tranxene)	Fast	Yes	30–200	++
Fluazepam (Dalmane)	Fast	Yes	30–200	+++
Triazolam (Halcion)	Intermediate	No	1.5–5	++
Lorazepam (Ativan)	Intermediate	No	10–20	+++
Alprazolam (Xanax)	Intermediate	Yes	12–15	+
Halazepam (Paxipam)	Intermediate	Yes	12–15	++
Chlordiazepoxide (Librium)	Intermediate	Yes	5–30	++
Oxazepam (Serax)	Slow	No	5–15	+
Temazepam (Restoril)	Slow	No	9–12	++
Clonazepam (Klonopin)	Slow	No	18–50	++
Prazepam (Centrax)	Slow	No	30–200	+

Lorazepam is a long-acting benzodiazepine with excellent sedative and anxiolytic effects. Its peak effect is about 40 min and its amnestic effect lasts at least 4 h. Due to its lower cost and favorable pharmacokinetic properties, lorazepam has become a commonly used benzodiazepine for long-term sedation in ICU patients.

Antipsychotics

Haloperidol, a potent dopamine antagonist, is the preferred antipsychotic agent in the ICU. It has little effect on the patient's cardiovascular status and respiratory drive. Acute dystonic reactions are rare in this setting. Although it is an excellent medication for agitation and delirium, it has not been shown to affect memory or recall.

Narcotics (Opioids)

Narcotic infusions (e.g., morphine, fentanyl) are often used in the ICU to provide analgesia and augment sedation. These agents are generally not amnestic and should be used with amnestic sedatives. Narcotics can, however, affect memory by modulating the learning process. Other problems with the use of narcotics in critically ill patients is the significant effect of end-organ disease on the metabolism of these agents, and their effect on the GI tract, which may impact the ability to utilize enteral nutrition.

Sedative-Hypnotics

Propofol is a short-acting intravenous sedative agent. Although predominantly used for the induction of general anesthesia, it has been used as a sedative in the ICU. It seems to have significant anterograde amnestic effects when used in the operating room, but a similar conclusion has not been reached in the critical care studies.

Barbiturate use in the ICU is primarily reserved for anesthetic induction, to provide cerebral protection, and in the treatment of seizures. These agents have long half-lives and are not suited for routine sedation of critically ill patients. Little information exists on the amnestic properties of barbiturates.

Ketamine

Ketamine, a phencyclidine derivative, is a rapid-acting, dissociative anesthetic agent with analgesic properties. Ketamine may be used as an anesthetic induction agent. It is generally reserved for use in patients with significant cardiovascular instability. It exhibits dose-dependent

analgesic, sedative, and amnestic properties. Unfortunately, ketamine can increase intracranial pressure and commonly leads to unpleasant dreams and emergence delirium; patients often find these to be extremely disturbing. Premedication with an amnestic (commonly a benzodiazepine) will help mitigate this problem.

SUMMARY

Psychological disorders such as delirium and anxiety are frequently seen in critically ill patients. Their etiology is not clearly understood, and these disorders can go unrecognized for days, which can lead to misdiagnosis, improper management, and often increased frustration for staff. Daily screening for the presence of delirium is suggested in all ICU patients.[17] Further research with long-term follow-up of ICU patients is required to determine the prevalence of psychological disorders and their natural course. Etiologic factors also need to be understood. The nature of the trauma or initial illness seems to be of primary importance; however, the patient's personality plays a role, and the ICU environment may predispose to long-term psychological problems. Detection of psychological disorders in ICU patients is certainly worthwhile. Clinical experience suggests that early intervention improves prognosis, and that the long-term sequelae can be treated with a variety of medications, psychotherapy, desensitization, and changes in the ICU environment to improve cognitive functioning.

REVIEW QUESTIONS

1. **The most important factor contributing to psychological dysfunction in the ICU patient is:**
   - **A.** Isolation
   - **B.** Beeping monitors
   - **C.** Sleep deprivation
   - **D.** Type and severity of underlying illness
   - **E.** Patient psychologic response to illness

2. **The most common psychiatric disorder observed in the ICU is:**
   - **A.** Depression
   - **B.** Anxiety
   - **C.** Delirium
   - **D.** Schizophrenia
   - **E.** Passive–aggressive behavior

3. **Delirium is twice as common in ICU patients who are:**
   - **A.** Receiving benzodiazepines
   - **B.** On mechanical ventilation
   - **C.** Housed in rooms without visible windows
   - **D.** With sleep deprivation
   - **E.** With pain

4. **The incidence of delirium in critically ill ICU patients is approximately:**
   - **A.** 50%
   - **B.** 80%
   - **C.** 30–40%
   - **D.** 15%
   - **E.** 5%

5. **The psychological disturbance associated with high mortality in the ICU patient is:**
   - **A.** Depression
   - **B.** Anxiety
   - **C.** Delirium
   - **D.** Behavioral disorder

6. **The diagnosis of delirium is based on the presence of all the following except:**
   - **A.** Inattention
   - **B.** Acute change in mental status
   - **C.** Disordered thought
   - **D.** An altered level of consciousness
   - **E.** Anxiety

ANSWERS

1. The answer is D. Type and severity of underlying illness. Patient isolation and beeping monitors (e.g., a form of monotonous sensory input) are important environmental factors that contribute to psychological dysfunction in the critically ill patient. However, the type and severity of the underlying disease is the most important factor contributing to the development of delirium. Sleep deprivation and the patient's psychological response to illness are also important factors that modify psychological response but are not as important as the type and severity of the underlying disease in necessitating ICU care.
2. The answer is C. Delirium. Depression, anxiety, and abnormal behavior patterns are other types of psychological disturbances observed in critically ill ICU patients, but delirium is the most common and the most important disorder. Patients with delirium tend to have longer ICU and hospital stays, higher mortality rates, and delirium can provoke dangerous behavioral patterns that lead to self-extubation and removal of needed lines and catheters, unduly contributing to cardiovascular stress.
3. The answer is C. Housed in rooms without visible windows. Benzodiazepines are a form of pharmacologic treatment for delirium, not a precipitating cause. Although the process of mechanical ventilation, which negates the patient's ability to communicate, along with sleep deprivation and pain can all contribute to patient discomfort, patients housed in ICU rooms without visible windows have twice the incidence of delirium compared to ICU patients housed in rooms with visible windows. The value of a visible window is that it allows the patient to orient themselves to time of year, and time of day, which helps to restore normal sleep–wake patterns, and reinforces patient self-monitoring of environmental cues to modify their behavioral response.
4. The answer is C. 30–40%. Although the exact incidence of delirium is not carefully delineated, it is believed that 10–15% of patients hospitalized on a general medical or surgical ward suffer from delirium. This incidence doubles in critically ill patients admitted to the ICU. Age may be another important factor, further increasing the incidence of delirium to approximately 50% in elderly, critically ill patients.
5. The answer is C. Delirium. Although depression, anxiety, and behavioral disorders are important issues that afflict the critically ill patient, delirium is the most important psychological disturbance that carries with it a clear-cut increased mortality. In some respects, the 20% mortality associated with delirium reflects the severity of the underlying medical or surgical disease or signifies an acute or chronic disorder with limited physiologic patient reserve. Delirium represents lack of success in improving end-organ function due to the severity of the underlying illness or its refractoriness to therapy. The development of delirium is an important factor that requires proper attention to identify the underlying disease process, maximizing optimal therapy, or searching for concomitant disorders that may have been initially overlooked by attending to the primary disorder. In addition, environmental factors such as monotonous sensory input, absence of a visible window, and sleep deprivation should be sought and corrected.
6. The answer is E. The Confusion Assessment Method (CAM) is a simple validated tool used for the detection of delirium in both the clinical and research settings. During the assessment, observations are made to evaluate four key delirium criteria: (1) acute change in mental status, (2) inattention, (3) disordered thinking, and (4) an altered level of consciousness. The CAM has been shown to be a reliable, reproducible measurement of the presence of delirium compared to assessments made by psychiatrists with reported sensitivities and specificities of 94–100% and 90–95%, respectively.

CHAPTER 39

FRIEDRICH KUEPPERS

Host Defenses

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the complexity of defense mechanisms
- Distinguish among mechanical, biochemical, cellular, and immunologic defenses
- Understand that defensive responses can overwhelm their controlling counter-regulatory mechanisms and thereby can become harmful to the organism as a whole

The body as a whole is built to defend itself against a potentially hostile environment. The specific features in the environment that are potential threats to the body's integrity may be mechanical, chemical, or biologic in nature. This chapter describes the most important defense mechanisms that protect against various insults including those which originate from the body itself. Situations that occur frequently in intensive care units when these mechanisms fail or are compromised are also described.

Invasion of the body by bacteria, fungi, or viruses is an ever-present threat to the body's integrity. The intact skin cannot be penetrated by these organisms. However, patients who are on prolonged bed rest, particularly when they are unable to shift their body position because of paraplegia or weakness, frequently develop decubitus ulcers at pressure points, commonly the sacrum, heels, and shoulder blades. These ulcers can serve as portals of entry for organisms. The skin is also penetrated by the frequent injections that are medically necessary. Intravenous catheters that often remain in place for prolonged periods of time are other potential sites of entrance for infectious organisms.[1]

The intact skin is essentially impenetrable for microbial pathogens.

Indwelling catheters themselves can also be sites for bacterial colonization; the bacteria, most often staphylococci, either are introduced with the catheter or may settle at the catheter site following bacteremia. The bacteria can form colonies on the catheters and give rise to bacteremia by continuously shedding bacteria into the circulation.

Mucosal surfaces are vulnerable to bacterial attacks when they are compromised by tubes or catheters. The tube can interfere with the protective mucus layer that covers the mucosa; it can also damage the mucosal cells directly by mechanical injury or indirectly by producing ischemia. These situations are common in the urinary tract with urethral catheters and in the

The mucosal surface is covered with protective mucus.

lung with tracheal tubes when patients require mechanical ventilation. In the lung, an additional problem exists in that the endotracheal tube will interfere with mucociliary transport, an issue discussed later in more detail.

THE LUNG

The large (70–75 m^2) surface of the lung is exposed to ambient air and its contents.

The lung is particularly vulnerable to the environment because it is continuously exposed to the ambient air and its various contents. The total air-exposed alveolar surface of the lung of an adult is approximately 70–75 m^2. The amount of air that moves in and out of the lung in an adult at rest is approximately 10,000 L/24 h. With exercise, this amount increases considerably. The alveolar surface is covered by only a thin layer of lining fluid and surfactant. Dust particles, including bacteria suspended in the ambient air as well as gases and vapors, can settle directly on the alveolar surface. However, only the smallest particles, 0.3–2.0 μm, are actually carried to the alveoli. Larger particles (2–10 μm) settle on the tracheal, bronchial, and bronchiolar mucosa, while particles larger than 10 μm are almost entirely filtered out in the nose and the throat.[2]

The trachea and the bronchi are covered with a layer of mucus. Any particle therefore settles on the mucus layer and not directly on the cell surface. Mucus consists of a liquid sol phase and a mucoid gel phase. The gel phase floats on the sol layer.[3] Both components are produced by the submucosal mucous glands and, to a lesser extent, by the goblet cells that are located in the mucosal epithelium. Other cell types of the mucosal epithelium are ciliated cells and brush cells. Ciliated cells are present throughout the trachea and the bronchi, except for the smallest bronchioli, the respiratory bronchioli. Cilia are hair-like protrusions with a complex internal structure (Fig. 39-1), that beat rhythmically, approximately 10–20 times per second. They beat in the liquid sol phase of mucus and, by their motion, drive the sheet of gel that is floating on the liquid phase in one direction, toward the larynx, and therefore up the bronchial tree and the trachea. When the mucus, including bacteria and particles that have settled on it, arrives at the level of the larynx, it can either be swallowed or expectorated.

MUCOCILIARY CLEARANCE

Ciliated cells of the mucosa move the mucus toward the trachea and up the trachea to the larynx.

This clearing mechanism of the lung is often referred to as the mucociliary elevator. Its efficiency is quite remarkable. It can move the mucus layer and its contents at a speed of 1–2 cm/min, and its activity is continuous because the cilia beat continuously day and night. The importance of this continuous clearing mechanism can best be appreciated when it is malfunctioning or when it experiences interference. In the immotile cilia syndrome, or ciliary dyskinesia, the cilia

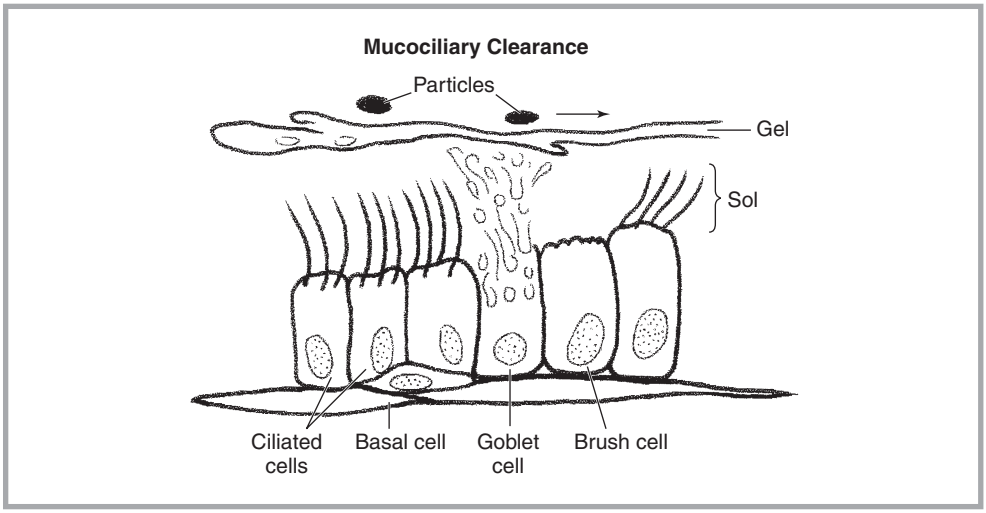

FIGURE 39-1

Schematic representation of the tracheal mucosa shows the major cell types. Note that the cilia beat within the sol phase of the respiratory secretions. The sheet of mucus (gel phase) that is being moved by the beating cilia is floating on the sol phase.

CASE STUDY

K.M. is a 25-year-old male who presented to the pulmonary clinic because of frequent upper respiratory infections and chronic sinusitis. He states that he had frequent bouts of bronchitis and ear infections since childhood. At age 7 a myringotomy was performed.

On physical examination he was a thin, but otherwise normally developed male. Ausculation of the chest revealed rhonchi and crackles throughout the lungs and dextracordia was suspected.

The nasal mucosa was found to be "boggy" and the tonsils were enlarged.

A chest X-ray confirmed the suspected dextrocardia. It also showed evidence of bronchiectis in the lower lung fields bilaterally. A nasal mucosal biopsy was performed and was subjected to electronmicroscopy that revealed defective cilia; the outer dynein arms of the peripheral microtubules within the cilia were missing in all ciliary sections. This finding established the diagnosis of primary ciliary dyskinesia. The outer dynein arms contain the emzyme ATP'ase that is essential for ciliary motility as ATP is the only energy source for ciliary beating. Lack of ciliary beating will lead to mucus accumulation within the bronchial lumen that in turn will predispose the patient to chronic bronchitis and bronchietasis.

are defective on a genetic basis, and they either do not functional at all or function insufficiently. The clinical consequences are frequent respiratory infections, chronic bronchitis, and sinusitis, to mention only the most severe symptoms. The obvious reason for these respiratory infections is insufficient clearing of respiratory secretions and bacteria that then can establish infectious colonies within the bronchi and the lung.[4]

Some bacteria secrete substances that damage cilia and stop their activity. *Pseudomonas aeruginosa,* for example, has the ability to damage the ciliary membrane so that ATP leaks out. As a consequence, the cilia stop beating because ATP is their only source of energy. Ciliated cells can also be damaged or destroyed by chronic bronchitis, virus infections, cigarette smoke, and noxious gases, again resulting in defective mucociliary transport.

The consistency of respiratory mucus is important for clearing efficiency.

The consistency of respiratory secretions is critical for optimal functioning of mucociliary clearance. Loss of water leads to lowering of the liquid sol layer, which does not allow the cilia to function at their optimal efficiency. Too much water in respiratory secretions increases the sol layer; as a consequence, the cilia beat freely but the transfer of mechanical energy to the gel layer is insufficient, and the gel layer moves slowly or not at all. Introduction of mechanical barriers into the trachea in the form of endotracheal tubes or stents also interferes with mucus clearance and is therefore a predisposing factor for bronchitis and pneumonia. The ventilator-associated pneumonia discussed elsewhere in this textbook is a consequence of insufficient clearing of mucus, which fosters bacterial colonization.

COUGH REFLEX

Cough is the second major clearing mechanism for bronchi and trachea.

The second mechanism available to clear secretions from the bronchi and trachea is cough. Cough is a complex maneuver. The first part consists of a forced expiratory motion against a closed glottis, producing high intrathoracic and intrapulmonary pressures. The glottis then opens rapidly, releasing the air from the lung. At the same time, the intrathoracic airways are compressed, forcing the noncartilagenous flaccid portion of the trachea and bronchi into the lumen, thereby decreasing the total cross-sectional area of the large airways and trachea to one-sixth of normal size at rest during tidal breathing. The velocity of air rushing through the narrowed trachea may be as high as 280 m/s as compared to 6.7 m/s with normal breathing at rest. With such a high air speed, accumulated mucus and particles on the mucosal surface can be expectorated (Fig. 39-2).[5]

Particles 2 μm in diameter or less may settle on the alveolar surface. There are several ways such a particle may be handled.

Particles or bacteria in the alveoli are phagocytized and processed by alveolar macrophages.

1. An alveolar macrophage may phagocytize the particle. If the particle consists of organic material, it can be digested. If it is mineral dust, the macrophage can migrate out of the alveolus beyond the respiratory bronchioles and find access to the mucociliary elevator,

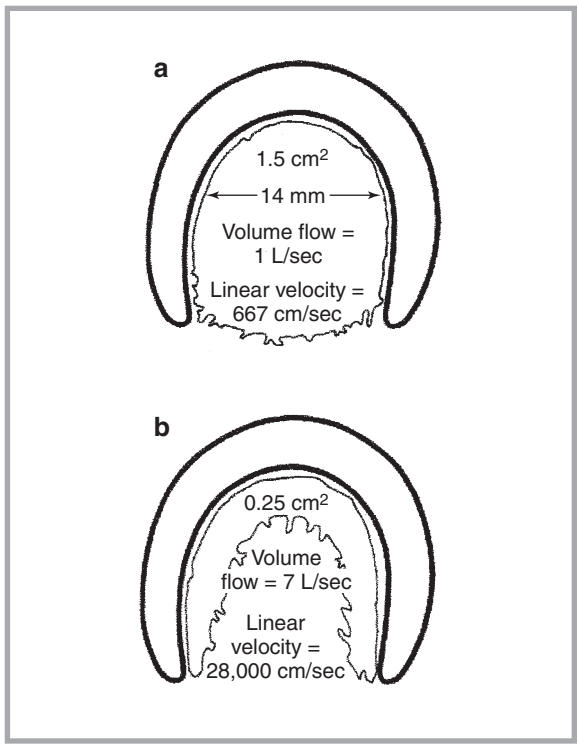

FIGURE 39-2

Changes in cross-sectional area of trachea. (**a**) Contours and dimensions of trachea during normal breathing. (**b**) During cough, the positive intrathoracic pressure inverts the noncartilaginous part of the intrathoracic trachea and decreases its cross-sectional area to one-sixth of normal; added to a sevenfold increase in flow rate, this increases the linear velocity 42-fold.

where the phagocytized particle will be transported up the bronchi into the trachea from which it will eventually be swallowed or expectorated. The macrophage can also find access to a lymphatic vessel that will drain into a lymph node or toward the pleura. The macrophage usually dies at either of these sites, leaving the dust particle behind. The remaining dust particles can be demonstrated in hilar lymph nodes or at the pleural surface, where they form an easily visible network of dark material. Asbestos particles that are deposited close to the pleura can give rise to mesotheliomas.[6]

2. If the offending particle happens to be a bacterium, the macrophage will also phagocytize it and process it internally. Internal processing of bacteria is initiated by the production of free oxygen radicals that oxidize the bacterial cell membrane and make it leaky and susceptible to further enzymatic attack. This initial step is essential to the killing of bacteria by phagocytic cells. Several defects are known that lead to decreased or total absence of oxygen free radical production. The result is chronic granulomatous disease[7] that is characterized by chronic infections with *Staphylococcus aureus*, *Serratia marcescens*, *Escherichia coli*, and *P. aeruginosa*, and formation of multiple granulomas. It is a rare disorder, but it is mentioned here to highlight the importance of this reaction in the defense against bacteria. If the macrophages are not successful in killing the invading bacteria, or if they are overwhelmed by too many organisms, the reaction may not be limited locally; instead, an inflammatory response can ensue.

The activated alveolar macrophage initiates the inflammatory response.

THE INFLAMMATORY RESPONSE

The initial response of the alveolar macrophage is the excretion of tumor necrosis factor (TNF), interleukin (IL) 1, and IL-6.

The factor that is best understood as a stimulant of macrophage activation is the lipopolysaccharide (LPS) component of the bacterial cell wall of gram-negative bacteria. LPS is released when gram-negative bacteria are lysed by macrophages or by antibiotics. LPS binds to a specific receptor (CD 14), located mainly on macrophages.[8] A somewhat complex signaling sequence results in increased production and release of TNF-α, IL-1β, and IL-6. These factors in turn induce the production and release of other cytokines (Fig. 39-3). As the number

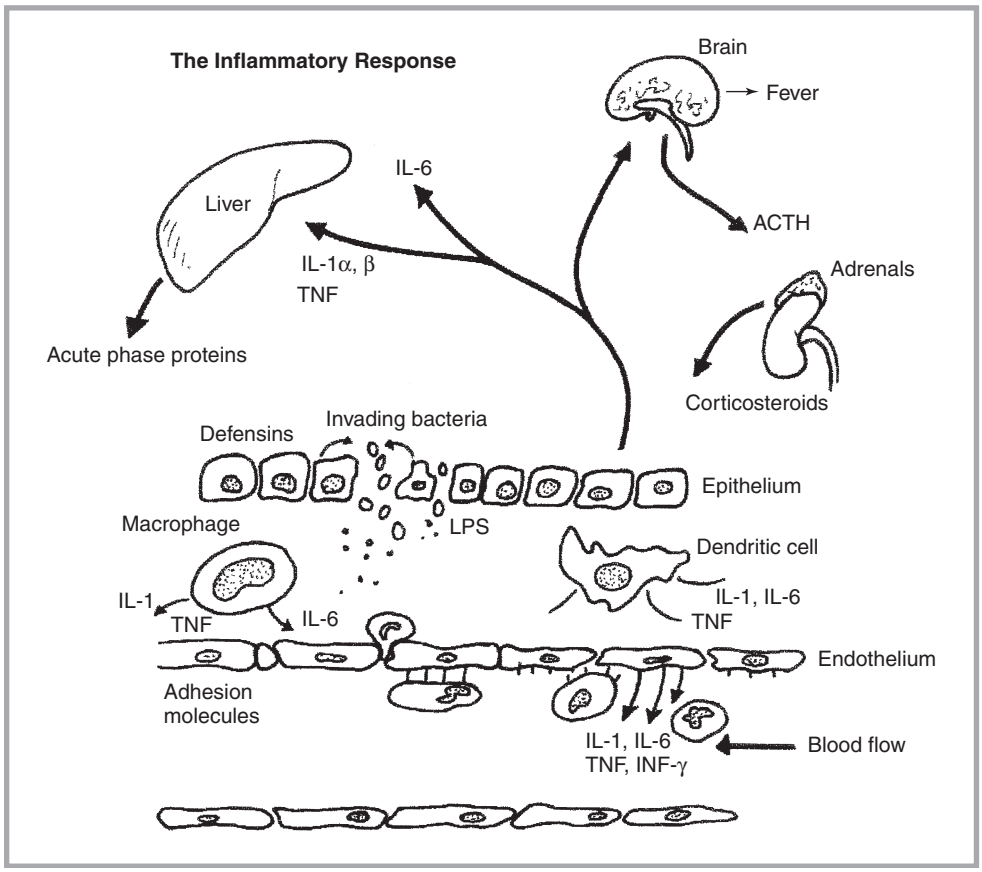

FIGURE 39-3

Bacteria have invaded the subepithelial space and release lipopolysaccharide (LPS). Inflammatory cytokines (interleukin-1 [IL-1], tumor necrosis factor (TNF), IL-6, and others) and defensins are released by the damaged epithelium, endothelial cells, dendritic cells, and macrophages. Under the influence of the inflammatory cytokines, the endothelial cells express adhesion molecules of the selectin family, which leads to initial slowing and then rolling of the polymorphonuclear neutrophils (PMNs) along the endothelial surface. Further chemokine release stimulates endothelial expression of binding proteins (I-CAM). The activated PMNs express integrins that interact with I-CAM and establish firm binding of the PMN to the endothelial wall. The PMN flattens out and penetrates the endothelial layer (diapedesis), and, following a chemokine gradient, migrates toward the site of the bacterial damage, where it will engage in phagocytosis and lysis of bacteria. The cytokines that are released into the general circulation reach the brain and the liver. The hypothalamus responds with temperature elevation; other areas of the brain may be responsible for the feeling of fatigue and malaise. The pituitary gland is stimulated to release ACTH, which in turn leads to increased release of corticosteroids from the adrenals. The liver responds to the cytokines, principally IL-6, with increased synthesis and release of acute-phase proteins: C-reactive protein, complement C3, fibrinogen, alpha-1-acid glycoprotein, alpha-1-antitrypsin, alpha-1-antichymotrypsin, haptoglobin, and alpha-2-macroglobulin.

of cytokines has grown to more than 20, we discuss here only the major cytokines that have well-established functions.

TNF-α has several systemic effects: it lowers blood pressure and leads to an initial leukopenia and subsequent leukocytosis and temperature elevation. On the cellular level, TNF-α stimulates the immune response and bactericidal activity (see Fig. 39-3). Studies in animal models have shown that complete blockade of TNF-α renders the animals unable to clear bacteria from the bloodstream and leads to death due to overwhelming bacteremia. However, prolonged elevated blood levels of TNF-α produce a sepsis-like picture.

Experiments have shown that TNF-α appears within 90 min in the peripheral circulation after an injection of LPS and that it afterward disappears or is present in only very low concentrations. It is apparently no longer needed to maintain an adequate acute-phase response and an immune response.

IL-1 has several functional similarities to TNF. Three distinct proteins are known: IL-1α, IL-1β, and IL-1ra. IL-1β is produced as a precursor peptide and only after processing by a cysteine protease (interleukin-converting enzyme) can it leave the cytoplasm. It has proinflammatory effects similar to those of TNF. The effects are mediated through binding to a receptor that is present on several cell types. A unique feature is the production of a truncated and modified form of IL-1β, known as IL-1ra, which is a separate gene product. It can bind to the IL-1β receptor and can block the action of IL-1β on the target cell. IL-1α is directly secreted by mononuclear phagocytes; it is functionally similar if not identical to IL-1β. Both interleukins are powerful inducers of the inflammatory response by directly affecting other cells to produce mediators such as other cytokines, arachidonic acid metabolites, nitric oxide, adhesion molecules, and chemotactic factors, to name just a few. These interleukins also have a direct central effect by inducing fever and fatigue (Fig. 39-3).

IL-6 stimulates production of acute-phase reactant proteins by the liver.

IL-6 is of particular importance among the various cytokines because it occupies a central role in the acute-phase response.[9] It is a 26-kDa protein that is produced by activated macrophages but to a lesser extent is also made by lymphocytes and fibroblasts. IL-6 has a major activity on hepatocytes by stimulating the production and secretion of acute-phase reactant proteins including fibrinogen, C-reactive protein, alpha-1 acid glycoprotein, alpha-1 antitrypsin, alpha-1 antichymotryphin, alpha-2 macroglobulin, and haptoglobulin[10]. It also stimulates immunoglobulin production by B lymphocytes and induces proliferation of T lymphocytes. Following LPS stimulation, its production and release by macrophages occurs after 4–6 h, in contrast to TNF and IL-1, which are produced within 60–90 min. IL-6 is elevated in septic shock as are other cytokines. A contributory etiologic role in sepsis is likely but it is not easy to separate its impact from that of other cytokines.[11]

Similar statements can be made about other cytokines. IL-8 is a chemotactic factor that is produced by several cell types including macrophages, lymphocytes, endothelial cells, and fibroblasts stimulated by LPS or IL-1 and TNF. Its principal function is chemotactic activity for polymorphonuclear granulocytes, attracting them to the site of inflammation. High concentrations in the general circulation, however, are detrimental, as they have been associated with defective neutrophil recruitment and high mortality.

Interferons have antiviral activity.

There are three types of interferons. IFN-α and IFN-β are products of multiple cell types, whereas IFN-γ is only produced by activated T lymphocytes. The interferons have in common the ability to interfere with viral RNA or protein synthesis. However, they also promote CD8 T-cell activation and the activation of natural killer (NK) cells. High doses of IFN-α have increased mortality in mice infected with gram-negative bacteria. Blocking the IFN-α receptor with a specific antibody has been reported to protect mice from the effects of high doses of LPS. A protective effect in sepsis from gram-negative organisms has been seen in IL-10. IL-10 apparently exerts its protective effect by inhibiting the action of TNF-α, IL-1, -6, -8, IFN-α, and nitric oxide. The precise mechanism by which this is achieved has not been fully elucidated.

The human body responds to invading infectious organisms with a powerful inflammatory response that is mediated by multiple cytokines such as TNF, IL-1, IL-6, and many others. These mediators act in a cascade-like fashion in that one mediator induces the production of others. Other cytokines such as IL-8 and IL-1ra and IL-10 can downregulate proinflammatory cytokines. A summary of some activities of cytokines is given in Table 39-1. In healthy individuals these mechanisms are capable of limiting a bacterial insult to a local site or, in case of a bacteremia, to eliminate the bacteria quickly by phagocytosis and lysis.

The inflammatory response is deregulated in sepsis.

However, these defense mechanisms may break down. The result is overwhelming bacteremia or a sepsis syndrome. The sepsis syndrome is apparently initially triggered by an inflammatory response that becomes so overwhelming that all natural counter-regulations fail. Details of this catastrophic event are the subject of current research.[12]

TABLE 39-1

ACTIVITIES OF SOME CYTOKINES

CYTOKINE	CELLULAR SOURCES	MAJOR ACTIVITIES
Interleukin-1	Macrophages	Activation of T cells and macrophages; promotion of inflammation
Interleukin-2	Type 1 (Th1) helper T cells	Activation of lymphocytes, natural killer (NK) cells, and macrophages
Interleukin-4	Type 2 (Th2) helper T cells, mast cells, basophils, and eosinophils	Activation of lymphocytes, monocytes, and IgE class switching
Interleukin-5	Type 2 (Th2) helper T cells, mast cells, and eosinophils	Differentiation of eosinophils
Interleukin-6	Type 2 (Th2) helper T cells	Activation of lymphocytes; differentiation of B cells; stimulation of the production of acute-phase proteins
Interleukin-8	T cells and macrophages	Chemotaxis of neutrophils, basophils, and T cells
Interleukin-10	Type 2 (Th2) helper T cells	Suppression of some macrophage functions, including secretion of cytokines; enhanced B-cell proliferation and Ig secretion
Interleukin-11	Bone marrow stromal cells	Stimulation of the production of acute-phase proteins
Interleukin-12	Macrophages and B cells	Stimulation of the production of interferon-γ by type 1 helper T cells (Th1) and by NK cells; induction of type 1 helper T cells (Th1)
Tumor necrosis factor-α	Macrophages, NK cell, T cells, B cells, and mast cells	Promotion of inflammation
Tumor necrosis factor-β	Type 1 (Th1) helper T cells and B cells	Promotion of inflammation
Granulocyte macrophage-stimulating factor	T cells, macrophages, NK cells, and B cells	Promotion of the growth of granulocytes and monocytes
Interferon-α	Virus-infected cells	Induction of resistance of cells to viral infection
Interferon-β	Virus-infected cells	Induction of resistance of cells to viral infection
Interferon-γ	Type 1 (Th1) helper T cells and NK cells	Activation of macrophages; inhibition of type 2 helper T cells (Th2)

SOURCE: Data from von Andrian and Mackay[16]

THE IMMUNE RESPONSE

The immune response is a powerful protective mechanism against invading organisms. In contrast to the inflammatory response (discussed in the previous section), which is immediate and directed against all invading organisms and agents, the immune response is adaptive in nature and can target specific organisms and offending antigens. Because its complexity is enormous, a somewhat simplified description is presented here. However, this discussion is detailed enough for understanding some of the situations important in critical care medicine.

Two cell types are involved in the immune response: T and B lymphocytes. T lymphocytes, or simply T cells, consist of two major subgroups: cytotoxic T cells (CD8+) and helper T cells (CD4+, Th1 and Th2). Cytotoxic T cells recognize foreign antigens on cells that are infected by viruses or bacteria (Fig. 39-4). They can also recognize mutated proteins on the surface of cancer cells and thus provide a continuous immune surveillance system. The offending cells are lysed directly by perforins, which are secreted by the T cells. Perforins

The role of T cells in the cellular immune response is to recognize foreign antigens on cell surfaces and lyse those cells; T-cells also attract other T cells.

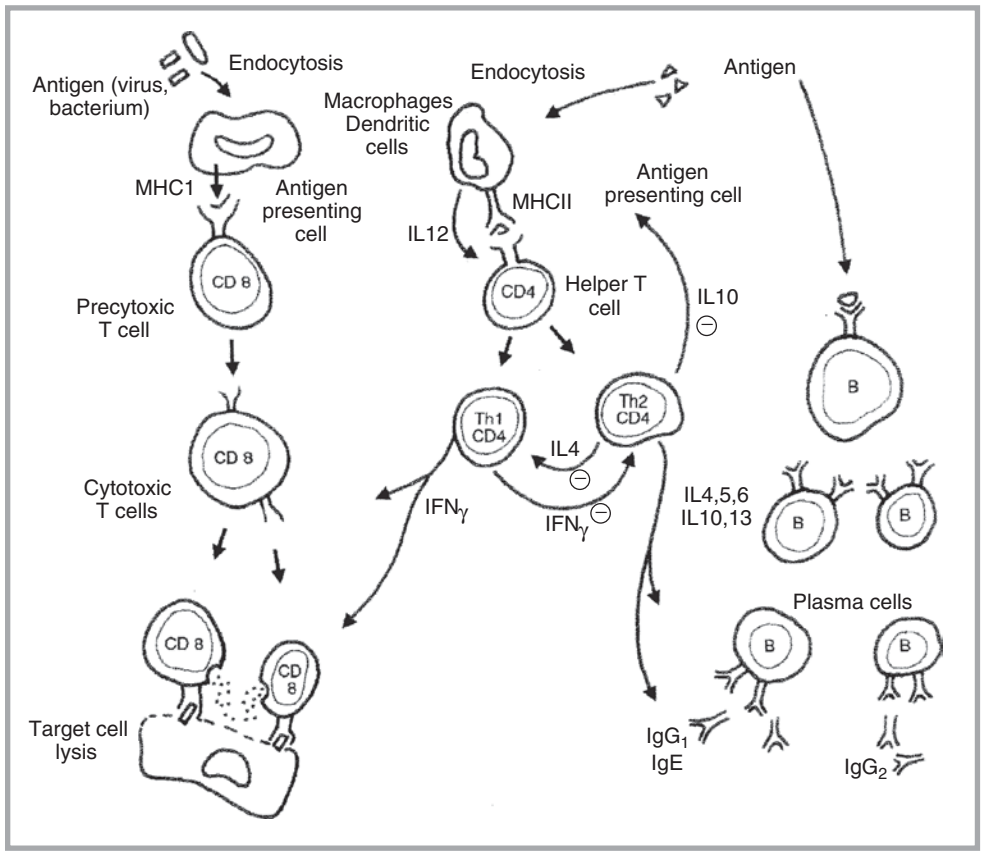

FIGURE 39-4

A macrophage or a dendritic cell encounters an antigen (a soluble protein or a virus or a bacterium). If the antigen is small (in most cases, a soluble protein), it is internalized and broken up into smaller peptides by proteases. These peptides, complexed with the major histocompatibility complex class II (MHC II), are presented to helper T lymphocyte CD4T cells. These cells become activated and are further differentiated into type 1 and 2 helper cells (Th1 and Th2). Activated Th1 lymphocytes produce predominantly IFN-γ, TNF, and IL-2, which activate cytotoxic T cells (CD8T) and B cells; these B cells produce predominantly IgG-2. Th2 cells produce IL-4, -5, -6, -10, and -13, which stimulate antigen-specific B cells to produce antibody IgG-1 and IgE. If the original antigen is a virus or a bacterium, these organisms are phagocytized by macrophages or dendritic cells and internally lysed and processed. Antigens combined with the (MHC I) are presented to CD8 cells. Under the influence of CD4+ helper cells, specific cytotoxic cells will recognize and lyse cells that express the original antigen combined with MHC I at their surface.

are proteins that insert themselves into cell membranes, thereby lysing the cell. The T cells are limited in their response because they can only recognize relatively small (8–15 amino acids long) peptide antigens. Stimulated CD4+ T-helper cells secrete multiple cytokines that in turn stimulate B cells but also other T cells that have several other activities to initiate an inflammatory response (see Fig. 39-4).

Macrophages and dendritic cells present antigens complexed with class II surface proteins (major histocompatibility complex; MHC class II) to the CD4+ helper T cells. B cells carry a large variety of immunoglobulin (Ig) molecules on their surface that recognize and bind the presented antigens. Under the influence of the stimulus by the CD4+ cells, they start to divide and to produce more Ig antibody specific for the antigen that was presented to them, leading to a full humoral immune response. The high specificity of the antibody is achieved by complex reshuffling of several components of the immunoglobin genes. Different immunoglobulins are expressed at different anatomic sites: IgG with its four subclasses (IgG-1–IgG-4) is the predominant immunoglobulin type in circulating blood and in inflammatory exudates, whereas IgA is the major immunoglobulin in the respiratory and intestinal tracts. Of all

immunoglobins, IgE is present in the lowest concentration in plasma (approximately 0.05 to 0.5 μg/mL). It is also found in respiratory and intestinal secretions. Its importance lies in the fact that it has a high affinity to specific receptors on mast cells and basophilic granulocytes. In response, these cells release histamine, serotonin, and other vasoactive substances that can initiate an anaphylactic shock which can be life-threatening. The role of IgE in immune defense is probably its direct activity against some intestinal parasites. The mature human lung contains a large assortment of lymphoid tissue (bronchus associated lymphoid tissue; BALT) that is probably capable to mount a local humoral and cellular immune response.[13]

It is intuitively apparent that a system of such complexity as the immune response can fail. Genetic defects are known for many steps that are necessary for a full immune response. These defects are only discussed here with respect to the pathologic outcome that may be encountered in critically ill adult patients.

The cellular immune response or the humoral immune response can be affected. Major deficiencies of these responses usually become evident in childhood. However, there are some specific genetically determined immunodeficiencies that manifest themselves later in life.

B cells produce the humoral immune response.

1. In common variable hypogammaglobulinemia, the nature of the defect is not known, but its presence leads to suppression of B-cell maturation. The clinical manifestations are frequent bacterial infections, hemolytic anemia, frequent malignancies, and autoimmune diseases. The onset of symptoms occurs in the age range 20–40 years.[14]
2. Less well-understood immune defects are IgG subclass deficiencies in which one of the IgG subclasses is missing. These deficiencies can cause chronic respiratory and other infections, presumably because one or several specific antibodies are simply missing from the total arsenal of antibodies.
3. Selective IgA deficiency is probably the most common inherited immunoglobulin deficiency in the US white population, with a prevalence of approximately 1 in 600. A wide clinical spectrum is associated with IgA deficiency, ranging from the absence of any clinical symptoms to chronic and recurrent respiratory infections.[15]

Common humoral immunodeficiencies that are manifested in adults may be encountered in an intensive care unit.

The cellular immune response can also be impaired by specific genetic defects. These defects manifest themselves in early childhood and are not likely to be seen in adult critically ill patients. The most prominent acquired cellular immune defect is the acquired immunodeficiency syndrome (AIDS). Although many different cells are infected by the human immunodeficiency virus (HIV-1 and HIV-2), the CD4+ T lymphocyte is the major target of the virus, leading to decrease and eventually a virtual disappearance of these cells. The patient loses the ability to eliminate infectious organisms that are normally targets of activated T cells such as *Candida albicans*, *Cryptococcus neoformans*, *Pneumocystis carinii*, tubercle bacilli, and a host of viruses.[16]

Cellular immunodeficiency in AIDS leaves the patient defenseless against many organisms that are normal T-cell targets, including *Pneumocystis*, *Candida*, and *Cryptococcus*.

The humoral immune response is also impaired, but to a lesser extent, as B cells retain the ability to produce antibodies that they made before the HIV infection, but their ability to mount an immune response to newly encountered antigens is severely weakened. AIDS is probably the most drastic example of an immunodeficiency that develops during adult life. There are, however other conditions that weaken the cellular as well as the humoral immune responses: malnutrition, chronic disease, malignancies, alcoholism, and iatrogenic regimens such as chemotherapy and, of course, immunosuppressive treatments that may be given to counteract the immunologic rejection of a transplanted allograft.

The humoral immune response is also impaired when T cells are suppressed.

A special situation is immune tolerance, which can develop when either very high doses of an antigen are infused, or low levels of an antigen are present, for prolonged periods of time. Low-dose tolerance is important because it can explain chronic carrier states for some viruses such as hepatitis B or C.

THE COMPLEMENT SYSTEM

The complement system closely interacts with the humoral immune response and thus is part of the body's defense against invading organisms.[17] This system consists of several plasma proteins that interact in a cascade-like fashion. The complement proteins make up

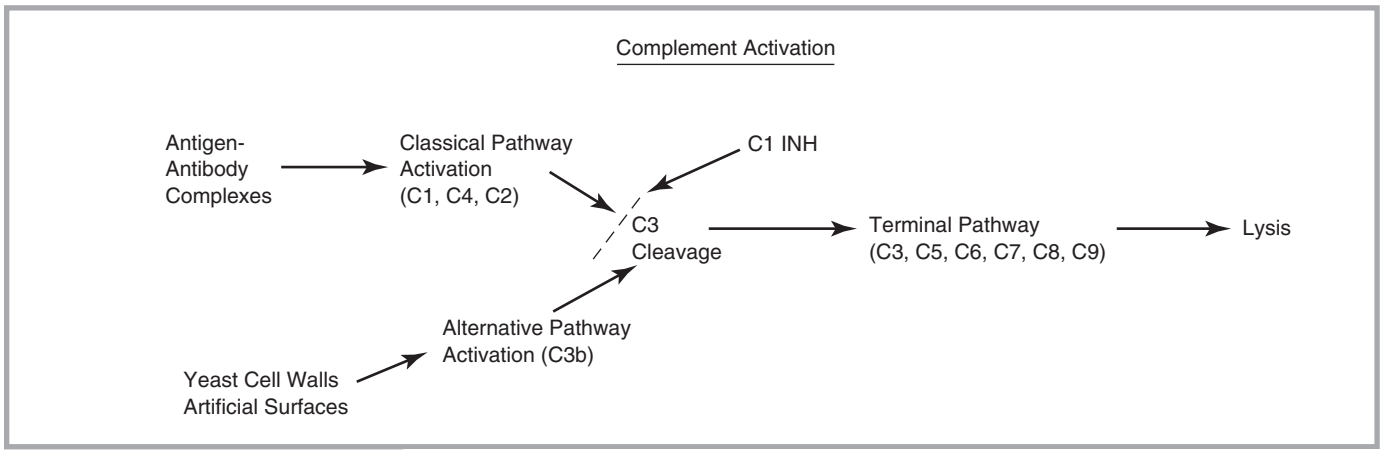

FIGURE 39-5

The complement components are labeled C with sequential numbers (C1, C2, etc.). Activation of the first three components C1, C4, and C2 by an antigen–antibody complex leads to cleavage of C3 by the activated C1 esterase in the C1–C4–C2 complex. The C1 esterase activity is regulated by a specific inhibitor (INH). By a sequence of intermediate steps, the C3 components catalyze the final attack complex, a cylindrical macromolecule that lyses a targeted cell or bacterium. C3 can also be activated directly by the alternative pathway (artificial surfaces, yeast, and other substances). Activated C3 will also lead to the formation of an attack complex.

Complement binds to immune complexes.

approximately 10% of the total plasma proteins. The usual activation process starts when an antigen–antibody complex is formed with most types of IgG molecules, or IgM. However, complexes with IgG-4, IgA, IgD, and IgE do not activate complement. The first complement component binds to a specific region of the IgG or IgM molecule in the antigen–antibody complex. This step leads to further activation of complement components C4 and C2 and, most important, C3. C3 splits into three components that are important because of their activity as anaphylatoxins. Anaphylatoxins induce degranulation and liberation of vasoactive substances and histamine from mast cells and basophilic granulocytes, thereby promoting vascular permeability and anaphylactic shock in extreme situations.

Complement activation leads to liberation of vasoactive peptides.

The esterase of the C1–C4–C2 complex that activates C3 is regulated by a specific inhibitor (C1 INH). Genetic or acquired low concentration of this inhibitor leads to angioneurotic edema, which consists of localized extreme vascular permeability resulting in localized edema often following a trivial insult or trauma. Angioneurotic edema may occur in many soft tissues. It can be life-threatening if the larynx and vocal cords are involved.

C3b, one of the C3 products, is also important as an opsonin; that is, it favors uptake of C3b-containing immune complexes, or C3b-coated bacteria by phagocytic cells. C3 can also be activated directly, bypassing the "classical" activation cascade. The final result of complement activation is the formation of the so-called attack complex, which is a circular protein complex that inserts itself into the bacterial cell wall or the cell that was the initial target of an immune response, leading to lysis and destruction of the offending cell (Fig. 39-5).

SUMMARY

Multiple mechanisms defend the body against external and internal agents – mechanical, biochemical, and immunologic. The most important feature to understand about defense mechanisms is their redundancy; if the defense fails on one level there are several backup mechanisms that can limit the damage to the host which would otherwise occur. For example, if a bacterium settles on the alveolar surface, an alveolar macrophage engulfs the bacterium and lyses it. If this fails, polymorphonuclear granulocytes that have been attracted by cytokine signals attempt to phagocytize the offending agent. The next level is a more generalized

inflammatory response involving a massive mobilization of granulocytes and production of acute-phase proteins that have antibacterial activity. The immune response that would then be activated has again multiple layers of cellular as well as humoral components.

Adding to the complexity are counter-regulatory mechanisms that control almost every step in inflammation and immune response. Last, the defense mechanisms can fail or can simply be insufficient to control an overwhelming insult or they can overshoot and can become detrimental to the host, as probably happens in the sepsis syndrome and the adult respiratory distress syndrome, where massive cytokine production leads to capillary leak, hypotension, complement activation, and coagulation anomalies that characterize these catastrophic events.

REVIEW QUESTIONS

1. Ciliated cells in the respiratory mucosa are important in pulmonary clearance because they
- **A.** Adjust the hydration of respiratory secretions
- **B.** Move mucus
- **C.** Produce glycoproteins (components of normal mucus)
- **D.** Absorb electrolytes

2. Ventilator-associated pneumonia is usually caused by
- **A.** Bacterial growth in the ventilator tubes
- **B.** High humidity of the gas mixture from the vent
- **C.** The unphysiologic O_2 concentration in the inhaled gas mixture
- **D.** Interference with the pulmonary clearance of the vent tube
- **E.** Aspiration of gastric content

3. The most common genetically determined immune deficiency in the US population is
- **A.** AIDS
- **B.** Severe combined immunodeficiency
- **C.** IgE deficiency
- **D.** IgA deficiency
- **E.** IgM deficiency

4. The predominant immunoglobin in the intestinal tract is
- **A.** IgG
- **B.** IgA
- **C.** IgM
- **D.** IgE

5. Dust particles that settle on the alveolar surface are readily taken up by:
- **A.** Mast cells
- **B.** Type I pneumocytes
- **C.** Type II pneumocytes
- **D.** Alveolar macrophages
- **E.** Polymorphonuclear granulocytes

6. Factors that impair pulmonary clearance of airborne particles include all but one of the following:
- **A.** Tracheotomy
- **B.** IgE deficiency
- **C.** Increased water content of respiratory secretions
- **D.** Decreased water content of respiratory secretions
- **E.** Bronchiectasis

ANSWERS

1. The answer is B. The major function of the ciliated cells is the transport of respiratory mucus toward the trachea. In the trachea, the transport is cephalad toward the larynx. Brush cells are involved in fluid and electrolyte transport. Mucus production is by submucosal glands and goblet cells.

2. The answer is D. The endotracheal tube is a barrier to normal mucous transport. Mucus accumulates distally of the tube, and inhaled bacteria are not transported toward the larynx; they are thus able to form infectious colonies. In addition, the endotracheal tube acts as an irritant of the tracheal mucosa that responds with increased mucus production.

3. The answer is D. IgA deficiency has been found in approximately 1 of 600 persons in a white population sample. The prevalence in other populations is not known; it may be very different.

4. The answer is B. In the resting intestinal tract and in bronchial secretions at baseline, i.e., in the absence of inflammation, IgA is the predominant immunoglobulin. With inflammation, however, the basement membrane and mucosa become permeable to plasma, and IgG overtakes IgA in concentration.

5. The answer is D. Alveolar macrophages are the initial phagocytic cells. With inflammation, polymorphonuclear granulocytes move into the alveolar space and also engage in phagocytosis.

6. The answer is B. IgE deficiency alone is not associated with impairment of pulmonary clearance. Tracheotomy interferes with mucociliary transport. Increased and decreased water content of respiratory secretion lowers the efficiency of the mucociliary transport. With too much water, the sol phase is increased and the transfer of mechanical energy of the beating cilia to the gel phase decreases. Secretions that are too dry have a diminished sol phase; the cilia are compressed and cannot beat at their full efficiency. In bronchiectasis there is usually overproduction of secretions and loss of ciliated cells, resulting in a net transport defect.

Burn Critical Care

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Rapidly assess the burned patient, determine unique risk factors, and appropriately involve the burn specialist when criteria are met.
- Intervene with management strategies, including proper resuscitation, airway management, and surgical evaluation.
- Recognize when special circumstances alter management such as chemical, electrical, or inhalation injuries.
- Monitor for complications to individual injuries and develop a comprehensive approach to nutrition and rehabilitation that allows for complete recovery.

BACKGROUND

Epidemiology

There are an estimated 1.2 million burn injuries per year in the United States, the vast majority involving a small body surface injury that can be treated on an outpatient basis. Each year, there are 4,500 fire-related deaths and 50,000 hospitalizations for burn injury. According to the National Burn Repository (2006 data),[1] 70% of patients who required hospitalization are men with a mean age of 30 years. Patients greater than 60 years old represent 14% of admissions. The majority of burns are accidental (90%), occurring in the home (42%), on the highway (20%), or at the workplace (17%). Five percent represent intentional injury from abuse or an intent to harm oneself. Overall, the mortality is 5%, generally related to advanced age, burn size (% body surface area, BSA), and the presence of an associated inhalational injury.

Risk factors for mortality from burns include advanced age, burn size, and inhalation injury.

A mortality estimation tool has been developed based upon these risk factors: an age of >60, a BSA >40%, and the presence of inhalation injury. Mortality was 0.3% with zero risk factors, and 3, 33, and 90% with 1, 2, or 3 risk factors present, respectively.[2]

Burn Centers in the United States

Patients with >10% BSA second-degree burns, third-degree burns, inhalation injury, chemical or electrical burns, or burns to special areas such as the face, hands, joints, or perineum warrant referral to a burn center.

The critically ill burn patient has unique problems that present specific challenges for the ICU team. Specialization over the past several decades has led to substantial improvements in the care of these patients, resulting in the development of highly specialized burn centers.[3] There are now approximately 130 burn centers in the United States, delivering specialized multidisciplinary care to patients with serious burns. These patients require both acute care and specialized long-term follow-up, not only to enhance initial survival but also to provide the greatest chance to return to an independent and productive lifestyle. From 1996 to 2006, 56% of burn center admissions were transferred from another acute care facility.[1] Because of the need for frequent acute care hospital to burn center transfer of patients, the American Burn Association has developed transfer guidelines. These guidelines suggest that second degree burns involving greater than 10% BSA, third-degree burns, inhalation injuries, chemical or electrical burns, and burns involving complex areas such as the face, hands, joints, and perineum should be cared for by burn specialists at specialized burn centers.[4]

Patients who meet transfer criteria should be sent to a burn center for definitive treatment. However, prior to transfer all burned patients require rapid assessment and stabilization.

BURN INJURY

The Skin as a Barrier

Our skin protects us from the environment, keeping out bacteria and contaminants and water and electrolytes in. It assists us in sensing our environment and regulates our temperature. The outermost, cornified layer of skin is the epidermis, and beneath this is the dermis, which contains hair follicles, nerves, and blood vessels. Importantly, the hair follicles are lined deeply with epithelium permitting the regrowth of epithelium over a partial thickness injury.

The severity of a burn is both time- and temperature-dependent.

Skin is thickest on the soles of the feet and palms of the hands and it thins as we age. It can tolerate temperatures up to 120°F but higher temperatures cause cell damage and death. This injury is both time- and temperature-dependent, e.g., 150°F water can cause a full thickness skin injury within 3 s.

Involvement of the volar surfaces of the arms and legs as well as the ears and perineum should always be considered a deep burn.

Depth of Injury

Loss of pain and pressure sensation is indicative of a full-thickness burn injury.

First-degree burns are limited to the epidermis and cause erythema and pain, similar to sunburn. Blisters do not form. Second-degree burns; also known as partial-thickness burns, involve epidermis and dermis and blisters form early. If the area is denuded, the underlying dermis will be red and moist due to enhanced blood flow to this layer. The dermis will also retain its elasticity. Nerve tissue remains viable with second-degree burns, so there is pain and intact proprioception. Third-degree burns, also known as full-thickness burns, involve all skin layers. The dermis will be charred and tough with a texture of leather. Sensation is absent, since the nerves are burned and the skin loses its elasticity. Pinprick sensation can be used to distinguish between a partial and full-thickness burn. Pain may be absent in a partial thickness burn but the sensation of pressure from the pin should remain.

Fourth-degree burns describe wounds down to muscle or bone, usually seen in patients who were trapped or unconscious at the time of injury.

Pathophysiology of Burn Injury

Heat may injure tissue directly by the coagulation of blood vessels, and indirectly through the activation of arachadonic acid and compliment cascades. This leads to the release of

secondary mediators causing vasoconstriction, increased permeability of capillaries, and marginization and migration of neutrophils into the interstitium, leading to tissue edema and further perfusion compromise to already threatened tissue.

An area of burn can be divided into three zones as if you are looking at a target (Fig. 40-1).[6] The inner zone of coagulation is the area of full-thickness burn with nonviable tissue where the vessels are coagulated and there is no blood flow.[6] The outermost area is the zone of hyperemia in which there is blood flow and viable tissue.[6] The important layer is the intermediate area, the zone of stasis, where the vessels are intact and dermal cells remain viable, but there is impaired blood flow resulting from burn shock.[6]

The intermediate zone or zone of stasis is threatened tissue that is at risk for progression to necrosis if proper resuscitation is not implemented.

Because of increased systemic vascular resistance, effective loss of plasma volume from extravasation, and the direct suppressing effects on cardiac myocytes, there is an initial decrease in cardiac output, and if not properly resuscitated, this puts the tissue in the zone of stasis at risk to convert to a full-thickness injury (see Fig. 40-1).

Jackson's burn zones and the effects of adequate and inadequate resuscitation. (Modified from Hettiaratchy and Dziewulski,[5] with permission from BJM Publishing Group, Ltd. Illustration by Alice Y. Chen).

CASE STUDY: PART 1

A 47-year-old woman involved in a motor vehicle accident, in which the airbag deployed, became trapped suffering severe burns prior to her rescue. She is rushed to a nearby emergency department. A 20-gauge intravenous line is started with fluids "wide open" in the ambulance. What critical treatment steps are essential for her early management in the emergency room?

At the initial point of contact, the burn patient must be immediately assessed and treatment should be started. Management should follow the ATLS Guidelines, with the burn injury being dealt with after the airway and circulation are established. Associated trauma should be ruled out. Critical management, specific to the burn injury, includes an accurate estimation of the size, distribution, and depth of the burn as well as an assessment of the likelihood of an associated inhalation injury. The decision to refer to a burn center should be made promptly, pain controlled and transfer initiated as soon as it may be done safely.

Burn Shock

Burn shock is both a hypovolemic and cellular shock state that results from both profound systemic capillary leak and fluid and salt sequestration within cells.

Burn shock may be thought of as a systemic manifestation of a local burn injury. Burn shock is both a hypovolemic and cellular shock.[4] Activation of histamine, bradykinin, prostaglandins, leukotrienes, complement, and fibrinolytic mechanisms contributes to capillary leak phenomena that persist through the first 6 h after injury and begins to resolve over the next 24 h. There is a rapid equilibration of fluids between the intravascular and extravascular compartments, resulting in hypoalbuminemia and loss of oncotic pressure, favoring edema formation in both burned and nonburned tissue and intravascular hypovolemia.[4]

Inhibition of sodium ATPase results in sequestration of sodium within cells exacerbating cellular edema formation further reducing extracellular volume and a decrease in the cellular transmembrane potential.[7] The resultant effect is a hypovolemic induced reduction of cardiac output, an elevation in systemic vascular resistance, and direct myocardial suppression. If resuscitation is inadequate, transmembrane potential progressively decreases leading to cell death.[7]

EVALUATION OF THE BURNED PATIENT

The initial management of the burn patient should include an assessment for associated traumatic injuries.

The arrival of a patient with a large burn to the emergency room can be dramatic. The appearance and odor of the wounds can easily become the focus of attention. Treating physicians and nurses must initially "ignore" the burn and treat any associated trauma according to the Advanced Trauma and Life Support (ATLS) Guidelines of the American Academy of Surgeons. Airway management, breathing, circulation, and environmental exposure must be initially addressed, followed by a complete history and physical examination.

Resuscitation then moves quickly to specific burn injury issues, such as, an estimation of burn depth and size, the presence of an associated inhalation injury, exposure to electricity or a chemical agent, involvement of the face, eyes, ears, hands, perineum or feet, evaluation for circumferential injury, and finally, a consideration of suspected abuse.

Burn Size Estimation

Estimation of burn size is critical, since it guides the volume of fluid resuscitation (see below) and provides an estimate for mortality. The most accurate tool is the (BSA) chart of Lund and Browder (see Fig. 40-2). A useful supplement for scattered distribution of burns is an estimation based on the patient's palm representing 0.5% of the total BSA.

STOPPING THE BURNING PROCESS

After associated trauma has been ruled out, it is essential to stop the burning process. In some cases, the patient's skin is still smoldering on with the products of combustion on clothing or imbedded in the skin. Once stabilized, the patient should be washed thoroughly

with mild soap. This removes soot, loose debris, and collapsed blisters. Appropriate pain control during the washing process is essential. Layered dressings are then used to cover the wounds but allow for mobility. Wounds should be cleaned and sterilely dressed daily. Silver sulfadiazene is a popular topical antibacterial agent, since it is generally effective against most gram-negative organisms that are found early in wound infections that are left untreated. Bacitracin, polymyxin B, and Neomycin may also be used. Broken bullae can be debrided or left intact. There may be an increase risk of cellulitis if blisters are left intact; however, they should never be aspirated. There is no role for prophylactic systemic antibiotics, but early excision of full-thickness necrosis is an important means of infection prevention.

CASE STUDY: PART 2

On physical examination, the blood pressure is 90/50 mmHg, heart rate is 118 beats/min, respiratory rate is 22 breath/min, pulse oximetry is 98%, and her weight is 60 kg. She is awake, anxious, and answering questions. Her voice is hoarse. Burns cover 60% BSA and are circumferential in both lower extremities and the torso but spare the perineum. Pain and pressure sensation are absent over the majority of the burns and the underlying dermis is inelastic. Head is atraumatic. Eyes are anicteric and tearful, pupils equal, throat is clear, and her face is uninvolved. Neck is non-tender and jugular veins are flat. The chest is clear and heart sounds are normal. The abdomen is soft, and there are minimal bowel sounds. The pelvis is stable. Rectal exam is normal. She is able to move all extremities. Is she a candidate for transfer to a burn center? How likely is she to survive her injury? How should she be resuscitated?

Her burn injuries examine as full-thickness or third-degree burns and with 60% involvement; thus, she meets more than one criterion for transfer. She may also have inhalation injury based on her hoarseness, which also indicates a need for transfer. Her predicted mortality is 33% based on burn size, age, and inhalation injury. Her estimated fluid resuscitation volume based on the Parkland formula would be 4 mL × 60 kg × 60(%) or 14.4 L. Due to the presence of an inhalation injury she should receive 25% more volume for a total of 18 L. Half should be administered over the first 8 h and the remainder over the next 16 h. Adjustments should be made to keep her urine output between 0.5 and 1.0 mL/kg/h.

RESUSCITATION OF BURN SHOCK

Resuscitation regimens have dramatically reduced burn-related mortality.[1] The resuscitative period of burn shock should be considered a brief critical time. Progression to a full-thickness injury in the zone of stasis and the development of multi-organ system failure may result from under-resuscitation. Furthermore, too-aggressive fluid resuscitation increases tissue edema and lung water, contributing to respiratory compromise. Resuscitation cannot achieve normal cardiac output in the first 24 h and adequate perfusion is generally achieved at a low central venous pressure. For these reasons estimates of the fluid resuscitation required in the first 24 h has been derived from the size of the burn in % BSA, using the Parkland formula.

(Parkland formula) Volume = 4mL x weight (kg) x % BSA burned.

Adjusting resuscitation volume to a goal of 0.5–1.0 mL/kg hourly urine output is essential regardless of the calculated estimates of fluid requirements.

One-half of the calculated volume is administered intravenously over the first 8 h (from the time of injury), with the rest given over the next 16 h. Variations of this formula exist with slight differences in necessary volume.

It is important to remember that any volume estimate is not as important as individualization of the need for fluid to a particular patient's response once the resuscitation has begun. It is recommended to maintain an approximate urine output of 0.5–1 mL/kg/h. Higher rates of urine output serves only to increase edema formation. More fluid may be required if there is an associated inhalation injury and in electrical burns.

Centers differ in the type of fluid used. Ringer's lactate is used most commonly, but certain centers use 0.9% normal saline, 3% hypertonic saline, and colloid infusions. The type of fluid used does not matter as much as the process of tailoring a regimen to an individual patient's early response. Because of the extracellular salt deficiency that exists in burn shock, a salt-containing solution is recommended.[4] Monitoring of renal function, serum sodium and osmolality is recommended when hypertonic saline is used at experienced centers, as this therapy has been associated with delayed renal failure and other complications.[4] Due to dilution and equilibration across leaky capillary membranes, resuscitation leads to a profound hypoalbuminemia, which accelerates edema formation. Colloid has been shown to reduce the amount of resuscitative fluid required making it an attractive strategy; however, early use simply contributes to protein and fluid accumulation in the interstitium. About 8 h after injury, the capillary leak begins to resolve, and many advocate the addition of colloid using either salt-poor albumin or fresh frozen plasma to restore oncotic pressure and reduce edema formation.[9]

Early (<8 h postburn) use of colloid promotes edema formation and should be avoided.

Albumin can be replenished at 0.1 mL of salt poor albumin per kilogram per % BSA injury.

Increased attention to the importance of volume resuscitation has led to the use of higher volumes thus risking over-resuscitation, a phenomenon termed "fluid creep." It is as important

to adjust infusion rates to keep urine output within a defined range and prevent over-resuscitation morbidity. Routine use of a pulmonary artery catheter is generally not recommended but it may have value in cases where there is concomitant cardiomyopathy or when the traditional resuscitative approach is failing.

INHALATION INJURY

Diagnosis

The presence of inhalation injury impacts both the burn patient's medical management and prognosis. Inhalation injury is present in 20–50% of admitted patients and accounts for up to 70% of deaths.[1] A keen level of suspicion is needed to diagnose inhalation burn injury since many patients will have normal pulmonary function for the first 24–72 h.[4]

Pulmonary function is usually normal for the first few days after an inhalation burn injury; therefore, a high index of suspicion must be maintained since its presence effects early management and mortality.

Inhalation injury should be suspected when the burn occurs in a closed space, results from an explosion, and when there is a loss of consciousness. Clues are often found on examination and include singed nasal or facial hair, carbonaceous material in the mouth or oropharynx, and facial burns. A blood carboxyhemoglobin level >10% is also suggestive of inhalation burn. The definitive diagnostic test is bronchoscopy; however, a history and physical examination suffice for the majority of patients.

Inhalation injury can be divided into injury above and below the glottis and by the presence of carbon monoxide (CO) poisoning. Injury above the glottis is associated with upper airway edema. The oropharynx is very efficient at removing heat from air. Air will be almost normal temperature when it enters the lungs. The oropharynx will be erythematous and soot may be present. Hoarseness may signal the presence of laryngeal edema and should prompt an immediate evaluation, since tissue edema commonly progresses during resuscitation and laryngeal obstruction can occur.

An injury below the glottis occurs when noxious particles in smoke are inhaled into the lungs. With this type of injury, there is mucosal edema, loss of ciliary function, bronchorrhea, vasoconstriction, and bronchospasm. Bronchial casts form, which are similar to an eschar on the skin. Cellular debris may cause catastrophic obstruction of the airways. More often there are occlusions of numerous bronchioles. Actual thermal damage to the lungs can occur in hot liquid aspiration, explosions where hot air is forced into the lungs, and from steam, which has a much higher heat carrying capability. This is a rare occurrence and usually presents with respiratory failure within the first few hours and it is a poor prognostic indicator.

The composition of smoke is complex. It is often 10–20% CO_2 and thus narcosis ensues rapidly, aided by paroxysm of coughing that occurs during smoke inhalation. CO blood levels may be elevated but generally an individual's level is not significant because of a relatively short exposure to smoke. Levels of 15% may cause neurological impairment; levels >60% may be fatal. High flow oxygen should be administered to the patient to shorten the half-life of CO (which is 250 min in room air and 40 min with 100% oxygen) until the CO level normalizes and acidosis improves. Hyperbaric oxygen (which lowers the half-life to 20 min) could be considered if there has been an unusually large exposure with neurological dysfunction; however, the risks of patient transfer must be weighed, and evidence supporting long-term benefit is lacking. In patients with CO poisoning, associated cyanide toxicity should be suspected. Cyanide is formed from the combustion of modern synthetics such as furniture foam during house fires. Treatment is rarely needed and the half-life is short; however, it is warranted if tissue poisoning persists, evidenced by ongoing acidosis in the presence of adequate resuscitation. Sodium thiosulphate followed by hydroxycobalamin is considered a safe and effective treatment.

Treatment

Management of inhalation injury includes adequate fluid resuscitation, maintenance of airway patency, mechanical ventilation when appropriate, pulmonary toilet, and bronchodilation. Fluid resuscitation following inhalation injury may require 25% more volume than patients without this complication owing to the accumulation of lung water.[4]

Patients with inhalation injury may require as much as 25% more volume than during resuscitation from burn shock.

CASE STUDY: PART 3

Her spine is stabilized; appropriate films are obtained showing no evidence of associated fracture or blunt trauma to the head, chest, and abdomen. Normal saline was increased to a rate of 1,100 mL/h and her hemodynamics have begun to stabilize. She is transferred to the region's qualified burn center within 90 min of presentation. What additional care should be administered over the next 24 h?

An airway inspection may be done if hoarseness worsens, stridor develops, or there is evidence of oropharyngeal edema in an attempt to diagnose inhalation injury and determine the need for elective intubation. Compartment pressures should be monitored in areas of circumferential injury and prophylactic escharotomies should be planned due to the likelihood of elevated compartment pressures developing as fluid resuscitation ensues. Careful monitoring of hourly urine output is necessary to monitor the response to fluid resuscitation and adjust intake as necessary to avoid under or over-resuscitation. All wounds should be cleansed, debrided, and sterilely dressed. Pain control should be provided and assessed frequently. At 24 h, if she is stable from resuscitation she should undergo operative excision of the burn eschar to prevent wound infection and limit the inflammatory cascade. General anesthesia should be administered.

Routine prophylactic intubation should be avoided; however, progressive hoarseness and edema of the upper airway should prompt a strong consideration for early intubation. The lung protective ventilation strategy should be employed as detailed in Chap. 16. The goal is to maintain patency of small airways while limiting further injury to alveoli. Some success has been achieved with oscillating ventilation but any mode of ventilation is appropriate as long as over-inflation is avoided. The compliance of the chest wall can be reduced when it is burned or edematous, contributing to respiratory failure and high ventilator pressures, which will ultimately require escharotomy. Airway hyper-responsiveness can develop and it should be treated with bronchodilators that may also improve fluid resorption by the lung. The evidence for use of nebulized heparin and mucolytics is limited but they are often employed to prevent the formation of airway casts. A sedation strategy that preserves some cough is preferable. Periodic bronchoscopy, with or without lung lavage, can aid in pulmonary toilet. Currently, there is no evidence for the use of either inhaled or systemic steroids or prophylactic antibiotics.

SPECIAL CIRCUMSTANCES

Thermal Injury

The vast majority of burns is thermal, through either fire or flame (44%), scald (36%), or contact with an object (8%), or the inhalation of a hot gas (0.2%).[1] Scald injuries tend to be superficial dermal injuries, most often resulting from a hot liquid spill or bath water.[5] Flame burns are deep dermal or full-thickness and are often associated with inhalation injury.[5] Contact burns, which also can be deep dermal or full-thickness, occur in two settings; touching an extremely hot object which most often occurs in the workplace or after prolonged exposure to an object at lower temperature in those who are often elderly, intoxicated, or have epilepsy.[5] Elderly patients should have causes of syncope ruled out.

Electrical Injury

Electrical burns (4% of burn admissions) are less common but have important acute management issues.[1] Electricity damages tissue by three mechanisms: direct cellular damage, thermal injury, and blunt trauma from associated falls.[10-13]Also, lightning may injure by blunt trauma (see below).

In general, damage produced by electricity is proportional to the current (amperes).[14] The current that can be generated is proportional to the electrical potential of the source or voltage (volts) and inversely proportional to the resistance of the involved tissue (ohms):

$$V = I \cdot \text{R}(\text{Ohm's Law})$$

$$I = V/R$$

(V = voltage, I = current, and R = resistance).

The resistance of skin is reduced 40-fold by the presence of moisture and further by submersion in water, thus maximizing the damage from an electrical source.[14,15] The resistances of tissues vary, influencing the pathway of current flow through the body. Resistance is high in bone, tendons, and fat but low in nerves and blood vessels and intermediate through skin.[15]

Thermal energy (joules) generated by electrical current is proportional to the current, voltage, and the time of contact:

$$\text{Thermal energy } (E) = I \cdot V \cdot T.$$

Or by substituting Ohm's Law ($V = I\,R$),

$$E = I^2 \cdot R \cdot T$$

(T = exposure time)

The damage produced is also influenced by the type of current (direct [DC] or alternating [AC]), duration of contact, and the pathway the current takes.[16] High tension and domestic current are AC sources whereas lightning is DC. AC is three times more damaging at the same voltage as DC and accounts for the majority of injuries.[15]

AC tends to lead to gripping the source by the victim prolonging exposure, whereas DC throws the victim from the source perhaps leading to a fall.

DC tends to produce a single powerful contraction of skeletal muscles throwing the victim away from the source whereas AC leads to repetitive stimulation and because the flexor muscles tend to be stronger than the extensors the hands tend to grip the source, thus prolonging exposure.[17]

Among the paths that current may take, the vertical pathway is most lethal because it may involve the brain, heart, spinal cord, and respiratory muscles. However, a horizontal pathway entering one hand and leaving the other may also involve the heart and spinal cord. Typically lower body injuries, below the symphysis pubis, are not deadly but may cause extensive local injury.[17]

Electrical injury by domestic, low voltage current typically causes small deep contact wounds at the entry and exit portals of the current.[5] A high-voltage injury involves voltages of 1,000 V or more and may have associated trauma from a fall, fracture from muscle contracture, rhabdomyolysis, cardiac rhythm disturbances, or a compartment syndrome of an involved extremity.[5] A high-tension injury to an extremity is common because of the increased current density to a smaller cross-sectional area. Arc injury can occur as in high-tension injury when the electricity crosses a distance prior to contact generating heat up to 5,000°F and causing severe thermal injuries.[18]

Lightning generates >10,000,000 V but current travels for milliseconds limiting exposure. The pathognomonic picture is a punctate necrotic depression burn of full thickness with surrounding congestion and a feathering erythema known as Licthenberg figures. Lightning may injure by a variety of mechanisms, the most common of which is the flashover phenomenon in which the current travels over the surface of the body.[19] This scenario seldom causes more than superficial burns unless clothing is ignited. In a direct strike, the majority of the current passes through the victim when they are well-grounded. Side flash results when lightning strikes a nearby object and sends a secondary discharge to a person who is standing nearby. Stride potential occurs when lightning strikes the ground passing up one leg and down the other. Lightning may also injure by blunt force.[20] Expanding gas surrounding the advancing bolt of lightning creates a 20-atmosphere shock wave, which damages any organ in its path. This results from high temperatures (up to 30,000 K, a temperature five times hotter than the surface of the sun) within the column.[20]

There are many organ-specific electrical injuries.[17,18] Cardiac asystole may accompany lightning injuries and lower voltages produce ventricular fibrillation. Myocardial damage is less common. The brain and spinal cord may be involved, leading to seizure, respiratory depression, coma, and paralysis.

Electrical injury damages all organs within its path.

Injury to the autonomic nervous system may produce fixed and dilated pupils, hypertension, and cool pulseless extremities for the first few hours. Abdominal organ damage is rare but may occur. More common is adynamic ileus and Curling's ulcers that occur at a higher incidence than with other types of burns. Muscle and bone may undergo deep necrosis, leading to rhabdomyolysis and requiring eventual surgical debridement. Tympanic membrane rupture is common and cataracts may develop as either an early or late complication.

There are numerous management principles specific to electrical burn care. There should be an initial careful evaluation for occult injury, as the size of a surface burn may be misleading in relation to the amount of deep muscle necrosis or thoraco-abdominal injury.[18] Burn size estimation as a guide to resuscitation can lead to lethal error. Fluid resuscitation should be augmented by a factor of 1.7, except in lightning injury, which does not require resuscitation.[21] There should be serial evaluation for rhabdomyolysis as well as monitoring of liver, pancreatic, and renal function.[16] The presence of persistent ileus should prompt imaging, diagnostic peritoneal lavage, or exploratory laparoscopy with a second look after 2–5 days to look for other injuries, since this is a common scenario.[22,23] Imaging of the head and spine is indicated in cases where there may have been a fall or a neurological abnormality persists.[22] Spinal precautions should be instituted as fracture may have occurred in the presence of muscular tetany. Monitoring of compartment pressures of involved limbs is warranted, as well as otoscopic and ophthalmologic exams.[18] Patients admitted with a history of loss of consciousness or an EKG abnormality warrants 24 h telemetry monitoring. Lastly, stress ulcer prophylaxis is indicated to prevent a Curling's ulcer.[18]

Chemical Injury

Chemical burns, though infrequent (3%), may have devastating systemic effects and they account for 30% of burn deaths.[1,24] Exposure leads to a coagulative necrosis resulting in deep wounds with increased systemic absorption and significant systemic toxicity when only 1–2% of the BSA are involved.[25] General principles of management include the removal of clothing and loose particles, followed by copious irrigation with cool water for 1–2 h.[25] Exceptions include elemental sodium, potassium or lithium, which ignite when contacting water, and organic phenol, as dilute phenol absorbs more readily.[25] Alkali penetrate deeper and require longer irrigation for up to 8–24 h in severe cases.[26,27]

Dilution is preferred to antidote because the latter will cause delay and may lead to an exothermic reaction worsening the extent of injury.

Dilution is preferable to antidote because the latter is rarely readily available. Delay in irrigation has been demonstrated to extend burn depth and furthermore the antidote may undergo an exothermic reaction causing additional injury.[28,29]

Certain exposures (chromic acid >2% BSA) are managed with surgical excision to prevent further absorption.[7] Other compounds have unique systemic phenomena. Formic acid interferes with body metabolism, increasing lactic acid production resulting in profound acidosis, which may require dialysis. Chromic acid binds to hemoglobin, reducing its oxygen-carrying capacity, and it may be necessary to perform dialysis or even exchange transfusion.[28] Hydrofluoric acid absorption induces hypocalcemia, hypomagnesemia, and hyponatremia that may result in seizures, hypotension, and ventricular fibrillation.[25] Calcium gluconate by topical gel or by subcutaneous injection and repletion of electrolytes with close monitoring is required.[25]

Caustic ingestion, usually related to a suicide attempt in an adult or an accidental event in a child, can lead to serious local and systemic injury. The esophagus must be inspected endoscopically to rule out perforation. Superficial esophageal burn will involve the mucosa with edema and erythema. Partial injury is transmural with tissue sloughing. Full-thickness wounds will erode through the esophagus and into the peri-esophageal tissue. The airway must be secured due to edema from the initial injury and to protect the patient from aspiration of stomach contents. Endoscopy can be carefully done past the initial burn, or a gastrografin swallow could be performed. Superficial injury can be observed for 24–48 h. Late stricture formation is rare. Partial-thickness injuries should be kept NPO and reevaluated in 2–3 days to rule out perforation and the diet can then be advanced. Follow-up contrast studies should be performed in 6–8 weeks and dilation may be needed if esophageal strictures develop. Perforation requires operation and diversion, with delayed esophageal replacement.

CASE STUDY: PART 4

On the third hospital day she is tachypnic, with an increased oxygen requirement. She is afebrile, has stable hemodynamics, and her oxygen saturation is 93% on 100% non-rebreather facemask. Intubation is necessary for an elevated work of breathing and hypoxemic respiratory failure. Bilateral infiltrates are apparent on chest X-ray. Why did she develop respiratory failure? How should she be ventilated?

The patient has developed the adult respiratory distress syndrome (ARDS) as a result of systemic inflammation and inhalation injury. It is typical, as in this case, for pulmonary function to remain normal for the first 24–72 h. The ventilator should be managed in keeping with a low tidal volume (6–10 mL/kg=360–600 mL), high positive-end-expiratory pressure, as detailed in Chap. 16. Sedation should be maintained at a level that preserves some cough.

SURGICAL MANAGEMENT

Escharotomy

The 5 Ps (pallor, pain, paresthesia, pulselessness, and paralysis) are inaccurate in burn patients, compartmental pressures should be monitored in any circumferential injury.

Following full-thickness, circumferential injury to an extremity compartment pressures become elevated over the first 24 h causing ischemia to muscles and nerves resulting in increased disability. Compartment syndrome of the chest and abdomen may lead to respiratory and/or hemodynamic compromise. Compartment syndrome may manifest as the five Ps (pallor, pain, paresthesia, pulselessness, and paralysis); however, these signs are extremely unreliable in the burn patient.

Monitoring of compartmental pressures has become standard in severely burned patients with a pressure of 40 mmHg indicating the need for escharotomy. Escharotomy should be performed by experienced personnel and may be done prophylactically in obvious circumferential full-thickness injuries, as long-term morbidity as a result of the procedure is minimal. Doppler pulses and compartmental pressures should continue following the procedure to ensure adequate pressure release.

Early Wound Excision and Grafting

Early excision of eschar reduces the SIRS cascade and decreases the incidence of invasive wound infection.

The importance of early removal of the eschar and temporary or permanent wound closure is to reduce the stimulus for the systemic inflammatory response (SIRS) and prevent burn wound sepsis.[30] The burn is initially sterile but provides a protein-rich environment for bacterial growth. In the setting of host immune suppression that occurs after burn injury the risk for bacterial invasion is high.[30]

Bacteria in the eschar become invasive around the sixth or seventh postburn day, the histological hallmark of invasive infection. Starting on the first postburn day, after adequate stabilization, the patient should be taken to the operating room for removal of obvious third-degree eschar. The excised eschar may be cultured to identify which bacteria are present since if the patient becomes septic early appropriate antibiotic therapy can be initiated. The excised burn is covered with the patient's own skin (autograft), if possible. If there is not sufficient skin for coverage, there are other options, including using a xenograft (porcine), a cadaver allograft, or a biosynthetic dermal template such as *Integra*.

EARLY NUTRITIONAL SUPPORT AND SPECIAL ISSUES

Early (within 24 h), oral, high-protein nutrition is optimal to promote wound healing, prevent infection, and improve survival.

Nutrition should be initiated within the first 24 h. The oral or enteral route is preferable unless there is a contraindication. Due to hypermetabolism and protein catabolism, up to two times the basal nutritional rate may be needed.

Estimation of caloric needs using the modified Harris-Benedict and Curreri formulas (see below) followed by examination of wound healing, indirect calorimetry, and measures of nitrogen balance are required to ensure adequate nutrition. With proper nutritional support

consisting of a calorie:nitrogen ratio of <1:110, wound healing is aided, infection is reduced, and survival is improved.[4]

Curreri Formula = 25kcal x weight (kg) x % BSA[4].

Due to loss of excised skin and altered perfusion, burn patients have difficulty regulating body temperature. Therefore, they generally need to be in a warm environment. Additionally, care must be taken in the operating room to avoid hypothermia that can quickly develop.

Aggressive occupational and physical therapy is started at the time of admission. Burned fingers should not be splinted and the patient is encouraged to use his hands. Patients should be out of bed as early as tolerated. Most patients should be able to return to their pre-injury level of function

SUMMARY

The critically ill burn patient has suffered a major insult to an important body system that not only has deleterious systemic effects, but also eminently threatens survival. The identification of associated trauma and risk factors on presentation, assessment of injury, and appropriate interventions are critical. Proper resuscitative efforts, careful management of the airway, and surgical excision of full-thickness eschar are essential in avoiding disastrous complications. Special circumstances such as chemical, electrical, and inhalational injuries require tailored management. With appropriate diligence, the advances in burn care that have occurred over the recent decades provide guidance to the ICU team and hope to those who have suffered the most devastating of injuries.

REVIEW QUESTIONS

Select the best answer for each of the questions below. There may be more than one correct answer.

1. **A 29-year-old man is the victim of a 40% BSA flame burn which resulted from an ignited gas leak. Facial burns are evident. Which of the following factors are relevant in planning the appropriate resuscitation for this patient?**
   - **A.** Flame burn origin
   - **B.** 40% BSA involvement
   - **C.** Likely inhalation injury
   - **D.** Urine output during resuscitation
   - **E.** A and B
   - **F.** B, C, and D

2. **All of the following are risk factors indicative of a possible inhalation injury, *except?***
   - **A.** Facial burn
   - **B.** Trapped or unconscious
   - **C.** Singed nasal hair
   - **D.** CO level 14%
   - **E.** Carbonaceous secretions
   - **F.** Hoarseness
   - **G.** Lichtenberg figures

3. **An electrician contacts a main power line during an installation suffering a third-degree electrical burn to his right palm. Which of the following statements regarding this patient is *incorrect?***
   - **A.** The severity is in part due to the type of current
   - **B.** The hand should be immobilized
   - **C.** The extremity is at risk for compartment syndrome
   - **D.** The nature of the injury warrants referral to a burn center
   - **E.** Associated organ involvement depends upon the path that the current traveled through his body

4. **A factory worker involved in a chemical spill suffers 65% BSA burns from an unlabeled chemical source. Which of the following statements is true regarding the chemical burns in this patient?**
   - **A.** The type of chemical is irrelevant; all patients should be treated with copious irrigation with water
   - **B.** The identity of the chemical should be determined so the appropriate antidote may be sought
   - **C.** Serum electrolytes should be monitored while the identity of the chemical is sought
   - **D.** Most chemicals may safely be diluted, including phenol and elemental sodium
   - **E.** Alkalis are typically innocuous substances
   - **F.** Endoscopy is warranted to rule out caustic ingestion

5. **A 50-year-old woman is severely injured in a house fire with 50% BSA full-thickness burns; she is unconscious and intubated. She undergoes resuscitation and airway inspection, which reveals carbonaceous debris and edematous tracheal mucosa. What is her predicted mortality and what is the best care plan to prevent wound infection?**
   - **A.** 90% mortality and a combination of topical and intravenous antibiotics
   - **B.** 33% mortality and a combination of topical and intravenous antibiotics
   - **C.** 90% mortality and surgical excision with closure if possible
   - **D.** 33% mortality and surgical excision with closure if possible
   - **E.** 100% mortality and begin discussion with the family regarding hospice, intervention for infection not relevant

ANSWERS

1. F. Elements of the history and physical examination are crucial in determining the appropriate resuscitation plan, which is largely credited with the dramatic reduction in burn mortality rates over recent decades. Care plan determinants include burn size and body weight in kilograms (see the Parkland equation). A 25% increase fluid resuscitation is made for inhalation injury. There is no correction for flame injury although they are more likely to be associated with inhalation. Monitoring urine output response is important in ensuring adequate but not over-resuscitation.
2. G. Lichtenberg figures, which are violaceous feathery patterns on the skin, are apparent after lightning injury. Evidence of burns to the face or facial hair, burnt debris in the sputum or mouth is high risk for inhalation injury. Hoarseness and certainly pharyngeal edema would be worrisome and require inspection and close monitoring for airway compromise. A history of being trapped or unconscious increases the exposure and thus makes noxious gas exposure higher. A CO level >10% is suggestive of inhalation; a level of 3–5% seen in active smokers.
3. B. Movement of the hand should be encouraged and analgesia provided as necessary to facilitate movement. This will help to preserve function. The current in domestic sources is alternating current (AC) which causes repetitive contraction and gripping of the source which prolongs exposure and therefore increases injury. Burns at the contact point and grounding point may indicate the path of the current and thus the organs (heart, brain, spinal cord) most at risk for damage and in need of monitoring. The vertical path is the most damaging. The involvement of the hand and the depth of the injury are both criteria for referral to a burn center. All third-degree burns should be referred. Characteristic of electrical injury is deep-tissue injury that belies the surface burn. In addition, the arm has a small cross-sectional area and suffers more concentrated damage from passing current. For both of these reasons compartment syndrome should be anticipated in this case.
4. C. While it is true that most chemicals can safely be diluted, the safest approach would be to obtain the identity of the substance quickly if able to ensure that dilution will not cause further harm. While doing so, obtaining electrolytes to assess for systemic consequences of absorption and removing as much of the chemical as possible with appropriate protection would be the safest approach and best of the choices available. The chemical is indeed relevant as, with dilution, phenol absorbs more readily and elemental sodium has and exothermic reaction with water that would worsen the burn (A and D incorrect). Delay for the purpose of retrieving antidote is discouraged as the burn worsens in this time, and antidote can react releasing thermal energy as well (B incorrect). Alkalis are in fact more damaging and involve tissues more deeply requiring prolonged irrigation for 24 h (E incorrect). There is no indication that the chemical was ingested and therefore the need for endoscopy can be eliminated based on the history of a spill rather than a suicide attempt (D incorrect).
5. D. Mortality estimation is based upon 2 of 3 risk factors (age >60, >40% BSA, inhalation present) present in this patient that predicts a 33% mortality (A and C incorrect). Surgical excision reduces invasive wound infections and reduces the inflammatory stimulus. There is no role for discussions of hospice in a patient who is likely to survive (E incorrect). While topical antibiotics are utilized commonly, there is no role for prophylactic parenteral antibiotics for the prevention of burn wound infection (A and B incorrect).

CHAPTER 41

MATTHEW R. LAMMI, JNANESH THACKER, AND NAMRATA PATEL

ICU Care of the Solid Organ Transplant Recipient

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Identify and approach the management of perioperative complications after solid organ transplantation.
- Recognize the role of immunosuppressive therapy in allograft preservation as well as patient toxicity.
- Discuss the evaluation and management of posttransplant organ rejection.
- Recognize the broad spectrum of infections that occur in this immunocompromised patient population.
- Describe the prophylaxis and treatment of infections after solid organ transplantation.

INTRODUCTION

Organ transplant recipients, either perioperatively or long-term, may require intensive care for a wide range of issues that are either specific to the need for immunosuppressants, side effects from the immunosuppressive drugs, or the underlying disorder that prompted the need for transplantation. Given the complexity imposed by the patients' surgery, medications, immunosupression, and medical morbidities, ICU management of these patients can be quite challenging. Fortunately, most patients have had an extensive multidisciplinary evaluation prior to transplantation as well as close postoperative follow-up; thus, a detailed medical history exists and is invaluable in regard to patient management.

Extensive patient evaluation and multidisciplinary expertise are crucial in managing the ICU care of an organ transplant recipient.

CASE STUDY: PART 1

TP is a 62-year-old-man with a history of prior smoking, hypertension, and idiopathic pulmonary fibrosis (IPF) who presents for transplant evaluation. He was diagnosed with pulmonary fibrosis 1 year ago by a high resolution CT scan followed by a video-assisted thoracoscopic lung biopsy of the left lung. He is short of breath walking less than one block or one flight of stairs. His testing shows a vital capacity of 55% predicted, which has decreased from 67% predicted 6 months prior. TP undergoes an extensive medical and psychosocial evaluation. He desaturates to 85% on a 6-min walk test. He is not found to have any significant additional medical problems and demonstrates adequate compliance and social support. Given the high risk of mortality in IPF compared to that predicted after transplantation, particularly in patients who have significant restrictive lung disease, poor gas exchange, and disease progression, TP is listed for lung transplantation.

Also, due to the degree of complexity and nuance in the field of transplantation, it is helpful to communicate with those who have special expertise in treating these patients including the transplant medical physician and surgeon, as well as the pharmacist. Herein, we review topics pertinent to the ICU care of the organ transplant recipient by focusing on issues wherein management differs from the general ICU patient population. We limit our discussion to the most commonly transplanted organs, kidney, liver, heart, and lung.

HISTORICAL PERSPECTIVES IN TRANSPLANTATION

The first human kidney was successfully transplanted from one identical twin to another in 1954.[1] Pancreas, liver, and heart transplants were performed in the 1960s.[2] However, graft and patient survival were limited primarily by allograft rejection and toxicities of the immunosuppressive medications available at that time. These included total body irradiation, corticosteroids, azathioprine, and antilymphocyte antibodies. It was not until the 1980s, with the advent of the calcineurin inhibitor, cyclosporine, that solid organ transplantation was revolutionized and long-term survival after transplantation became possible.[2] Despite its recent beginnings, the field of transplantation has had tremendous growth; in the United States, 27,958 solid organ transplants were performed in 2008 alone.[3]

CANDIDATE SELECTION

Organ transplant candidates should be chosen only after careful evaluation and comparison of predicted patient morbidity, mortality, and quality-of-life with and without transplantation.

Given the scarcity of donor organs and the morbidity, mortality, and costs related to organ transplantation, it is imperative to choose transplant candidates whose risk-benefit ratio favors a successful transplantation. Recommendations that help guide the selection of appropriate candidates are outlined in Table 41-1.[3-10] A thorough assessment of the factors that may increase morbidity and mortality from the underlying disease prompting organ failure, and a consideration of parameters that help predict posttransplant outcomes, are reviewed by a multidisciplinary team prior to patient listing.[4]

Because an increasing number of patients require transplantation, and donor organs are in short supply, the United Network for Organ Sharing (UNOS) utilizes organ-specific, organ allocation schemes to triage organs to the sickest patients in an attempt to minimize death while awaiting transplantation.[3]

Essential to all organ transplantation is the ability to: match ABO blood groups, choose functional donor organs, and limit the potential transmission of clinically important infections and malignancies, by using readily available laboratory testing in a constrained time period.

DONOR SELECTION AND MATCHING

Essential to all organ transplantation is the need to match ABO blood groups, choose functional donor organs, and limit the potential transmission of clinically important infections and malignancies; all of this must take place in a constrained time period.[3,4]

TABLE 41-1

INDICATIONS FOR SOLID ORGAN TRANSPLANTATION

	KIDNEY	LIVER	HEART	LUNG
Common etiologies of organ failure	Diabetes mellitus Hypertension Glomerular diseases Polycystic kidney disease Tubulo-interstitial diseases	Hepatitis B cirrhosis Hepatitis C cirrhosis Alcoholic cirrhosis Autoimmune hepatitis Hepatocellular carcinoma and other focal hepatic tumors Metabolic and genetic disorders Vascular disorders Fulminant liver failure from acetaminophen or other toxic agent or acute infectious hepatitis	Systolic heart failure from ischemic cardiomyopathy, dilated cardiomyopathy, valvular heart disease, or hypertension Ischemic heart disease Intractable arrhythmias Hypertrophic cardiomyopathy	Chronic obstructive pulmonary disease (COPD) Pulmonary fibrosis Pulmonary hypertension Cystic fibrosis Sarcoidosis
Therapeutic options prior to transplantation	Maximal medical therapy Dialysis	Maximal medical therapy Paracentesis Transjugular intrahepatic portosystemic shunt	Maximal medical therapy Myocardial revascularization Pacing cardioverter defibrillator Valve repair or replacement Myomectomy	Maximal medical therapy Noninvasive ventilation Lung volume reduction surgery
Disease severity criteria	GFR <20 mL/min	Child-Pugh score ≥7 (based on degree of ascites, bilirubinemia, hypoalbuminemia, coagulopathy, and encephalopathy) MELD score of >10 (based on serum bilirubin, serum creatinine, and international normalized ratio for prothrombin) with a defined complication of end-stage liver disease	NYHA class 3 and 4 VO_2 max <14 mL/kg, especially <10 mL/kg Refractory arrhythmias	COPD: BODE index of 7–10, hospitalization with hypercapnia ($PaCO_2$ >50 mmHg), PAH, or FEV_1 of less than 20% predicted and either DL_{CO} of less than 20% predicted or homogenous distribution of emphysema IPF with DL_{CO} <39% predicted, >10% decrement in FVC in 6 months, SpO_2 <88% during a 6-MWT, honeycombing on HRCT (fibrosis score of >2) Pulmonary hypertension: NYHA class III or IV, 6-MWT <350 m, CI <2 L/min/m², RAP >15 mmHg Cystic fibrosis: hypoxemia, hypercapnea, or PAH Sarcoidosis: NYHA class III or IV, hypoxemia at rest, PAH, RAP >15 mmHg

Indications for solid organ transplant: *GFR* glomerular filtration rate; *MELD* model of end-stage liver disease; *NYHA* New York Heart Association; *VO_2* oxygen consumption; *BODE* multidimensional score based on body-mass index, forced expiratory volume in 1 s, dyspnea measured by the Medical Research Council Score, and 6-min walk distance; *PAH* pulmonary hypertension; *FEV_1* forced expiratory volume in 1 s, *DL_{CO}* diffusing capacity of the lung for carbon monoxide; *IPF* idiopathic pulmonary fibrosis; *6MWT* distance walked in 6 min; *RAP* right atrial pressure

CASE STUDY: PART 2

Four months after listing, an ABO compatible lung donor becomes available for TP. The donor is a 35-year-old-man who suffered severe head injury from a motor vehicle accident. The chest X-ray is reported to show a right lower lobe infiltrate. The PaO_2 on mechanical ventilation on FiO_2 of 100% is 400 mmHg. TP is called in for lung transplantation. The procurement surgeon finds purulent secretions in the right lower lung and minimal clear secretions on the left, and harvests and transports the left lung. The left lung is then implanted into TP via a left thoracotomy. The organ ischemic time was 5 h.

The parameters used to match appropriate transplant organs can vary by organ type. For example, human leukocyte antigen (HLA) matching is predictive of allograft and patient survival in renal transplantation, and size-matching, to ensure appropriate allograft fit into the thoracic cavity, is important in lung transplantation.[11,12] A variety of organ donor information should be utilized to determine the appropriateness of transplantation including age, gender, race, ABO blood type, HLA profile, weight, height, details of the cause of death, clinical course of the donor, and serological testing for hepatitis B and C and HIV.[3,4] Organ-specific evaluation includes laboratory testing of renal and hepatic function, abdominal ultrasonography for kidney and liver transplantation, cardiac enzymes, electrocardiogram, echocardiogram, and hemodynamic parameters for heart transplantation, and chest X-ray, oxygenation parameters, and bronchoscopic evaluation for lung transplantation. Living donor transplantation is routinely performed in kidney transplantation (e.g., roughly 40% of all renal transplants) and may result in improved graft and patient outcomes.[13]

Living donor kidney transplants may result in improved graft and patient outcomes.

Lobar liver and lobar lung living donor transplants are rarely performed given the high risk to the donor as well as suboptimal recipient outcomes.[14]

OVERVIEW OF THE ORGAN TRANSPLANT PROCEDURE

Once a determination has been made to harvest organs from the prospective organ donor, the donor is fully heparinized, the organs are cooled in an ice slurry and infused with preservative solution. The organs are then dissected and removed from the donor's body and transported to the recipient, in whom preparations have already commenced to prepare them for organ implantation. The entire procedure requires precise coordination efforts between the organ procurement organization and the multiple transplant teams who will simultaneously harvest different organs to be implanted into patients at several different institutions.

The entire procedure requires precise coordination efforts between the organ procurement organization and the multiple transplant teams who will simultaneously harvest different organs to be implanted into patients at several different institutions.

All of these activities must be done in a manner that maximizes organ viability prior to harvest, the recipient's safety, and minimizes the time when the organ is without perfusion (cold-ischemic time) in order to improve postimplantation organ function.[3]

For kidney implantation, an incision is made above the inguinal ligament; the donor kidney is placed in the iliac fossa.[15] The donor renal artery and vein are anastomosed to the sides of the external iliac artery and vein, respectively, and the donor ureter is then implanted into the recipient bladder.

For liver transplantation, bilateral subcostal incisions are made and the recipient's native liver is first mobilized by dissecting its ligaments.[15] Next, the hepatic artery, portal vein, bile and cystic ducts, and supra- and infrahepatic inferior vena cava (IVC) are dissected. The native liver is then detached from the retroperitonium and removed. The suprahepatic IVC and infrahepatic IVC of the donor is anastomosed, end-to-end with the recipient suprahepatic and infrahepatic IVC, respectively. The portal veins are then anastomosed end-to-end and the liver is perfused first with portal blood. This is followed by arterial revascularization, biliary reconstruction, and surgical closure.[15] Intraoperative management and immediate post surgical ICU care are often complicated by coagulopathy and the need for multiple blood products, portopulmonary hypertension, intrapulmonary shunting from hepatopulmonary syndrome, and the hemodynamic effects of cirrhosis, which includes vasodilatation.[6]

CASE STUDY: PART 3

After transplantation, TP arrives to the ICU intubated, ventilated with a FiO_2 of 40% and hemodynamically stable. A bronchoscopy reveals an intact anastomosis with only minimal blood in the airway. His initial PaO_2 is 120 mmHg but declines over the next few hours to 55 mmHg on the same ventilator settings. The chest X-ray shows diffuse alveolar infiltrates in the right allograft and the left shows reticular markings which are unchanged.

Heart transplantation is usually performed via a median sternotomy. The heart is excised, leaving behind the posterior wall of the left atrium. The donor and recipient left atria, aortas, pulmonary arteries, and right atria are anastamosed sequentially in the biatrial technique (or superior and IVCs in the bicaval technique).[16]

Single lung transplant is generally performed via a posteriolateral thoracotomy, and bilateral lung transplantation via a transsternal bilateral anterior thoracotomy (clamshell incision) or occasionally bilateral antero-axillary thoracotomies or sternotomy. Cardiopulmonary bypass may be instituted for significant oxygenation or hemodynamic failure. After the pneumonectomy is performed, the procured donor lung is implanted by joining the bronchus, the pulmonary artery, and the pulmonary veins (with a small left atrial cuff) of the donor to that of the recipient.[17]

IMMEDIATE POSTTRANSPLANT COMPLICATIONS

Renal Transplantation

Following kidney transplantation, patients may not require ICU care; reasons for ICU admission include postoperative respiratory failure requiring mechanical ventilation, cardiac disease, the need for hemodynamic monitoring, or the need for renal replacement therapy. ICU mortality postrenal transplantation is generally low; 3.7% in one study.[18] Persistent renal failure posttransplantation is generally defined as oliguria or the requirement for dialysis in the first week posttransplantation. Renal failure postrenal transplantation occurs in 20–30% of cases.[18,19]

The major causes of renal failure posttransplantation include postischemic ATN, hyperacute rejection, urinary tract obstruction (most commonly by urethral strictures or compressing fluid collections), atheroembolic events, thrombosis of the renal artery or vein, and prerenal azotemia.[18,20,21] Of these, postischemic ATN is the most common cause and the treatment is generally supportive once other diagnoses are excluded.[20] Hyperacute and antibody-mediated rejection can be diagnosed by renal biopsy. Thrombosis most commonly occurs associated with rejection; thrombosis as a primary event is rare but often leads to graft loss. Causes of thrombosis include: technical issues, hypercoagulability (as seen in patients with nephrotic syndrome) and decreased vascular perfusion.[21]

The major causes of renal failure posttransplantation include post ischemic acute tubular necrosis (ATN), hyperacute rejection, urinary tract obstruction, atheroembolic events, thrombosis of the renal artery or vein, and prerenal azotemia.

Doppler ultrasonography is utilized to look for thrombosis of the renal artery or vein and urinary obstruction.[21]

Evaluation for renal dysfunction can include Doppler ultrasonography and renal biopsy.

A renal biopsy can be performed to obtain a specific diagnosis. Treatment is variable depending on the cause of the renal failure and may include supportive care in the case of ATN, increased immunomodulation for acute rejection, and lymphoceal drainage or surgical reexploration for urinary obstruction.[19-21] Depleting and nondepleting T-cell antibodies have been used in the immediate posttransplantation period in patients with renal failure to avoid additional calcineurin inhibitor-related nephrotoxicity, while maintaining adequate immunosuppression.

Liver Transplantation

Lack of hepatic function after transplantation is most often due to PGD, acute rejection, and hepatic artery stenosis.

After liver transplantation, liver functions studies can remain markedly abnormal for 48–72 h postoperatively.[22] Allograft function can be monitored clinically by bilious output from the

T-tube (if placed) and systemic indicators, such as an improvement in central hemodynamics, urine output, and neurologic function. Liver biochemical tests should also improve over time. A lack of such recovery can be secondary to primary graft dysfunction (PGD), acute rejection, and hepatic artery stenosis.[7,22]

Biliary complications occur at a rate of 15–30% and include strictures and bile leaks.

Primary nonfunction can occur in up to 10% of liver transplantations; risk factors include donor steatosis, the extremes of age, prolonged hospital time, and cold-ischemic times >18 h.[7] Therapy is generally supportive, but if recovery does not occur, retransplantation may be necessary. Acute cellular rejection can be diagnosed by liver biopsy, which will reveal mononuclear cell inflammation of the portal vessels, bile ducts, and central vein endothelium. Hepatic artery stenosis defined as >50% angiographic reduction in lumen size is found in 4–5% of cases. It can present acutely with fulminant hepatic failure or with manifestations such as biliary tract complications (resulting from ischemia), abscess formation, or bacteremia.[7,22] However, it may also present asymptomatically. If diagnosed early, the hepatic artery can be repaired and the organ salvaged, but retransplantation may be necessary. Biliary complications occur at a rate of 15–30% and include strictures and bile leaks.[7,22]

Diagnostic evaluation should include hepatic sonography, which can reveal complications such as hepatic artery stenosis, portocaval stenosis, and biliary complications. Liver biopsy is diagnostic of acute cellular rejection and Cytomegalovirus (CMV) hepatitis. Cholangiography, with MRI, or via ERCP or the T-tube, can also be useful for the diagnosis and treatment of biliary complications.[7,22]

Neurological complications after liver transplantation include encephalopathy, convulsions, immunosuppression-related neurotoxicity, cerebrovascular events, and central pontine myelinolysis.

Neurological complications after liver transplantation include encephalopathy (11.85%), convulsions (8.2%), immunosuppression-related neurotoxicity (5.6%), cerebrovascular events, and central pontine myelinolysis, which can occur as a result of a too rapid correction of hyponatremia.[23]

Renal complications are common and may result from fluid shifts, hypoproteinemia, hepatorenal syndrome, and calcineurin inhibitor therapy.[23] In one review, 8.3% of liver transplant recipients required dialysis; the mortality rate for these patients was 40%.[23] Pulmonary complications are also common and include pleural effusions, atelectasis, persistence of hepatopulmonary syndrome-related hypoxemia, and pulmonary hypertension, either from prestanding portopulmonary hypertension, or from pulmonary emboli.[7,23] However, patients can often be safely extubated within hours post-liver transplantation.[6] A reperfusion syndrome characterized by hypotension, bradycardia, pulmonary hypertension, and hyperkalemia may also occur, presumably secondary to gut or hepatic vasoactive mediators reaching the systemic circulation.[7]

Heart Transplantation

Pulmonary hypertension may result in acute right heart dysfunction and can be managed by optimizing the patient's volume status, and the use of pulmonary vasodilators and inotropic agents.

After heart transplantation, cardiac function should improve fairly rapidly if the organ was well preserved and is a good match for the recipient. Systemic hypertension should be aggressively controlled, as it may be poorly tolerated by the allograft. Pulmonary hypertension may result in acute right ventricular dysfunction and the development of right heart failure.[24] This can be managed by limiting right ventricular volume, pulmonary vasodilator therapy (inhaled nitric oxide, inhaled iloprost, or intravenous epoprostenol), inotropic support (with norepinephrine, epinephrine, dobutamine, dopamine, and/or milrinone), or right ventricular assist device implantation.[24,25]

Given the vagal denervation of the transplanted heart, the allograft commonly has a resting tachycardia of approximately 100 beats/min; bradyarrythmias should be considered when the heart rate is less than 80 beats/min.[25] Bradycardia postheart transplantation most commonly results from sinus node dysfunction and less commonly from conduction system dysfunction. As a result of vagal denervation, atropine is ineffective, and beta-agonists such as isoproterenol, methylxanthines, and/or a temporary (or rarely permanent) pacemaker may be necessary. Tachyarrhythmias rarely arise in the heart transplant recipient, and their occurrence should be considered an indicator of acute rejection.[25]

Lung Transplantation

Lung transplant recipients require ICU care postoperatively in order to receive mechanical ventilation and close monitoring; a fragile respiratory status is common in the immediate postoperative period. The most frequent cause of oxygenation failure post-lung transplantation is PGD, for which the predominant cause is ischemia-reperfusion injury.[26]

The most frequent cause of oxygenation failure post-lung transplantation is PGD, for which the predominant cause is ischemia-reperfusion injury.

It presents as noncardiogenic pulmonary edema and hypoxia in the absence of infection and rejection; a lung biopsy commonly shows diffuse alveolar damage. Inhaled nitric oxide decreases pulmonary hypertension and improves oxygenation in PGD, but has not been shown to consistently prevent its occurrence.[27] Most clinicians attempt to minimize the transcapillary pressure gradient in order to limit the extravasation of fluid into the newly transplanted lung; this will hopefully allow a lower inspired oxygen concentration and reduce oxidant injury to the allograft.[28] Other complications that may present in a similar fashion, and should be considered, include volume overload and myocardial dysfunction, which can be detected by right heart catheterization or echocardiography, respectively, and pneumonia, which can be evaluated by sputum culture or bronchoscopy.

Other complications after lung transplantation include volume overload, pneumonia, hyperacute rejection, airway complications, and bleeding.

Hyperacute rejection of the newly transplanted lung is a more plausible diagnosis of graft dysfunction in patients with an increased panel of reactive antibodies or a positive crossmatch between recipient blood and donor tissue. Noncardiogenic pulmonary edema can also occur in patients in whom pulmonary vein anastomotic narrowing or kinking leads to increased transcapillary pressures. This possibility can be identified by esophageal doppler echocardiography, CT angiography, and/or MR angiography.[29]

Other complications include airway dehiscence and stenosis, although these have become less common in recent series with the use of improved surgical techniques such as end-to-end bronchial anastamoses and anastamotic wrapping with omentum.[29] Single lung transplant recipients with emphysema may develop native lung hyperinflation, which can lead to mediastinal shift, allograft compression, and hypotension. This can be managed with aggressive bronchodilator therapy for the native lung, heliox administration, ventilator strategies that include minimal positive end-expiratory pressure, independent lung ventilation, and even lung volume reduction surgery of the native lung.[29] Diaphragm weakness due to phrenic nerve dysfunction occurs in heart-lung transplant recipients more frequently than in bilateral lung transplant recipients; this complication is least likely in single lung transplant recipients.[30,31] It can prolong hospital stay but does not seem to impact survival.[30,31] Hemothoraces and pneumothoraces may also occur. The most common cardiovascular complication that occurs with lung transplantation is atrial fibrillation, which occurs in almost 40% of recipients. In the absence of data specific to lung transplantation, the management is similar to the management of postoperative atrial fibrillation that occurs with other forms of thoracic surgery.[32] Other complications that occur following lung transplantation may include gastroparesis and thromboembolic disease.[29]

The most common cardiovascular complication that occurs with lung transplantation is atrial fibrillation, which occurs in almost 40% of recipients.

IMMUNOSUPPRESSION AFTER SOLID ORGAN TRANSPLANTATION

Immune-mediated graft rejection involves complex cellular and molecular pathways, which center on naïve and memory lymphocytes.[33] These cells are activated by tissue dendritic cells and then migrate, proliferate, and differentiate into effector T cells. Recipient B-cells are also activated to produce antibodies against donor HLA. This can result in allograft rejection, the primary clinical manifestation of which is allograft dysfunction. Thus, immunomodulation is crucial for allograft acceptance and adequate transplanted organ function. Immune therapy has three major effects: therapeutic effect (suppression of rejection), adverse consequences of immune deficiency (infection or cancer), and nonimmune drug toxicity (outlined in Table 41-2).

Immune therapy has three major effects: therapeutic effect (suppression of rejection), adverse consequences of immune deficiency (infection or cancer), and nonimmune drug toxicity.

Common immunosuppressive agents are listed in Table 41-2.[34] Immune therapy is largely directed towards T-cell activation and proliferation. Calcineurin, a protein phosphatase,

Suppression of T-cell activation and proliferation with calcineurin inhibitors is the cornerstone of immunosuppressive therapy.

CASE STUDY: PART 4

The retrospective crossmatch is negative and a transesophageal ultrasound shows a normal ejection fraction and normal Doppler flow of the pulmonary vessels. A presumptive diagnosis is PGD, and the patient is given diuretics. TP's oxygenation improves over the next 24 h and he is extubated 2 days after transplantation. He is started on tacrolimus and mycophenolate mofetil in addition to the corticosteroids that were begun at the time of surgery. He is discharged 2 weeks after transplantation.

activates the nuclear factor of activated T cell (NFATc), a transcription factor, by dephosphorylating it. Activated NFATc is then translocated into the cell's nucleus, where it up-regulates the expression of interleukin 2 (IL-2), which, in turn, stimulates the growth and differentiation of the T cell.

Calcineurin inhibitors are used in concert with cell-cycle inhibitors and glucocorticoids and occasionally with rapamycin receptor inhibitors to immunosuppress the solid organ transplant recipient.

Calcineurin is the target of the class of drugs known as calcineurin inhibitors (CI), which includes cyclosporin and tacrolimus (FK506); these agents are the cornerstone of transplant immunosupression therapy. The blood levels of calcineurin inhibitors require monitoring, either trough or peak levels, which are taken 2 h after administration.[34] Target levels depend on a multitude of factors including the type of transplanted organ, the time posttransplantation, the risk of rejection, as well as the nature and severity of medication-related adverse effects. Inhibitors of purine synthesis, including azathioprine and mycophenolate, impede leukocyte proliferation. When used with the calcineurin inhibitors, they reduce early and late allograft rejection and improve allograft and patient survival.[35] Glucocorticoids bind to the cytosolic glucocorticoid receptor; the activated hormone receptor then interacts with specific transcription factors (e.g., AP-1 and NF-κB) and prevents the transcription of targeted genes. Glucocorticoids also prevent the transcription of proinflammatory genes, including interleukins IL-1B, IL-4, IL-5, and IL-8, chemokines, cytokines, GM-CSF, and TNFA genes. The target of rapamycin inhibitors (sirolimus or everolimus) is to prevent cytokine receptors (particularly that of IL-2) from activating the cell cycle. They have been used in addition to, or in place of, cell-cycle inhibitors in order to decrease the level of CIs in patients who have manifested toxicities to other agents. Given that they impair wound healing, their use early in the posttransplant cause should be avoided.[36]

Depleting and nondepleting anti T-cell antibodies have also been employed in induction therapy, treatment of refractory rejection, and when toxicity limits the use of calcineurin inhibitors.

Depleting antibodies directed at lymphocytes have been used for both the induction and treatment of acute cellular rejection. Polyclonal antithymocyte globulins, Muromonab-CD3 (OKT3), and Alemtusimab (Campath) produce durable lymphopenia and immunosuppression.[34,37] They also have multiple toxicities, including "cytokine release syndrome" which is due to the antithymocyte globulins binding to the T cell receptor and activating the T cells before they are destroyed. Cytokines released by the activated T cells produce a systemic inflammatory response syndrome (SIRS) characterized by hypotension, fever, and chills. Deaths due to the cytokine release syndrome with OKT3 have been reported, and life-threatening pulmonary edema can occur, particularly if the patient is volume overloaded.[34,37] Rituximab (Rituxan), which binds to CD20 on B-cells and mediates B cell lysis, has been used in patients with alloantibodies or antibody-mediated rejection.[38] Nondepleting antibodies including Daclizumab (Zenapax) and Basiliximab (Simulect) are widely used as inducing agents.[34,37] These antibodies block CD25, which is the alpha chain of the IL-2 receptor that is expressed only on activated T cells, and thus reduce both T-cell proliferation and episodes of acute rejection without causing significant lymphopenia.

ALLOGRAFT REJECTION

Hyperacute rejection occurs when the host has preformed antibodies to donor antigens, including ABO antigens and occasionally HLA antigens; it manifests within minutes to hours after organ perfusion.

Rejection is the immune recognition and attack of the donor allograft that occurs in three major manifestations: hyperacute, acute, and chronic. Organ-specific manifestations of rejection are presented in Table 41-3.[38-42] Hyperacute rejection occurs when the host has preformed antibodies to donor antigens, including ABO antigens and occasionally HLA antigens.[39,40,42] This complement-mediated injury to the organ occurs within minutes to hours

TABLE 41-2

COMMON IMMUNOSUPPRESSIVE AGENTS USED IN SOLID ORGAN TRANSPLANTATION

DRUG	CLASSIFICATION	MECHANISM	MONITORING	NONIMMUNE SIDE EFFECTS
Glucocorticoids		Binds cytosolic glucocorticoid receptor and prevents the transcription of proinflammatory genes	None	Diabetes mellitus, weight gain, adrenal suppression, glaucoma, osteoporosis, mood/mental status changes, thin skin
Cyclosporine	Calcineurin inhibitor	Binds to cyclophillin; complex inhibits calcineurin phosphatase and T-cell activation	Level 2 h after administration and/or trough, serum creatinine	Nephrotoxicity, hypertension, hemolytic uremic syndromes, neurotoxicity, gum hyperplasia, skin changes, diabetes mellitus, hyperlipidemia
Tacrolimus (FK506)	Calcineurin inhibitor	Binds to FKBP12; complex inhibits calcineurin phosphatase and T-cell activation	Trough level, serum creatinine	Nephrotoxicity, hyperlipidemia, diabetes mellitus, neurotoxicity, hypertension
Sirolimus (rapamycin)	Target of rapamycin-inhibitor	Binds to FKP12; complex inhibits target of rapamycin inhibitors and interleukin-2 derives T-cell proliferation	Monitoring of levels, monitoring of lipids	Delayed wound healing, hyperlipidemia, mouth ulcers, thrombocytopenia, pneumonitis, interstitial lung disease
Everolimus	Derivative of sirolimus	Same as sirolimus	Same as sirolimus	Same as sirolimus
Mycophenolate mofetil	Cell-cycle inhibitor	Inhibits synthesis of guanosine monophosphate nucleotides; blocks purine synthesis	Monitoring of levels and blood count	Gastrointestinal symptoms (mainly diarrhea), neutropenia, mild anemia
Azathioprine	Cell-cycle inhibitor	Converts 6-mercaptopurine to 6-thioinosine-5′-monophosphate to tissue inhibitor of metalloproteinase, which is converted to thioguanine nucleotides that interfere with DNA synthesis	Blood count monitoring	Leukopenia, bone marrow depression, macrocytosis, liver toxicity
Polyclonal antithymocyte globulin	Polyclonal IgG from horses or rabbits	Blocks T-cell membrane proteins (CD2, CD3, CD45, etc.) causing altered function, lysis, and T-cell depletion	Monitor platelet and white blood cell count	Cytokine release syndrome (fever, chills, hypotension), leukopenia thrombocytopenia, serum sickness
Muromonab-CD3	Murine monoclonal antibody	Binds to the CD3 associated with T-cell receptor, leading to initial activation and cytokine release, followed by blockade of function, lysis, and T-cell depletion	Monitor platelet and white blood cell count	Cytokine release syndrome (fever, chills, hypotension), thrombocytopenia, leukopenia, serum sickness

(*continued*)

TABLE 41-2

(Continued)

DRUG	CLASSIFICATION	MECHANISM	MONITORING	NONIMMUNE SIDE EFFECTS
Alemtuzumab	Humanized monoclonal antibody	Binds to CD52 on all B and T cells, most monocytes, macrophages, and natural killer cells, causing lysis and prolonged depletion	Monitor platelet and white blood cell count	Mild cytokine release syndrome, neutropenia, anemia, idiosyncratic pancytopenia, autoimmune thrombocytopenia, thyroid disease
Basiliximab	Chimeric monoclonal antibody against CD25	Binds to and blocks the interleukin 2-receptor α chain (CD 25 antigen) of activated T cells, depleting them and inhibiting interleukin 2-induced activation	No monitoring required, two doses	Hypersensitivity reactions, (uncommon)
Daclizumab	Humanized monoclonal antibody against CD25	Similar action to basiliximab	No monitoring required, five doses recommended, two may suffice	Hypersensitivity reactions, (uncommon)
Rituximab	Chimeric monoclonal antibody against CD20	Binds to CD20 on B-cells and mediates B cell lysis	Can follow B cell levels	Infusion reactions, hypersensitivity reactions, (uncommon)

CASE STUDY: PART 5

Five months after transplantation, TP presents with shortness of breath worsening over 2 days, associated with a decrement in his home spirometry reading and low-grade fevers. He is on tacrolimus with appropriate levels, mycophenolate mofetil, and prednisone. He was also on prophylaxis with timethoprim/sulfamethoxazole and valganciclovir. His saturation is 80% on room air and his chest X-ray shows a new right lung alveolar infiltrates. He is hospitalized in the ICU and a bronchoscopy showed an intact anastomosis, no evidence of infection, and the transbronchial lung biopsy shows perivascular lymphocytic infiltrate consistent with grade 2 acute rejection. TP receives three consecutive days of pulse corticosteroids and the symptoms are much improved.

after perfusion and can result in profound organ dysfunction as well as SIRS. Treatment options include plasmapheresis to remove the circulating antibodies, intravenous immunoglobulin to deplete bound antibodies, B cell suppression with Rituximab, and, occasionally, retransplantation.[38,39,42,43]

Acute cellular rejection is predominantly a T-cell mediated lymphocytic mononuclear inflammatory response directed against the allograft and commonly occurs from the first week to 2 years after transplantation.[33,34] The rates and nature of the presentation of the patient who develops acute cellular rejection varies organ by organ. Initial episodes of acute rejection that appear 6 months after solid organ transplantation are rare without a prior reduction in the level of immunosupression or medication noncompliance. Acute humoral rejection is less common, but can be initiated by alloantibodies directed against the donor's HLA or endothelial cell antigens and is identified by a biopsy of the transplanted organ demonstrating immunoglobulin and/or complement deposition in the allograft.[38,39] Its rates are the highest in women and those patients with preexisting high levels of panel-reactive antibodies. In renal transplantation, this is somewhat mitigated by HLA matching. The diagnosis of acute cellular rejection may be presumed based on the clinical presentation and markers of organ dysfunction, but given the large number of possible diagnoses that usually accompanies dysfunction of a transplanted organ, rejection is commonly confirmed by biopsy. Some posttransplant protocols, particularly in those who have received heart and lung transplants, include routine allograft biopsies used to detect sub-clinical rejection. Peripheral blood gene array assays may correlate with rejection, but experience with their use in clinical practice is limited.[24] Treatment of acute cellular rejection is predominantly done with pulsed doses of glucocorticoids and the response is generally good.[44] Anti T-cell antibodies can be used for refractory cases.

Acute cellular rejection is predominantly a T-cell mediated lymphocytic mononuclear inflammatory response directed against the allograft and commonly occurs from the first week to 2 years after transplantation.

Baseline immunosuppressant therapy should be reexamined for appropriateness and adjusted if necessary.

Treatment of acute cellular rejection is with pulsed doses of glucocorticoids; T-cell antibodies can be used for refractory cases.

Chronic rejection occurs in a more subtle fashion with slowly progressive allograft dysfunction, which is less amenable to reversal with immunosuppressive therapy. It is likely a manifestation of multiple and/or chronic immune-mediated and nonimmune-meditated injuries to the allograft. It can result in severe graft dysfunction and may be an indication for retransplantation.

INFECTION AFTER SOLID ORGAN TRANSPLANTATION

Infection is one the most common and important complications of solid organ transplantation in the critical care setting. Fifty to seventy five percent of solid organ transplant recipients have evidence of microbial invasion in the first year.[45] Infectious complications are the number one reason for ICU admission in this patient population. In one study of 352 emergency room visits of transplant recipients, infections accounted for 35% of admissions, making it the most common diagnosis prompting admission in the posttransplant patient.[46] Eleven percent of those transplant patients admitted with infection developed severe sepsis. Urinary tract infections and pneumonias accounted for two-thirds of the infections.[46]

Given the prevalence and impact of infection in solid organ transplant recipients, many programs now institute routine prophylaxis against common infections. Although some data

Common regimens include prophylaxis for surgical and/ or hospital-acquired infections, CMV, *Pneumocystis jirovecii*, and fungi.

TABLE 41-3

MANIFESTATIONS OF REJECTION IN VARIOUS TRANSPLANTED ORGANS

	HYPERACUTE REJECTION	ACUTE REJECTION	CHRONIC REJECTION
Kidney	Allograft turns mottled and cyanotic Decreased urine output Diminished renal blood flow	Fever, oliguria, graft pain Increased creatinine	Uremia Increased creatinine
Liver	Organ edema and mottling after implantation	Fever, malaise, abdominal pain, or portal hypertensive changes such as ascites Increased transaminases, bilirubin, alkaline phosphatase, and γ-glutamyltransferase	*Chronic ductopenic rejection* Jaundice Increased alkaline phosphatase, and γ-glutamyltransferase
Heart	Allograft bogginess and edema Decreased cardiac function	Breathlessness Volume overload Atrial fibrillation	*Cardiac allograft vasculopathy* Chest pain Cardiac ischemia Arrhythmias
Lung	Desaturation Pulmonary edema fluid on bronchoscopy	Fever, breathlessness, airflow obstruction Desaturation Spirometric decline Chest X-ray infiltrates	*Bronchiolitis obliterans syndrome* Breathlessness Spirometric decline

CASE STUDY: PART 6

Seven months after transplant, TP presents to the emergency room with 3 days of worsening shortness of breath and low-grade fevers, and 1 week of loose stools and fatigue. His oxygen saturation is 90% on room air and his chest X-ray shows diffuse alveolar infiltrates with more in the allograft. He is on his immunosuppressive therapy at appropriate levels. His valganciclovir was discontinued 6 months after transplant as per protocol, and the dose of trimethoprim /sulfamethoxazole was discontinued 2 weeks prior to presentation due to a rash. His respiratory status quickly deteriorates and he is intubated and placed on mechanical ventilation.

exist for the prevention of certain posttransplant infections, the optimal agents and the duration of prophylaxis are not clearly defined. Transplant programs often use a compilation of factors such as medication efficacy, medication costs, drug tolerance, and individual patient risk, due to exposure and level of immunosuppression, to assign a certain prophylactic regimen. Common regimens include prophylaxis for surgical and/or hospital-acquired infections, CMV, *Pneumocystis jiroveci* (PCP), and fungi.[45,47] In certain cases, such as with CMV, prophylaxis serves to delay the onset of the opportunistic infection (OI) until later in the posttransplant course, presumably when a patient has recovered from postsurgical morbidities and is less immunosuppressed.[45,47]

Differential Diagnosis

The type of infection often correlates with the duration of time since transplantation (Fig. 41-1).[47] This timeline takes into account both infections related to the surgical procedure and the level of immunosuppression, which is generally gradually decreased following transplantation. Immune function in the individual patient, however, may vary depending on predictable factors such as the level of immunosuppression due to induction therapy or treatment of rejection, and less predictable factors that may impact a particular individual's immune function (age, gender, and other illnesses) as well as comorbidities such as diabetes and renal failure. Recognition of the temporal variance in infectious agents following transplantation can be helpful in determining the diagnostic tests required and initiating empiric antimicrobial therapy.

Recognition of the variance in infectious agents that depends on the time after transplant can be helpful in both determining the diagnostic tests required and initiating empiric antimicrobial therapy.

From the time of transplant to 1 month afterwards, the majority of infections in the solid organ transplant patient are nosocomial or surgical site related.[47] Nosocomial infections include Methicillin-resistant *Staphylococcus aureus* (MRSA), Vancomycin-resistant Enterococcus (VRE), catheter and wound infections, and *Clostridium difficile*. Fungal infections can occur early and are primarily due to *Candida* and *Aspergillus* species.[45] Surgical site infections can arise from bronchial anastomotic leaks, airway and lung ischemia, and wound infections.

From the time of transplant to 1 month afterwards, the majority of infections in the solid organ transplant patient are nosocomial or surgical site related.

Infections in the first month post transplantation can be further classified as recipient-derived and donor-derived. Infections arising from the recipient are generally the result of pretransplant colonization with organisms such as *Aspergillus*, Pseudomonas, endemic fungi (Coccidioides, Histoplasma), *Mycobacterium tuberculi,* and other nontuberculous Mycobacteria. Patients awaiting transplantation may also develop colonization with resistant pathogens such as MRSA, VRE, or fluconazole-resistant *Candida* species, which can infect the surgical site, ascitic fluid, catheters, or cause pneumonia. Knowledge of the patients' medical and social history may be crucial in identifying and treating some of these infections, for instance pulmonary aspergillosis which is associated with marijuana use and *Cryptococcus neoformans* infection, which is related to pigeon exposure.[47]

Donor-derived infections such as tuberculosis, herpes simplex virus (HSV), CMV, rabies, and West Nile Virus, are rarer and often latent at the time of transplant, although active viral and bacterial infections may also be transmitted.[47] In cases of either suspicion or confirmation of a donor-derived infection, it is important to communicate this information to the organ procurement agency. That agency will then contact the physicians caring for other patients who received organs from that donor. OIs, although unusual, should be considered in patients who have received antilymphocyte antibodies for induction or have other risk factors.

Donor-derived infections such as tuberculosis, HSV, CMV, rabies, and West Nile Virus, are uncommon.

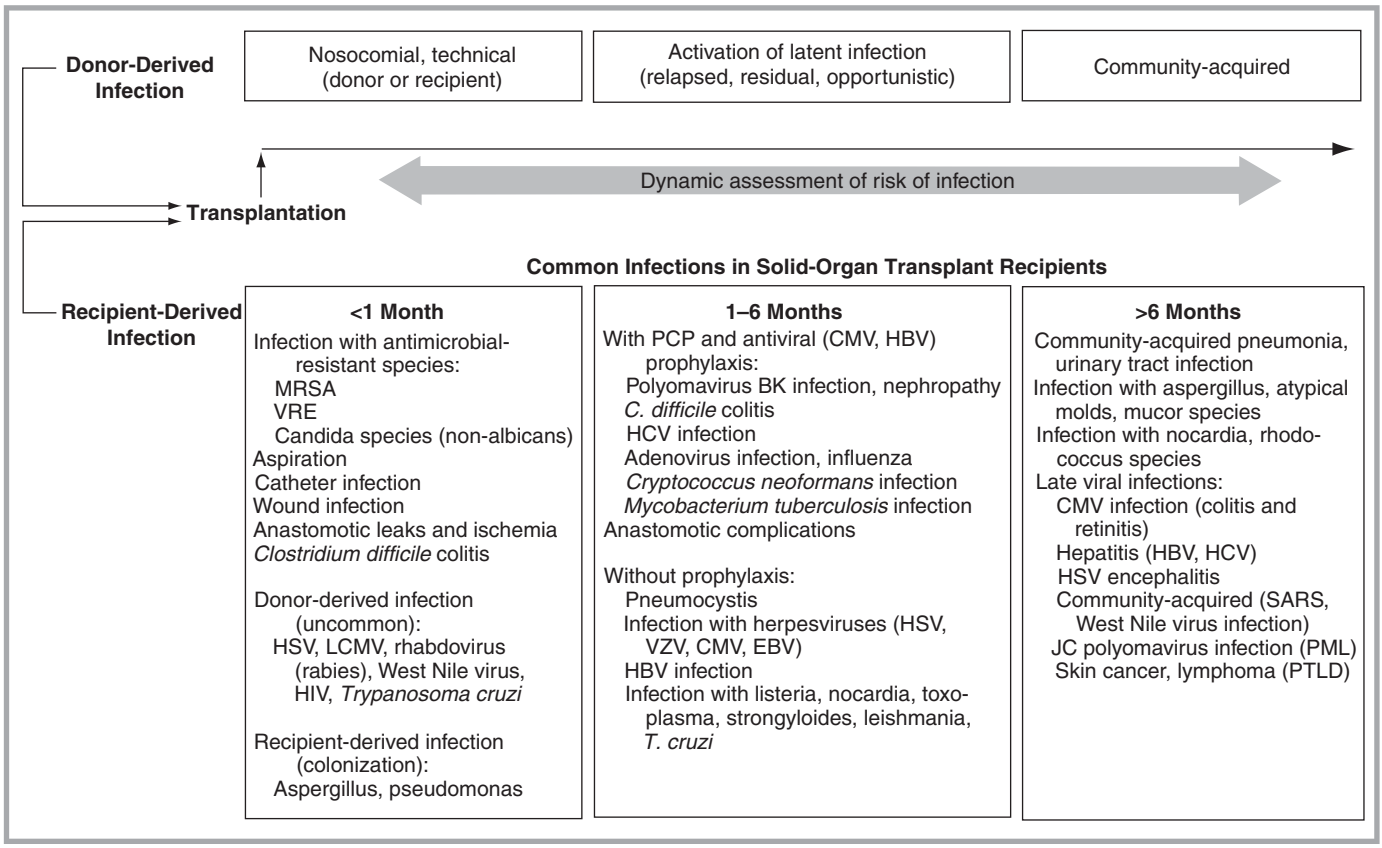

FIGURE 41-1

Timeline of infections after solid organ transplantation (reprinted with permission from Fishman.[47] Copyright 1997 Massachusetts Medical Society. All rights reserved).

From 1 to 6 months posttransplant is when OIs, such as Pneumocystis, CMV, listeria, nocardia, toxoplasmosis, and HSV, and fungi, become increasingly important.

From 1 to 6 months posttransplant is when OIs become increasingly important. Patients who have acute rejection are at the highest risk for OIs.[45] Prior to the institution of common prophylactic regimens, implicated organisms included Pneumocystis, CMV, listeria, nocardia, toxoplasmosis, HSV, and fungi.[47] With antimicrobial, antiviral, and antifungal prophylaxis, organisms now implicated in OIs include *Clostridium difficile*, *Cryptococcus neoformans*, Mycobacteria, and resistant fungal infections.

With decreasing levels of immunosuppression, generally 6 months after solid organ transplantation, OIs become less common, and community-acquired infections such as urinary tract infections and pneumonia become more prevalent.[47] Late viral infections such as CMV colitis or retinitis, HSV retinitis, and viral hepatitis still occur. Cryptococcus and the endemic mycoses are the fungal infections that may also arise in the late period.[47,48]

Evaluation

Invasive testing is often needed and is directed towards the area that combines acceptable risk with maximal yield.

Chest radiography, peripheral blood, urine, sputum, and stool cultures, and *Clostridium difficile* toxin assay for patients with diarrhea are minimally invasive studies and are standard practice for transplant recipients in the ICU with a suspicion of infection.[45] If clinical suspicion exists for CMV infection, laboratory testing on peripheral blood includes the shell vial assay, quantitative polymerase chain reaction (PCR), and pp65 CMV antigen detection; the later two being highly sensitive for viral replication.[49,50] Fungal infections (candidemia and disseminated aspergillosis) may also be detectable by blood cultures.[51,52] Clinical syndromes and specific testing for common OIs in transplant recipients are outlined in Table 41-4. Invasive testing is often needed and is directed towards the area that combines acceptable risk with maximal yield.[52,53]

TABLE 41-4

CLINICAL MANIFESTATIONS, PROPHYLAXIS, DIAGNOSIS, AND TREATMENT OF COMMON OPPORTUNISTIC INFECTIONS POSTTRANSPLANTATION

PATHOGEN	CLINICAL MANIFESTATIONS	PROPHYLAXIS	LAB DIAGNOSIS	TREATMENT
Cytomegalovirus	Pneumonia Colitis Hepatitis Viremia Encephalitis	Ganciclovir Valganciclovir CMV hyperimmunoglobulin	CMV pp 65 antigen CMV blood culture CMV shell vial assay CMV blood PCR Bronchoalveolar lavage culture, PCR Biopsy: Owl's eyes inclusions	Ganciclovir Valganciclovir CMV hyperimmunoglobulin
Pneumocystis jiroveci	Pneumonia: cough, dyspnea, hypoxia, tachypnea, CXR infiltrates	TMP/SMX Aerosolized pentamadine Atovoquone	Induced sputum Bronchoalveolar lavage Lung biopsy, transbronchial Immunofluorescent stain PCR	TMP/SMX Pentamidine, IV Atovaquone Primaqine+ clindamycin TMP+ dapsone Consider Corticosteroids for hypoxemic patients
Candida	Mucocutaneous Abdominal Candiduria Candidemia Endocarditis Brain abscess Endophthalmitis Pneumonia	Fluconazole Aerosolized Amphotericin	Culture of blood or sterile site Tissue invasion on pathology PCR	Azoles Caspofungin (based on speciation and susceptibility)
Aspergillus	Invasive pulmonary disease Empyema Brain abscess Fungal ball Disseminated disease Ulcerative tracheobronchitis	Aerosolized amphoterecin Voriconazole Itraconazole	Culture of respiratory tract or sterile site Antigen detection Direct visualization on pathology	Voriconazole Amphoterecin B Caspofungin Surgical intervention for fungus balls and endovascular, bronchial, or soft tissue involvement

CASE STUDY: PART 7

TP has a bronchoscopy with bronchoalveolar lavage which showed cells with intranuclear inclusion bodies. The Gram stain and silver stain were negative. He was started on intravenous gancyclovir and slowly improved and was extubated. The gancyclovir was continued for 3 weeks until the CMV PCR from peripheral blood drawn weekly was less than 200 copies, and valgancyclovir for secondary prophylaxis was continued for 3 months thereafter.

A biopsy is particularly helpful when the differential diagnosis includes rejection and infection. These two etiologies have divergent management paths: one of additional immunosuppression and the other of immune augmentation; thus, obtaining a confirmatory diagnosis is crucial.

Treatment

Given the importance of early treatment and the limitations in obtaining an accurate diagnosis in a safe and timely manner, treatment should be initiated empirically based on clinical suspicion and initial tests, and modified as additional information becomes available. Patients with sepsis (see Chap. 23 on sepsis syndromes) should be treated with proven therapies, such as early goal-directed therapy, and stress dose steroids since most patients are on corticosteroid therapy.[53] Patients who have inadequate initiation of therapy have poorer survival than those in whom initial therapy adequately covered the (eventually identified) pathogen. Thus, early broad-spectrum therapy, which takes into account the risk factors for resistant or unusual organisms, is extremely important.[53] Therapy for common OIs is listed in Table 41-4. Given the suboptimal sensitivity of many tests, including tissue biopsy in certain settings, and the risks of invasive testing, therapy based on clinical information may be warranted in certain circumstances; in such a setting, careful evaluation of the response to therapy is crucial.

CMV Infection

CMV prophylaxis with agents such as ganciclovir, valganciclovir, acyclovir, and CMV hyperimmune globulins has been used to delay the onset of CMV-related disease.

Confirmatory tests for CMV include the shell vial assay, quantitative PCR, CMV antigenemia, and organ biopsy with typical pathological findings.

CMV infection occurs in 30–75% of transplant patients at risk, with a mortality of 5%.[50] Rates of infection are highest in lung or heart-lung recipients and lowest in kidney recipients.[49,50] The highest rate of disease occurs in seropositive organs being transplanted into seronegative recipients.[49,50] CMV prophylaxis with agents such as ganciclovir, valganciclovir, acyclovir, and CMV hyperimmune globulins have been used to delay the onset of CMV-related disease.[49,50] Medication intolerance, particularly from lymphopenias, and medication cost sometimes limits routine prophylaxis. Disease while on these agents may indicate viral resistance or merely a manifestation of the immunosuppression. CMV disease can manifest as viremia with malaise, fever, leukopenia, pneumonia, colitis, hepatitis, and encephalitis. Specific laboratory testing for CMV include the shell vial assay, quantitative PCR, and CMV antigenemia.[49] Depending on the site of disease, invasive testing, including lung biopsy, lumbar puncture, and colonic mucosal biopsy may be required. A biopsy with the characteristic "Owl's eyes" intranuclear inclusion bodies is diagnostic. Intravenous gancyclovir is the drug-of-choice for treating acute CMV infection.[50] Foscarnet can be used for clinical nonresponsiveness, but its use is limited by nephrotoxicity. Anti-CMV hyperimmunglobulins can be adjunctive in seronegative recipients of seropositive organs, and has been shown to reduce the rate of severe disease.[50] Valganciclovir has excellent oral bioavailability and has been shown to have some effectiveness, but outcome data in severe disease are lacking. Laboratory measures of CMV viremia can be used to guide treatment, with antivirals continued until these are adequately reduced.[49]

Fungal infections with *Candida* and *Aspergillus* can be seen early after transplant.

Endemic fungi are seen later in the posttransplant period when the patient is not on a prophylactic regimen and has more interaction with his/her environment.

Fungal Infections

Fungal infections, including organisms such as *Candida*, *Aspergillus*, and Cryptococcus, have a wide range of clinical manifestations. *Candida* can infect intravenous catheters, ascites fluid, and urine. Early disease is most common in lung transplant recipients, presumably because of surgical denervation of the bronchial airways and lung, which leads to

poor mucociliary function and cough. Long-term pretransplant steroids for end-stage lung disease and pretransplant colonization also likely play a role.[48] *Aspergillus* is the most common in lung transplant recipients and has been implicated in causing bronchial anastomotic dehiscence and invasive pneumonia. With prophylactic regimens, the likelihood of fungal infection can be reduced, but there may be an increased rate of infection with resistant molds such Mucormycosis, Paecilomyces, Zygomycetes, Scedosporium, and Fusarium. Endemic fungi can also be seen later in the posttransplant period when the patient is not on a prophylactic regimen and has more interaction with his/her environment.[48] The use of prophylaxis is determined by the organ transplanted as well as the presence of certain risk factors. Those liver transplant patients with pretransplant fulminant hepatic failure, primary allograft dysfunction, hemodialysis, and OKT3 antibody use may benefit from prophylactic therapy with amphotericin B 2.5–5 mg/kg/day for 4 weeks.[48] Lung transplant patients with acute graft failure, ischemic bronchial segments, induction therapy, recovery of *Aspergillus* on respiratory culture, and CMV infection can receive aerosolized amphotericin B, itraconazole, or voriconazole. Kidney transplant recipients with persistent candiduria are candidates for fluconazole prophylaxis. Heart transplant patients are less likely to have fungal infections and no prophylaxis is recommended.[48]

Clinical manifestations, laboratory diagnosis, and treatment are varied and are presented in Table 41-4. The major antifungals available for use include amphotericin B, caspofungin, and the azoles. Fluconazole susceptibility for *Candida* varies by species: albicans > parapsilosis > glabrata > krusei (tropicalis is variable).[48] Caspofungin is indicated for candidemia, esophageal candidiasis, intraabdominal abscesses, peritonitis, pleural space disease, and in refractory, invasive Aspergillosis. It is critical to note that caspofungin coadministered with cyclosporine carries a high risk for hepatotoxicity and should only be used when benefit clearly outweighs the risk; close monitoring of liver enzymes is necessary. Azole usage, especially voriconazole and itraconazole, necessitates dosage adjustment of cyclosporine, tacrolimus, and sirolimus.[48]

Pneumocystis jiroveci Pneumonia

CXR findings of Pneumocystis are highly variable, and staining of the organism, or PCR positive sputum, bronchoalveolar lavage fluid, or lung biopsy is needed for diagnosis.

Pneumocystis jiroveci pneumonia (PCP) occurs in 5–15% of solid organ transplant recipients and in up to 50% of lung transplant recipients without prophylaxis.[54] Trimethoprim/Sulfamethoxazole (TMP/SMX) single or double strength 3 times per week has been shown to be highly effective for prevention of PCP in transplant patients, but its use may be limited by leukopenia, hyperkalemia, and increased creatinine, particularly in conjunction with other medications that have similar side effect profiles (valganciclovir, calcineurin inhibitors). The duration of prophylaxis is recommended to be 6–12 months in patients receiving renal transplants and lifelong in patients receiving heart, liver, small bowel, and lung transplants.[54] PCP disease is seen with less optimal medications or after withdrawal of prophylaxis. Clinical manifestations include the subacute onset of progressive dyspnea, tachypnea, and a nonproductive cough. Chest X-ray findings are highly variable, ranging from normal to diffuse interstitial infiltrates. Diagnosis can be obtained by stain or PCR of the organism from sputum or, more commonly, with invasive techniques such as bronchoalveolar lavage or biopsy.[52,54] TMP/SMX is the optimal agent for treatment; pentamidine is for those who are intolerant of TMP/SMX, but carries risks of hyper- or hypoglycemia, neutropenia, thrombocytopenia, pancreatitis, and azotemia. Corticosteroids should be considered for those with more severe disease, manifested as a PaO_2 on room air <72 mmgHg or a PaO_2:FiO_2 ratio of <350. Prednisone at 40–60-mg twice daily for 5–7 days, followed by a taper over 21 days has been shown to lower intubation and mortality rates if given within 72 h.[54]

PTLD can present as nodal or extra nodal masses, with disease in the stomach, intestines, lungs, skin, liver, CNS, or the allograft itself.

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDER

Therapy for PTLD includes reduction of immunosuppression, Rituximab, and cytotoxic chemotherapy.

It is important for the ICU physician to recognize posttransplant lymphoproliferative disorder (PTLD) because it may cause multisystem disease. It may be nodal or extra nodal (about 50% each), with disease in the stomach, intestines, lungs, skin, liver, central nervous

system (CNS), or the allograft itself.[54] The disease may be self-limited or can progress to multisystem organ failure, which is difficult to distinguish from sepsis.[55] PTLD may be seen early (within the first year) in which case it is likely related to Epstein Barr virus replication, or late.[54] Risk factors include the type of transplant (small intestine > heart > lung > liver > kidney), increased immunosuppression, use of OKT3 and monoclonal antibodies, CMV infection, younger age at transplant, and recipient and donor serostatus. Diagnosis is made by pathology, either by needle aspiration or, preferably, by excisional biopsy. EBV viral load has low specificity and is not useful if there is non EBV-related disease.[55,56] If CNS involvement is suspected, a sample of CSF should be obtained for EBV PCR. The primary approach to the treatment of PTLD is reduction of immunosuppression. In up to half of cases, PTLD regresses with reduction or cessation of immunosuppression, with most successes being seen in early EBV-related disease.[55,56] Surgical resection or irradiation can be used to treat local complications. Monoclonal B cell antibodies (Rituximab) have shown remission rates of 63% for CD20+ cases; cytotoxic chemotherapy is reserved for salvage therapy.[56]

BLOOD TRANSFUSION

The major concerns associated with blood transfusions are CMV transmission, GVHD, and HLA alloimmunization.

Due to the inherent immunologic issues associated with organ transplants, blood transfusions are of particular concern, both before and after transplantation. The three major concerns are CMV transmission, graft-vs.-host disease (GVHD), and HLA alloimmunization and its possible impact on graft survival.[57]

In seronegative individuals, the rate of CMV transmission ranges from 5 to 15%, but given the high disease-related morbidity, it is prudent to use CMV negative blood for these patients.[47,57] Although data are limited, there is no support for eliminating CMV-positive individuals from the donor pool, for patients who are seropositive. In both bone marrow transplant and heart or lung transplant recipients, using leukocyte filtration was as effective as using CMV negative blood in reducing the rates of CMV disease.[57]

GVHD is caused by foreign cytotoxic T cells, derived either from the donor organ or a blood transfusion, which can lead to a disease in the recipient's liver, skin, gastrointestinal system, and lungs. Although this entity is much more of a concern in bone marrow transplant patients, it has been reported in solid organ transplant recipients. GVHD can be prevented by irradiation of red blood cells, which reduces lymphocyte transmission. However, given the rarity of GVHD in solid organ transplantation, the role of routine leuko-irradiation of red blood cells in these patients is unclear.[57]

A final concern in using blood transfusions in solid organ candidates and recipients is the issue of HLA alloimmunization, which has been associated with shorter long-term graft survival in certain organs. Since transfused leukocytes are thought to play a role in this process, leuko-reduction is recommended for kidney, heart, and lung transplant candidates.[57]

SUMMARY

Issues specific to solid organ transplant patients, including surgical complications, toxicity related to immunosuppressive agents, allograft rejection, and a wide breadth of potential infections can make their care extremely challenging. Awareness of these complex issues and interactions, good communication with the multiple members of the team, and a high degree of vigilance are key to effective and safe management. Future research is necessary to enhance our knowledge and improve outcomes in this highly specialized patient population.

REVIEW QUESTIONS

1. **A 52-year-old-man arrives to the ICU after a living donor kidney transplant with 6/6 HLA match and is afebrile, BP 90/50 on neosynephrine 20 μg/min, saturating 100% on 2LPM nasal cannula. Urine output is 5 mL–10 mL/h for the past 4 h. An ultrasound shows no evidence of urinary obstruction. The next most appropriate step in management is:**
   - **A.** Renal biopsy to establish the etiology of oliguria
   - **B.** Surgical reexploration to exclude arterial anastomotic issues
   - **C.** Volume resuscitation and supportive care
   - **D.** Additional immunosuppression to treat hyperacute rejection

2. **Which one of the following is not a part of the initial treatment for hyperacute rejection?**
   - **A.** Plasmapheresis
   - **B.** Intravenous immunoglobulin
   - **C.** Cyclosporine
   - **D.** Rituximab

3. **A 66-year-old-man presents 4 years after a bilateral lung transplantation complicated by two rejections in the first year now with 2 months of progressive shortness of breath and the chest X-ray with 4 cm mass like infiltrate in the right mid-lung field. All of the following should be a consideration except:**
   - **A.** Histoplasmosis
   - **B.** Post transplant lymphoproliferative disorder
   - **C.** CMV pneumonia
   - **D.** Lung cancer

4. **A 54-year-old-man with a history of heart transplantation 6 weeks prior to presentation comes in with a fever. He has been maintained on prednisone, azathioprine, and cyclosporine without rejection. Based on the time course, which of the following is an *unlikely* cause of this patient's fever:**
   - **A.** C. Difficille colitis
   - **B.** MRSA bacteremia
   - **C.** CMV colitis
   - **D.** *Candida* UTI

5. **A 48-year-old-woman with a history of liver transplantation is readmitted to the ICU with pneumonia. During her ICU stay, she develops a catheter-related infection with a yet to be speciated fungus. She is empirically started on caspofungin. Her immunosuppressive regimen includes cyclosporine. Which of the following laboratory tests should be closely monitored with this drug combination?**
   - **A.** Creatine kinase
   - **B.** Liver function tests
   - **C.** Serum creatinine
   - **D.** White blood count

6. **A 59-year-old-man with prior renal transplantation presents to the ICU with multisystem organ failure. His infectious work up is negative and PTLD is suspected. Which of the following is *NOT* a potential therapy?**
   - **A.** Increased immunosuppression
   - **B.** Rituximab
   - **C.** Cytotoxic chemotherapy
   - **D.** Surgical resection

ANSWERS

1. The answer is C. Volume resuscitation and supportive care. This is most likely ATN, which is the most common etiology of renal dysfunction after transplant. Hyperacute rejection can be diagnosed by renal biopsy or treated by additional immunosuppressive therapy, but is unlikely with the 6/6 HLA match. Arterial anastomotic issues should be evident on ultrasonography
2. The answer is C. Cyclosporine. Hyperacute rejection is a manifestation of rejection related to preformed antibodies, and thus therapies targeting antibodies and B-cells are crucial. Cyclosporine affects T cell function, and although needed for long-term graft function, will not treat the immediate hyperacute rejection
3. The answer is C. CMV pneumonia is not likely this far out after lung transplant. Fungal infections, PTLD, and lung cancer are all seen and present in a subacute fashion.
4. The answer is C. CMV colitis. In the period from transplant to 1 month, the most common infections are nosocomial or surgical site related. The differential can include infections with MRSA, VRE, *Candida*, C. diff colitis, and surgical site infections. OIs and CMV become more common 1–6 months posttransplant period.
5. The answer is B. Liver function tests. The concomitant use of cyclosporine increases the levels of caspofungin and greatly increases the risk for hepatotoxicity. Caspofungin should only be used in patients on cyclosporine when the benefits of the antifungal outweigh the high risk of liver damage. If these medications are administered together, the liver function tests should be followed closely for early signs of hepatic damage. Although both medications are known to cause nephrotoxicity, this is of less concern than the risk of liver damage. Neither medication is thought to significantly cause lymphopenia or muscle breakdown.
6. The answer is A. Increased immunosuppression. PTLD can cause multisystem organ failure and might be confused with sepsis. The main therapeutic approach is to *reduce* immunosuppression as much as possible; the progression of PTLD must be balanced with the risk of rejection with less immune suppression. In recalcitrant cases, Rituximab, cytotoxic chemotherapy, and surgical resection can be used to treat PTLD.

CHAPTER 42

SHEELA S. PAI, AARON CROOKSHANK, AND WISSAM CHATILA

Postoperative Care of the Cardiac Surgery Patient

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Recognize common causes of postoperative complications in cardiac surgery patients.
- Understand the pathophysiology of cardiac and hematologic dysfunction following cardiac surgery.
- Treat common events that lead to hemodynamic instability in the early postoperative period.

Advances in invasive cardiac interventions during the last decade have dramatically impacted cardiac surgery. Currently, the number of coronary artery stent insertions is approximately 15% greater than surgical coronary artery bypass grafting (CABG).[1] Cardiac surgical intervention is now reserved for complex cases that are usually not amenable to interventional cardiac procedures. This has required the cardiothoracic surgery team to adapt to the management of a much sicker patient population afflicted with multiple comorbidities and often comprised of older patients who have failed previous procedures.[2] Nonetheless, as diagnostic and therapeutic armamentaria expand and evolve, the principals discussed below have stood the test-of-time and need to be consistently followed in order to ensure good patient care and outcome.

CASE STUDY: PART 1

A 56-year-old male presents to the intensive care unit (ICU), postoperatively, after a CABG and mitral valve repair. The procedure was performed on cardiopulmonary bypass (CPB) with aortic cross clamping. The total bypass time was 136 min, and the cross clamp time was 78 min. He is brought to the ICU on epinephrine and milrinone infusions. He is tracheally intubated and being ventilated to achieve both oxygenation and ventilation. The ventilator is set on assist control (AC) at a rate of 12, tidal volume 650, FiO_2 60%, and positive end-expiratory pressure (PEEP) of 5. He appears comfortable, and his hemodynamic parameters are as follows: BP 110/70, HR 100 in sinus rhythm, pulmonary artery pressures 35/15 mmHg, central venous pressure 12 mmHg, and mixed venous saturation of 72%.

PRINCIPLES GUIDING CARDIAC POSTOPERATIVE MANAGEMENT

Effective postoperative management depends on a comprehensive understanding of the patient's preoperative status and intraoperative events. Comorbid conditions such as hypertension, diabetes mellitus, cerebrovascular disease, renal dysfunction, and abnormal cardiac function contribute significantly to potential complications in the immediate postoperative period. Therefore, for any relevant perioperative event, the probability of a correct diagnosis is often dependant on an accurate and complete pre and intraoperative history. Incorrect diagnoses lead to inappropriate treatment and poor outcome.

The second major principle is appropriate and accurate hemodynamic monitoring, coupled with frequent reassessment of the patient's hemodynamics after each intervention and/or change in clinical status. It is not uncommon to face a complex pathophysiology caused by multiple factors.

The third principle is related to rapidly determining the underlying cause of significant hemodynamic or respiratory instability, in order to differentiate complications that require surgical intervention from those requiring medical management. Patients with surgical complications that require going back to the operating room fare poorly if only treated medically. This chapter reviews the diagnosis and management of common conditions and complications during the first critical days following cardiac surgery.[3]

Intraoperative history and events may help identify the pathophysiology of hypotension and guide diagnostic studies as well as therapeutic intervention.

BLOOD PRESSURE MANAGEMENT

Mean arterial pressure (MAP) is a major determinant of blood supply to the target organ. The goal for MAP in the postoperative setting is generally in the range of 65–85 mmHg, but lower or higher pressures are desirable under specific circumstances, such as aortic regurgitation (60–70 mmHg) or preexisting hypertension, renal dysfunction, and/or cerebrovascular disease in the elderly (80–100 mmHg). In patients with severe aortic insufficiency or recently placed aortic sutures, a higher MAP may be associated with an increased risk of suture disruption. The ultimate goal of blood pressure management is to avoid tissue hypoperfusion while maintaining overall hemodynamic stability. Shock, organ hypoperfusion, and myocardial injury occur with severe hypertension or hypotension, both of which can be extremely common in the immediate postoperative period.

Postoperative Hypertension

Postoperative hypertension is common and may be related to a history of chronic hypertension, anxiety, agitation during emergence from anesthesia, or increased sympathetic discharge secondary to incisional pain or discomfort from the presence of the endotracheal tube (ETT). It can be aggravated by perioperative withdrawal of β-blocking and antihypertensive agents. Intraoperative institution of vasopressors or aggressive fluid administration may also play a role.

CASE STUDY: PART 2

After being in the ICU for 4 h the patient demonstrates some hemodynamic instability. His hemodynamics are as follows: BP 92/65 mmHg, PAP 30/12 mmHg, CVP 8 mmHg, and HR 112 beats/min; cardiac output and index are 3.2 L/min and 1.6 L/min/m^2, respectively, and mixed venous oxygenation 66%. The chest tube output has been minimal. The urine output has decreased in the past hour to 25 mL/h; his ventilator settings and oxygenation status remain unchanged.

Treatment of Postoperative Hypertension

Sedation or pain control: Medications should be titrated to hemodynamic and clinical response. If the ETT is the culprit and the goal is to perform tracheal extubation in the next several hours, short-acting agents are preferred as this allows titration to the desired effect and a more rapid emergence. In many instances, reassuring the patient and optimizing ventilatory settings to allow better synchrony abate much of the agitation and anxiety. If analgesia and anxiolysis do not fully control the hypertension, additional pharmacologic intervention should be initiated.

Antihypertensive therapy: Information regarding the operative course may help determine the most efficacious antihypertensive therapy. Cardiopulmonary bypass (CPB) induces a state of myocardial depression, which in patients with depressed left ventricular (LV) function can persist for multiple days. During this period there is enhanced sensitivity to negative inotropy; therefore, β-blocking agents should be used with caution. Additionally, there have been case reports describing an increased duration of action of some short-acting drugs, so initiating therapy with small doses is prudent. Available and frequently used agents include[4]:

- Sodium nitroprusside: start at 0.1 μg/kg/min and titrated to 8 μg/kg/min; tachyphylaxis is often a first sign of cyanide toxicity.
- Nitroglycerine: start at 50–100 μg/min and increase to a maximum of 400 μg/min. It is preferred if there is suspicion of inadequate revascularization, but it is not as effective as other options for severe hypertension.
- Nicardipine: start at 5 mg/h and increase by 2.5 mg every 5–15 min, up to 15 mg/h. It is a reasonable option for hypertensive patients with end-stage renal disease.
- β-blockers: rebound β-blocker withdrawal usually manifests in the first 24 h. Preoperative β-blockers should be reinstituted on the morning of the first postoperative day if the hemodynamics allow. β-blockers also reduce the incidence of postoperative atrial fibrillation (AF). Metoprolol 12.5–25 mg orally or via nasogastric tube twice a day is a reasonable initial adult dose, with titration to a heart rate of 60–80.

On the first or second postoperative day, the patient may be converted to longer-acting antihypertensive agents if he or she is hemodynamically stable.

Postoperative Hypotension

Postoperative hypotension may be more common than postoperative hypertension in patients undergoing cardiac surgery. The operative course and postoperative hemodynamics often point to the pathophysiology of hypotension and help guide resuscitation efforts (Table 42-1). Three common scenarios, occurring either in isolation or in combination, are responsible for the majority of the cases: hypovolemia (reduced preload), myocardial dysfunction (poor contractility), and vasodilation (reduced afterload).[3] Communication with the cardiothoracic surgical team and close monitoring of hemodynamic parameters are vital to ensure recognition of the underlying cause of hypotension and initiation of proper therapeutic interventions. For example, if the LV is thickened, due to aortic stenosis or chronic hypertension, identification of the optimal intraoperative LV filling pressures (e.g., pulmonary artery diastolic (PAD) pressure) may help prevent hypotension due to hypovolemia. In addition to the hemodynamic

TABLE 42-1

HEMODYNAMIC ASSESSMENT OF HYPOTENSION

			MYOCARDIAL DYSFUNCTION		
	HYPOVOLEMIA	**VASODILATION**	**LV FAILURE**	**RV FAILURE**	**TAMPONADE**
CI	Low[a]	Normal/high (>2.6 L/min/m^2)	Low	Low	Low
CVP	Low	Low	Variable	High (>18 mmHg)	High (>18 mmHg)
PAOP	Low	Low	High (>18 mmHg)	Low	Variable
Echo	Underfilled LV and RV cavities	Hyperdynamic LV	Poor LV function, with adequate filling Normal LV function, with small thick LV	Hypokinetic RV with underfilled LV	Restrictive mitral inflow pattern, possible visualization of clot or pericardial effusion
Etiology	Hypovolemia or bleeding Pneumothorax Cardiac tamponade Excessive PEEP AutoPEEP RV failure/severe pulmonary Hypertension	Prolonged CPB Vasodilator drugs/sedatives Residual protamine reaction	Prolonged CPB Inadequate revascularization Stunned myocardium Graft occlusion Coronary vasospasm	Pre-op RV dysfunction RV ischemia Severe pulmonary hypertension	

CI cardiac index; *CVP* central venous pressure; *PAOP* pulmonary artery occlusion pressure; *LV* left ventricle; *PEEP* positive end-expiratory pressure; *CPB* cardiopulmonary bypass

[a]Low CI<2.2 L/min/m^2

Intraoperative events that suggest left ventricular dysfunction include the presence of ischemia by EKG, new onset arrhythmias, wall motion change on echocardiography, and the need for inotropic support for separation from CPB. Coagulopathy often leads to hypovolemia due to excessive hemorrhage.

The presence of wall motion abnormalities on echocardiography after coronary artery grafting has been completed may portend inadequate or incomplete revascularization.

New onset atrioventricular blocks (AVB) in the setting of nonvalvular cardiac surgery may signify ischemic injury or edema of the AV node, usually the first manifestation of inadequate myocardial protection.

Prolonged CPB support creates a vasodilated state, in addition to coagulopathy. Worsening ventricular dysfunction in patients with preoperative heart failure and coagulopathy is common in this setting.

The Society for Thoracic Surgeons and the American Society of Anesthesiologists[8] make the following recommendations:
- A hemoglobin <7 g/dL in patients 65 years of age or older, with chronic cardiovascular, respiratory, or cerebrovascular disease justifies transfusion.
- Acute blood loss (>1,500 mL or 30% of blood volume) justifies transfusion.
- Point-of-care testing to assess hemostatic function may direct the use of non-red cell blood products in the setting of coagulopathy in the postoperative period.

parameters noted in Table 42-1, being familiar with the individual patient's pathophysiology will help focus diagnosis and expedite treatment. For example, in patients with significant LV dysfunction (LVEF ≤ 40%), there is a significant decrement in LV and RV function postcardiopulmonary bypass, which is partially (≈50%) reversed 24 h postoperatively; full recovery may take >72 h. Similarly, patients with ongoing ischemia undergoing emergent coronary artery bypass grafting (CABG) are at high risk of postoperative ventricular dysfunction, which is often severe and may be indistinguishable from a perioperative myocardial infarct. In contrast, graft compression is often recognized before leaving the operating room as patients generally have persistent EKG changes or new wall motion abnormalities. Treatment involves revision of the graft in most cases. Graft spasms are rare but maybe clinically significant events. They are diagnosed in the OR by EKG changes or regional wall motion abnormalities on echocardiography. Spasms are more likely in arterial grafts than venous grafts. Of the arterial grafts, free arterial grafts are more likely to spasm than pedicled grafts. Graft spasms follow the clinical pattern of acute myocardial infarctions. When a patient receives a free arterial usually radial graft, prophylactic use of an arterial dilator may be considered in the first 24 h postoperatively. Various agents such as nitroglycerin, calcium channel blockers (CCBs), and milrinone have been shown in studies to abate spasm. Choice of agent usually is predicated by institutional preference. In our institution, the preference has been to start the patient on an intravenous calcium channel blocker (titrated to BP) for the first 24 h, to be converted to an oral agent on the first postoperative day.

Treatment Goal

The goal of resuscitation is the maintenance of adequate end-organ perfusion. Urine output and mixed venous oxygen saturation are often used to assess the adequacy of end-organ perfusion, but these parameters may not accurately reflect perfusion to all organs. Other markers of acceptable end-organ perfusion include mental status, gas exchange, and an acceptable mean arterial pressure (MAP) and cardiac index (CI). A CI ≥ 2.2 L/min/m^2 is often used as the lower limit of normal CI; in the presence of significant valvular disease, calculation of the CI by the Fick principle may be required.

Fluid Resuscitation

In the immediate postoperative setting following cardiac surgery, there is little scientific evidence to preferentially support the choice of colloid or crystalloid solutions. Fluid resuscitation strategies should be discussed with team members and institutional protocols developed. Colloids are synthetic (gelatins, starches, dextrans) or nonsynthetic (predominantly albumin). Commonly used intravenous solutions in the ICU setting are hydroxy-ethyl starch (Hetastarch), albumin (both 5 and 25%), and dextran. The coagulation system is affected by colloid administration, predominantly by dextran and hetastarch. Hetastarch affects the clotting factors, predominantly factor 8 and von Willebrand factor; additionally, there may be impaired platelet aggregation. There have been disruption of coagulation studies, specifically prothrombin time and partial thromboplastin time, when volumes greater than 1,500 mL/day have been used.[5] Colloids appear to have greater volume expansion per unit infused and a longer intravascular half-life compared to crystalloids. The debate between colloid vs. crystalloid has not been reconciled as of yet. End points of mortality or morbidity have not declared either fluid the winner. In patients with sepsis synthetic colloids were associated with higher rates of acute renal failure and renal-replacement therapy than Ringer's Lactate.[6]

Blood Transfusion

The decision to transfuse should be made after evaluation of patient symptoms, cardiac reserve, and the presence and rapidity of active bleeding.[7] Hemoglobins between 6 and 7 g/dL are generally well tolerated in patients with little to no postoperative bleeding and preserved cardiac function. In patients with poor cardiac function and concomitant cerebrovascular disease, higher hemoglobin levels may be advisable.

Pharmacologic Therapy: Ino-Vasopressors

The choice of vasopressor and/or inotropic therapy should be based on the underlying pathophysiology responsible for the hemodynamic instability. In the setting of vasodilation and prolonged CPB, the use of epinephrine to increase contractility in combination with vasopressin is often successful; studies have demonstrated a physiologic depletion of vasopressin in these patients.[9,10] Phenylephrine is a noncatecholamine direct stimulator of the α1 receptor, and may be a more appropriate first-line vasopressor in the presence of tachycardia or tachyarrhythmias. Norepinephrine should be considered in the setting of vasodilation and mild myocardial depression as it has both α and β agonist properties.[3] Patients with low ionized calcium are candidates for calcium administration. Calcium acts transiently as an inotrope and vasopressor in this setting. Care should be taken in administering calcium to patients with incomplete coronary revascularization as it may worsen myocardial oxygen balance.

Epinephrine, dobutamine, and/or milrinone infusions may be indicated in the setting of myocardial depression. If the left ventricular dysfunction is associated with elevated pulmonary pressure and right ventricular dysfunction, milrinone, a phosphodiesterase inhibitor, may be a more appropriate choice than dobutamine because of its favorable effects on the right ventricle and pulmonary vasculature.

Regardless of the pharmaceutical agent chosen, adequate preload is an essential component of therapy. For the failing heart, regardless of the PaOP recorded prior to beginning inotropic agents, higher filling pressures should be pursued if intravascular volume challenges result in an improved CI. Similarly, in patients with hypertrophied ventricles, a PaOP ≥ 18 and PAD ≥ 20–22 mmHg should be attained before initiating or increasing ino-vasopressor therapy as inadequate ventricular filling, rather than systolic dysfunction, may be the more important etiologic factor.

Nonpharmacologic Therapy

In addition to vasopressor and inotropic support, treatment options for refractory hypotension and low CI include additional volume resuscitation, transfusion, cardiac pacing, intra-aortic balloon counter-pulsation therapy, and the use of ventricular assist devices. Escalation of therapy should always be discussed with the surgical team. Communication is absolutely vital; if all other strategies fail, it may be prudent to return to the OR for surgical exploration and/or implantation of ventricular assist devices.

The intraoperative management of the low cardiac output state often dictates the choice of pressors/mechanical devices in the immediate postoperative period.

Weaning Pharmacologic Therapy

No withdrawal of ino-vasopressors should be attempted until the patient has been stable for a minimum of 4–6 h. Plans and strategies to wean mechanical devices should be discussed daily with the surgical team. Weaning from mechanical ventilation and extubation need not to be delayed because of an ongoing need for hemodynamic support, unless the patient continues to be labile (MAP and CI fluctuating below set goals or urine output <30–40 mL/h in the absence of preexisting renal insufficiency).

Cardiac Tamponade

Cardiac tamponade is a rare postoperative complication that needs prompt surgical intervention. It usually occurs in the setting of excessive perioperative bleeding; the traditional signs (including a widened mediastinum, low voltage EKG, or equalization of pressures) may not be seen. Tamponade may present insidiously, often in stages until a precipitous drop in cardiac output occurs. As blood and clot accumulate, diastolic filling is progressively impaired resulting in a decreased stroke volume. As preload is reduced, a compensatory tachycardia ensues with rising CVP and RA pressures and a decrease in BP. Transesophageal echocardiography (TEE) is the imaging procedure of choice for the diagnosis of tamponade, and the definitive treatment is surgical evacuation of the blood clots. Prior to surgery, resuscitation

In the postoperative period, the classic signs of tamponade are seen infrequently; TEE may be needed to confirm the presence of tamponade.

with fluids and vasopressors is required to maintain adequate filling pressures and organ perfusion. If the patient is breathing spontaneously and not compromised, positive pressure ventilation should be avoided as it may further reduce cardiac preload.

POSTOPERATIVE ARRHYTHMIAS

Arrhythmias in the postoperative period may be an indicator of graft dysfunction, ischemia, hypoxemia, acid base disorder, or electrolyte imbalance.[11] Rapid exclusion of the above etiologies will lead to a correct diagnosis and appropriate therapy. Prompt intervention may also prevent worsening of a borderline cardiac performance and permit more optimal intra-aortic balloon counterpulsation (IABC) synchrony. Overdrive pacing may be helpful in cases of refractory arrhythmia as in bradycardias and arterial fibrillation (AF) in patients with heart failure or during IABC therapy.

Bradyarrhythmia

Common etiologies of postoperative bradyarrhythmias include intraoperative use of β blockers, cardioprotection solution with CCBs, sinoatrial ischemia/edema, electrolyte disturbances, and postoperative sympatholysis. The best approach for the management of bradycardias is atrial pacing because it optimizes hemodynamics during sinus bradycardia and junctional rhythms. Ventricular pacing is most useful during atrioventricular (AV) dissociation and AF with slow junctional rhythms.[3] On the other hand, ventricular pacing leads to inefficient contraction and a decreased stroke volume, due to the lack of synchronized atrial contraction. Of note, most postcardiotomy patients have better cardiac outputs and MAP with sinus bradycardia at approximately 60 bpm than a ventricular paced rhythm at 90 (particularly if the LV is hypertrophied or ventricular function is impaired). Catecholamine drips (epinephrine, dopamine, dobutamine) are another option in lieu of pacing, and may be more successful in increasing heart rate and cardiac output.

Supraventricular Tachyarrhythmia

Supraventricular tachyarrhythmias are common in patients undergoing cardiac surgery and are often associated with other postoperative complications and prolonged ICU stays. Treatment of hypovolemia, anemia, pain, hypoxia, alcohol withdrawal, fever, and electrolyte disturbances will minimize but not eliminate these tachyarrhythmias. The management approach to atrial flutter is somewhat similar to AF, but the former tends to be more responsive to atrial pacing; therefore, a trial of atrial pacing (20 mA, for 30–60 s at 110–150% of atrial rate) is often the first therapeutic choice if atrial pacing wires were placed during surgery.

The most common postcardiac surgery arrhythmia is AF occurring in 25–40% of patients with a peak onset between postoperative days 2 and 3.[12,13] There may be decreases in blood pressure and urine output and/or the development of congestive heart failure. Postoperative AF increases the risk of stroke three to fourfold.[12,14] Although AF uncommonly persists long-term, in those who develop chronic AF it is an independent risk factor for death (RR 1.5 men and 1.9 women). Risk factors for the development of AF are summarized in Table 42-2. Proper treatment of AF including β-blockers, CCBs, antiarrhythmic medications, anticoagulation, and pacing helps to reduce the burden of the disease and minimize potential adverse effects. As 85% of patients will convert to sinus rhythm in the first 24 h of AF, a rate-control strategy, followed by rhythm control after 48 h in patients in whom AF does not spontaneously convert, should help minimize anticoagulation use and medication side effects. A management algorithm incorporates recommendations for the prevention and treatment of AF.

TABLE 42-2

RISK FACTORS FOR POSTOPERATIVE ATRIAL FIBRILLATION

Increasing age
Chronic lung disease
Rheumatic heart disease
Peripheral vascular disease
Left ventricular hypertrophy
Preoperative digoxin use
Withdrawal of preoperative beta-blockade
Hypomagnesemia
Hypokalemia
Hypothyroidism
Right coronary stenosis
Heightened sympathetic tone
Combined valve and CABG surgery
Duration of aortic cross clamping
Early return of electrical activity after cardioplegia

Prophylaxis of Atrial Fibrillation

Pharmaceutical agents that are effective as monotherapy have β-blocking properties such as Vaughan-Williams Class II (β-blockers) and III agents (amiodarone and sotalol).[15] Additionally, there is clear data that withdrawal of β-blocking agents prior to surgery and witholding them subsequently place patients at high risk for AF. There is little evidence that Class III agents, amiodarone and sotalol, offer any benefit beyond those of β-blockers. Because these agents have significant side effects, β-blocker therapy is recommended as first-line for prophylaxis for AF; however, no large randomized trial has been conducted comparing prophylactic regimens to a regimen of rate control and anticoagulation. In patients intolerant of β-blocking agents (due to hypotension or bronchospasm), amiodarone may be used. Preoperative loading of amiodarone over several days may be impractical, though it has been shown to be effacious. [15] The most common adverse event was bradycardia in 2.5% of patients on amiodarone vs. 1.5% in controls.[15] Sotalol remains an alternative; however, daily recording of the QT interval is necessary and close monitoring of renal function required in order to minimize the risks of ventricular arrhythmias. For these reasons, sotalol is not routinely used for prophylaxis.

Rate Control

The evidence comparing agents for ventricular rate control of AF is limited. In hemodynamically stable patients in whom there is no contraindication for anticoagulation, a rate-control strategy should be pursued for the first 24 h; 85% of patients with AF will convert to sinus rhythm within this time period. β-blockers (metoprolol and esmolol) are preferred as first-line therapy when compared with class IV agents (verapamil and diltiazem) due to the hyper-adrenergic state which contributes to the pathogenesis of AF.[16] Nonetheless, CCBs are efficacious and are considered a reasonable alternative to β-blockers.[17] Amiodarone is not considered a first-line therapy or first alternative due to the excess bradycardia that can occur. There is little evidence to suggest that digoxin is effective at rate control of AF and it does not affect adrenergic tone; therefore, it is not first-line or first alternative. Propafenone may be efficacious; however, it may cause bradycardia and is contraindicated in coronary artery disease. Dofetelide should not be used for rate control of AF because it is not efficacious and may actually be proarrhythmic.

Rhythm Control

There is little evidence comparing rate-control vs. rhythm-control strategies for AF. Additionally, few studies that evaluate antiarrhythmic therapies for the conversion of AF exist. For patients who are hemodynamically stable but are symptomatic or have

a contraindication to anticoagulation, antiarrhythmic therapy is recommended based upon literature for AF in nonsurgical patients.[18] Close monitoring for bradycardia and *torsade des pointes* and access to cardioversion with or without epicardial or transvenous pacing are recommended due to the risk of a proarrhythmic event during initiation of therapy. In patients with depressed LV function, amiodarone is considered first-line therapy. In patients with normal LV function, amiodarone, sotalol, or ibutilide can be used. Class IA agents (disopyramide, procainamide, and quinidine) are alternative therapies. Treatment should be continued for 4–6 weeks postoperatively with appropriate monitoring of the QT interval and renal function. Class IC agents and dofetilide have been associated with increased mortality (flecainide) and ventricular arrhythmias and therefore should not be used.

Anticoagulation

The majority of patients undergoing cardiac surgery have risk factors for stroke (history of stroke, TIA, hypertension, LV dysfunction, advanced age, diabetes, and coronary artery disease) that have already been identified in the chronic AF population.[18] As a result, it is advisable to use either aspirin, or warfarin, or heparin in cases of AF when the risk of stroke outweigh the risk of bleeding. Studies that evaluated the efficacy of anticoagulants on graft patency post-CABG surgery demonstrated that aspirin or warfarin could be employed with minimal increase in bleeding risk; risks of pericardial effusion and tamponade were higher in the warfarin group.[19] Heparin has been shown to have a higher incidence of bleeding; however, it may be used in high-risk cases in which patients have prior stroke or transient ischemic attack. In patients less than 60 years of age without comorbidities that place them at high risk for stroke, aspirin is sufficient. For patients 65 years of age or older with risk factors or any patient 75 years or older, warfarin without heparin should be used with a target INR of 2.0–3.0 as per ACC/AHA/ESC guidelines for nonoperative patients.[18] In patients with intermediate risk (60–65 years of age with or without one risk factor), treatment options should be weighed against risk. In high-risk patients, with a history of stroke or TIA, heparin should be considered.[18,19] Cases with thrombocytopenia or high chest tube output should prompt a more conservative approach. If the patient converts to sinus rhythm, therapy may be discontinued if the risk of bleeding is thought to outweigh the benefit of anticoagulation. Ideally, anticoagulation should be continued for 30 days because of evidence of reduced systolic atria function upon return of sinus rhythm.[19]

Ventricular Tachyarrhythmias

The initial approach to minimize risk and treat ventricular arrhythmias is to correct hypoxia, electrolyte imbalance, hypothermia, and acid–base derangement while excluding graft dysfunction and ischemia and titrating catecholamine infusions to the lowest possible dose.

The initial approach to minimize risk and treat ventricular arrhythmias is to correct hypoxia, electrolyte imbalance, hypothermia, and acid–base derangement while excluding graft dysfunction and ischemia and titrating catecholamine infusions to the lowest possible dose. For early postoperatively ventricular tachyarrhythmias (e.g., ventricular tachycardia [VT], multifocal premature ventricular contractions [PVCs], sustained unifocal PVCs, bigeminy, trigeminy, couplets, and triplets), lidocaine or procainamide are often considered if the primary approach fails. After 48 h of treatment, antiarrhythmics are usually discontinued and the incidence of arrhythmias is reassessed. For delayed ventricular arrhythmias, an electrophysiological evaluation is warranted. Acutely, and during tachyarrthymic events, burst ventricular pacing via the transthoracic wires or antiarrhythmics boluses (lidocaine or procainamide) followed by infusions (at 2 mg/min for both drugs) is appropriate for stable VT. Symptomatic and urgent treatment of VT includes synchronized DC cardioversion, usually with low energy shock; unsynchronized shocks should be used for ventricular fibrillation (VF) or if the defibrillator cannot track the rhythm in the synchronized mode. Of note, early VT can be caused by graft occlusion and should prompt consideration of open chest CPR and mediastinal exploration, thus the surgeon should be notified immediately. Open chest CPR in this setting will also permit the use of internal defibrillator paddles. Regarding polymorphic VT/*torsade de pointes*, treatment consists of magnesium sulfate and correction of electrolyte abnormalities. It is often related to QT prolongation secondary to electrolyte

imbalance or type I antiarrhythmics (procainamide, quinidine); if this is suspected, the offending antiarrhythmic agent must be immediately discontinued. Ventricular pacing or AV sequential pacing at 85–100 bpm may also terminate this arrhythmia.

POSTOPERATIVE HEMORRHAGE

Persistent chest tube drainage in the early postoperative period is worrisome. Surgical causes should be considered while coagulation studies are being processed. Communication with the surgical team is crucial in the face of increased chest tube output. Reexploration of the mediastinum is generally warranted for the following chest tube outputs: 500 mL/1 h, 400 mL/2 h, or sustained drainage of 200–300 mL/h after the second postoperative hour. Determining the etiology of the hemorrhage is critical as medical interventions will be ineffective if there is a surgical cause (Table 42-3). In addition, several factors, discussed below, should be considered when faced with excessive postoperative bleeding.

The evaluation of postoperative hemorrhage should be a multidisciplinary one. It should include a complete laboratory work-up including disseminated intravascular coagulopathy (DIC) work-up, platelet count, and assessment of hepatic and renal function. The surgeon must be kept informed regarding the severity of the hemorrhage because of the potential need for surgical exploration and intervention.

Temperature

The patient's temperature is relevant in the approach to postoperative bleeding as hypothermia promotes coagulopathy. Measures such as warming blankets, forced air warming, warm fluids, and an elevated room temperature should be used to maintain the patient's temperature ≥36.5°C.

Blood Pressure

Higher blood pressures cause or contribute to excessive bleeding. Without compromising organ perfusion, efforts should be made to maintain a MAP between 70 and 75 mmHg and systolic blood pressure ≤110–120 to decrease the likelihood of rupture of suture lines and the avulsion of hemostatic clips from conduit branches. Judicious use of short-acting antihypertensives such as nitroglycerin, nitroprusside or nicardipine may be beneficial.

Heparin Reversal

Protamine may be given postoperatively in the ICU because of residual heparin effect or heparin rebound but is often avoided because of its potential for serious side effects. Protamine dose is based on a 1:1 ratio with heparin in the operating room (1 mg protamine:

TABLE 42-3

CAUSES AND FACTORS ASSOCIATED WITH EXCESSIVE POSTOPERATIVE BLEEDING

Surgical causes
Anastomotic leaks at the suture lines
Leaks from improperly ligated side branches of arterial or venous conduits
Generalized oozing from substernal soft tissues, sternal surface, bone marrow, or periosteum
Oozing from raw surfaces caused by an inflammatory response
Scarring from previous old surgeries
Pericarditis
Radiation
Medical causes
Residual heparin effect: incomplete reversal of heparin with protamine or heparin rebound
Platelet consumption and dysfunction from prolonged CPB
Preoperative platelet inactivation: preoperative use of agents such as clopidogrel, aspirin, glycoprotein IIb/IIIa inhibitors
Depletion of clotting factors: hemodilution with pump priming results in depletion of clotting factors
Preoperative coagulopathy: preexisting liver dysfunction, residual warfarin effect, vitamin K deficiency, von Willebrand's disease, and fibrinolysis resulting in depletion of clotting factors
Fibrinolysis: the inflammatory response to the CPB circuit results in fibrinolysis with resultant degradation of clotting factors and platelet dysfunction

CPB cardiopulmonary bypass

100 unit(s) heparin), but other reversal ratios have been reported. Protamine reactions range from mild hypotension to severe anaphylactoid reactions associated with pulmonary vasoconstriction and cardiovascular collapse (Table 42-4). There is no specific therapy for protamine reactions; treatment is supportive. Administration of fluid, intravenous calcium, α agonist agents to support blood pressure, or intravenous epinephrine in the event of a severe reaction has been reported.

Positive End-Expiratory Pressure

Adding PEEP to positive pressure ventilation increases intrathoracic pressure and hypothetically could decrease venous bleeding. This is the basis for the use of PEEP in the face of increased postoperative hemorrhage, but clinical studies have not supported this theory. In the face of active bleeding, PEEP may be applied if venous return and blood pressure are not compromised.

Heparin-Induced Thrombocytopenia (HIT)

Thrombocytopenia in HIT is not a cause for excessive bleeding, rather it is associated with thrombosis.

In the immediate postoperative period (first 8–24 h), thrombocytopenia is almost invariably non-HIT related. HIT is an immune mediated response to heparin administration in which antibodies are formed against platelet factor 4 (PF4)-heparin complexes.[20] Platelet activation by these antibodies leads to thrombocytopenia (≥50% reduction in platelet count), which usually occurs 4–20 days after heparin exposure and results in clot formation rather than bleeding. Although cardiac surgery patients are at high risk of developing this PF4 antibody, only a small subset of these patients (1–5%) develop thrombocytopenia with or without thrombosis. The presence of antibodies is required to confirm the diagnosis and any evaluation of a new onset thrombosis, especially at sites of vascular injury (catheter sites, conduit sites), should include HIT in the differential diagnosis. In the presence of HIT, treatment is indicated irrespective of platelet count because of the unfavorable natural history of HIT managed by heparin cessation alone: 25–50% thrombosis at approximately 1 month follow-up with 5% fatality. Treatment consists of stopping all heparin and heparin analogues, clearing all catheters of heparin, and initiating nonheparin anticoagulants. The choice of alternative nonheparin anticoagulation depends on patient-specific factors. Argatroban and lepirudin are excreted through hepatobiliary and renal routes, respectively; therefore, argatroban may be more suited for patients with renal insufficiency (to maintain aPTT 1.5–3.0× baseline), whereas liperudin is preferred in patients with hepatic dysfunction. Bivalrudin (0.15 mg/kg/h) is another alternative nonheparin because of its shorter half-life (25 min). Argatroban is known to increase INR, and liperudin is immunogenic with a small risk of anaphylaxis (<1%). Platelets transfusions are unnecessary as HIT is associated with thrombosis rather than bleeding.

TABLE 42-4

PROTAMINE REACTIONS

Type I	A benign of reaction resulting of histamine release and causes systemic hypotension. Type I reaction may be avoided by slower administration of protamine
Type II	Anaphylactoid reaction resulting in hypotension, flushing, edema, and bronchospasm. This reaction may be: ■ Idiosyncratic, IgE, or IgG-mediated anaphylactic type reaction, occurring within the first 10 m in of administration ■ Immediate nonimmunologic anaphylactoid reaction, also within the first 10 min of administration ■ Delayed reactions, occurring after 20 min of start of protamine administration and related to complement activation and leukotriene release
Type III	Catastrophic pulmonary vasoconstriction with severely elevated pulmonary pressures and subsequent cardiopulmonary collapse and noncardiogenic pulmonary edema. These reactions occur between 10 and 20 min of start of protamine possibly caused by heparin-protamine complex complement activation

SUMMARY

Although this chapter covered frequently encountered emergent issues in the immediate postoperative period, other principles of critical care practice apply in this setting as well.[21-25] Common ICU morbidities, such as catheter-related infections, hyperglycemia, acute kidney injury, respiratory failure, and polyneuropathy of critical illness, among others, need to be meticulously managed; providing proper nutritional support in this setting will also improve patient outcome.

The postoperative care of cardiac surgery patients is highly complex but is often associated with predictable complications and morbidities. In this era of increasingly more complicated surgical procedures, the challenge to the intensivists delivering postoperative critical care is to prevent these complications or treat them expeditiously and aggressively in order to minimize secondary injury.

As problems develop, it is often initially unclear if the etiology is surgical in nature and will thus require surgical exploration and intervention. For this reason, communication with the surgical team is imperative in the immediate postoperative period.

REVIEW QUESTIONS

1. What are the goals for blood pressure management in the immediate postoperative period?
- **A.** Maintenance of end-organ perfusion
- **B.** Control of chest tube output
- **C.** Protect fresh suture lines
- **D.** All of the above

2. What is the etiology of postoperative hemorrhage?
- **A.** Platelet dysfunction
- **B.** Clotting factor deficiency
- **C.** Hepatic injury
- **D.** Surgical site
- **E.** All of the above

3. The timing of thrombocytopenia in majority of postoperative patients with heparin-induced thrombocytopenia is
- **A.** Immediate
- **B.** 4–10 days after heparin exposure
- **C.** Two days after heparin exposure
- **D.** One month after heparin exposure
- **E.** All of the above

4. The indications for full anticoagulation in patients with atrial fibrillation occurring in the postoperative period include
- **A.** Prophylaxis against DVT
- **B.** Resolution of the atrial fibrillation in <24 h of onset
- **C.** Persistent atrial fibrillation with rate control lasting >24 h after onset in a 68-year-old patient
- **D.** New onset atrial fibrillation occurring 24 h after mitral valve replacement surgery in a 68-year-old patient
- **E.** None of the above

5. The causes for postoperative ventricular dysfunction include
- **A.** Preexisting ventricular dysfunction
- **B.** Inadequate coronary revascularization
- **C.** Postcardiotomy shock
- **D.** Graft thrombosis or dysfunction
- **E.** All of the above

ANSWERS

1. D. The goals for blood pressure include preservation of end-organ perfusion while preserving the integrity of surgical suture lines. In the presence of preoperative hypertension, it should be recognized that the limits of auto regulation are shifted rightward and need to be taken into consideration. Surgical suture lines, especially on the aorta, are fragile and are subject to come apart in the face of a very high afterload. These factors need to be addressed while controlling blood pressure.

2. E. Etiology of postoperative hemorrhage is multifactorial. It tends to be a combination of surgical and medical bleeding. Surgical input is a key in the evaluation of bleeding. All the options mentioned above play a role in postoperative bleeding. Cardiopulmonary bypass renders platelets dysfunctional while depleting clotting factors. Prolonged intraoperative hypotension or improper venous cannula placement may impair hepatic perfusion leading to a synthetic hepatic dysfunction. Sepsis in the immediate postoperative phase is rare and should be considered only after all other causes have been ruled out.

3. B. Thrombocytopenia secondary to heparin-induced thrombocytopenia typically occurs 4–10 days after heparin exposure. If the patient has preexisting HIT antibodies, the response may be accelerated and more dramatic after reexposure to heparin.

4. C. Full anticoagulation is indicated neither immediately after the onset of atrial fibrillation nor for one episode of paroxysmal atrial fibrillation that lasts less than 24 h. Although there is no consensus on exact timing to start full anticoagulation after the onset of atrial fibrillation, patients who are at high risk to have thromboembolic events are fully anticoagulated for persistent atrial fibrillation as early as 24 h after onset of this atrial arrhythmia.

5. E. Ventricular dysfunction in the postoperative period occurs as the result of combination of factors. Cardiopulmonary bypass with the use of cardioplegia tends to cause myocardial edema and inadequate myocardial protection. Reperfusion injury plays a role as does graft dysfunction.

CHAPTER 43

A. JAMES MAMARY

Obstetrical Care in the ICU Patient

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Identify the major causes and incidence of maternal morbidity and mortality.
- Distinguish the physiologic circulatory and respiratory adaptations of pregnancy from those of disease.
- Understand aspects of airway management and acute resuscitation unique to pregnant patients.
- Describe hypertensive disease of pregnancy and its contribution to maternal morbidity and mortality.
- Recognize the potential role of pregnancy in developing hemorrhagic, cardiogenic, septic, and obstructive shock.
- Understand diagnostic approaches and treatment of venous thrombosis and thromboembolism in pregnancy.
- Understand critical illnesses unique to pregnancy such as amniotic fluid embolism, tocolytic-induced pulmonary edema, and ovarian hyperstimulation syndrome.

The presence of a fetus should not be permitted to compromise the survival and well-being of the mother.

The obstetrical team must remain vigilant to deliver a viable fetus in anticipation and avoidance of prolonged fetal hypoxemia.

INTRODUCTION

The medical care of the critically ill pregnant patient is complicated by the circulatory needs of a fetus and potential toxicities of therapies directed toward the mother. The primary responsibility and focus of the critical care physician are the health and recovery of the adult woman. Conversely, maternal critical illness should not be allowed to compromise the long-term well-being of a viable fetus. Typically, fetal scalp oxygen saturation monitoring and continuous heart rate monitoring are employed at approximately 24 weeks gestation.

CASE STUDY

B.V. is a 32-year-old G1P0 with well controlled chronic essential hypertension on appropriate medications. She has participated in routine prenatal care. At a 36 week obstetrical exam, she complained of modestly worsening shortness of breath at rest. She also told her physician that she was increasingly uncomfortable at night and was sleeping sitting up in a chair in the bedroom. She had evidence of preterm labor and was admitted to the obstetrical ward for monitoring. She was comfortable without fever. Her blood pressure was elevated to 150/93 mmHg despite the regular use of her oral antihypertensive medications. She had an intermittent S3 gallop with normal breath sounds and 1+ lower extremity edema. Her urine dipped positive for protein. The fetus was monitored continuously and was in no distress. Plans were made for urgent cesarean section delivery with rapid-sequence endotracheal intubation and mechanical ventilation. In the minutes prior to delivery, B.V. vomited and became acutely short of breath with room air oxygen saturation of 86%, respiratory rate of 34 breaths/min, and blood pressure of 160/95 mmHg. She was endotracheally intubated and mechanically ventilated. A chest X-ray showed bilateral infiltrates. B.V. was ventilated with volume controlled ventilation with tidal volumes of 6 mL/kg. Over the next 6 h, her oxygenation deteriorated with a PaO_2 of 180 mmHg on FiO_2 of 100% and PEEP of 7.5 cmH_20. The fetus was delivered. She received magnesium for 24 h. She did not receive antibiotics. She recovered and was extubated 8 days later.

MODELS OF CRITICAL CARE DELIVERY TO OBSTETRIC PATIENTS

Perinatal ICU services vary widely from the dedicated obstetrical ICU to the transfer of the critically ill pregnant and puerperal patient to the medical ICU. The choice of specialty of the physician to provide medical care to the critically ill obstetric patient varies by institution and specific training of its specialists. A traditional model draws upon medical critical care specialists to deliver care to critically ill patients with primarily nonobstetrical critical illness with a consulting team of obstetrical specialists. Many major training institutions in the United States offer a 3-year fellowship in maternal-fetal medicine. Additional training in maternal critical care medicine is available to diplomats in maternal-fetal medicine through a 1-year fellowship in maternal critical care medicine. Currently, very few obstetricians are board-certified in maternal critical care.[1] In facilities without adequate technological and physician support, critically ill obstetrical patients may require transfer to other institutions that have those capabilities.

EPIDEMIOLOGY OF OBSTETRICAL CRITICAL CARE

In Europe and North America, obstetrical admissions to an intensive care unit occur in 2–4/1,000 deliveries. Even at large volume facilities, these ICU admissions are relatively uncommon and account for less than 1% of total ICU admissions.[2]

Typically, these women are young and frequently primapara. Rapid recovery is common; the average ICU stay is <48 h and is far shorter than that for nonpregnant patients.[3] The most common ICU admitting diagnoses are obstetrical-related and include preeclampsia-related complications and postpartum hemorrhage. Mechanical ventilation for general anesthesia for emergency cesarean section necessitates ICU transfer. Need for prolonged ventilatory support is uncommon.[4,5]

The average gestational age at the onset of mechanical ventilation is 31.6 weeks (range 22–41) with an average duration of 3.4 ventilator days (range 0.2–18).[6] Pregnancy-related mortality rates in the United States from the years 1991 to 1999 was 11.8 deaths per 100,000 live births.[7]

The leading causes of the maternal deaths after live births (60% of maternal deaths) were embolism and pregnancy-induced hypertension, followed by hemorrhage, infection, cardiomyopathy, stroke, anesthesia complications, and other nonpregnancy-related medical illness. Abortion and stillbirth yield significantly higher rates of infection and related maternal deaths (Table 43-1). Maternal deaths related to coexisting medical illnesses and cardiomyopathy

Most critical care admissions occur in low-risk pregnancies without an obstetrical history predictive of increased medical risk.

The most frequent causes of respiratory failure leading to invasive mechanical ventilation in obstetric patients are preeclampsia/eclampsia (43%), labor and delivery (14%), and pneumonia (12%).

Most maternal deaths were attributable to complications of hypertensive diseases, pulmonary illness, and cardiac disease.

increased throughout this decade, and probably to some degree, reflects improved ascertainment of data, but more importantly, a significant increase in the age at which women in the United States are conceiving, and an increase in the prevalence of underlying maternal chronic medical illnesses. Older women are at increased risk for pregnancy-related death. The risk for pregnancy-related death after live birth is highest among women receiving the least or no prenatal care and among those with the least education. Black women have a higher risk of pregnancy-related death than White women. This racial disparity may reflect persistent inequalities in access to quality health care, differences in the seriousness of morbidity, differences in the diagnosis and treatment of pregnancy-related complications, or a combination of factors.

Pregnancy was not found to increase mortality in critical illness in an age-matched case-controlled retrospective analysis.

Existing severity of illness tools are not specifically validated for predicting outcomes in critically ill pregnant or puerperal patients. Illness severity assessment tools, such as the Acute Physiology and Chronic Health Evaluation (APACHE) II and the Simplified Acute Physiology Score (SAPS) II, produce variable results in obstetrical patients. Each typically overestimates mortality in critically ill pregnant patients with obstetrical illness. Normal physiologic reductions in creatinine, blood urea nitrogen and hematocrit, and increased respiratory and heart rate are scored as abnormal. Conversely, laboratory values relevant to obstetric critical illness such as liver function and platelet values are not often weighted in these scores.

It is generally accepted that when obstetric patients are admitted for medical disorders, the predicted mortality rate matches an observed mortality for an age-matched cohort.

Mortality, need for invasive positive pressure ventilation, and the prevalence of respiratory illness were similar. APACHE II and SAPS scores appropriately predicted similar mortality in both groups.[2]

When patients are admitted with obstetrical disorders such as hemorrhage and preeclampsia-related complications, the observed mortality is much lower than predicted.[3]

NORMAL MATERNAL PHYSIOLOGY OF PREGNANCY

Knowledge of normal changes of maternal physiology is required to appropriately assess, diagnose, and treat critically ill obstetrical patients.

Physiologic alterations induced by pregnancy affect all maternal organ systems.

It is essential for the critical care physician to distinguish between adaptive physiologic changes of pregnancy and pathologic derangements caused by critical illness. The two most important systems relevant to critical care are the pulmonary and cardiovascular systems.

Adaptations of the Circulatory System

Maternal blood volume expansion begins early in pregnancy and plateaus at 140–150% of prepregnancy levels at 30 weeks gestation.

Cardiac output increases 30–50% mostly by the end of the first trimester.

Activation of the renin-angiotensin system results in an expansion of extracellular volume. The plasma volume expands more than erythrocyte mass, which leads to a mild anemia with a decrease in hemoglobin of approximately 1 g/dL. This represents a 1,000 mL plasma and 500 mL erythrocyte expansion. Colloid osmotic pressure decreases as serum albumin falls from 4.0 to 3.4 g dL. Mild peripheral edema complicates 50–80% of normal pregnancies (Table 43-2).

Pregnant patients are at risk of developing pulmonary edema with aggressive volume resuscitation in this setting of lower oncotic pressure and decreased colloid oncotic pressure to pulmonary capillary occlusion pressure gradient.[8]

Heart rate increases and to a lesser extent stroke volume. Heart rate reaches a maximum of 15–20 beats per minute above nonpregnant resting levels by the middle of the third trimester. Stroke volume rises as a consequence of increased preload and a 20–30% drop in systemic vascular resistance. Pulmonary vascular resistance falls. Pulmonary capillary wedge pressure does not change.

This is most pronounced in the supine position and partially relieved in the left lateral decubitus position, and is termed the "supine hypotensive syndrome." During labor, the contracting uterus can increase blood return and cardiac output by 10–15%.

During the third trimester, the gravid uterus can significantly obstruct the inferior vena cava and disrupt venous return and cardiac output.

Diastolic pressures of 75 and 85 mmHg are the upper limits of normal during the second and third trimesters, respectively.[9] A physiologic S3 is normal.

Blood pressure decreases early in pregnancy with maximal average drops of 5–9 mmHg systolic and 6–17 mmHg diastolic by 16–28 weeks.

Adaptations of the Respiratory System

Renal compensation results in minimal chronic compensated respiratory alkalosis (pH 7.45) and serum bicarbonate levels of 18–21 mEq/L. Maternal PaO_2 is increased throughout pregnancy because of increased minute ventilation. An increased alveolar to arterial oxygen

TABLE 43-2

NORMAL HEMODYNAMIC PARAMETERS OF THIRD TRIMESTER PREGNANCY

	NONPREGNANT	PREGNANT
Cardiac output (L/min)	4.3 ± 0.9	6.2 ± 1.0
Heart rate (beats/min)	71 ± 10.0	83 ± 10.0
Systemic vascular resistance (dyne cm s^{-3})	1,530 ± 320	1,210 ± 266
Pulmonary vascular resistance (dyne cm s^{-3})	119 ± 47.0	78 ± 22
Colloid oncotic pressure (mmHg)	20.8 ± 1.0	18.0 ± 1.5
Colloid oncotic pressure − pulmonary capillary wedge pressure (mmHg)	14.5 ± 2.3	10.5 ± 2.7
Mean arterial pressure (mmHg)	86.4 ± 7.5	90.3 ± 3.8
Pulmonary capillary wedge pressure (mmHg)	6.3 ± 2.1	7.5 ± 1.8
Central venous pressure (mmHg)	3.7 ± 2.6	3.6 ± 2.5
Left ventricular stroke work index (g m m^{-1})	41 ± 8	48 ± 6

*n = 10 patients each measured at 36–38 weeks gestation and again at 11–13 weeks postpartum. Source: reprinted with permission from Clark et al.[8] Copyright Elsevier (1989)

Oxygen consumption increases 20–35% in normal pregnancy to meet the fetal, placental, and maternal needs generated by increased cardiac output and work of breathing. Carbon dioxide production also increases.

Pregnancy-induced increases in progesterone augment tidal volume by 30–35% from 450 to 600 mL with no substantial change in respiratory rate. Alveolar ventilation increases beyond what is required to eliminate additional CO_2 and $PaCO_2$ levels fall to 27–32 mmHg.

gradient and mild hypoxemia may be seen in the supine position because of ventilation-perfusion mismatch. The gravid uterus eventually causes a 4 cm elevation of the diaphragm and a 5–7 cm increase in lower thoracic circumference, and a widening of the subcostal angle from 68 to 103°. These adaptations minimize reduction of total lung capacity to 5% at term. Functional residual capacity drops during the second half of pregnancy and residual volume decreases by 10–25% at term.[10] Abdominal pressure increases elevating the diaphragm and decreasing chest wall compliance. Inspiratory capacity is augmented by widening of the thoracic cage. FEV_1, FEV_1/FVC, conductance, and lung compliance are unchanged.[9]

Fetal Oxygen Delivery

Fetoplacental tissue oxygen delivery is entirely dependent on adequate blood flow and maternal blood oxygen content. In health, umbilical vein partial pressures of oxygen are typically 30–40 mmHg, and fetal PaO_2 ranges from 20 to 25 mmHg. Fetal hemoglobin has a higher affinity for oxygen than maternal hemoglobin. These and other mechanisms protect the fetus from transient hypoxic stress and its adverse sequelae including high hemoglobin (15 g/dL), high cardiac output, a shift to anaerobic metabolism, and reduction of cardiac output to the brain.

ACUTE RESUSCITATION OF THE PREGNANT PATIENT

During cardiopulmonary resuscitation, standard protocol should be accompanied with appropriate patient positioning. The right hip should be elevated 15° and the torso 27°.

Optimal body positioning during acute hemodynamic resuscitation of the second and third trimester pregnant patient is essential. In the supine position, the gravid uterus compresses the inferior vena cava and the aorta, which leads to a decreased venous return, cardiac output, and blood pressure. This effect is most profound in intravascular volume-depleted patients. After the 24th week of pregnancy, placing the patient in the left lateral decubitus position can improve maternal blood pressure and placental blood flow.

Various devices can be used to position patients including pillows, the knees of the medical staff performing resuscitation, and commercially available wedge pillows. At this angle, 80% of maximal compressive forces can be delivered while relieving mechanical obstruction to venous return.[10]

AIRWAY MANAGEMENT

Anesthesia is the seventh leading cause of maternal mortality in the United States.[11] Because of the risks associated with general anesthesia in this patient population, regional anesthesia is used for the vast majority of planned cesarean deliveries in the United States. Complications stem from changes

in maternal physiology that predispose a greater risk of hypoxemia, aspiration of gastric contents, and failed endotracheal intubation. Estrogen induces airway edema and friability. Progesterone reduces lower esophageal sphincter tone and slows gastric emptying. The compressive effects of the gravid uterus may decrease central venous blood flow and increase gastric pressures.

Aspiration precautions and antacid prophylaxis are universally applied. This technique should be considered standard procedure in the emergency setting when possible. Application of posteriorly directed cricoid pressure can occlude and prevent the outlet of gastric flow from up to a 100 mmHg rise in gastric pressure by compressing the esophagus into the adjacent vertebral body. The force required can be estimated as the force that produces discomfort when applied to the bridge of the nose. Airway rescue devices, including laryngeal mask airways and cricothyroidotomy equipment, should be available for use in the event of failed intubation.[11,12]

Endotracheal intubation in the obstetric population is technically more difficult, fails eight times more often than other patients undergoing general anesthesia, and is associated with significantly increased mortality.

Emergent airway management in pregnant patients should be performed by operators highly skilled in rapid-sequence endotracheal intubation (with cricoid pressure) or awake endotracheal intubation.

HYPERTENSIVE DISEASES

Pregnancy-induced hypertension is the second leading cause of maternal death after live birth (19.3%).[7] Approximately 10% of pregnancies are complicated by hypertension with 70% caused by preeclampsia and 30% chronic essential hypertension. The American College of Obstetricians and Gynecologists Committee on Terminology defines hypertension in pregnancy as a systolic pressure ≥140, a diastolic ≥90, or a mean arterial blood pressure ≥105 mmHg. While gestational hypertension and chronic essential hypertension accompany pregnancy, preeclampsia/eclampsia causes most hypertension-related morbidity and mortality. Preeclampsia is characterized by edema, proteinuria, and new onset hypertension after 20 weeks gestation. Risk factors for preeclampsia are a primigravid state, multiple gestations, preexisting hypertension or diabetes, severe obesity, age >40 years, and the presence of antiphospholipid antibody syndrome. Its pathobiology is thought to be driven by maternal endothelial dysfunction. Hyperuricemia is common. HEELP syndrome (hemolysis, elevated liver enzyme levels, and a low platelet count), a fulminate form of preeclampsia, is characterized by hemolysis (LDH ≥ 600 IU/L), elevated liver enzymes and low platelets. Maternal morbidity and mortality from severe preeclampsia are the result of seizures (eclampsia), cerebral hemorrhage, brain edema, renal failure, liver infarction, liver hemorrhage or rupture, pulmonary edema, and placental abruption. Pulmonary edema is uncommon, typically occurring after parturition in the setting of overly aggressive fluid resuscitation.[13]

Fetal Delivery is usually curative treatment and should be pursued in cases of eclampsia, multisystem organ failure, and in patients greater than 34 weeks pregnant.

Chronic administration of antihypertensive medications does not appear to alter the progression of preeclampsia.

Complications of magnesium sulfate administration include respiratory depression, hypotension, and asystole, which may be potentiated by the use of calcium channel blockers. Reports from case series and small clinical trials have generated significant enthusiasm for the use of glucocorticosteroids in the treatment of patients with the HELLP syndrome. However, recent double-blind, placebo-controlled, randomized clinical trials do not support the use of glucocorticoids for the treatment of HELLP syndrome.[15,16] Plasma exchange therapy is used in cases refractory to medical therapy.

Antihypertensive medications such as hydralazine, labetalol, and nicardipine are used to prevent intracerebral complications.

Magnesium sulfate prophylaxis is effective in preventing and treating seizures and should be given to all preeclamptic and eclamptic women for at least 24 h postpartum.[14]

SHOCK

Hemorrhagic Shock

Massive uterine hemorrhage is the second leading cause of maternal death and ICU admission (all pregnancy and birth types). Frequent causes of uterine hemorrhage include placenta previa, placental abruption, uterine atony, and profound coagulopathies.

Prior to delivery, placental abruption (premature detachment of the placenta), placenta previa (malpositioned placental attachment), and uterine rupture are the primary causes of massive hemorrhage.

Pelvic trauma from assaults, falls, and motor vehicle accidents may lead to massive hemorrhage at any point during pregnancy.

Postpartum hemorrhage commonly results from uterine atony, uterine inversion, retained placental tissue, surgical trauma, and DIC subsequent to amniotic fluid embolism.

Cardiogenic Shock

Patients with Eisenmenger's syndrome, cyanotic congenital heart disease, and pulmonary hypertension have very high maternal mortality rates,and should, in most cases, be counseled against pregnancy.

Heart failure may arise from preexisting structural or valvular disease, or may arise de novo as observed with peripartum cardiomyopathy. The prevalence of heart disease complicating pregnancy is low. However, heart disease accounts for approximately 7% of maternal deaths after live births.

Mitral and aortic stenosis and left ventricular systolic dysfunction associated with poor functional class predict maternal complication.

When heart failure develops in the last month of pregnancy or within 5 months of delivery, in the absence of preexisting heart disease, it is called peripartum cardiomyopathy.

The onset of peripartum cardiomyopathy is typically abrupt, severe, and life-threatening. The diagnosis may be challenging in late pregnancy when the symptoms overlap with the symptoms of pregnancy. It occurs in 1 per 3,000–4,000 live births with an annual incidence in the US of 1,000–1,300 new cases. The cause of peripartum cardiomyopathy is unknown but is hypothesized to be inflammatory and immune-mediated. High titers of autoantibodies against normal human cardiac tissue proteins are found in the serum of peripartum vs. idiopathic dilated cardiomyopathy patients.[17-19] Several case series demonstrate variable presence of inflammatory myocarditis ranging from <10 to 78%. The variable timing of endomyocardial biopsy may account for a significant percentage of the variability.[17] Peripartum cardiomyopathy can occur in any pregnancy but is more likely in multiparous women over thirty and is strongly associated with gestational hypertension, tocolytic therapy and cesarean delivery and multifetal pregnancy.

Treatment of peripartum cardiomyopathy includes traditional afterload reduction and loop diuretics with the exclusion of ACE inhibitors until the fetus is delivered.

The diagnosis should be suspected in peripartum women with hypotension, shock, and less dramatic signs of heart failure, such as orthopnea, edema, weight gain, cough, and fatigue. Diagnosis depends upon the evidence of new systolic left ventricular function during the last month of pregnancy and the 5 months after delivery. Other causes of cardiomyopathy and shock must be excluded. Hemodynamic assessment with right heart catheterization and evaluation of coronary anatomy may be required. Venous thrombosis and pulmonary thromboembolism are more common in pregnancy and must be considered in the differential diagnosis or as a complicating diagnosis.

Approximately 50% of peripartum cardiomyopathy patients have a dramatic recovery soon after delivery. The others with lower ejection fraction and larger left ventricular cavity size at presentation face a 85% 5-year cardiac mortality rate.[20]

Continuous inotrope infusions and mechanical afterload reduction with intra-aortic balloon counter pulsation or ventricular assist devices may be required in the most severe cases.

Consultation of an advanced heart failure and heart transplantation specialist should be initiated rapidly for patients requiring intensive care unit level-of-care.

Septic Shock

In obstetric patients, most life-threatening infections are pelvic and require drainage or surgery.[22]

Septic shock in pregnant woman is rare and is less common in developed countries. The relative youth and the absence of chronic illness in obstetric populations decrease the incidence and severity of sepsis. Lack of access to prenatal care is strongly associated with increased risk for sepsis. The pelvis is frequently the site of infection including chorioamnionitis, endomyometriitis, urinary tract infections, septic abortions, and wound infections. Cesarean section is the most common risk factor for obstetric sepsis.[21] Asymptomatic bacturia, urinary tract infections, and pyelonephritis are more common in pregnancy and lead to sepsis. Pelvic infections are typically polymicrobial and responsive to treatment with broad spectrum antibiotics. In contrast to sepsis, in the general medical population, mortality is low.

Normal augmentation in maternal cardiac output and reduction in systemic vascular resistance in the second and third trimester mimic early septic shock.

Treatment decisions must account for microbiologic pathogens more common in obstetric patients with septic shock such as *Escherichia coli*, *Enterococci* and *Beta-hemolytic streptococci,* and anaerobes (e.g., *Peptostreptococci, Peptococci*, and *Bacteroides). Group B streptococcus* and *Listeria monocytogenes* are more common in pregnancy. Typical empiric therapy may include the synthetic penicillins, an aminoglycoside, and clindamycin. Delivery may improve maternal gas exchange through improved thoracic compliance and ventilation-perfusion matching. Maternal sepsis requiring mechanical ventilation is minimally studied, but existing data demonstrate a trend toward fetal delivery regardless of the cause of sepsis.[6] Early goal-directed therapy is discussed in detail in Chap. 27. It is important to recognize normal physiologic changes of pregnancy that may be confused for early sepsis physiology.

Normal increases in tidal volume and increased minute ventilation yield arterial oxygen content CaO_2 levels of 28–32 and serum bicarbonate levels of 19–22 mEq/L.

PULMONARY DISEASE

Asthma

A third of asthmatic women experience worsening of asthma control during pregnancy, and 18% will require at least one emergency department visit.[23] Those with most severe underlying disease are most likely to experience diminished control. Symptoms typically worsen during the second and third trimesters. Although most pregnant asthmatics do not require hospitalization, a minority experience life-threatening exacerbations. Severe asthma exacerbations during pregnancy are treated similarly to nonpregnancy exacerbations. The goals of medical therapy are to relieve bronchospasm and to avoid maternal hypoxemia and hypercapnia.

Most medications used to treat acute asthma exacerbations are considered safe for administration during pregnancy including systemic glucocorticoids, inhaled and intravenous beta-agonists, magnesium sulfate, heliox, and theophylline.

Systemic epinephrine is avoided. Supplemental oxygen should be administered in doses necessary to keep pulse oxymetry saturations >95% or a PaO_2 >60 mmHg. Recognize that a normal second and third trimester $PaCO_2$ is 27–32 mmHg. A similar value during an asthma exacerbation in a pregnant patient may signify impending respiratory failure. As $PaCO_2$ levels rise >35 mmHg, mechanical ventilation should be considered. The diffusion of CO_2 across the placenta is dependent upon a fetal-maternal circulatory gradient of approximately 10 mmHg. Severe maternal hypercapnia ($PaCO_2 > 40$ mmHg) results in fetal acidosis and a shift of the fetal hemoglobin dissociation curve to the right. This compromises fetal hemoglobin oxygen binding and fetal oxygen delivery, and contributes to fetal distress. Intubation and mechanical ventilation are indicated to prevent maternal and fetal acidosis, regardless of satisfactory oxygenation. Ventilation strategies employed to limit autopeep and dynamic hyperinflation in life-threatening asthma result in purposefully elevated $PaCO_2$ levels (permissive hypercapnia). Dynamic hyperinflation results in high intrathoracic pressures, high airway pressures, and decreased central venous blood flow resulting in hypotension. Maternal hypotension compromises fetal blood flow. Fetal risk complicates the choice of ventilation strategy in severe asthma exacerbation in pregnancy.

ARDS

Acute respiratory distress syndrome (ARDS) occurs uncommonly in pregnant patients, but with high risk of maternal and fetal mortality. Causes include those typical in nonpregnant patients and can be reviewed in Chap. 16.

Several causes of ARDS and risk factors are unique to pregnancy. Amniotic fluid embolism, air embolism, ovarian hyperstimulation syndrome (OHSS), tocolytic-induced pulmonary edema, and preeclampsia may result in ARDS.[24] Aspiration of gastric contents (Mendelson's syndrome) occurs with greatest risk during labor and delivery because of decreased esophageal sphincter tone, delayed gastric emptying, and increased gastric pressure.

Magnesium sulfate and Trendelenburg and supine positioning used to delay labor increase the aspiration risk. Treatment of ARDS in pregnancy is the same as in nonpregnant patients with the addition of the medical and obstetrical decision of when to deliver the fetus. Pregnancy increases the oxygen demands and decreases maternal thoracic compliance. Generally, maintaining a maternal $PaO_2 \geq 90$ will avoid fetal distress. Maternal positioning in a left lateral position will relieve inferior vena cava and aortic compression, and improve venous return, cardiac output, and both maternal and fetal tissue perfusion. Pharmacologic therapy for ARDS is similar in pregnancy. Antibiotics must be chosen carefully. Benzodiazepines may cause cleft palate deformities if used in the first trimester. Nondepolarizing neuromuscular blocking agents, narcotics, and vasopressors are generally safe. Case reports demonstrate the use of inhaled nitric oxide (INO) in pregnant patients with life-threatening pulmonary arterial hypertension. While it is generally assumed that INO is immediately bound and metabolized in the adult lung, there is no data demonstrating the effects of INO on fetal outcomes.

Venous Thromboembolism

Venous thromboembolism is the leading cause of maternal death (21% after live birth) during and shortly after pregnancy.[7] The relative risk of VTE increases by 4.29 among pregnant and postpartum woman.

The greatest maternal risk of venous thromboembolism occurs in the postpartum period.

Massive pulmonary embolism producing obstructive shock and hypoxemia is a life-threatening emergency. In this setting, TPA has been used when benefits of treatment are thought to outweigh the risks of maternal and fetal hemorrhage, teratogenesis, and fetal demise.[26]

The postpartum annual incidence of VTE is five times higher than during pregnancy (511.2 vs. 95.8 per 100,000).[25] Additional maternal risk factors are age >35 years, obesity, cesarean section, and a family history of thrombosis. The majority of deep venous thrombosis of pregnancy originates in the left ileofemoral veins and has high embolic potential. A high index of suspicion is required for VTE during all phases of pregnancy. All diagnostic tests available to nonpregnant patients can be applied during pregnancy. Compressive venous ultrasound has less negative predictive value later in pregnancy and will miss DVT in deep pelvic veins. Iliac vein DVT may be most effectively exclude by magnetic resonance imaging.[26] Contrast venography is the accepted diagnostic gold standard but is rarely utilized because it is invasive and involves radiation exposure. Helical CT angiogram with fetal shielding is safe during any trimester and exposes the fetus to low and safe doses of ionizing radiation.[27] Alternatively, ventilation-perfusion scanning is an appropriate first test to evaluate pulmonary embolism. D-dimer has little negative predictive value in pregnancy. Low molecular weight heparin is preferred for long-term therapy with transition to IV unfractionated heparin prior to labor. Warfarin is generally contraindicated during pregnancy. However, recent studies demonstrate acceptably low rates of fetal embryopathy when warfarin is avoided between weeks 6 and 12 of gestation.[28] Heparin and recombinant tissue plasminogen activator do not cross into fetal circulation.

TPA is generally avoided at term. Other therapeutic considerations include emergent surgical embolectomy in patients who cannot receive TPA and inferior vena cava filters in patients with persistent lower extremity clot burden. Updated ACCP guidelines for prophylaxis and treatment of venous thromboembolism in pregnancy are recently published.[28]

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare catastrophic complication of pregnancy that typically occurs in association with labor and delivery, amniocentesis, placental abruption, or abortion. The incidence is 1 in 8,000 to 1 in 80,000 pregnancies, with an associated 80–90% mortality. The clinical presentation is similar to septic or anaphylactic shock. There is an abrupt onset of hypoxia, hypotension, altered cognitive function, and disseminated intravascular coagulation. Hypoxemia, hypotension, and shock are universal. These findings typically present together and suddenly within the 48 h after delivery.[29] The fulminate course results in death rate of 50% in the first hour due to cardiovascular collapse. Other common presenting signs and symptoms include seizures, agitation, fevers, chill, nausea, vomiting, and headache. A high index of suspicion is paramount. The majority (70%) who survive the initial period of cardiovascular instability will develop ARDS. Transient left ventricular dysfunction is common. Diagnosis is clinical and of exclusion. The appropriate clinical setting is supportive of the diagnosis. Aspirated fetal lanugo hairs or squamous cells from a pulmonary artery catheter placed in the maternal circulation may lend support to the diagnosis. However, these are present under normal circumstances and have no significant positive or negative predictive value. A PA catheter should not be placed for the purpose of obtaining circulating fetal debris, but should be placed if needed to guide supportive measures. Uncertainty about the cause of pulmonary edema in an obstetric patient frequently slows decision-making. When alveolar flooding and gas exchange do not improve with initial therapy, invasive hemodynamic monitoring is indicated. Other treatment is supportive including invasive mechanical ventilation, sedation, paralytics, and vasopressors. Hemorrhage may necessitate blood component therapy.

Initial treatment of venous air embolism includes positioning in the left lateral decubitus or Trendelenburg position, which permits the air to migrate away from the right ventricular outflow tract to a nonobstructing position. Ventilation with 100% oxygen increases the gradient for egress of nitrogen from the bubble.

Venous Air Embolism

Venous air embolism originating from air being entrained into subplacental venous sinuses can occur during normal delivery, abortion, gynecologic procedures using air insufflation, and during oral-genital sex; the presence of placenta previa increases the risk. Air entering the pulmonary circulation can obstruct blood flow. The pulmonary arterial pressure

increases and increased right ventricular afterload decreases pulmonary venous return and left ventricular filling. Acute systemic cardiovascular collapse may result. Volumes ≥50 mL are likely to produce acute right heart failure and/or asystole.[30] Neutrophilic activation and precipitation of microemboli at the site of air embolization account for significant local injury and obstruction. The incidence of air embolism is difficult to estimate; however, 1% of maternal deaths are likely secondary to venous air embolism. Patients present with hypotension and nonspecific respiratory complaints, which may progress to respiratory failure. Severe cases can produce seizure, stroke, and thrombocytopenia, and progress to ARDS similar to amniotic fluid embolism. A classic precordial mill-wheel splashing murmur is rarely heard. Both the left lateral decubitus position (Durant's maneuver) and the Trendelenburg position can restore forward blood flow by placing the right ventricular outflow tract inferior to the right ventricular cavity, permitting air to migrate superiorly to a nonobstructing position.

Case reports demonstrate successful aspiration of air from the right heart through central venous catheters. Arterial gas embolism may occur as a result of paradoxical embolism and should be considered if acute neurologic signs accompany an appropriate clinical situation. Hyperbaric oxygen is the first-line treatment for arterial gas embolism.

Tocolytic-Induced Pulmonary Edema

Tocolytic-induced pulmonary edema should be considered when hypoxemia develops in women receiving intravenous therapy to forestall preterm labor.

Tocolytic-induced pulmonary edema complicates the care of 4.4% of patients receiving B-adrenergic agents to inhibit preterm labor. Most reported cases involve the intravenous administration of terbutaline, salbutamol, isoxuprine, and ritodrine. Dyspnea and hypoxemia may begin during or within hours of withdrawal of intravenous tocolytic therapy. Risk factors parallel risk for preterm labor such as twin gestation, multiparous state, and include volume overload and anemia.[31] The mechanism is likely related to increased hydrostatic pressure. B-adrenergic agents decrease peripheral vascular resistance and, upon withdrawal, cause a dramatic rise in cardiac afterload.[32]

Treatment involves stopping tocolytic therapy if it is still being administered. Hypoxemia and symptoms are treated with oxygen and diuretics. Noninvasive continuous positive pressure ventilation should be applied in hypoxemic patients to improve gas exchange and, if possible, to avoid invasive ventilation. Rapid resolution within hours is anticipated.

Ovarian Hyperstimulation Syndrome

Ascites, pleural and pericardial effusions, rapid intravascular volume depletion, hemoconcentration, and shock with organ failure account for most morbidity and mortality.

OHSS is a potentially fatal iatrogenic complication of ovarian induction resulting from almost every agent used for ovarian stimulation. OHSS may occur early or late in response to the patients' human chorionic gonadotropin response to stimulation. Marked ovarian enlargement may result in overproduction and release of angiotensin and cytokines such as vascular endothelial growth factor. Clinical manifestations relate to increases in capillary membrane permeability, arterial dilatation, and massive extravascular fluid shifts. Extravasated protein rich fluid accumulates in interstitial and potential spaces.

Therapeutic paracentesis, thoracentesis, and pericardiocentesis should be performed to relieve hemodynamic and respiratory embarrassment.

Pulmonary manifestations often include hydrothorax, lobar pneumonia, pulmonary embolism, atelectasis, and less often ARDS. Intravascular depletion of IgG and IgA may increase the risk for secondary infection. Thromboembolism complicates approximately 10% of severe OHSS. The prevalence of OHSS ranges from 0.5 to 5% of stimulated ovarian cycles.[33] Treatment is supportive and aimed at maintaining effective circulating plasma volume. Volume expansion with normal saline is preferred. Dextran and fresh frozen plasma have limited data to support their use in severe OHSS).[34]

Care should be taken to avoid rupture of large ovarian cysts. Therapeutic interest exists in nonsteroidal anti-inflammatory drugs, anti-histamines, and ACE inhibitors; though uncontrolled trials exist, none of these therapies has been rigorously studied. Clinical resolution typically parallels the decline in hCG levels and resolves in 2–3 weeks in moderate cases. Severe OHSS, especially when pregnancy results, may progress to life-threatening disease.[33]

HEPATIC DISEASE

Minor liver function test abnormalities are physiologically normal during pregnancy. Rarely acute pregnancy-related liver disease is life-threatening. As noted earlier in this chapter, the HELLP (hemolysis, elevated liver enzyme levels, and a low platelet count) syndrome is a complication of preeclampsia that is characterized by endothelial dysfunction, microvascular hemolysis, and liver injury. Laboratory abnormalities include elevated bilirubin levels, LDH >600 IU/L, AST and ALT > 70 IU/L, and platelets <150,000/mL. Nausea, vomiting, and epigastric pain are independent risk factors for complicated severe preeclampsia. LDH level >1,400 IU/L, AST > 150 IU/L, ALT > 100 IU/L, uric acid >7.8 mg/dL, and 4+ urinary protein predict high risk for maternal morbidity and mortality. Late hepatic complications include parenchymal necrosis, hepatic infarction, and rupture. Focused attention is necessary to rule out other diagnosis such as TTP, HUS, and systemic lupus erythematosus. Delivery is the definitive treatment. Corticosteroids, magnesium, and antihypertensive medications aid in fetal lung maturation and prevention of maternal neurologic dysfunction.

Acute fatty liver of pregnancy (AFLP) is uncommon but dangerous with an 18% maternal mortality. An enzymatic deficiency alters maternal fatty acid oxidation, leading to toxic levels of long chain fatty acids in the liver. Presenting features are frequently nonspecific including nausea, vomiting, fatigue, and vague abdominal pain. As the disease progresses, encephalopathy, renal failure, and hypoglycemia are more common. Fifty percent of patients will have features of preeclampsia. Marked elevation of bilirubin distinguishes AFLP from preeclampsia.

Acute thrombosis of the hepatic vein (Budd Chiari Syndrome) occurs in women with underlying thrombophylic disorders. Presenting features include abdominal pain, ascites, and jaundice. Treatment is anticoagulation with heparin. If complicated by liver failure, surgical decompression or transjugular intrahepatic portosystemic shunt may be necessary. Some may progress and require liver transplantation.

Most patients with acute hepatitis B infection recover with supportive care, while 0.5–1.5% develop fulminate liver failure. Viral hepatitis E is more virulent in pregnant women and confers a 10–20% maternal mortality.[35] There is a national registry for pregnancy after solid organ transplantation.

SUMMARY

Critical illnesses in pregnant woman may be unique to pregnancy, such as amniotic fluid embolism, peripartum cardiomyopathy, and HELLP syndrome. However, the full spectrum of admitting diagnoses seen in a medical ICU may beset pregnant women. This population is generally young and healthy, although advances in maternal medicine have allowed women with chronic illness and older women to conceive and carry a pregnancy to term. Critically ill obstetric patients receive care in obstetric or medical intensive care units depending on the nature of the illness, resources of the hospital, and the training of the obstetrical physicians. Maternal critical care medicine poses the unique challenges of providing optimal critical medical care for the mother, and when possible, preserving the health of a viable fetus. Effective ICU care for the obstetric patient is delivered by teams of physicians with training and expertise in critical care medicine, obstetrics, and knowledge of the basic cardiac, pulmonary, and circulatory changes that occur during pregnancy.

REVIEW QUESTIONS

1. **Respiratory failure leading to invasive mechanical ventilation in obstetrical patients is most commonly a result of:**
   - **A.** Pneumonia
   - **B.** Asthma exacerbation
   - **C.** Preeclampsia/eclampsia
   - **D.** Labor and delivery
   - **E.** ARDS

2. **All of the following are physiologic changes of pregnancy except:**
   - **A.** Increased plasma volume
   - **B.** Increased cardiac output
   - **C.** Decreased $PaCO_2$
   - **D.** Decreased systemic vascular resistance
   - **E.** Decreases tidal volume

3. **What is the optimal body position for a hypotensive patient who is 30 weeks pregnant?**
   - **A.** Supine
   - **B.** Trendelineberg
   - **C.** Left lateral decubitus
   - **D.** Prone
   - **E.** Seated with arms braced

4. **All of the following statements concerning peripartum cardiomyopathy are true except:**
   - **A.** Defined by new systolic left ventricular dysfunction during the last month of pregnancy and the first 5 months after delivery
   - **B.** Caused by unrecognized pulmonary arterial hypertension
   - **C.** Symptoms may overlap with symptoms of late pregnancy
   - **D.** Occurs in approximately 1 per 3,500 live births in the US
   - **E.** Approximately 50% recovery dramatically soon after delivery

5. **Which of the following conditions is not associated with ARDS in obstetrical patients?**
   - **A.** Amniotic fluid embolism
   - **B.** Air embolism
   - **C.** Venous thromboembolism
   - **D.** Ovarian hyperstimulation syndrome
   - **E.** Tocolytic-induced pulmonary edema
   - **F.** Preeclampsia
   - **G.** Aspiration of gastric contents (Mendelson's syndrome)

ANSWERS

1. The answer is C. All of the responses are associated with respiratory failure in the obstetrical patient. Nearly half of all cases of respiratory failure are due to complications of preeclampsia and eclampsia, followed by labor and delivery (14%) and pneumonia (12%). The average gestational age at the time of respiratory failure is 31.6 weeks. The need for prolonged mechanical ventilation in obstetrical patients is uncommon.
2. The answer is E. Pregnancy-induced increases in progesterone increase tidal volume by 30–35% early in pregnancy. Minute ventilation remains elevated throughout pregnancy as a result of increased tidal volumes. A mild chronic compensated respiratory alkalosis is a normal consequence of pregnancy. Plasma volume and cardiac output increase by as much as 50% with a concomitant decrease in systemic vascular resistance.
3. The answer is C. After the 24th week of pregnancy, placing the patient in the left lateral decubitus position can improve maternal blood pressure and placental blood flow. In the supine position the gravid uterus compresses the inferior vena cava and the aorta, which leads to a decreased venous return, cardiac output, and blood pressure. This negative effect is most profound in the volume-depleted patient. The Trendelineberg position is a modified supine position that does not overcome the negative central venous effects. There is no role for the prone or seated position in a hemodynamically unstable patient.
4. The answer is B. Pulmonary arterial hypertension is not implicated in the pathogenesis of peripartum cardiomyopathy. The cause of peripartum cardiomyopathy is unknown; however, recent evidence of circulating autoantibodies against normal human cardiac tissue protein in the serum of peripartum cardiomyopathy patients has lead to an autoimmune hypothesis.
5. The answer is C. Venous thromboembolism is not associated with ARDS. Massive pulmonary embolism may produce hypoxemia, shock, and increased dead space ventilation. Peripheral emboli may lead to infarction and hemoptysis; however, ARDS is not an anticipated consequence of VTE. The other choices are either unique to pregnancy or of increased likelihood in pregnancy. The critical care physician must be aware of these diagnostic possibilities. Their presentations may be sudden and potentially catastrophic.

Modes of Mechanical Ventilation: Part 1

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the indications for mechanical ventilation, distinguishing hypercapnic vs. hypoxemic respiratory failure.
- Recognize the various modes of mechanical ventilation and their specific indications.
- Recognize alternate modes of mechanical ventilation and adjunctive therapies.

INTRODUCTION

The origin of mechanical ventilation can be traced back to Galen who initially described ventilating animals for vivisection purposes. During the eighteenth century, delivery of air to the lungs with a bellows was used to resuscitate near-drowning victims. This early technique of applying positive pressure to the victim's lungs fell into disfavor by 1827 after several experiments by Leroy showed that this method of resuscitation leads to the development of pneumothorax. For the next 100 years, external devices that provided cyclical periods of negative pressure to the thorax to achieve lung inflation were developed. These initial devices led to the development of the "iron lung" by Phillip Drinker in the 1920s. The iron lung remained the mainstay of therapy for respiratory failure outside of the operating room until the 1950s and was primarily used to support patients with poliomyelitis-induced respiratory failure.

During the 1952 polio epidemic in Denmark, the number of polio patients with respiratory failure far outnumbered the availability of negative pressure ventilators. Ibsen, an

anesthesiologist from Copenhagen, provided an alternate mode of respiratory support. He ventilated a 12-year-old girl through a tracheostomy tube with positive pressure generated by manual compression of a rubber bag. As a result, positive pressure ventilation was applied to other polio patients, with teams of medical students manually providing ventilation throughout the epidemic. Mechanical ventilators were soon designed to provide positive pressure ventilation to the lungs, with the earliest machines designed by Engstrom to deliver a preset volume of gas from a piston-driven cylinder at a preset rate.

Over the last 50 years, mechanical ventilation has become an essential life-support therapy and is widely used to treat a diverse array of diseases causing respiratory failure. A significant evolution in mechanical ventilators has occurred during this time that has contributed to improved patient comfort and enhanced survival. This review provides the reader with basic knowledge of the mechanics and physiology of mechanical ventilation, as well as insight into the more complex modes of mechanical ventilation and their application in specific disease processes.

INDICATIONS FOR MECHANICAL VENTILATION

Mild-to-moderate hypoxemia can be managed by delivery systems such as nasal cannula or facial mask.

Endotracheal intubation provides a stable airway and may avoid the need for mechanical ventilation during hypoxemic respiratory failure.

Mechanical ventilation recruits collapsed lung units, improves ventilation and perfusion mismatching, decreases work-of-breathing, and unloads the respiratory muscles.

The indications and settings of mechanical ventilation are best understood after characterizing the causes of respiratory failure into hypoxemic and hypercapnic components (Table 44-1). Hypoxemia of mild-to-moderate severity can often be managed by the administration of oxygen through delivery systems ranging from a nasal cannula to facemask. With more severe hypoxemia caused by shunt or ventilation–perfusion mismatch, it may become increasingly difficult to maintain adequate oxygenation (PaO_2) and oxygen delivery (DO_2). Securing a stable airway via endotracheal intubation may be sufficient to improve oxygenation and avoid the need for ventilation in the setting of hypoxemic respiratory failure, thereby ensuring adequate delivery of inspired oxygen and removal of airway secretions. However, in many cases of acute hypoxemic respiratory failure, institution of positive pressure ventilation is required in addition to intubation to improve oxygenation. Positive pressure ventilation, delivered either by a manual method (see Chap. 2), or noninvasive ventilation (see Chap. 46), or intubation with mechanical ventilation, may recruit collapsed lung units, improve ventilation and

TABLE 44-1

INDICATIONS FOR MECHANICAL VENTILATION

- *Hypercapnic respiratory failure*
  - Increased respiratory workload
    - Increased resistive workload (i.e., asthma, airway obstruction)
    - Increased elastic workload (i.e., pulmonary fibrosis, pneumonia, or congestive heart failure)
    - Metabolic acidosis
    - Increased CO_2 production
    - Secretions
  - Impaired respiratory central drive
    - Sedation
    - Idiopathic central alveolar hypoventilation
    - Brainstem injury
  - Impaired respiratory muscle function
    - Mechanical disadvantage
      - Chest wall deformity
      - Dynamic hyperinflation (i.e., chronic obstructive pulmonary disease [COPD])
    - Muscle weakness
      - Electrolyte abnormalities
      - Myopathies
      - Neuropathies
      - Deconditioning
- *Hypoxemic respiratory failure*
  - Ventilation–perfusion imbalance
  - Right-to-left shunt
  - Alveolar hypoventilation
  - Diffusion deficit
  - Inadequate inspired oxygen

CASE STUDY: PART 1

A 35-year-old male presents to the emergency room (ER) with 2–3 days of fever, cough, and purulent sputum. The patient has a known history of asthma and also reports increased wheezing and shortness of breath that preceded the fever. On arrival in the ER, he appears to be in mild respiratory distress with minimal increased work-of-breathing. Vital signs were as follows: T=101°F, P=139 beats/min, BP=80/55 mmHg, RR=30 breaths/min, and S_pO_2=92% on 6 L/min of nasal cannula oxygen. Pertinent physical exam findings include diffuse wheezing bilaterally with egophony and bronchial breath sounds in the right midlung field. CXR shows dense right middle and lower lobe infiltrates with air bronchograms present, and an arterial blood gas reveals respiratory alkalosis (pH 7.49, P_aCO_2 28 mmHg, P_aO_2 of 60 mmHg with a saturation of 90% on 6 L/min of oxygen). The patient is diagnosed with an asthma exacerbation secondary to acute community acquired pneumonia, and is treated with parenteral antibiotics, oxygen, intravenous fluids, bronchodilators, and systemic corticosteroids.

perfusion matching, and decrease the work-of-breathing, while simultaneously decreasing oxygen utilization by unloading the respiratory muscles.

Another group of patients who are candidates for mechanical ventilation are those that are described as "tiring out" or developing respiratory muscle fatigue. These patients may have clinical findings that include nasal flaring, recruitment of the accessory muscles of respiration (sternocleidomastoid and intercostal muscles), paradoxical or asynchronous movements of the rib cage and abdomen, and an increased pulsus paradoxus. Patients develop an increased respiratory workload as a result of increased airway resistance in the setting of upper airway obstruction, copious secretions, acute asthma, or an exacerbation of chronic obstructive pulmonary disease (COPD). In COPD and asthma patients, hyperinflation may further contribute to increased work-of-breathing by placing the respiratory muscles at mechanical disadvantage. Decreased lung compliance as found in congestive heart failure, the acute respiratory distress syndrome (ARDS), or decreased chest wall compliance in kyphoscoliosis or circumferential skin burns over the chest are other conditions that may contribute to an increased respiratory workload.

Patients developing respiratory muscle fatigue may exhibit nasal flaring, accessory muscle use, paradoxical movements of the rib cage and abdomen, and increased pulsus paradoxus.

Decreased lung and chest wall compliance may contribute to an increased respiratory workload.

If the ventilatory workload progressively increases, breathing demand will, at some point, exceed respiratory pump capabilities. As a result, patients will be unable to sustain adequate levels of ventilation to effectively eliminate CO_2, and progressive hypercapnic respiratory failure will ensue. Under conditions of high respiratory workload, the oxygen cost of breathing may increase to more than 50% of total oxygen consumption; and the respiratory muscles will disproportionally consume oxygen at the expense of other organs, such as the brain, heart, and kidneys. Under these circumstances, mechanical ventilation will reduce the oxygen cost of breathing, by decreasing the respiratory pump demands, and allow for restoration of oxygen delivery to other organs.

At high respiratory workloads, the oxygen cost of breathing may increase to more than 50% of total oxygen consumption.

Mechanical ventilation decreases the oxygen cost of breathing.

In the setting of acute hypoxemic or hypercapnic respiratory failure, the primary goals are to maintain an adequate oxygen delivery by providing sufficient levels of oxygenation, while decreasing the work-of-breathing, and simultaneously providing cardiac and metabolic stability. If the underlying respiratory pathology is only transient or readily reversible, ventilation may be achieved through noninvasive modes of ventilation (see Chap. 46). Patients who exhibit altered mental status or cardiac or airway instability, or have copious secretions, are poor candidates for noninvasive ventilation and require endotracheal intubation and positive pressure ventilation.

Noninvasive ventilation is an option in patients with transient or readily reversible causes of respiratory failure.

PRINCIPLES OF MECHANICAL VENTILATION

The Ventilator

The mechanical ventilator comprises a pneumatic system that delivers breaths to the patient via flexible tubing connected to endotracheal or tracheostomy tubes (Fig. 44-1). The earliest ventilators delivered a set volume of air to the patient by means of a bellows or pneumatic piston. The pneumatic system of modern ventilators is powered by a pressurized gas source

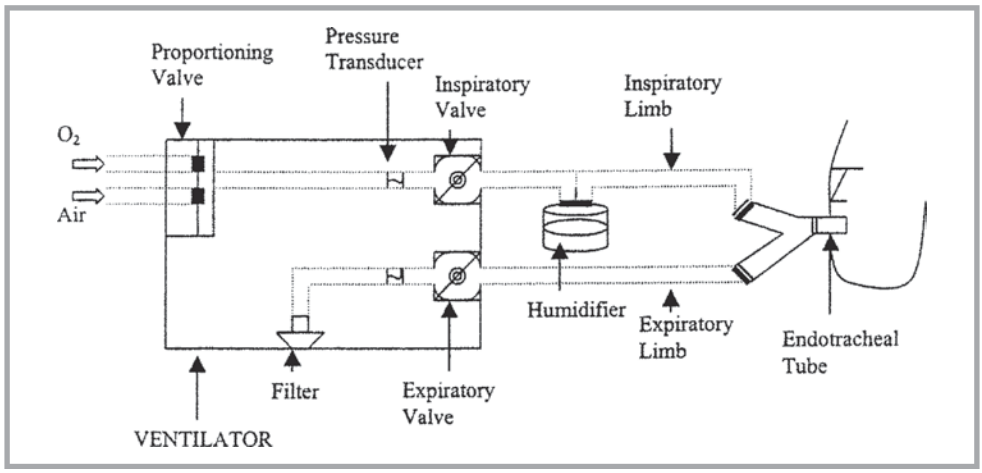

FIGURE 44-1

Schematic of a mechanical ventilator. Pressurized air and oxygen are delivered into the ventilator. A proportioning valve achieves the blend of oxygen and air specified by the operator. The amount of pressure and flow delivered to the patient is controlled by one of several mechanisms (piston, compressor bellows, or proportional solenoid), in this case a flow-control valve. The mixture of air and oxygen is warmed, humidified, and then delivered to the patient by an inspiratory circuit. The exhaled gas is expelled through the expiratory circuit and filtered before being released to the ambient air.

providing oxygen and medical air. To avoid harm to the patient and to minimize wear on the ventilator components, the initial pressure is regulated within an acceptable range of working pressures. A proportioning valve achieves the specific blend of oxygen and medical air chosen by the operator. Control valves then regulate the volume, pressure, and flow from the gas source to achieve the desired mode of ventilator support. Before delivering a breath to the patient, the gas is humidified, warmed, and filtered.

Mechanical ventilator breaths are humidified, warmed, and filtered before delivery to the patient.

The inspiratory and expiratory circuits contribute to the overall airway resistance. Because of the elastic nature of the inspiratory limb, a portion of energy of the ventilator breath is displaced within the tubing. The amount of energy dispersed depends on the compliance and resistance of the ventilator circuit. For example, when a patient is intubated with a small endotracheal tube (6 mm internal diameter), there is a greater amount of energy displaced within the endotracheal tube compared to a larger endotracheal tube (8.5 mm internal diameter) due to the increased resistance of flow through the smaller endotracheal tube. The expiratory circuit remains closed during inspiration. When the inspiratory cycle is completed, a valve in the expiratory circuit opens to atmospheric pressure with the exhaled gases passing through a filter and venting outside the ventilator. The exhalation valve, which is closed during inspiration, is responsible for regulating the level of extrinsic positive end-expiratory pressure (PEEP).

Modern ventilators usually incorporate a microprocessor that controls the inspiratory and expiratory valves; the microprocessor also controls information that is monitored, displayed, and used in the alarm settings. In the event of pneumatic failure, a valve opens in the inspiratory limb, allowing the patient to breathe room air. In the event of electrical or pneumatic failure, some ventilators open both the inspiratory and expiratory valves so that gas flows throughout the circuit's inspiratory and expiratory limbs, thereby preventing CO_2 rebreathing, dynamic hyperinflation, or intrinsic PEEP.

Classification of Ventilators

To understand mechanical ventilation, it is necessary to understand some of the terms commonly used in regard to ventilators and their functions. Before discussing the available modes of mechanical ventilation, it is important to review basic concepts that allow us to classify and differentiate mechanical ventilators.

Control Variables

Control variables refer to those variables that the ventilator manipulates to deliver a breath. These variables are intimately related, and this relationship is expressed in the simplified equation of motion:

The variable that the ventilator manipulates to deliver a breath is called the control variable.

$$P_{mus} + P_{vent} = \frac{\Delta Volume}{Compliance} + Flow \times Resistance \quad (44\text{-}1)$$

where P_{mus} is the pressure exerted by the respiratory muscles and P_{vent} is the pressure exerted by the ventilator. The right side of the equation simply states that the pressure generated by the combination of respiratory muscles and ventilator results in a volume displacement, which is opposed by the respiratory system's compliance, and flow, which is opposed by the respiratory system's resistance. The equation of motion further illustrates that ventilators can only control one variable at a time, either pressure, volume, flow, or time. The controlled variable becomes the independent variable and the others will be dependent variables. For example, if a ventilator delivers pressure, the pressure applied to the respiratory system and its opposing forces, namely resistance and compliance, will determine flow and volume. Thus, ventilators are classified as flow, pressure, or volume controllers.

At a particular point-in-time, ventilators can only control a single variable, pressure, flow, volume, or time.

Phase Variables

The period between the beginning of one breath and the beginning of the next one is called a cycle. The events within a cycle, that is, the beginning, duration, and end of a breath, are determined by the so-called phase variables.

Trigger

To initiate a breath, the ventilator must recognize that a preset value has been reached. The trigger or initiating variable can be time, so that after a certain amount of time has elapsed, the ventilator will deliver a breath. Ventilators can also be triggered by the patient's effort (Fig. 44-2). Traditionally, ventilators have been triggered by pressure; in this case, the patient must exert a predetermined amount of negative pressure to elicit a ventilator-assisted breath (–1 to –5 cm H_2O). More recently, alternatives such as flow and volume triggering have become available. In flow triggering, the patient's effort decreases the bias flow in the ventilator circuit by a determined value (1–3 L/min), which then initiates a breath. Flow triggering results in less work for the patient and a faster ventilator response time.

Ventilator breaths are triggered by exerting a determined pressure or achieving a specific volume or flow.

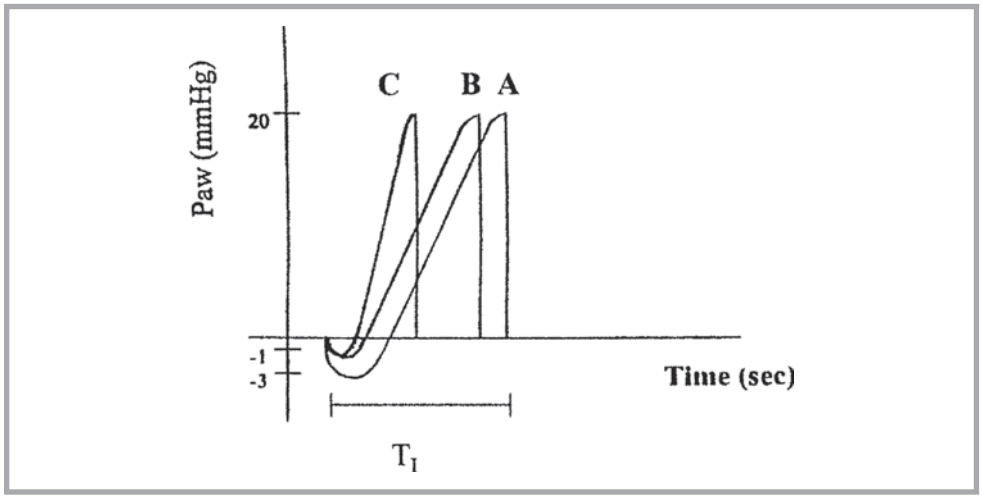

FIGURE 44-2

The effect of sensitivity and inspiratory flow rate on inspiratory time (T_I). In pressure curve *A,* the ventilator was triggered at a sensitivity of −3 cm H_2O. Curves *A* and *B* have the same inspiratory flow rate (notice the slope of the curve is the same, but the ventilator was triggered at −1.5 cm H_2O, which resulted in a shorter T_I. The sensitivity in *A* and *B* is the same, but the inspiratory flow rate is greater in *C,* resulting in a further decrease in T_I.

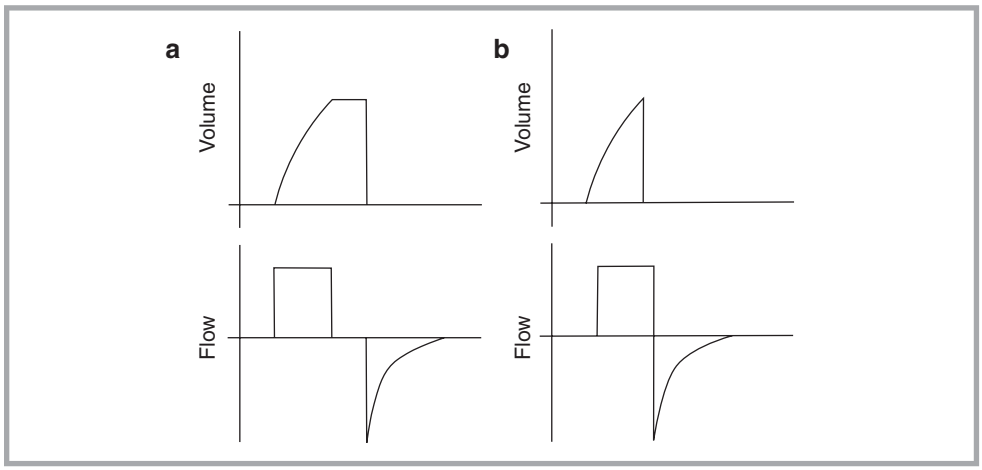

FIGURE 44-3

The difference between limit and cycle. (**a**) Both flow and volume are limited (they reach preset values before end-inspiration) and the inspiration is time-cycled (after an inspiratory pause ends). (**b**) Flow is limited because it reaches its maximal value without ending the cycle, and the inspiration is volume-cycled. Note expiration starts once volume has reached a preset maximum.

Limit and Cycle

The terms limit and cycle are frequently confused. For our purposes, if a variable such as pressure reaches a preset value and causes inspiration to end, it is called a cycle variable. If the preset value is reached without causing inspiration to end, it is called a limit variable (Fig. 44-3).

Breath Types

When a patient determines the beginning, duration, and end of a ventilator-assisted breath, it is called spontaneous breathing.

Breath types can be classified in several different ways. A breath is said to be spontaneous if the patient determines its beginning, duration, and end. If the ventilator controls any of these aspects, the breath is termed mandatory or controlled.

Modes of Mechanical Ventilation

The mode of mechanical ventilation describes a particular set of characteristics or control and phase variables (cycle, trigger, and limit) that define how ventilation is provided. It allows clinicians to communicate how ventilatory support is being delivered via a short and concise format.

Setting the Ventilator

Fractional Inspired Oxygen Concentration (FiO_2)

To raise the level of PaO_2, the physician can increase the ventilator-delivered volume or increase the FiO_2.

FiO_2 should be rapidly titrated to minimize possible O_2 toxicity.

The principal means by which the physician increases PaO_2 is to raise the FiO_2 or the mean airway pressure. An increase in mean airway pressure increases oxygenation by increasing the lung volume at which the lungs are ventilated. If a patient shows appropriate oxygen saturation with a particular level of FiO_2 before intubation, a similar FiO_2 can be used as an initial setting; otherwise, it is generally acceptable to initiate ventilatory support with a FiO_2 of 1.0. FiO_2 should subsequently be reduced to minimize the potential for O_2 mediated lung toxicity, particularly in patients who are receiving concomitant treatment with drugs such as amiodarone or bleomycin, which can enhance the toxic effects of oxygen.

Tidal Volume (V_T)

To decrease alveolar over distension, delivered tidal volumes should be set between 6 and 10 mL/kg.

Tidal volumes of 10–15 mL/kg were traditionally used to ventilate patients. In the past decade, however, data have demonstrated that these volumes may cause alveolar over distension, alveolar fracture, and ventilator-induced lung injury (VILI). Some investigators currently suggest using tidal volumes between 6 and 10 mL/kg of lean body weight. It has been shown that survival is improved when V_T is set at 6 mL/kg in ARDS,[1] but whether or not this strategy should be extended to all patients is less clear. Gajic et al. attempted to answer this question in a retrospective chart review of patients admitted to an academic medical center

with respiratory failure, who were considered at risk for developing acute lung injury (ALI) or ARDS. They studied the risk factors for developing ALI and found that higher tidal volumes resulted in an increased risk for developing ALI (OR 1.29, CI 1.12–1.51).[2] Further studies examining this question prospectively are needed because these new "protective ventilator strategies" may not be applicable in patients with conditions resulting in decreased chest wall compliance such as kyphoscoliosis, large pleural effusions, and obesity. Setting tidal volumes lower in these patients will result in increased work-of-breathing, atelectasis, hypoventilation, and poor synchrony with the ventilator.

Positive End-Expiratory Pressure (PEEP)

PEEP is applied to the patient via the exhalation valve of the ventilator and is one of the clinician-chosen variables. PEEP recruits alveoli and helps to prevent alveolar collapse, which in turn decreases ventilation/perfusion (V/Q) mismatch and intrapulmonary shunt, thereby improving oxygenation. PEEP is typically set at 5 cm H_2O and titrated according to the clinical situation. More is discussed about PEEP later in this chapter.

Inspiratory Flow Rate

The inspiratory flow rate, measured in liters per minute (L/min), determines how fast a V_T is delivered. The inspiratory time (T_I) is a function of V_T and flow rate:

$$T_I = V_T(L)/\text{flow rate (1/min)} \quad (44\text{-}2)$$

Expiratory time during mechanical ventilation is determined by the ventilator settings of inspiratory time and respiratory rate.

The expiratory time (TE) is determined by the inspiratory flow rate and the ventilator's frequency. For a set rate of 10 breaths/mm, the total respiratory cycle time (T_{tot}) is 6 s. The TE can be determined by subtracting T_I from T_{tot}. The flow rate may also be altered during the inspiratory cycle by the use of a specific inspiratory flow pattern. Types of inspiratory patterns include rectangular, ascending ramp, descending ramp, and sinusoidal waveforms. The square waveform results in a low *I*:*E* ratio at the expense of high peak inspiratory pressure, the decelerating ramp waveform results in the highest *I*:*E* ratio with a low peak inspiratory pressure, and the sine waveform results in an intermediate *I*:*E* ratio and peak inspiratory pressure. The decelerating waveform is most commonly chosen because it is the most physiological choice. The relationship between inspiration and expiration is best expressed by the inspiration–expiration (*I*:*E*) time ratio.

The inspiratory flow rate affects the inspiration–expiration ratio.

Respiratory Rate

Once the tidal volume and FiO_2 have been set, a respiratory rate must be chosen that takes into account the patient's spontaneous rate, the patient's anticipated ventilatory requirements, and the impact of the set respiratory rate on patient–ventilator interaction (Fig. 44-4).

The machine rate should be set close (usually about 80% of the patient's spontaneous rate) to the patient's own respiratory rate.

Unless the patient is sedated or paralyzed, respiratory rates below 12–16 breaths/min are poorly tolerated. Neurohumoral feedback from lung edema and inflammation generally results in a rapid, shallow breathing pattern that is independent of chemical or mechanical receptor effects on respiratory pattern. Additionally, discrepancies between actual and machine-set respiratory rates may lead to breathing patterns with inverted inspiratory to expiratory time (*I*:*E*) ratios, which are poorly tolerated. The machine rate should therefore be set close to the patient's own rate (usually about 80% of the patient's spontaneous rate). If the actual rate is so high that effective ventilation cannot be accomplished, sedation or paralysis may be required after a careful search for rapidly reversible causes of tachypnea (pain, discomfort, fever, etc.).

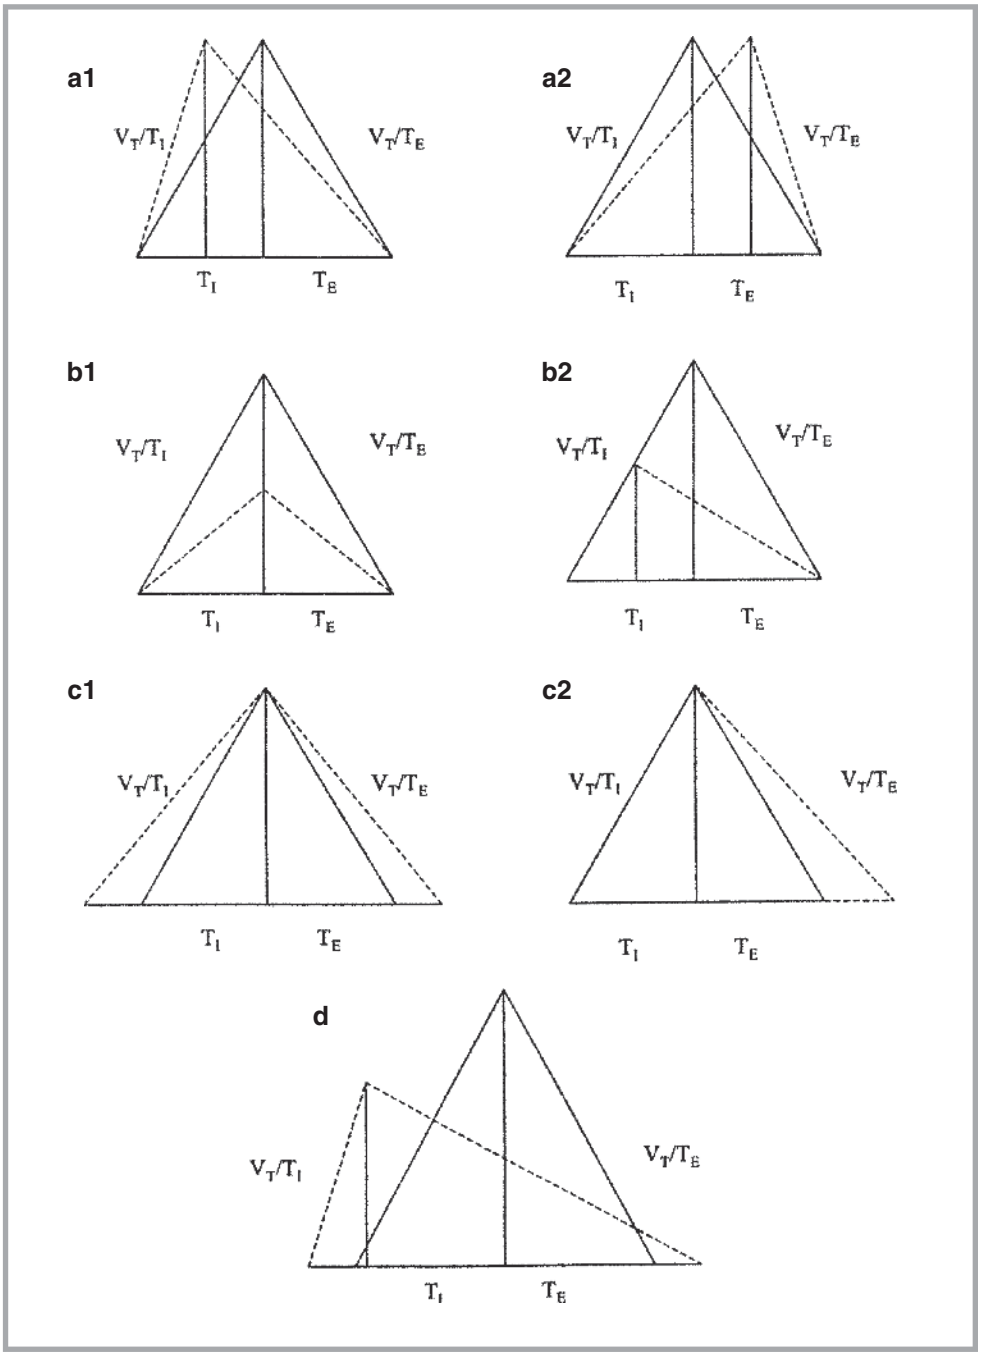
Ventilator respiratory rates below 12–16 breaths/min are poorly tolerated unless the patient is sedated or paralyzed.

I:*E* Ratio

The relationship between the time spent in inspiration and expiration is called the *I*:*E* ratio. The *I*:*E* ratio is not set by the operator; it results from altering the parameters (i.e., respiratory rate, tidal volume, inspiratory flow rate, or inspiratory time) previously discussed. In normal spontaneously breathing subjects, there is usually more than adequate time to empty

FIGURE 44-4

Relationship between tidal volume (V_T), inspiratory time (T_I), expiratory time (T_E), and inspiratory flow rate (V_T/T_I) (see text).



Patients with asthma and COPD require a prolonged Expiratory time T_E to empty the inspired lung volume.

the lungs. In certain pathologic states, such as asthma and COPD, the decrement in expiratory flow may require a prolonged time to totally exhale the inspired volume. Figure 44-4 depicts how tidal volume (V_T), respiratory rate (f_b), and inspiratory flow rate independently affect the *I*:*E* ratio and how changes in these variables affect the *I*:*E* ratio. If inspiratory flow is increased and V_T and f_b remain constant, the inspiratory time will be shortened and the *I*:*E* ratio will be decreased (1:2 to 1:4, for example) (Fig. 44-4a1). Decreasing inspiratory flow under the same conditions results in the opposite effect (Fig. 44-4a2).

Increasing inspiratory flow rate with a constant respiratory rate and tidal volume results in a shorter inspiratory time and a longer expiratory time.

Decreasing V_T will have different effects, depending on the type of ventilator or ventilator mode being used. In ventilators or ventilatory modes that maintain a fixed *I*:*E* ratio and f_b, decreasing V_T will result in a decreased inspiratory flow while T_{tot} is held constant (Fig. 44-4b1). If the ventilator maintains a constant inspiratory flow and f, decreasing V_T will shorten the inspiratory time and decrease the *I*:*E* ratio (Fig. 44-4b2). A decrement in respiratory rate,

coupled with a fixed *I*:*E* ratio and V_T, results in an increment in T_{tot} and decrease in inspiratory and expiratory flow (Fig. 44-4c1). Decreasing the respiratory rate while maintaining V_T and a constant inspiratory flow increases the duration of the cycle (T_{tot}); inspiratory time remains the same, expiratory time increases, and expiratory flow rate decreases (Fig. 44-4c2).

Knowing the effects of altering these parameters is extremely useful. In patients with emphysema who have expiratory flow limitation, decreasing tidal volumes, increasing the inspiratory flow rate, and decreasing the set respiratory rate all serve to decrease the inspiratory time and increase expiratory time, thereby reducing the demands for a higher expiratory flow rate. The additional expiratory time allows the ventilator-delivered tidal volumes to be more fully exhaled and decreases the risk of developing intrinsic PEEP and its negative consequences (see Fig. 44-4d).

In patients with emphysema, decreasing tidal volume, increasing inspiratory flow rate, and decreasing the preset respiratory rate allow more time for lung emptying.

BASIC MODES OF MECHANICAL VENTILATION

The mode of mechanical ventilation describes a particular set of characteristics or variables (cycle, trigger, limit) that define how ventilation is provided.

Assist-Control Ventilation

Assist-control ventilation (ACV) is the most common mode of mechanical ventilation initially applied to patients who present with hypercapnic or hypoxemic respiratory failure. With AC ventilation, the physician sets a minimal rate and tidal volume (or pressure). The patient may trigger the mechanical ventilator at a faster rate, but the set volume (or pressure) will be delivered with each breath. Figure 44-5 is a representative tracing of AC ventilation with targeted volume. In the AC mode, the ventilator can be triggered by preset flow or pressure variables. When the ventilator is set to be triggered by pressure, the patient must generate a certain amount of negative inspiratory generated pressure (usually –1-3 cm H_2O) to open the solenoid valve and receive a ventilator-assisted breath (see Fig. 44-2). If the ventilator is set to be triggered by flow, following a patient's inspiratory effort, the ventilator will sense a decrement in the circuit's baseline flow and only then deliver a breath. If the patient has no spontaneous inspiratory efforts, the ventilator will be time-triggered based on the preset respiratory rate.

With assist-control (AC) ventilation, a set volume (or pressure) is given every time the ventilator is triggered.

Tidal volume (V_T) is generally set at 6–8 mL/kg; larger inflation volumes are avoided, as they contribute to increased intrathoracic pressures and may adversely affect cardiac output. In addition, larger tidal volumes may complicate the ventilator management of patients with heterogeneous lung pathology or regional differences in lung compliance. In patients with emphysema, large volumes are preferentially delivered to the most diseased and compliant areas. As a result, a larger proportion of the delivered volume will not participate in gas exchange, but may possibly contribute to dynamic hyperinflation, intrinsic PEEP, decreased cardiac output, and worsening ventilation–perfusion mismatch. In ARDS patients who characteristically present with large regional variations in compliance, large tidal volumes will result in overdistension of the more compliant regions and may possibly contribute to VILI. During ACV, changes in flow or pressure within the respiratory circuit generated by the patient's inspiratory effort trigger the beginning of the inspiratory cycle.

If the patient does not trigger the ventilator during AC ventilation, tidal volumes will be delivered at the preset respiratory rate.

In ARDS, large ventilator volumes may result in overdistension of the more compliant lung regions and contribute to VILI.

Controlled mechanical ventilation (CMV), the predecessor of ACV, delivers mandatory tidal volumes at a set rate delivered independent of the patient's own respiratory cycle. The major disadvantage of CMV is patient discomfort, which results from an increased work-of-breathing that occurs when mandatory breaths are asynchronous with the patient's own respiratory efforts. Patients are unable to alter their minute ventilation (V_E) if their clinical situation changes (e.g., increased $PaCO_2$, decreased PaO_2, decreased pH); therefore, maintenance of the acid–base balance is solely the responsibility of the practitioner.

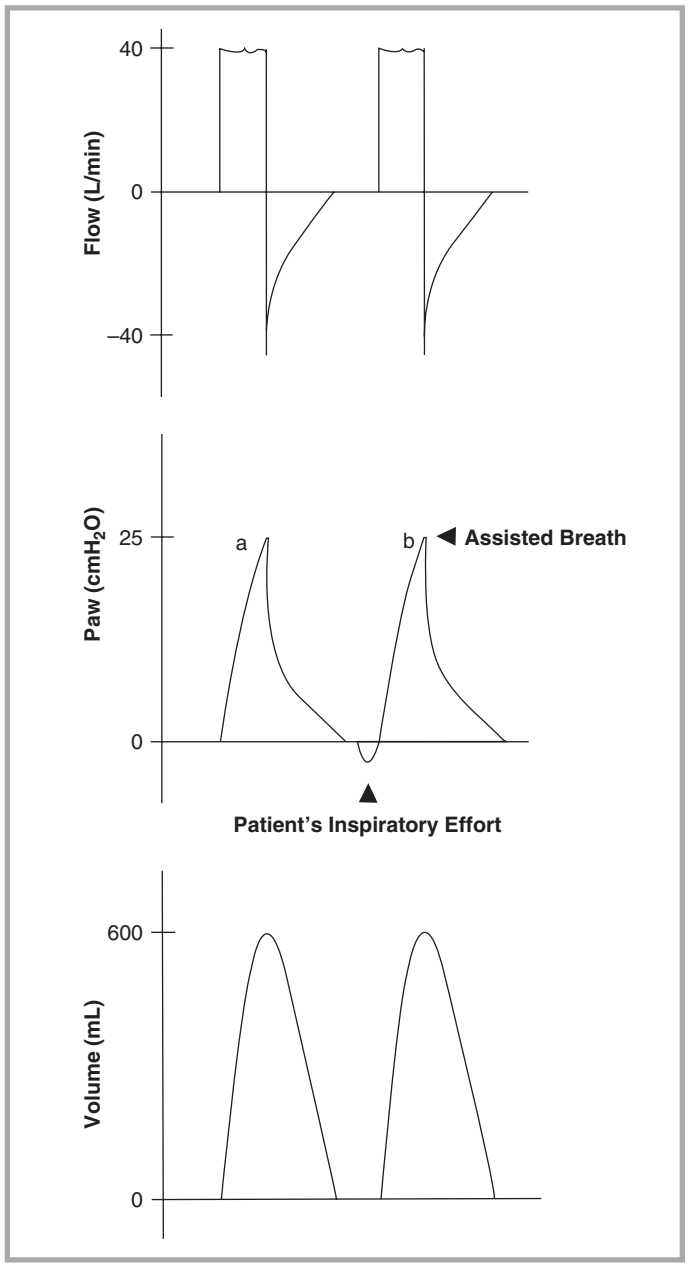
Synchronized Intermittent Mandatory Ventilation

SIMV is a ventilator mode in which the ventilator mandatory breaths are delivered in synchrony with the patient's own inspiratory effort. Breaths are delivered at a set rate and volume. Between mandatory breaths, the patient is allowed to breathe spontaneously from a demand

During synchronized intermittent mandatory ventilation (SIMV) between mandatory breaths, the patient is allowed to breathe spontaneously from a demand valve.

FIGURE 44-5

Pressure, flow, and volume waveforms during volume-targeted, assist-control ventilation. Breath *a* is not patient triggered. In contrast, a negative deflection is seen before breath *b,* representing the patient's inspiratory effort that triggers a ventilator breath.



valve or a continuous flow of gas (Fig. 44-6). Spontaneous breaths may also be supported with titratable levels of pressure support (PS) or continuous positive airway pressure (CPAP). During SIMV, each time cycle is divided into a mandatory and a spontaneous time period. If a patient is ordered an SIMV rate of 6 breaths/min, each cycle is 10 s. During the initial phase of each cycle, the ventilator, in synchrony with the patient's effort, will provide a preset tidal volume. If the patient makes no effort during this initial phase, a machine-delivered breath will be given at the beginning of the spontaneous phase to guarantee a backup rate. During the spontaneous phase, the patient's inspiratory effort will not trigger a mechanical ventilator breath, and tidal volumes are determined by the patient's spontaneous effort (Fig. 44-7).

SIMV was originally postulated to improve cardiac output and stabilize blood pressure, both in contrast to ACV, because it fosters negative changes in intrathoracic pressure during spontaneous breathing. Although these effects have been demonstrated in patients with normal left ventricular function, similar effects have not been demonstrated in patients with decreased left ventricular ejection fraction. SIMV was also originally believed to facilitate weaning by avoiding alkalemia and respiratory muscle disuse atrophy, by gradually reducing the number of ventilator-assisted breaths over time.

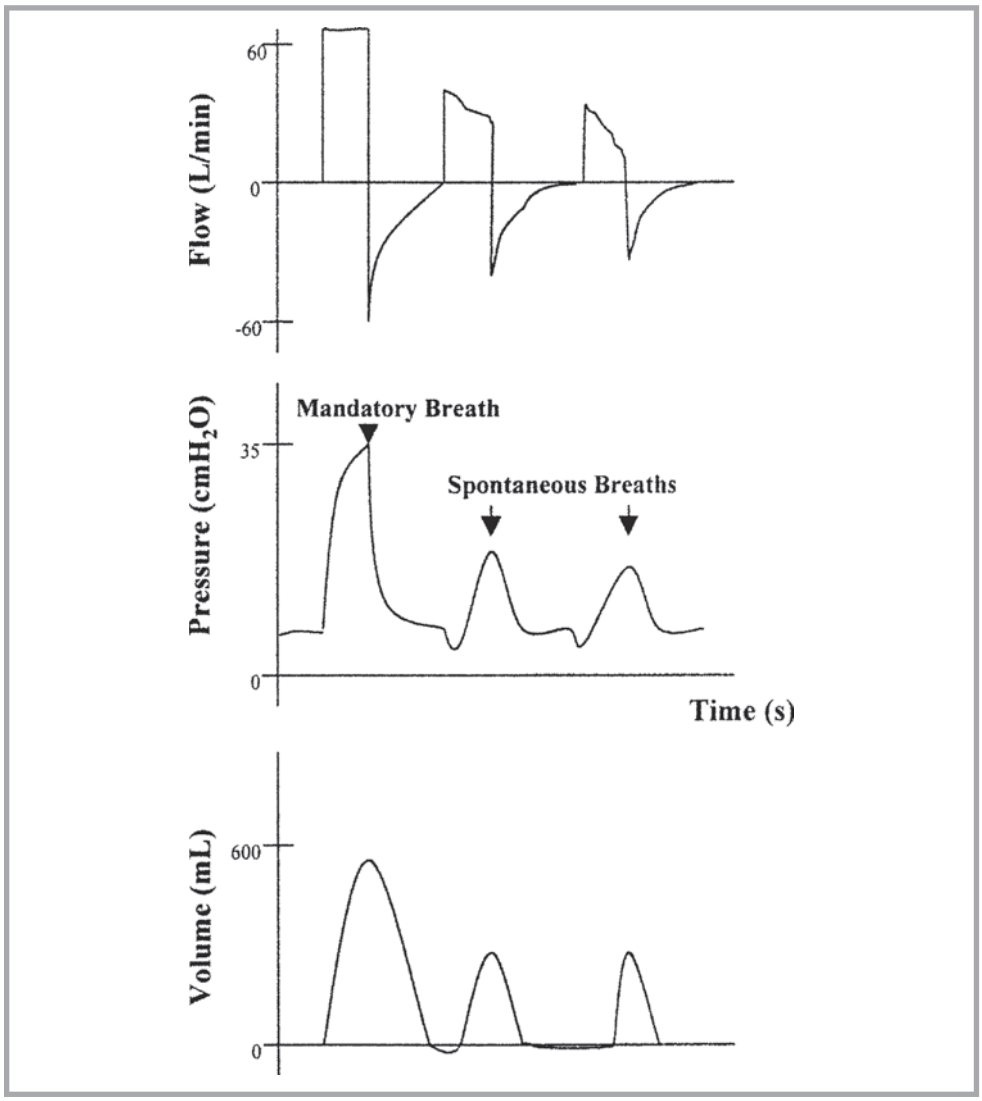


FIGURE 44-6

Pressure, flow, and volume tracings during volume-targeted, intermittent mandatory ventilation (IMV). The first breath is mandatory. The second and third breaths are spontaneous, evidencing a smaller volume displacement.

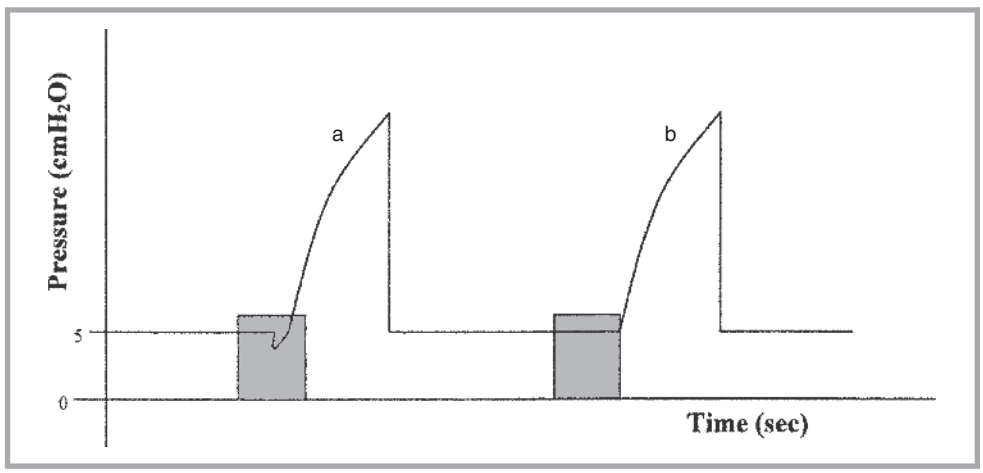

FIGURE 44-7

Pressure tracing during spontaneous intermittent mandatory ventilation (SIMV). The *shaded* areas represent the periods when the ventilator senses the patient's inspiratory effort and delivers a synchronized mandatory breath. After a preset time, if the ventilator does not sense a patient inspiratory effort, it automatically delivers a preset-volume breath.

CASE STUDY: PART 2

Despite aggressive medical therapy, the patient has increased work-of-breathing with accessory muscle use and a paradoxical breathing pattern. Auscultation of the chest reveals worsened wheezing with diminished breath sounds bilaterally. Repeat arterial blood gas analysis reveals pH of 7.38, P_aCO_2 44 mmHg, P_aO_2 60 mmHg with a saturation of 90% on 6 L/min and a respiratory rate of 38 breaths/min. The patient is electively intubated with a size 8.0 endotracheal tube due to the development of respiratory failure. The ventilator is set in the assist-control mode and ventilators settings are FiO_2 100%, respiratory rate 20 breaths/min, tidal volume of 8 mL/kg of body weight, PEEP 5 cm H_2O with an inspiratory flow rate of 60 L/min. The patient becomes progressively agitated, is dysynchronous with the ventilator, and develops significant hypotension. The inspiratory to expiratory (I/E) ratio is 1:1.2 and an intrinsic PEEP (auto-PEEP) of 15 cm H_2O is noted. The inspiratory flow rate is increased to 90 L/min, the respiratory rate is decreased to 10 bpm and the patient is given a low dose of an intravenous benzodiazepine. The patient–ventilator synchrony improves, and the auto-PEEP diminishes to 5 cm H_2O.

SIMV prolongs the weaning process over T-piece or PS weans and increases the work-of-breathing.

However, in contrast to these original hypotheses, two randomized controlled trials have shown that SIMV prolongs the weaning process over T-piece or PS weans (see Chap. 47). It has been shown that the respiratory muscles are activated to the same degree during the assisted and spontaneous breaths while on SIMV, suggesting that the respiratory center of the brain does not adjust to breath-to-breath variations in respiratory loads.[3] SIMV likely prolongs the weaning process because there is a paradoxical increase in the work-of-breathing while on SIMV.[4,5]

Pressure-Support Ventilation

During PSV, the patient triggers all breaths.

In contrast to ACV, pressure-support ventilation (PSV) is a pressure-preset, flow-cycled ventilator mode intended to support spontaneous respiratory efforts. With each inspiratory effort, the patient triggers the ventilator, which maintains the preset pressure level in the inspiratory circuit throughout inspiration (Fig. 44-8).

The inspiratory cycle ends when flow rate decreases to less than 25% of the peak inspiratory flow rate.

Pressurization of the inspiratory circuit ends when flow rate decreases at the end of the patient's inspiratory effort. Depending on the ventilator model, the inspiratory cycle ends when flow rate is less than 5 L/min or when flow rate decreases to less than 25% of the peak

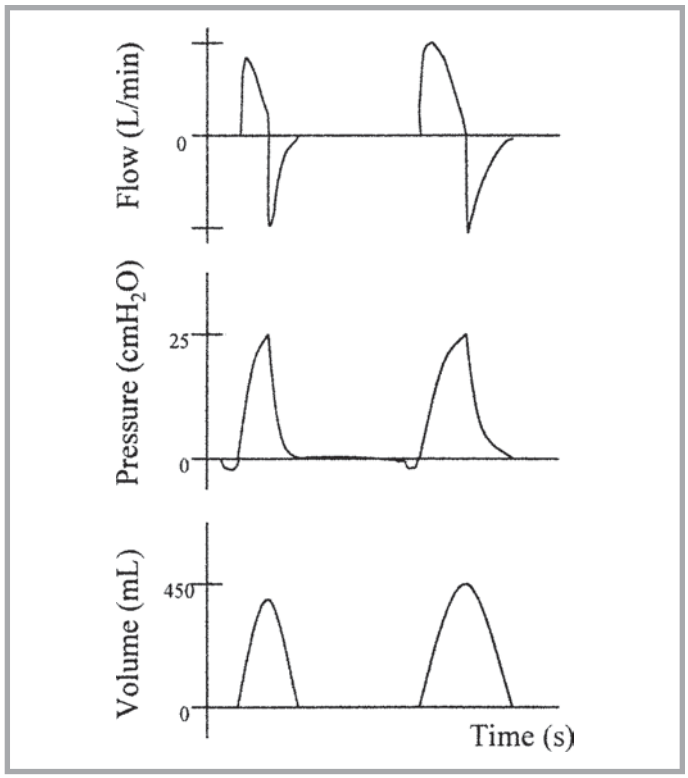

FIGURE 44-8

Pressure, flow, and volume tracings for pressure-support ventilation (PSV). All breaths are being triggered by the patient. Notice that the delivered volumes vary from breath-to-breath.

inspiratory flow rate. The inspiratory cycle may also be terminated by an increase in pressure above the preset value, indicating that expiration has begun. There are no set values for the amount of PS to be applied, but pressure is generally titrated toward achieving expired tidal volumes greater than 5–7 mL/kg, a decrease in respiratory rate (i.e., ≤35 breaths/min), and a decrement in the patient's work-of-breathing (i.e., decreased use of accessory inspiratory muscles). The patient retains control of the length and depth of the inspiratory cycle and may influence the percentage of the total support provided by the ventilator and the flow profile on a breath-to-breath basis. Tidal volumes are determined by a combination of PSV settings, the patient's effort, and the patient's underlying pulmonary mechanics.

Flow settings are not adjustable in the PSV mode, but the speed of initial pressurization may be set in newer ventilators. PSV has been successfully used as part of a weaning strategy in patients who have adequate baseline weaning parameters (see Chap. 47). PSV may decrease inspiratory workload, but muscle unloading may be variable and is dependent on underlying respiratory system mechanics. In COPD patients, PSV may contribute to an increased work-of-breathing because ventilator inflation persists into the patient's neural expiratory phase. Patient–ventilator asynchrony may also result.

During PSV, the tidal volume is the result of the applied pressure, the patient's effort, and underlying lung and chest wall mechanics.

Pressure Control Ventilation

The majority of patients receiving mechanical ventilation are ventilated using various forms of volume-control ventilation (VCV); a preset tidal volume is delivered with each breath. In VCV, the volume is held constant, while airway pressure varies with changes in airway, lung, or chest wall mechanics.

However, PCV is a form of pressure-limited ventilation in which airway pressure is the constant, while tidal volume varies with changes in airway resistance or lung and chest wall mechanics. As a result, patients may receive variable tidal volumes with each respiratory effort depending upon dynamic changes in the resistive and elastic components of the respiratory system. During PCV, the rate, pressure limit, and inspiratory time are set on the ventilator. Breaths are initiated at a preset rate (time-cycled), and gas flows into the patient breathing circuit until the preset pressure is reached. At this point, gas flow is reduced to the minimum flow required to maintain the airway pressure at the preset level until inspiratory time elapses (Fig. 44-9).

Pressure control ventilation (PCV) is a form of pressure-limited ventilation; airway pressure is held constant and tidal volumes vary according to the respiratory system mechanics.

In contrast to PSV, breaths are initiated at a preset rate during PCV.

PCV has been used in clinical settings where increased peak airway pressures (implying increased alveolar pressures) are encountered and the clinician is concerned that increased airway pressures predisposes the patient to VILI. It also has been used in ARDS where fine control of mean airway pressure is desired and other ventilatory modes have failed to adequately ventilate or oxygenate the patient. PCV usually results in a higher mean airway pressure than volume-limited ventilation, but allows for lower peak airway pressures. Patients treated with PCV must often be sedated or paralyzed to achieve adequate comfort and effective ventilation.

PCV usually results in higher mean and lower peak airway pressures than volume-limited ventilation.

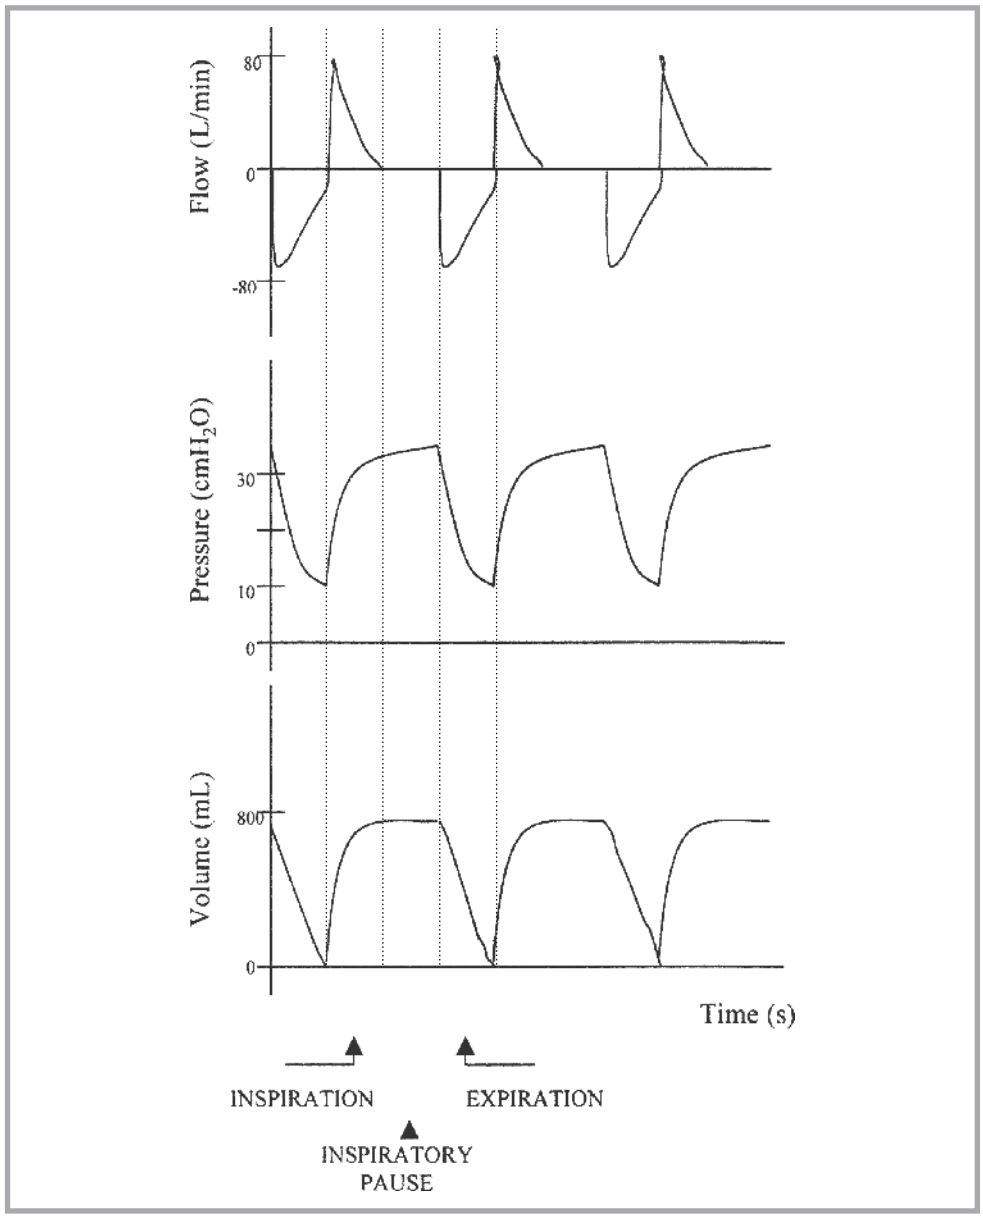
There has been one randomized controlled trial comparing PCV against VCV. 79 patients with ARDS were ventilated using PCV or VCV in order to maintain plateau pressures ≤35 cm H_2O. The study reported an increase in mortality and multiorgan system failure in the volume-control group, but by multivariate analysis, the ventilatory modality was not shown to be a predictor for mortality. The development of multisystem organ failure (OR 4.6, CI 1.36–15.4) and renal failure (OR 3.9, CI 1.10–14.28) were the two factors associated with increased mortality.[5] Two prior studies also failed to show differences in morbidity or mortality between these ventilatory modalities.

Care must be taken during PCV when trying to increase minute ventilation to reduce levels of P_aCO_2. Due to the fixed *I*:*E* ratio set by the operator, increasing respiratory rate only can lead to a decrease in minute ventilation. This seemingly paradoxical phenomenon occurs during PCV because the ventilator has less time (i.e., shorter inspiratory time) at the higher respiratory rates to reach the preset pressure limit. Hence, tidal volume, and therefore minute ventilation, may decrease despite the increased respiratory rate leading to an increased not decreased P_aCO_2.[6] To avoid this untoward effect, the *I*:*E* ratio will often need to be increased, in addition to increasing the respiratory rate, in order to increase minute ventilation. Although there are theoretical advantages to PCV, the requirements for prolonged sedation and paralysis are worrisome, and routine adoption of this mode of ventilation is not warranted at this

PCV generally requires sedation and paralysis and has not been shown to be superior to volume-limited ventilation in the setting of ARDS.

FIGURE 44-9

Pressure, flow, and volume tracings for pressure control ventilation (PCV). In this case, an inspiratory pause has been placed, resulting in a prolonged inspiratory time and a shortened expiratory time.



time. Currently, PCV is clinically used in individual patients when more conventional forms of mechanical ventilation fail to achieve sufficient oxygenation, or plateau airway pressures are unacceptably elevated.

Continuous Positive Airway Pressure and Positive End-Expiratory Pressure

During CPAP, a constant pressure is applied to the airway throughout inspiration and expiration.

CPAP is a mode of ventilatory support that is applied to spontaneously breathing patients. During the respiratory cycle, a constant pressure is applied to the airway throughout inspiration and expiration (Fig. 44-10). The level of CPAP is the only variable that is adjusted by the physician. CPAP is commonly combined with PSV. CPAP may be used with PSV to decrease the amount of respiratory effort required to trigger a ventilator breath. CPAP has been used with PSV or alone in patients weaning from mechanical ventilation to prevent small airway collapse and atelectasis. Noninvasive CPAP delivery by facemask without tracheal intubation is commonly used to treat obstructive sleep apnea and, more recently, to treat acute respiratory failure. For a full description of CPAP and its physiological consequences and uses, see Chap. 46.

CASE STUDY: PART 3

Over the next few days, the patient's oxygenation progressively worsens despite FiO_2 being 100%, while the plateau pressure (>35 cm H_2O) increased dramatically. Chest radiography shows development of diffuse alveolar infiltrates consistent with ARDS without evidence of pneumothorax. The ventilator is switched to pressure control mode with a driving pressure set to 28 cm H_2O with the I/E ratio set at 1:1 and RR set at 18, which results in a tidal volume of only 300 mL (4 mL/kg). Because the arterial blood gas shows a pH 7.0 P_aCO_2 80 mmHg, the driving pressure was increased to 32 cm H_2O, thereby increasing the tidal volume to 400 mL (6 mL/kg). Repeat arterial blood gas analysis showed a pH 7.2, with P_aCO_2 65 mmHg. Over the next few days, the patient gradually improves and is switched back to volume-cycled ventilation. Weaning is prolonged due to neuromuscular weakness, and the patient undergoes tracheostomy, receives aggressive total body rehabilitation, and is eventually weaned off of the ventilator.

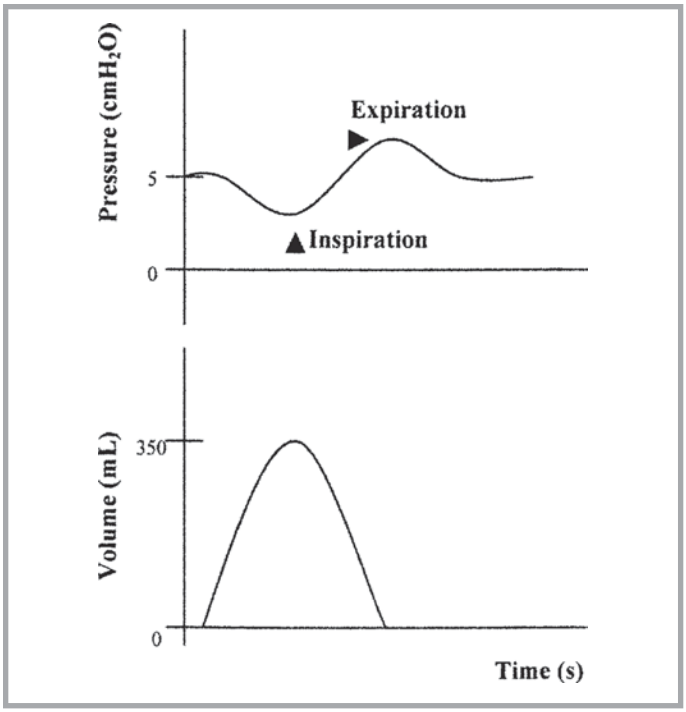


FIGURE 44-10

Pressure and volume waveforms for continuous positive airway pressure (CPAP). All breaths are spontaneously generated by the patient.

In the setting of respiratory failure from ARDS or congestive heart failure, decreases in lung compliance may lead to significant alveolar collapse, which increases the alveolar shunt fraction and may lead to refractory hypoxemia. Extrinsic PEEP has been used as an adjunctive technique during mechanical ventilation in these types of patients to prevent alveolar collapse, recruit nonventilated alveoli, and improve oxygenation by increasing end-expiratory lung volume (EELV), thereby decreasing intrapulmonary shunt. In patients with ARDS, the selection of the amount of extrinsic PEEP can be accomplished in one of two ways: (1) by titrating extrinsic PEEP upward in 2–3 cm H_2O increments while carefully following oxygenation and pulmonary mechanics or (2) by setting extrinsic PEEP above the lower inflection point obtained by constructing a pressure–volume curve (see following). The ARDSnet trial[1] addressed the use of low tidal volumes, but did not attempt to determine optimal PEEP settings in patients with ARDS. A subsequent study by the ARDSnet study group investigated whether a low or high PEEP strategy resulted in improved survival. ARDSnet investigators used a low (8.3±3.2 cm H_2O) and high PEEP (13.2±3.5 cm H_2O) titration strategy to titrate PEEP levels and found no difference in survival or ventilator-free days with either a low or high PEEP strategy.[7] Hence, it does not appear that an absolute level of PEEP is required in ARDS to impact clinical outcome.

Extrinsic PEEP prevents alveolar collapse, recruits alveoli, and improves oxygenation by increasing end-expiratory lung volume and decreasing intrapulmonary shunt.

A good correlation exists between application of clinically guided extrinsic PEEP and that determined by pressure–volume curve analysis. The addition of extrinsic PEEP may be

Once adequate oxygenation has been achieved, there is no benefit to further increases in the level of PEEP.

helpful in decreasing patients' respiratory workload while on assisted or supported modes of mechanical ventilation. In general, most patients benefit from low levels of extrinsic PEEP, applied to either improve oxygenation or decrease the work-of-breathing; the level of PEEP should be titrated to achieve the optimum desired clinical response.

Patients with intrinsic PEEP must overcome a significant amount of pressure before they can elicit flow from the ventilator, resulting in difficult ventilator triggering, delayed breath delivery, increased work-of-breathing, and patient–ventilator asynchrony. Some authors advocate applying extrinsic PEEP in these circumstances to facilitate triggering. In patients who are flow-limited (COPD exacerbations), the addition of extrinsic PEEP will not be seen at the alveolar level because of increased airway resistance, until the level of extrinsic PEEP exceeds 85% of the intrinsic PEEP.[8] Although the addition of extrinsic PEEP may decrease the workload required to initiate a ventilator breath, it is important to remember that, in many instances, hyperinflation and intrinsic PEEP are dynamic conditions. In this setting, therapy should be preferentially directed to strategies that relieve bronchospasm and decrease the *I*:*E* ratio in order to facilitate lung emptying.

The application of low levels of PEEP can reduce the work-of-breathing in patients with significant levels of intrinsic PEEP.

The application of extrinsic PEEP, however, also has distinct disadvantages. It increases intrathoracic pressure, which may decrease venous return and compromise cardiac output and O_2 delivery. Extrinsic PEEP has its predominate effect on the most compliant regions of the lungs. Thus, overdistension of normal lung units may occur and contribute to an increased alveolar dead space fraction. Additionally, concern exists that extrinsic PEEP, especially at higher levels, may contribute to overdistention and result in VILI.

ALTERNATE MODES OF VENTILATION

High-Frequency Ventilation

HFV results in higher mean airway pressures, but lower tidal volumes.

Broadly speaking, high-frequency ventilation (HFV) is defined as mechanical ventilatory support using higher than normal breathing frequencies. This section considers techniques that use respiratory frequencies that are several-fold higher than normal (>100 breaths/min in adults and >300 breaths/min in neonate/pediatric patients). When using these frequencies, tidal volumes are much smaller than in conventional mechanical ventilation and often lower than the physiologic dead space. Gas transport is thought to occur via different mechanisms during HFV; these mechanisms have been reviewed elsewhere[9] and are summarized in Fig. 44-11. One of the more interesting possible mechanisms is known as asymmetric velocity profiles. Air moving into the lung during this mode of ventilation has different velocities with the air closest to the tracheobronchial wall moving more slowly than the air in the center of the airway. This difference in velocities is more evident during inspiration, and with higher respiratory rates; therefore, gas in the center of the airway tends to move into the lung, while air closest to the tracheal wall moves out toward the subject's mouth during HFV (Fig. 44-11). Two main advantages have been postulated for using HFV. First, because this mode of ventilation results in a higher mean airway pressure (limiting alveolar derecruitment) and lower tidal volumes (limiting alveolar overdistension), it potentially provides an ideal lung protection strategy. Figure 44-12 is a pressure-time relationship comparing HFV to standard ACV and highlights the fact that mean airway pressure is greater in HFV. Second, in addition to better alveolar recruitment, the rapid flow pattern may enhance gas mixing and improve ventilation–perfusion mismatch.

High-Frequency Ventilation Modes

High-frequency ventilatory support uses ventilator frequencies greater than 60 breaths/min in adults.

High-frequency ventilation can be used during bronchoscopy to provide adequate ventilatory support and lower airway pressures.

High-frequency jet ventilation (HFJV), high-frequency percussion ventilation (HFPV), and high-frequency oscillatory ventilation (HFOV) are three different modes of HFV that have been used clinically. HFPV, the first mode of HVF, delivers small tidal volumes (3–4 mL/kg) at very high flow rates (175–250 L/min) very frequently (60–100 breaths/min). This mode of HFV is used during bronchoscopy and laryngeal surgery because upper airway motion is limited, thereby providing optimal surgical conditions.[9] HFJV utilizes humidified gas that is delivered at a high pressure (15–50 lbs/in^2) and rapid frequency (100–200 cycles/min) within

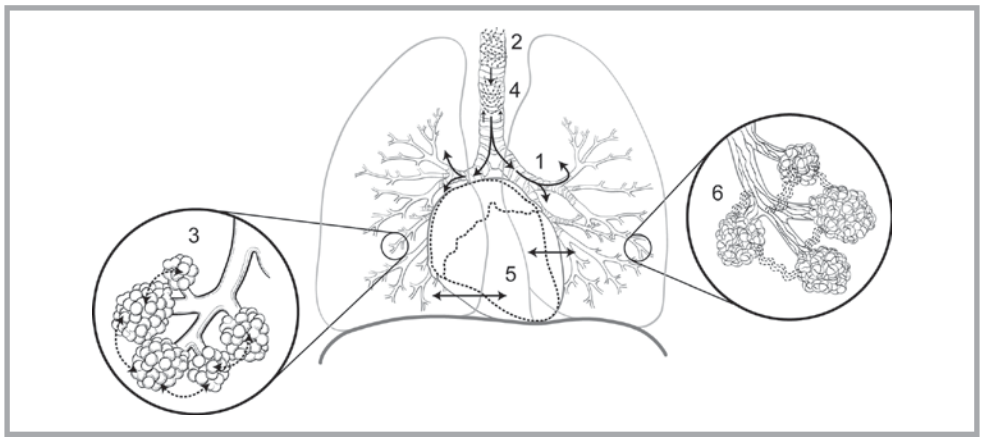

FIGURE 44-11

Cartoon drawing of six possible mechanisms for gas transport during high-frequency ventilation. *1*. Direct ventilation of proximal alveoli (direct bulk flow) *2*. Turbulent flow, known as longitudinal (Taylor) dispersion contributes to mixing of fresh air with alveolar air; *3*. Penddelluft transportation occurs due to regional variation in resistance and compliance resulting in asynchronous flow among alveoli; *4*. Asymmetric velocity profiles that differ between inspiration and expiration (see text for explanation); *5*. Contraction of the heart leading to gas mixing in lung units adjacent to the heart; *6*. Molecular diffusion of air near alveolocapillary membranes (illustration by Alice Y. Chen).

the endotracheal tube by a narrow injector, resulting in a tidal volume of about 2–5 mL/kg. The operator determines the jet pressure, the velocity of gas delivery, and the respiratory rate. At low frequencies, jet ventilation is effective in washing out dead space; elimination of $PaCO_2$ occurs through the principle of conductive ventilation. As the frequency of ventilation increases during jet ventilation, alveolar airway pressures approach those seen in conventional ventilation techniques. However, as the frequency of ventilation increases, conductive gas flow during jet ventilation decreases, and $PaCO_2$ may rise. Typically, the driving pressure and/or the inspiratory time is increased when greater alveolar ventilation is required. HFJV has also been used during bronchoscopy and upper airway surgical procedures. HFJV also has been proposed as a mode for ventilating patients with bronchopleural fistulas, but studies supporting this indication are limited. Although HFJV may have favorable hemodynamic effects in heart failure, if the inspiratory phase is synchronized with the heart rate, studies supporting this are limited and contradictory. HFOV works by having a

High-frequency ventilation (HFV) uses small tidal volumes, frequently in conjunction with high PEEP.

Potential uses for high-frequency ventilation include patients with large bronchopleural fistulas and those with cardiac dysfunction.

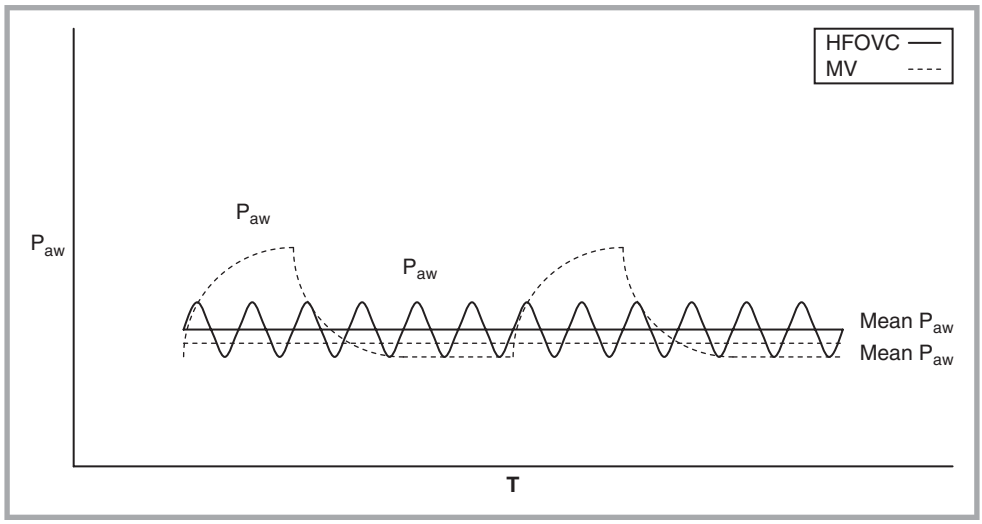

FIGURE 44-12

Airway pressure tracings (*curved lines*) and mean airway pressures (*straight lines*) for high-frequency oscillatory ventilation (HFOV) and controlled mechanical ventilation (CMV). The mean airway pressure is higher for HFOV even though the peak airway pressures are significantly higher for CMV. (T=time; P_{aw}=airway pressure).

HFOV provides active exhalation, which helps to limit the development of breath-stacking and the development of gas trapping.

piston pump oscillate at very high frequency (180–600 breaths/min) with fresh gas provided as a bias flow at a rate of 30–60 L/min. A resistance valve is placed in the bias flow circuit to control airway pressures.[10] The unique aspect of HFOV is that this mode of mechanical ventilation provides active exhalation during the return stroke of the piston. Most other ventilator modes rely on passive exhalation including the other two modes of HFV. This active exhalation is felt to reduce the likelihood of breath-stacking, which can lead to excessive levels of intrinsic PEEP and alveolar overdistension with the other modes of HFV. The mean airway pressure and the FiO_2 flowing through the bias flow determine oxygenation. Tidal volume relates directly to the distance the oscillator moves and relates inversely to the frequency of oscillation. This inverse relationship occurs because a higher frequency results in a shorter inspiratory time and less bulk flow (one of the mechanisms of gas transport in HFV in Fig. 44-11).[9,10]

Although there are hypothetical advantages to HFV, there have been no clinical trials to support its routine use in ALI/ARDS.

HFV has been used in neonates with the neonatal respiratory distress syndrome, but clinical trials do not support that HFV is superior to standard modes of mechanical ventilation and may be associated with an increased risk for intraventricular hemorrhage.[11] In the adult ICU population, there have been two randomized controlled studies examining the effectiveness of HFOV in severe ARDS. The first trial randomized 148 patients to HFOV vs. conventional mechanical ventilation utilizing lung protective strategy (mean V_T 8±2 mL/kg). At 30 days, there was no significant difference in mortality, although there was a trend toward less mortality with HFOV at 30 days (37% vs. 52% $p=0.102$).[12] A subsequent study randomized 61 ARDS patients to pressure control ventilation vs. HFOV. The study was terminated early after enrolling 37 and 24 patients in the HFOV and pressure control arms, respectively, because of lack of enrollment and publication of the previously mentioned trial, showing that there was no difference in mortality. Oxygenation index was better in the group that received HFOV. Thirty-day survival without oxygen or ventilator use was not different between HFOV or pressure control ventilation (32% vs. 38%; $p=0.79$), and there was no difference in the number of patients crossing over to the alternate arm due to clinical worsening.[13] While there are theoretical advantages of using HFV, there have not been any studies supporting its widespread use in an adult ICU population being treated for hypoxemic respiratory failure. An additional factor limiting the widespread use of HFOV is that patients with airflow obstruction due to asthma or COPD are at risk for developing severe intrinsic PEEP, leading to hemodynamic compromise and poor ventilation.

Airway Pressure Release Ventilation and Biphasic Airway Pressure Ventilation

A high and low pressure is set during APRV and this difference primarily determines the level of ventilation achieved.

These modes of mechanical ventilation have gained popularity among trauma surgeons ventilating patients with ALI/ARDS. Airway pressure release ventilation (APRV) utilizes a high level of CPAP, which by recruiting atelectatic alveoli improves oxygenation. The high level of CPAP recruits additional alveolar units, increases functional residual capacity, decreases shunt fraction, and improves ventilation–perfusion matching. The elevated airway pressure is periodically reduced to a low-pressure setting (P_{low}) through a release valve. Thus, each mechanical breath is created by the brief interruption and restoration of airway pressure (Fig. 44-13). The settings in APRV are the high-level CPAP (P_{high}), the low-level airway pressure (P_{low}), the duration of P_{high} (T_{high}), the duration of P_{low} (T_{low}), and the FiO_2. The difference between P_{high} (typically 20–35 cm H_2O) and P_{low} (usually 0–5 cm H_2O) determines tidal volume, while the ratio of T_{high} (typically 4–6 s) to T_{low} (usually 0.6–1.5 s depending on the clinical scenario, with a longer T_{low} employed in obstructive lung disease) is analogous to the *I*:*E* ratio. Most clinical trials utilizing APRV have set the P_{low} just above the lower inflection point on a pressure volume (PV) curve and set the P_{high} just below the upper inflection point.[14] The accurate construction of this curve in clinical practice is limited due to technical problems and inconsistency in measuring the lower inflection point. Therefore, most patient settings are initiated empirically by choosing a P_{high} just below the plateau pressure on assist-control mechanical ventilation and then adjusting the T_{low} and P_{low} to ensure adequate ventilation. Increasing P_{high} and T_{high} serves to increase mean airway pressure,

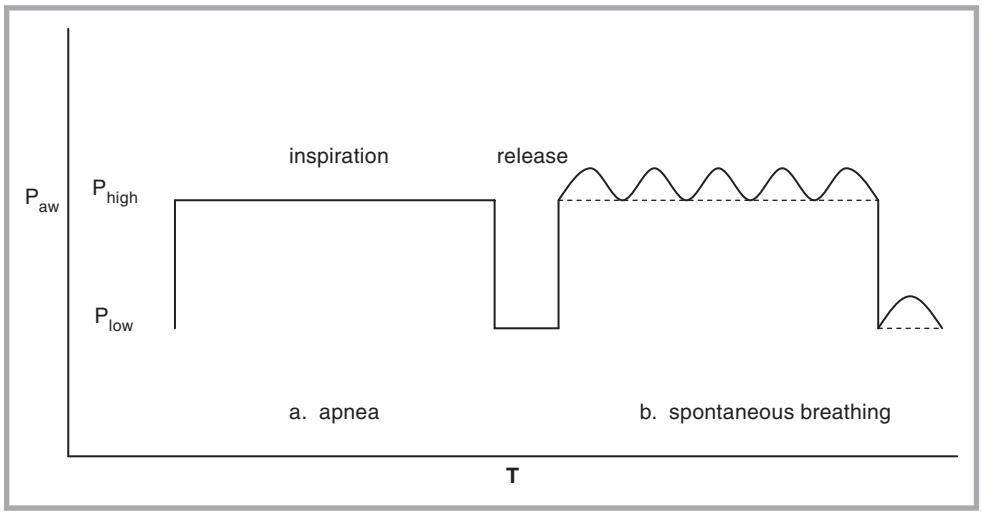

FIGURE 44-13

Airway pressure tracings vs. time for airway pressure release ventilation (APRV). *Panel a* represents the pressure tracing during apnea and *panel b* during spontaneously breathing patient. Ventilation occurs during the release of the P_{high} down to the P_{low}. Patients are able to breathe spontaneously during any phase of the respiratory cycle but will still be ventilated and oxygenated even if apneic. (P_{aw}=airway pressure; P_{low}=low pressure; P_{high}=high pressure).

thereby improving oxygenation by promoting alveolar recruitment and limiting alveolar derecruitment. The T_{low} needs to be long enough to permit complete emptying of the lung or significant intrinsic PEEP will develop,[15] which can be problematic for patients with severe airflow obstruction. APRV allows patients to breathe spontaneously during the high or low-pressure phase of the ventilator cycle, which is felt to be one of its major attributes. Further recruitment of alveoli is thought to occur when spontaneous breathing occurs during the P_{high} phase due to active contraction of the diaphragm, leading to increased recruitment of atelectatic alveoli at the bases.

APRV permits patients to spontaneously breathe during either the low or high pressure phase of the ventilator.

Biphasic airway pressure ventilation (not to be confused with BiPAP®/noninvasive ventilation, discussed in Chap. 46) is a ventilator mode that also employs high levels of CPAP and is set to decrease periodically after a preset number of respiratory cycles over a specified time duration. Biphasic airway pressure release ventilation differs from APRV only in that the time set at low pressure is typically longer than that in APRV. This results in a lower mean airway pressure, but does augment spontaneous ventilation that occurs during the P_{low} phase.[14]

Some of the potential benefits of APRV include improved oxygenation in patients with hypoxemic respiratory failure, decreased need for sedation, lower peak and mean alveolar pressures (thus a decreased risk of VILI), and increased venous return, leading to improved cardiac function. Some of these benefits have been observed in small clinical trials involving trauma patients with ALI/ARDS. Sydow performed a study in 18 patients with moderate-to-severe ALI by ventilating them with volume-control inverse ratio ventilation (VC-IRV) or APRV mode for 24 h each in a randomized, crossover design.[16] They found improved oxygenation and improved shunt fraction suggesting that there was improved alveolar recruitment. Putensen compared the effect of PSV vs. APRV with and without spontaneous breathing on the ventilation/perfusion ratio in ARDS. They found that APRV with spontaneous ventilation permitted improved ventilation-perfusion matching.[17] Putensen randomized 30 severe trauma patients to either PCV or APRV and found that patients ventilated with PCV had a greater sedation need (Ramsey sedation scale of 5) than those with APRV (Ramsey sedation scale of 3). The group ventilated with APRV also had less days of mechanical ventilation, but how this related to the differing sedation needs is unclear.[18] Cardiac function has been shown to be improved in patients ventilated with APRV as compared to PCV and is postulated to be due to decreased intrathoracic pressure and improved venous return.[18,19] Varpula has published the only randomized controlled study comparing APRV to SIMV in 58 patients with ALI where the primary end point was the number of ventilator-free days at day 28. They found there was no difference between the groups in ventilator-free days at day 28, P_aO_2/FiO_2 ratios, sedative use, or cardiac function.[20]

APRV has been shown to decrease ventilation-perfusion mismatching but has not had an effect on the number of ventilator-free days when used to treat patients with ALI.

Although APRV has certain theoretical advantages in ventilating patients with hypoxemic respiratory failure, there currently is not enough evidence to warrant its use on a routine

The use of APRV should be used cautiously in patients with airflow obstruction due to the risk of developing auto-PEEP.

basis. Most of the available studies that have been performed in trauma victims, are retrospective and lack appropriate controls. Additionally, the modality could be harmful to patients with obstructive lung disease such as emphysema where the short T_{low} can lead to the development of severe intrinsic PEEP.

Proportional-Assist Ventilation and Neurally Adjusted Ventilatory Assist

Proportional-assist ventilation (PAV) was designed to augment the patient's respiratory efforts with varying levels of PS throughout the inspiratory cycle in order to allow patients to breathe more physiologically. This mode of ventilation was designed in an attempt to improve patient–ventilator synchrony and thus increase patient comfort. The patient controls the inspired volume and the flow rate; the level of pressure assistance is achieved by measuring the flow and inspired volume. Pressure increases proportionately to overcome the elastic workload or the resistive workload. Unlike PSV, the degree of pressure assistance varies during the inspiratory portion of the respiratory cycle. PAV was intended to improve patient comfort by matching the degree of ventilator assistance to the patient's moment-to-moment respiratory workload. However, at the current time, PAV has not been shown to improve weaning success and, like PSV, does not eliminate the possible development of auto-PEEP. Triggering the ventilator during PAV still requires the patient to generate flow or exert negative pressure on the ventilator circuit. Patients can make respiratory efforts without generating flow or pressure, such as when significant auto-PEEP exists. Neurally adjusted ventilatory assist (NAVA) attempts to solve this problem by having the ventilator triggered when the diaphragm is stimulated. This is done by measuring diaphragm electromyographic acticity (EMG_{di}). EMG_{di} is measured at the crural diaphragm via a catheter placed into the esophagus. The ventilator will trigger a breath once the signal is received, and because the EMG_{di} can be quantified, the amount of pressure delivered can be increased proportional to the EMG_{di}.[21] Early studies suggest that this mode of ventilation may improve ventilator-patient synchrony, but the technique is still in development and is not yet available for clinical use.

Partial Liquid Ventilation

Perfluorocarbon is a gas-exchanging liquid used in partial liquid ventilation.

Partial liquid ventilation is an experimental adjunct to ventilation that utilizes a gas-exchanging liquid, perfluorocarbon (PFC), to fill collapsed alveolar units. Perfluro-octyl bromide is the most commonly used PFC; it is nontoxic, radiopaque, not readily absorbed into the blood, and evaporates hours to days after instillation into the respiratory tract. Technical limitations have prevented the use of complete liquid ventilation in human trials, but partial liquid ventilation in combination with gas ventilation has been employed with some degree of success.

Perfluorocarbon, used in conjunction with conventional ventilator techniques, is instilled into the lung, where it settles in the dependent portions.

While using traditional gas ventilation techniques, PFC is instilled into the lung where it settles into the dependent portions in an amount that equals the volume of the patient's functional residual capacity. The PFC fills the alveoli during inspiration and can mimic the action of adding extrinsic PEEP by recruiting additional alveoli. Its effect on reducing alveolar surface tension serves to improve lung compliance. It is also speculated that secretion clearance is improved as particulates float to the top of the PFC. This technique remains investigational. It most likely will not have widespread application because it is labor-intensive and evidence that it improves survival in patients with hypoxemic respiratory failure secondary to ARDS is lacking.

SUMMARY

Major changes in mechanical ventilation have occurred during the past several decades, and these changes have been closely associated with technologic advances. The advent of computers and microprocessors has allowed more complex ventilation algorithms and new ventilatory modalities. However, a large proportion of the advances in mechanical ventilation is

the direct result of a better understanding of the underlying pathophysiology of respiratory failure. No matter which mode of ventilation or ventilator settings are chosen, it is important that the patient's underlying pulmonary physiology dictate ventilator settings. Furthermore, patient comfort must be considered when choosing the mode of ventilation and its subsequent settings.

Although newer modes of mechanical ventilation such as airway pressure release ventilation, high-frequency ventilation, and neurally adjusted ventilatory assist ventilation appear promising, well-done randomized controlled trials are insufficient to recommend using these newer modes on a routine basis.

REVIEW QUESTIONS

1. When setting up pressure control ventilation the operator can alter all of the following settings except:
- **A.** Tidal volume
- **B.** Respiratory rate
- **C.** *I*:*E* ratio
- **D.** Extrinsic PEEP

2. Which of the following modes of mechanical ventilation utilize active exhalation?
- **A.** Assist-control mode
- **B.** Pressure control mode
- **C.** High-frequency oscillatory ventilation
- **D.** Airway pressure release ventilation

3. All the following statements regarding PSV are correct, except:
- **A.** It is a pressure-preset, flow-cycled ventilatory mode
- **B.** The patient triggers every breath
- **C.** Tidal volumes show little or no variation from breath-to-breath
- **D.** Inspiration ceases once flow decreases below 25% of peak inspiratory flow or when flow rate is <5 L/min

4. When ventilating a patient that requires a prolonged expiratory time (i.e., acute asthma exacerbation) which of the following interventions will lengthen the *I*:*E* ratio:
- **A.** Increasing the respiratory rate
- **B.** Increasing the inspiratory flow rate
- **C.** Lowering the tidal volume
- **D.** B and C

5. Assuming there is no leak at the endotracheal tube cuff or in the ventilator circuit, which mode of mechanical ventilation results in the same tidal volume being delivered with each breath?
- **A.** Pressure-support ventilation
- **B.** Assist-control ventilation
- **C.** Synchronized intermittent mandatory ventilation
- **D.** Pressure control ventilation

ANSWERS

1. The answer is A. During pressure control ventilation, the tidal volume is not set by the operator and is variable from breath-to-breath. The tidal volume will depend on the compliance of the respiratory system. This would include the compliance of the lung, thorax, and abdomen. Clinical situations that can reduce tidal volume in this situation would be development of acute pulmonary edema, severe generalized anasarca resulting in massive soft tissue edema of the thorax and abdomen. Sudden drops in tidal volume during pressure control ventilation should make one think of acute pulmonary edema or the development of a pneumothorax. Patients who have morbid obesity also will require higher driving pressure to receive adequate tidal volumes due to large amount of adipose tissue of the thorax and abdomen. The inspiratory to expiratory ratio is set by the operator, and the longer the inspiratory time the greater the mean airway pressure will be, resulting in more alveolar recruitment. The respiratory rate for pressure control ventilation is chosen as one would for conventional mechanical ventilation, but the intensivist should recognize that at higher respiratory rates, the *I*:*E* ration will need to be adjusted by increasing the inspiratory time. Failure to do this may result in paradoxical increase in P_aCO_2 due to increased dead space (see text).

2. The answer is C. High-frequency oscillatory ventilation (HFOV) works by having a piston pump oscillate back and forth very rapidly. The return stroke of the piston results in active exhalation during this mode of mechanical ventilation. This is thought to reduce the amount of intrinsic PEEP that develops during HFOV. All of the other modes of mechanical ventilation rely on the elastic properties of lung recoil resulting in passive exhalation.

3. The answer is C. During PSV, the patient triggers every breath. Pressure is preset by the operator, and the respiratory cycle is terminated once flow falls to a predetermined level, generally 25% of the initial peak inspiratory flow or <5 L/min. The delivered tidal volume is dependent on the preset pressure, the patient's effort, and the respiratory system mechanics. Variation in tidal volumes from breath-to-breath is expected.

4. The answer is D. When trying to prolong the *I*:*E* ratio in order to facilitate exhalation and decrease the chances of developing air trapping and intrinsic PEEP, the goal is to deliver as small a breath as quickly and infrequently as possible. In order to do this, the inspiratory flow rate must be increased (up to 110 L/min), the respiratory rate decreased, and the tidal volume lowered (see Fig. 44-4). In very severe cases, the patient may require sedation in order to help control the respiratory rate. When the inspiratory flow rate is increased there will be an increase in the peak inspiratory pressure, but this is not a major concern as long as the plateau pressure remains below 35 cm H_2O (see Chap. 46).
5. The answer is B, assist-control ventilation. During assist-control ventilation, the tidal volume is set, and as long as there is no leak in the ventilator circuit and the peak pressure alarm setting is not triggered, the set tidal volume will be delivered each time. During PSV, the tidal volume will depend on the patient effort and the compliance of the lungs and chest wall. During SIMV, the tidal volume will be the same on ventilator-delivered breaths, but during the spontaneous breaths, the tidal volume depends on patient effort and compliance of the chest wall and lungs. The tidal volume during pressure control ventilation depends on the compliance of the chest wall and lungs. The tidal volume will decrease as the compliance worsens (i.e., worsened pulmonary edema). If the compliance of the chest wall or lungs changes during assist-control ventilation, the tidal volume will remain the same but the airway pressures will increase.

CHAPTER 45

NATHANIEL MARCHETTI, CHRISTOPHER B. REMAKUS, UBALDO J. MARTIN, AND GERARD J. CRINER

Mechanical Ventilation – Part II: Monitoring of Respiratory Mechanics During Mechanical Ventilation and Ventilator Strategies

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Review basic concepts of respiratory mechanics and their implications for monitoring patients receiving mechanical ventilation.
- Review ventilator strategies for specific diseases.
- Understand the role of adjunctive therapies during mechanical ventilation.
- Understand and identify the complications associated with mechanical ventilation and the use of endotracheal and tracheostomy tubes.

MONITORING OF RESPIRATORY MECHANICS

Pressure, airflow, and volume measurements quantify basic physiologic properties of the respiratory system, such as resistance, compliance, and work-of-breathing; interpreting the relationship of these variables is essential for appropriate ventilator management. These variables also provide important information regarding the patient's underlying disease.

Basic Concepts of Respiratory Mechanics

In breathing, work must be performed to overcome the elastic and resistive forces of the respiratory system.

To fully understand ventilator–patient interactions, knowledge of basic respiratory mechanics is imperative. The act of breathing requires that work be performed to overcome several different impediments, the most important of which are the following:

- The elastic forces developed by the lung and chest wall when intrapulmonary volume is increased.
- Resistive forces resulting from the flow of gas through the ventilator circuit, endotracheal tube (ETT), and conducting airways.

Simple elastance/resistance models cannot fully explain the mechanical characteristics of the airway; it is clear that other forces play a lesser, yet important role. In addition to elastic and resistive forces, other factors have to be overcome, but their contribution is less important.

- Viscoelastic forces, a characteristic of certain materials that elongate when subjected to stress, followed by further elongation if stress is maintained constant. In this case, adaptation to mechanical distension will occur within the lung and chest wall tissue.
- Plastoelastic forces, a characteristic of plastoelastic materials (i.e., stretchable materials), which does not follow Newtonian physics. These materials exhibit different mechanical properties at different levels of stress. Plastoelastic forces explain the difference between the inspiratory and expiratory portions of the pressure–volume (P–V) curves. The lung and chest wall show a decrement in stiffness during expiration, following full lung inflation.
- The additional effect of gravitational forces and thoracic gas compressibility. These effects, however, are practically negligible.

Elementary Laws of Mechanics

A simple model of the respiratory system depicts the airway as a simple resistive element that is connected to an elastic element representing both lungs and the chest wall (Fig. 45-1). In such a model, the interaction between pressure, volume, and flow follow Newtonian physics. This model is particularly useful during assisted breathing on a mechanical ventilator because the applied force (or pressure) can be easily measured. In contrast, during unassisted breathing, the pressure generated by the respiratory muscles cannot be measured directly and can be calculated only if the elastic and resistive characteristics of the respiratory system are known.

In a simple analog of the respiratory system, the pressure that is applied (P_{appl}) at any instant (t) is the sum of the elastic pressure (P_{el}) and the resistive component (P_{res}):

$$P_{appl}(t) = P_{el}(t) + P_{res}(t) \quad (45\text{-}1)$$

This equation is a simplified version of Newton's equation of motion, an application of Newton's third law of motion, which states, "For each force applied *to* a body, there is an equal opposing force *by* the body."

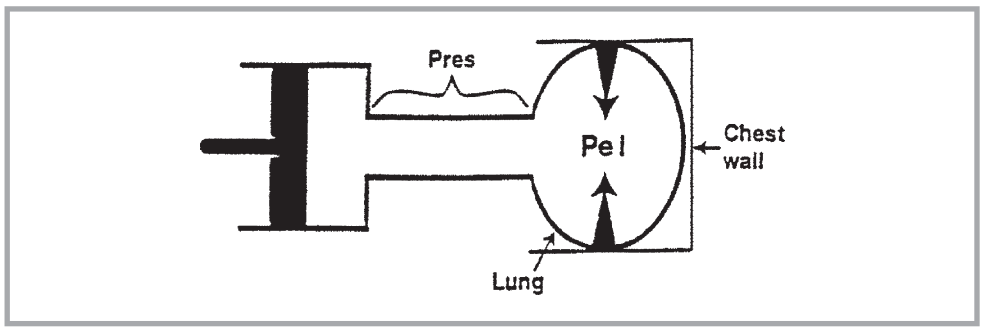

FIGURE 45-1

Simplified respiratory system model in which the airway is represented by a resistive element (P_{res}) and the lungs and chest are represented as an elastic element (P_{el}).

How does this apply to the respiratory system? In the respiratory system, a change in volume (ΔV) is opposed by the elastance (E) of the lungs and chest wall, and flow ($\dot{V}$) is opposed by the resistance (R) of the system. Equation 45-3 can be rearranged as

$$P_{appl} = \Delta V \times E + \dot{V} \times R \quad (45\text{-}2)$$

A change in volume is opposed by the elastance of the respiratory system, and the resistance of the respiratory system opposes flow.

Notice that inertial forces are not taken into consideration by the equation of motion in the respiratory system because friction plays a negligible role in gas motion. It follows from this equation that in the absence of flow ($\dot{V}$), applied pressure (P_{appl}) to respiratory system equals elastic pressure (P_{el}), which in the relaxed mechanically ventilated patient represents alveolar pressure (P_{alv}).

$$P_{appl} = P_{el} = \Delta V \times E = P_{alv} \quad (45\text{-}3)$$

Although physiologists favor the concept of elastance (E), in practice its inverse, compliance (C) is more frequently used ($C = 1/E$).

Peak Airway Pressure

Peak airway pressure is the maximal airway pressure recorded at the end of inspiration in a relaxed patient.

Peak airway pressure or peak inspiratory pressure is the maximal airway pressure recorded at the end of inspiration during positive pressure ventilation in a relaxed patient. It represents the total pressure needed to overcome the resistance related to the ventilator circuit, ETT, and airway, in addition to the elastic recoil of the lungs and chest wall (Fig. 45-2).

In the completely relaxed patient without airway obstruction or significant resistance from ventilator circuit, ETT, or secretions, peak pressure may reflect alveolar pressure. Peak pressure may not always be helpful in discerning between problems affecting the resistive (asthma/COPD) or the elastic component (ARDS/pneumonia) of the respiratory system. Because peak pressure also includes the resistive properties of the circuit, ETT, and airway, it does not always reflect alveolar pressure. A large amount of energy is dissipated in the airway, especially in the presence of small-bore ETTs, significant airway obstruction, and secretions. In these cases, high peak pressures do not represent alveolar pressure and are not necessarily associated with the development of barotrauma. Additionally, increased peak inspiratory pressures are also observed when ventilating patients with increased thoracoabdominal elastic loads, such as those who are morbidly obese, extremely edematous, or having massive ascites; once again, these pressures may not predispose these patients to alveolar rupture. However, a sudden rise in peak airway pressures should raise the suspicion of pneumothorax, significant bronchospasm, large airway atelectasis, pulmonary edema, or mucous plug formation.

A sudden increment in peak airway pressure should raise the suspicion of pneumothorax, significant bronchospasm, or a mucus plug in the airway.

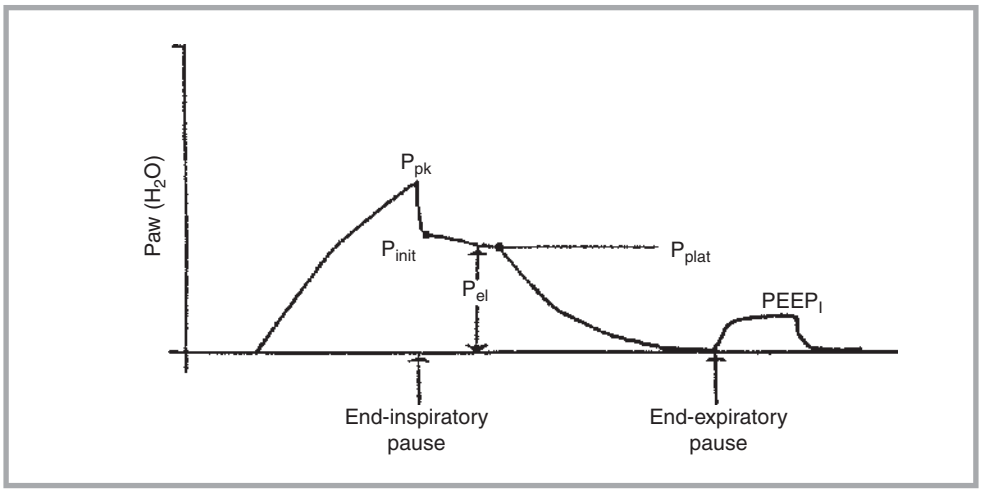

FIGURE 45-2

A typical waveform. P_{pk} represents peak pressure. If an inspiratory pause is set, a rapid drop in pressure can be observed. The initial drop in pressure at flow cessation (P_{init}) is followed by a more gradual drop in pressure; a plateau (P_{plat}) occurs after 3–5 s. The pressure difference between P_{pk} and P_{init} represents the pressure needed to overcome airway resistance. The difference between P_{init} and P_{plat} reflects the viscoelastic properties of the system. Notice that at end-expiration a pause has been set, revealing the presence of intrinsic ($PEEP_I$).

CASE STUDY: PART 1

A 73-year-old female is admitted to your intensive care unit for severe community acquired pneumonia. She has a past medical history significant for a myelodysplatic disorder that causes her to be chronically anemic and thrombocytopenic. She is a lifelong nonsmoker and has no history of prior lung disease. She is intubated (oral ETT size 7.5 mm) and mechanically ventilated in the assist control mode with a RR of 14, tidal volume of 600 mL, FiO_2 of 60%, PEEP 5 cm H_2O. You are called to see the patient because the peak pressure alarm is sounding on the ventilator. Her vital signs are: $T = 102°F$, HR 110 bpm, BP 110/70, S_pO_2 95%. You note copious purulent secretions in the ETT and the patient appears very uncomfortable. Physical exam is significant for bilateral bronchial breath sounds at the right base. No subcutaneous air is felt on palpation of the patient's thorax. The peak pressure on the ventilator is 75 cm H_2O (it was 32 earlier) and the plateau pressure is 40 cm H_2O. After ordering a chest X-ray to rule out a pneumothorax; you suction the ETT and remove a large amount of thick purulent secretions. The peak pressure decreases back to baseline, and the chest X-ray showed volume loss on the right consistent with atelectasis. You correctly attribute the increased peak pressure to a mucus plug.

Plateau Pressure

In a relaxed patient receiving assist-control ventilation, applying an inspiratory pause at the end of passive inflation (inspiration) will result in an immediate drop in airway opening pressure (P_{aw}) to a lower initial value (P_{init}). This rapid fall in pressure is followed by a more gradual decrement, until a plateau pressure (P_{plat}) is reached after 3–5 s (see Fig. 45-2). The difference between peak airway pressure and the initial pressure drop (P_{init}) is thought to reflect a purely resistive component. The difference between P_{init} and P_{plat} is likely to be due to volume redistribution in areas with different time constants and viscoelastic adaptation. Hence, plateau pressure reflects lung and chest wall elastance, whereas peak airway pressure reflects chest wall and lung elastance plus the resistive properties of the airways during inspiratory flow. High plateau pressures can be seen in patients with diffuse lung diseases, such as acute respiratory distress syndrome (ARDS) or multilobar pneumonia. Patients with morbid obesity or chest wall deformities (e.g., kyphoscoliosis) represent disorders with decreased chest wall compliance.

Plateau pressure reflects lung and chest wall elastance.

High plateau pressures can be seen in patients with diffuse lung diseases such as ARDS or multilobar pneumonia.

Increasing emphasis has been given to monitoring plateau pressures in mechanically ventilated patients in order to prevent ventilator-induced lung injury (VILI). In healthy lungs, a transpulmonary pressure of 35 cm H_2O would inflate the lungs to near-total lung capacity. In patients with acute lung injury or pulmonary edema, total lung capacity may be effectively reduced by alveolar loss or collapse. Therefore, the tidal volume delivered with each ventilator-assisted breath may over distend the more compliant regions of the lungs. The resultant higher plateau pressures may lead to alveolar overdistension of the more compliant alveolar units. Alveolar overdistension is suspected of causing "volutrauma" or VILI as a result of the mechanical shear forces applied to the alveoli as they are repeatedly opened and closed.

Alveolar overdistension is suspected to be one of the causes of VILI.

Several randomized, controlled trials have evaluated maintaining plateau pressures below 35 cm H_2O in patients with ARDS, with some studies demonstrating improved survival.[1] Maintaining plateau pressures below 35 cm H_2O has also been shown to reduce inflammatory markers and to reduce the incidence of multiple organ failure in patients with ARDS. Current guidelines call for keeping the plateau pressure below 30–35 cm H_2O, but it is not known if going below 30–35 would result in better outcomes. At least one meta-analysis suggests that the safest upper limit for a plateau pressure in ARDS has not been defined.[2] For ARDS patients with significant elevation of plateau pressures, pressure-control ventilation with or without permissive hypercapnia has been employed to avoid VILI. In other clinical conditions, the plateau pressure may reflect the forces generated by the chest wall, abdomen, and pulmonary parenchyma. For example, patients with marked chest wall edema, abdominal distension, and pleural effusions may have abnormally elevated plateau pressures. In this clinical scenario, limiting plateau pressure to less than 35 cm H_2O may be insufficient to maintain the alveoli open, resulting in an underventilated patient. In this setting, higher plateau pressures may be necessary to achieve effective ventilation.

Maintaining plateau pressure below 35 cm H_2O has been associated with a decrease in mortality and the incidence of multiple organ failure in patients with ARDS.

Intrinsic PEEP ($PEEP_I$)

$PEEP_I$ occurs when alveolar pressure exceeds atmospheric pressure at the end of expiration.

At the end of expiration, alveolar and airway pressures equal atmospheric pressure. Intrinsic positive end-expiratory pressure ($PEEP_I$) or auto-PEEP occurs when alveolar pressure exceeds atmospheric pressure at the end of expiration. $PEEP_I$ results in an increased intrathoracic pressure and elevated end-expiratory lung volume. In patients with underlying airflow obstruction secondary to asthma or emphysema, the patient may not be able to completely exhale. In these circumstances, if sufficient expiratory time is not permitted to allow full exhalation, progressive hyperinflation and $PEEP_I$ occur.

The increase in intrathoracic pressure may lead to profound hemodynamic consequences, such as decreased cardiac venous return and cardiac output. Dynamic hyperinflation foreshortens the respiratory muscles and places them at a mechanical disadvantage, thereby contributing to an increased work-of-breathing. $PEEP_I$ also contributes to an increased inspiratory elastic workload.

In patients with underlying airflow obstruction, insufficient expiratory time will prevent full exhalation and result in progressive hyperinflation and $PEEP_I$.

$PEEP_I$ may occur in patients with significant airflow obstruction, in patients ventilated at high respiratory rates with a small-bore ETT in place, or when the chosen ventilator settings result in an insufficient expiratory time to allow exhalation to the resting end-expiratory lung volume. Under these conditions, patients are not able to completely exhale before the next inspiratory cycle begins, leading to progressive air trapping.

Static PEEP may be determined by occluding the ventilator's exhalation valve at end-expiration and reading the positive deflection in the pressure–time waveform.

Two methods of determining $PEEP_I$ have been described. One method is to occlude the ventilator expiratory port at the end of exhalation, which will cause the pressure in the lungs tventilator's manometer or estimated from the positive deflection in the pressure–time waveform (Fig. 45-2); this has been termed static $PEEP_I$. The second method is to determine the drop in intrathoracic pressure that is required for inspiratory flow to begin (Fig. 45-3). The latter measurement is called dynamic $PEEP_I$ and has been reported to be lower than static $PEEP_I$; this is particularly true in patients with COPD and severe obstruction.

The drop in intrathoracic pressure that is required for inspiratory flow to begin is termed dynamic PEEP.

The dynamic to static $PEEP_I$ ratio appears to correlate with the difference between the initial drop (P_{init}) and final plateau pressure (P_{plat}), when a pause is set during inspiration. Because the difference between P_{init} and P_{plat} represents losses due to time constant inequalities and viscoelastic adaptation, the difference in dynamic and static $PEEP_I$ appears to be related to time–constant inequalities. It is believed that dynamic $PEEP_I$ represents the lowest regional end-expiratory pressure that must be overcome to initiate a breath, whereas static $PEEP_I$ represents the average value of PEEP present in a nonhomogenous lung tissue. Although the first method appears to be simpler, it requires precise timing with the patient's end-expiration, and $PEEP_I$ may also be underestimated because of ventilator circuit compliance and abnormally elevated lung compliance resulting in pressure dissipation. Newer ventilators have a software that allows automatic occlusion at the end of expiration. The second method requires the insertion of an esophageal balloon, a relatively invasive procedure, but it appears to yield more consistent results and allows for continuous measuring of $PEEP_I$.

Dynamic PEEP determination requires the insertion of an esophageal balloon, but allows more consistent results and continuous monitoring of $PEEP_I$.

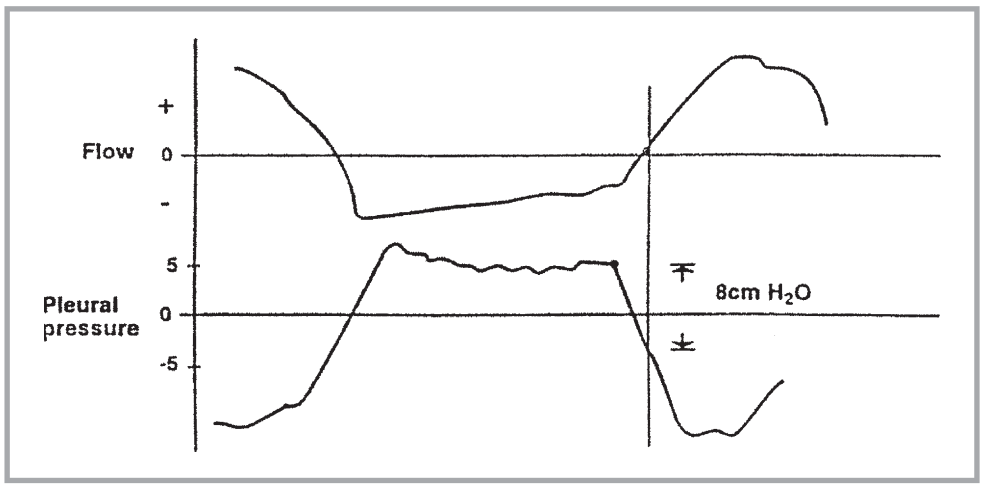

FIGURE 45-3

Dynamic intrinsic PEEP is measured by determining the difference in intrathoracic pressure (with an intraesophageal balloon) between the onset of inspiratory effort and the onset of respiratory flow (reprinted with permission from Haluszka J et al. *Am Rev Respir Dis*. 1990;141:1194-1197. Official Journal of the American Thoracic Society ©American Thoracic Society).

CASE STUDY: PART 2

The patient begins to improve slowly as evidenced by improvement in her pulmonary infiltrates, resolution of fever, and improved oxygen requirements. However, her hemoglobin has fallen to 6 mg/dL and she is transfused with two units of blood. About 1 h after the transfusion she develops progressive hypoxemia. The peak pressure on the ventilator has increased again to 45 cm H_2O, and the plateau pressure is also increased to 40 cm H_2O. Chest X-ray shows bilateral infiltrates consistent with pulmonary edema. You suspect that she has developed transfusion-related acute lung injury (TRALI).

Compliance

Compliance is defined as volume change per unit of pressure change.

Compliance is defined as volume change per unit of pressure change. If airway pressure is plotted against delivered volume, the slope of the resulting curve (P–V curve) represents compliance (Fig. 45-4). The curve is not linear at its extremes; the points at which a plateau is detected are called inflection points. In the curve depicted in Fig. 45-4, two inflection points, a lower inflection point (LIP) and an upper inflection point (UIP), can be identified.

Compliance can be calculated as:

$$C_{tot} = V_T / (P_{plat} - \text{total PEEP}), \tag{45-4}$$

where V_T is the tidal volume and total PEEP is the sum of extrinsic PEEP and intrinsic PEEP. Two common mistakes can lead to erroneous calculations of compliance. Because volume is dissipated by the distension of the ventilator circuit during the process of ventilation, tidal volume has to be adjusted. Each manufacturer provides compliance data for their ventilator tubing; generally 2–3 mL/cm H_2O of applied pressure are lost. Failing to include intrinsic PEEP in the equation introduces a large margin of error in the calculation of compliance, as much as 100% in patients with COPD. In a normal person, compliance is about 50–80 mL/cm H_2O.

Compliance can be partitioned into chest wall and lung components by measuring the esophageal pressure (P_{es}), which reflects the pleural pressure (P_{pl}). Lung compliance is calculated as

$$C_L = V_T / (P_{plat} - P_{pl}), \tag{45-5}$$

and chest wall compliance can be calculated as:

$$C_{CW} = V_T / P_{pl}. \tag{45-6}$$

Decreased chest wall compliance can be seen in disorders such as morbid obesity and chest wall deformities.

Increased compliance can be seen in patients with emphysema.

Decreased compliance can be seen in patients with ARDS or lung fibrosis. In these cases, lung compliance is the component primarily affected (Table 45-1). Decreased compliance can also be seen in patients with morbid obesity and chest wall deformities, conditions in which the chest wall component is decreased. On the other hand, increased compliance is observed in patients with emphysema because of decreased lung elastic recoil.

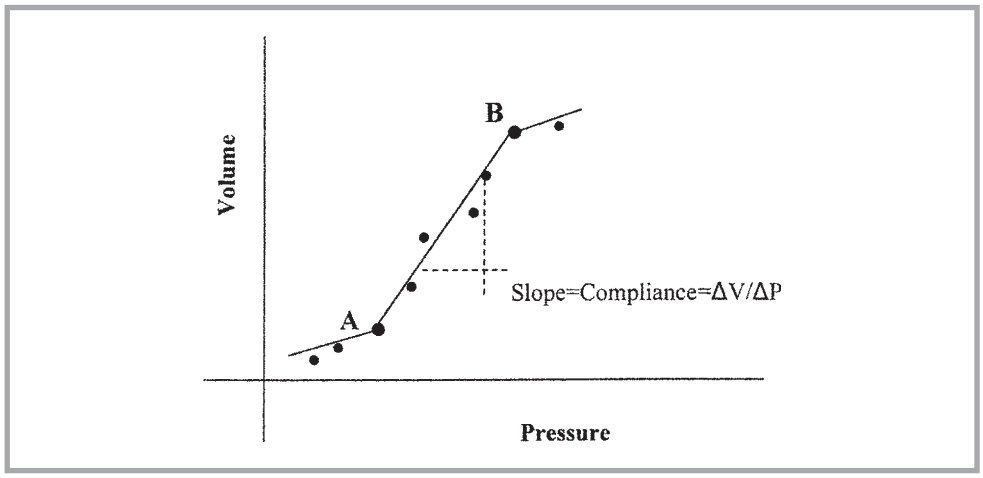

FIGURE 45-4

Resistance

Resistance is calculated as pressure in the respiratory system divided by flow.

Resistance is calculated as pressure in the respiratory system divided by the flow rate. Resistance of breathing comes from three sources: the airway, lung tissue, and system inertia. Airway resistance is the most important of the three. Airway resistance is caused by factors such as bronchospasm or retained secretions (Table 45-2). Airway resistance varies between inspiration and expiration; this difference is particularly important in patients with diseases such as COPD and asthma. Resistance also varies with changes in lung volume; expiratory resistance increases as lung volumes decrease. Airway resistance can be measured separately during inspiration and expiration.

Inspiratory resistance can be measured in relaxed patients receiving mechanical ventilation during constant flow. The driving pressure is the difference between the peak and plateau pressures. Inspiratory resistance can be calculated as:

$$R_{ins} = (P_{pk} - P_{plat})/\text{inspiratory flow.} \quad (45\text{-}7)$$

It is believed that the initial drop to P_{init} (see Fig. 45-2) represents a purely resistive component, whereas the drop to P_{plat} also includes the lung's viscoelastic properties. It has been suggested that the measurement of resistance based on the initial drop is more reflective of airway resistance, whereas resistance using plateau pressures includes tissue and inertial resistance as well.

Expiratory resistance increases at lower lung volumes due to decreased airway diameter.

Expiratory resistance increases at lower lung volumes due to decreased airway diameter. Expiratory resistance can be measured using the multiple occlusion technique. The airway is intermittently occluded in a stepwise fashion repeatedly during a single expiration. During each occlusion, alveolar pressure is measured and, on release, the initial flow is determined. After several data points are recorded, a pressure–flow curve is plotted, and the best-fit regression line is drawn. The slope of the regression line represents average expiratory resistance over the entire tidal volume.

Work-of-Breathing

To achieve normal ventilation, work has to be performed to overcome the elastic and frictional resistances of the lung and chest wall. Work is performed by patients while contracting their inspiratory muscles, by the mechanical ventilator, or by both to a variable degree. Mechanical work (W) implies that the applied pressure (P_{appl}) produces some displacement of the system, volume (V) in this case, according to the formula:

$$W = P_{appl} \times V_T, \quad (45\text{-}8)$$

Work can be calculated from the area subtended by the applied pressure and the inflation volume.

that represents the area under the volume–pressure curve. During CMV, in relaxed patients, the work-of-breathing can be computed from the area subtended by the inflation volume and applied pressure (airway pressure) and calculated from equation (45-8). In patients who are actively breathing and share a portion of work with the mechanical

Mucosal edema	Tracheal stenosis
Increased secretions	

ventilator, such as patients on pressure support, measurement of the patient's work-of-breathing requires an esophageal balloon to estimate pleural pressure (Fig. 45-5). The esophageal P–V loops also allow work to be separated into resistive and elastic components. Work can be expressed as work per breath, work per minute (work per breath × frequency), or work per liter (work per minute/minute ventilation). Work per liter appears to more closely reflect the abnormalities in pulmonary mechanics, whereas work per minute is dependent on minute ventilation and may be lower in patients with severe airway obstruction.

Pressure–Volume Curves

A P–V curve can be constructed or plotted in paralyzed patients by measuring the airway pressure while the lungs are progressively inflated with a supersyringe (1.5–3.0 L). By plotting the pressure for sequential volume points, a curve such as the one depicted in Fig. 45-4 is created. Compliance can be calculated from the slope of a regression line drawn over the curve.

Compliance can be calculated from the slope of the P–V curve.

A LIP and an UIP may be seen in a P–V curve; the LIP is thought to represent the point at which smaller airways and alveoli reopen, corresponding to closing volume. Several investigators have recommended that patients with acute lung injury and ARDS should be ventilated with PEEP set slightly above the LIP. One investigator used tidal volumes of 6–8 mL/kg and individually titrated the level of PEEP in each patient, showing a decrease in mortality in patients treated in this manner. Other investigators have not reproduced these results, raising the question whether individual titration is an important factor in ARDS management. The UIP possibly reflects encroachment on total lung capacity, and inflation beyond this point may result in lung injury.

Many investigators have recommended that ARDS patients be ventilated with PEEP set slightly above the LIP.

The UIP possibly reflects encroachment on total lung capacity; inflation beyond this point may result in lung injury.

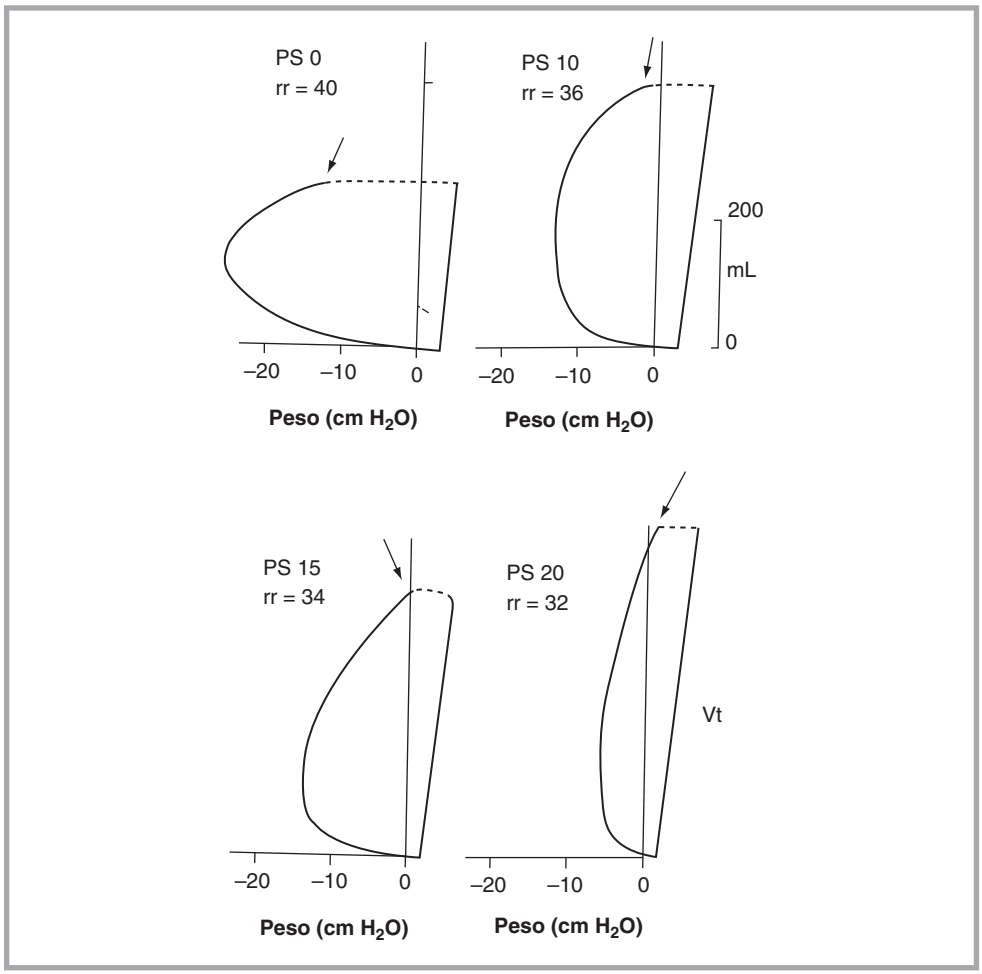

FIGURE 45-5

Loops of esophageal pressure (Peso) against volume, used for the determination of work in a patient ventilated with pressure support ventilation. A progressive decrement in work per breath can be observed as pressure is increased; this also correlates with a decrement in spontaneous respiratory rate (reprinted with permission from Brochard L et al. *Am Rev Respir Dis.* 1989;139:513-521. Official Journal of the American Thoracic Society ©American Thoracic Society).

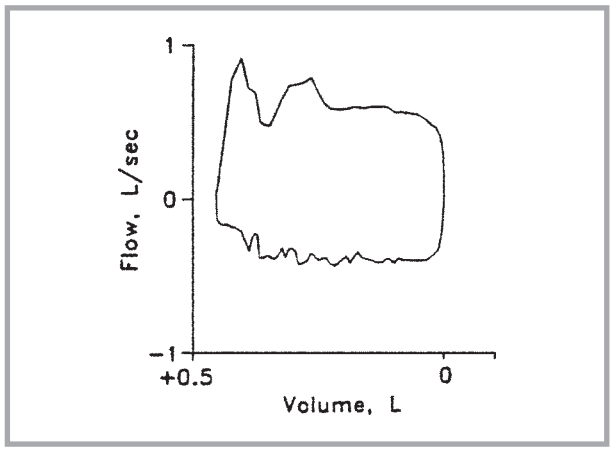

FIGURE 45-6

The sawtooth pattern of the flow–volume curve in a mechanically ventilated patient correlates with the presence of airway secretions (reprinted with permission from Jubran A et al. *Am J Respir Crit Care Med*. 1994;150:766-769. Official Journal of the American Thoracic Society ©American Thoracic Society).

One group of investigators was able to demonstrate an UIP in a group of 25 patients with ARDS ventilated with a tidal volume of 10 mL/kg and PEEP of 10 cm H_2O. The mean UIP was 26 cm H_2O for these patients, and most of the patients had higher plateau pressures. It is currently recommended that patients with ARDS be ventilated with plateau pressures below 35 cm H_2O, which is above the UIP observed by these authors. Whether this may contribute to the development of VILI is unclear.

Flow–Volume Curves

Flow–volume (F–V) curves may provide useful information in mechanically ventilated patients. It is important to notice that the expiratory flow contour is affected by patients breathing through a fixed-diameter (ETT). Normal subjects and patients with decreased compliance display a smooth decrease in flow during expiration, whereas patients with obstruction show a convex, curvilinear pattern. In patients with intrinsic PEEP, expiratory flow stops abruptly before the next mechanical breath, creating a characteristic truncated appearance on the F–V curve. In ventilator-dependent patients, the appearance of saw-toothing in the F–V curve has been associated with the presence of airway secretions and the need for endotracheal suctioning (Fig. 45-6).

The sawtooth appearance of the F–V curve in mechanically ventilated patients correlates with the presence of airway secretions and the need for suctioning.

VENTILATOR STRATEGIES

Permissive Hypercapnia

Permissive hypercapnia is a ventilator strategy that allows the $PaCO_2$ to rise above normal physiologic levels by decreasing the minute ventilation in selected cases of respiratory failure. It has been employed in ARDS and asthma to minimize peak and mean airway pressures and, consequently, the potential for VILI.

Permissive hypercapnia is used in ARDS and asthma to decrease peak and mean airway pressures.

A reduction in minute ventilation results in a reduction in alveolar ventilation which in turn, results in increased $PaCO_2$, a decrease in P_AO_2, and a consequent decrease in PaO_2 (see Chap. 15). Thus, higher extrinsic PEEP or a prolonged inspiratory time is frequently required to maintain oxygenation.

The acceptable degree of hypercapnia is controversial. Frequently, minute ventilation that results in $PaCO_2$ levels between 75 and 80 mmHg is sufficient to decrease mean airway and plateau pressures to acceptable levels. Most authors recommend maintaining pH above 7.20 to minimize the adverse effects of hypercapnic acidosis. This concept may not be entirely accurate for several reasons. The deleterious effects of hypercapnic acidosis are a consequence of intracellular pH alterations. Correction of intracellular pH occurs more rapidly than correction of extracellular pH; therefore, blood pH is likely a poor surrogate for intracellular pH, and a lower blood pH may be acceptable.

Many authors recommend maintaining pH above 7.20 to minimize the adverse effects of hypercapnia.

The potential benefits of permissive hypercapnia include a reduction in lung injury due to decreased shear forces at the alveolar level, decreased blood flow to the injured lung, and a decreased incidence of barotrauma. Permissive hypercapnia has many downsides, however. Patients will often mount a physiologic response to hypercapnia by increasing minute ventilation; therefore, sedation and paralysis are frequently required to prevent this compensatory attempt, and also to improve patient tolerance of the symptoms of hypercapnia. Acute hypercapnia may cause cerebral vasodilatation and elevated intracranial pressure, and may worsen cerebral edema. Acute hypercapnic acidosis has a direct depressant effect on myocardial contraction, increases sympathetic activity, and directly causes peripheral vasodilatation. Cardiac irritation may lead to the generation of arrhythmias. Finally, hypercapnic acidosis increases pulmonary vascular resistance.

Acute hypercapnia may cause cerebral vasodilatation, elevated intracranial pressure, and worsening cerebral edema.

Acute hypercapnia has a depressant effect on myocardial contractility.

Permissive hypercapnia is contraindicated in patients with cerebral edema and elevated intracranial pressures, a prior history of seizures or an active seizure disorder, depressed cardiac function and/or arrhythmias, and in patients with increased pulmonary vascular resistance. There is currently little evidence supporting the routine use of permissive hypercapnia in ARDS or status asthmaticus. Ideally, it should be used for short periods of time to reduce mean and plateau pressures in patients at risk for VILI, particularly in those who may have a rapidly reversible cause for elevated airway pressures.

Permissive hypercapnia is contraindicated in patients with cerebral edema, seizure disorders, or depressed cardiac function.

Inverse Ratio Ventilation

The I:E ratio during the respiratory cycle of average adults is approximately 1:2. During inverse ratio ventilation (IRV), inspiratory time is prolonged to exceed the expiratory duration in order to recruit additional alveolar units in situations wherein the extrinsic PEEP is insufficient to accomplish this goal. Because the inspiratory cycle may overlap with patients' neural expiratory phase, IRV ratios greater than 2:1 often necessitate the use of sedation and paralysis. Mean alveolar pressure rises as a result of the longer inspiratory time, and rapid increases in respiratory rate can dramatically increase both peak and mean airway pressures. Patients with underlying airflow obstruction at baseline are at risk for developing substantial degrees of auto-PEEP as a result of a decreased expiratory time.

Inspiratory to expiratory ratios greater than 2:1 have not shown improvements in oxygenation, and patients are at a greater risk for hemodynamic intolerance and VILI. IRV is commonly employed with PCV; given the dramatic nonphysiologic alterations in inspiratory and expiratory times that are required, sedation and paralysis of the patient are necessary to achieve satisfactory patient comfort and effective ventilation. IRV has been used in the setting of ARDS and hypoxemic respiratory failure in an attempt to improve oxygenation, but there is insufficient evidence to support its efficacy in reducing morbidity or mortality.

Independent Lung Ventilation

Patient with severe unilateral lung pathology may require different ventilation strategies applied to each lung. In certain cases, this can be achieved only through independent lung ventilation. Patients with whole lung pneumonia, unilateral pulmonary contusion, or following single lung transplant may require extrinsic PEEP selectively delivered to the involved lung to maintain gas exchange, while simultaneously avoiding PEEP delivery to the normal or overly compliant contralateral lung. The patient with a BPF and significant air leak may benefit from selective ventilation of the contralateral lung to promote closure of the BPF. In the presence of important tidal volume losses resulting from a large air leak, selective ventilation of the unaffected lung may allow for more effective ventilation.

In patients with severe unilateral lung disease, independent lung ventilation allows applying different ventilation strategies to each lung.

Patients with large bronchopleural fistulas (BPF) may benefit from selective ventilation to the contralateral lung to promote closure.

Independent lung ventilation may be achieved through the use of double lumen tubes (DLT), also known as endobronchial tubes. The endobronchial portion of the DLT tube is curved to the right or the left and intubates one of the two main bronchi. These tubes have cuffs on the tracheal and endobronchial segments; when inflated, they direct the airflow selectively into the right or left lung and ensure independent ventilation. A left DLT is preferred because of the risk of inadequate right upper lobe ventilation if a right DLT is incorrectly positioned or the latter migrates. These tubes allow different ventilator

Independent lung ventilation can be achieved through the use of double lumen tubes.

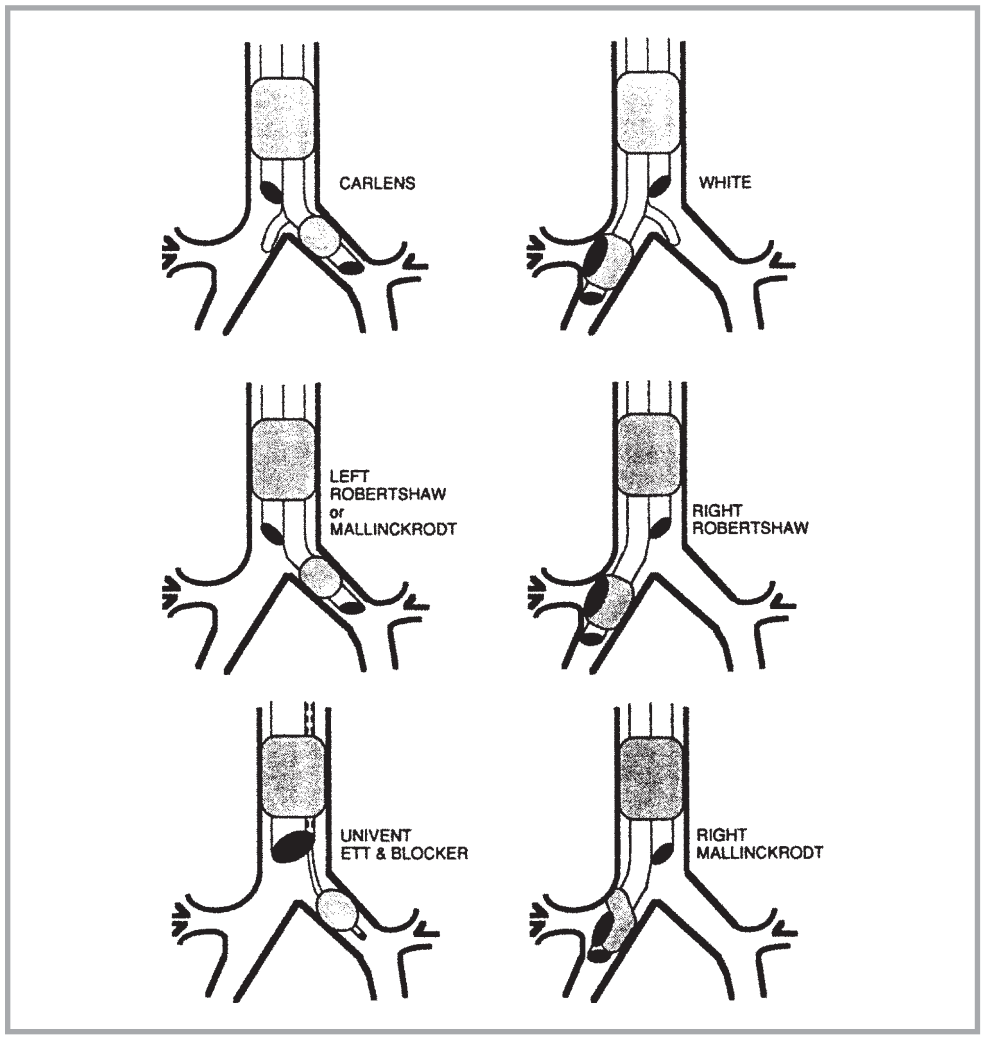

FIGURE 45-7

Common double lumen tubes.

settings to be applied to each lung, such as different PEEP levels or tidal volumes (Fig. 45-7). They are usually placed under direct laryngoscopy and their position is confirmed by bronchoscopy. Minimal patient movement may cause tube displacement; the use of sedative/hypnotics and paralytics is often required to ensure patient comfort and immobility. The narrow lumens of the tube increase the resistive workload, prohibit weaning attempts, and the difficulty in suctioning of airway secretions may prevent prolonged use.

Bronchial blocking techniques may be an alternative to DLT placement; however they are most often used to allow one-lung ventilation in an operative setting. A balloon-tipped catheter (kits are available commercially) is passed outside or within a conventional ETT and then inflated within the targeted main bronchus. These catheters have a narrow central channel that allow for lung deflation rather than ventilation.

Prone Position Ventilation

Prone positioning of patients on mechanical ventilation has been recently described as an adjunct to improve oxygenation in selected patients with hypoxemic respiratory failure who have a poor response to more conventional techniques of mechanical ventilation. The rotation of patients from the supine to prone position may have profound effects on respiratory physiology.

In patients with severe hypoxemia who are not responsive to increases in FiO_2 or extrinsic PEEP, prone positioning may have a transient effect in decreasing ventilation/perfusion mismatch and improving oxygenation by recruiting functional alveoli. After placement in the prone position, an improvement in gas exchange is seen in minutes to hours in 50–70% of ARDS patients. This beneficial effect appears to be transient and, because of the collapse of dependent alveolar units, is lost after several hours. Prone positioning should be reserved for those patients with marked hypoxemia, who are not responsive to other ventilatory support maneuvers. Movement to the prone position itself may place the patient at risk for inadvertent extubation, hypotension, desaturation, arrhythmias, and severe limitations in nursing care. There have been several randomized studies looking at the effectiveness of prone positioning during mechanical ventilation in ARDS. Gattinoni et al reported an improvement in oxygenation with the prone position in ARDS patients, but no effect on survival.[3] Posthoc analysis showed that there may have been an improvement in 10-day survival in patients who had lower PaO_2/FiO_2 ratios, with higher acuity of illness scores, and treated with higher tidal volumes. One of the potential criticisms of the prior study was that patients were not placed in the prone position early enough or maintained for an adequate period of time. Mancebo et al reported that patients who were placed in the prone position for an average of 17 h/day for 10.1 ± 10.3 days also had no difference in ICU mortality.[4] However, there were no serious adverse events suggesting that placing critically ill patients in the prone position can be performed safely.

Placement of patients in the prone position appears to decrease *V/Q* mismatch and improve oxygenation by recruiting functional alveoli.

The effect of prone position ventilation is transient and is generally lost after a few hours.

Prone position ventilation carries certain risks, such as inadvertent extubation, hypotension, and desaturation.

Although ventilation in the prone position temporarily improves oxygenation, it does not appear to alter mortality.

MECHANICAL VENTILATION FOR SPECIFIC CONDITIONS

Acute Respiratory Distress Syndrome

Recently, significant attention has been devoted to protective strategies of mechanical ventilation in ARDS. The rationale behind this comes from animal studies and clinical experience suggesting that mechanical stretch and alveolar overdistension may be responsible for lesions at the alveolar–capillary level that may lead to alterations in permeability and edema. In a study examining the impact of lower end-inspiratory plateau pressures (<25 cm H_2O) in the management of ARDS, 116 patients were randomized to two different groups. Tidal volume in the experimental group was about 7 mL/kg/lean body weight; the control group tidal volume was about 10 mL/kg/lean body weight. Both the groups were ventilated with similar levels of extrinsic PEEP. The low tidal volume group had a higher incidence of CO_2 retention and lower pH. Mortality did not significantly differ between groups (47 vs. 38% in the control group).

In another study, patients with the limited-ventilation strategy had similar mortality to those ventilated with a conventional strategy. Interestingly, in both studies patients in the control and experimental groups had plateau pressures <35 cm H_2O, the level thought to be associated with a higher incidence of alveolar overdistension and barotrauma. In contrast to these studies, a different investigative group reported a significant difference in mortality at 28 days between a group assigned to receive protective-strategy ventilation and a group receiving conventional ventilation; 38 and 71%, respectively. Protective ventilation in this group involved high extrinsic PEEP (above the LIP), tidal volumes less than 6 cm H_2O, and driving pressures less than 20 cm H_2O above the extrinsic PEEP value. The protective ventilation group also showed a higher weaning rate and a lower incidence of barotrauma. The results of this trial should be interpreted with caution because a large number of patients had parasitic disease-induced ARDS, resulting in a unique population.

Finally, the ARDS Network, a multicenter National Institutes of Health-sponsored collaborative ARDS study group, published the results of a multicenter, randomized trial comparing ARDS patients ventilated with a tidal volume of 12 mL/kg/lean body weight vs. patients ventilated with 6 mL/kg/lean body weight.[1] The trial enrolled 861 patients and was stopped early due to an evident reduction in mortality in the low tidal volume group. The lower tidal volume

ARDS patients ventilated with low tidal volumes (6 mL/kg) had less mortality in comparison to similar patients ventilated with larger tidal volumes (12 mL/kg) in a large, prospective, randomized controlled trial.

group had a 21% reduction in mortality and a significant reduction after 3 days of ventilation in inflammatory markers such as IL-6. The low tidal volume group had smaller plateau pressures compared to the traditional higher tidal volume ventilation group. The incidence of barotrauma was similar for both groups. The results of this study have led to a new approach to mechanical ventilation in ARDS, which involves titrating extrinsic PEEP to the highest level that improves oxygenation without affecting hemodynamics, using low tidal volumes to maintain plateau pressures below 35 cm H_2O, and allowing permissive hypercapnia to occur.

Chronic Obstructive Pulmonary Disease and Asthma

In mechanically ventilated patients with severe COPD or asthma, significant $PEEP_I$, pneumothorax, and inability to trigger the ventilator are frequent causes of agitation.

Patients who present with severe bronchospasm often present in acute distress are agitated and represent a significant clinical challenge. Although asthma and COPD differ in terms of their pathophysiology, the management of these patients is similar. When treating patients with severe obstructive disease, several points should be considered. Significant intrinsic PEEP, pneumothorax, and the inability to trigger are frequent causes of agitation. Therefore management should initially focus on maintaining patient–ventilator synchrony, aggressively treating bronchospasm, and avoiding intrinsic PEEP and dynamic hyperinflation. Judicious use of sedation and, if indicated, pharmacologic paralysis, are also helpful in managing these patients. The use of neuromuscular blocking agents in these patients has to be carefully considered: most of these patients will require high doses of systemic glucocorticoids and the concomitant use of neuromuscular blocking agents has been associated with the development of severe myopathy.

Aggressive use of bronchodilators and systemic steroids is paramount in treating patients with severe bronchospasm.

In patients with severe airflow obstruction, the initial ventilator settings should provide a long expiratory time.

Aggressive treatment with bronchodilator agents and systemic steroids is the standard of care for these patients. Patients with severe airflow limitation frequently have high respiratory rates and are unable to empty their tidal volumes completely, which leads to air trapping and the development of intrinsic PEEP. Initial settings should be aimed at providing the patient with adequate expiratory time (decreased I:E ratio). Increasing peak inspiratory flow rate and decreasing minute ventilation by reducing either respiratory rate or tidal volume will decrease I:E ratio; an I:E ratio of 1:4–1:6 is an appropriate goal.

Peak airway pressures are generally high, but most of this pressure is dissipated in the tube and upper airway. Frequent blood gases are needed, and special attention must be paid to the development of intrinsic PEEP (see previous section). Hypercapnia can be allowed to occur so long as pH is kept above 7.20. Because of the presence of intrinsic PEEP, these patients may have difficulty in triggering the ventilator. Switching from pressure triggering to flow triggering may reduce the work-of-breathing in this particular group, resulting in improved patient comfort and patient–ventilator synchrony.

ADJUNCTIVE THERAPIES

Extracorporeal Membrane Oxygenation and Extracorporeal CO_2 Removal

The use of ECMO in ARDS has not been shown to alter mortality.

Extracorporeal membrane oxygenation (ECMO) provides for blood oxygenation and CO_2 elimination in patients who have failed other ventilatory management strategies. ECMO is achieved via venous cannulation; blood is removed and drawn into an external motor-driven device that provides circulatory flow. Gas exchange is attained by the passage of blood across a thin, semipermeable membrane that enables oxygenation and CO_2 removal. Blood returns to the patient via an arterial or venous cannula. Once the ECMO circuit has been established, the respiratory rate and tidal volume are dramatically decreased. The goal of ECMO, in ARDS patients, is to prevent further VILI by decreasing the repeated shear forces at the alveolar level, while awaiting lung recovery. Attempts made in the past to apply ECMO to patients in the ICU with hypoxemic respiratory failure secondary to ARDS have resulted in high morbidity and mortality. The high mortality observed in these patients was largely the result of an increased incidence of sepsis and bleeding events.

CASE STUDY: PART 3

Despite increasing the FiO_2 and aggressive diuresis the hypoxemia and elevated plateau pressure continued. The tidal volume was decreased to 6 mL/kg and the plateau pressure stayed below 35 cm H_2O. PEEP was increased to 12.5 cm H_2O, and arterial blood gas analysis showed a pH of 7.2, $PaCO_2$ of 60 mmHg and a PaO_2 of 65 mmHg on 100% oxygen and 12.5 cm H_2O PEEP. Over the next 24 h, oxygenation gradually worsened even after the patient was heavily sedated and paralyzed. INO was started at 5 ppm and the oxygen saturation gradually improved to 98%.

Extracorporeal CO_2 removal has been attempted, often used in conjunction with permissive hypercapnia. This technique involves a venovenous circuit that diverts a portion of the cardiac output from the pulmonary vascular bed; it requires anticoagulation, which contributes to an increased complication rate. Studies have demonstrated a reduction in $PaCO_2$, but have not shown improvement in survival when compared with conventional therapy; the routine use of this technique in the intensive care unit cannot be supported at this time.

ECMO has been used successfully as an adjunct in newborns with respiratory distress syndrome, aspiration syndromes, pneumonia, and sepsis. Mainly because of its success in neonates and increasing reports of successful use in the adult population; a randomized controlled trial of ECMO is currently enrolling patients at sites across the United Kingdom. A detailed explanation of ECMO is provided in Chap. 48 (mechanical hemodynamic support).

ECMO has been used with success as an adjunct in newborns with respiratory distress syndrome, aspiration syndromes, and sepsis.

Inhaled Nitric Oxide

Nitric oxide is a potent vasodilator and bronchodilator. In humans, it is synthesized from arginine by the enzyme nitric oxide synthase, and has an extremely short half-life. Clinically, nitric oxide is delivered as a gas via the ventilator circuit, resulting in selective vasodilatation of the ventilated portions of the lung; this theoretically results in a decreased *V/Q* mismatch by preferentially directing and increasing pulmonary circulation to the ventilated portions of the lung. These qualities led to its use in ARDS patients. In clinical trials, the use of inhaled nitric oxide (INO) resulted in a temporary improvement in PaO_2 and a reduction in pulmonary artery pressures and pulmonary vascular resistance. A large multicenter, randomized, placebo-controlled study in 385 patients at 46 medical centers failed to show a difference in the number of days the patients were alive and off mechanical ventilation at day 28 despite improved oxygenation.[5] Patients with a PaO_2/FiO_2 <250 who did not have ARDS secondary to sepsis and did not have multisystem organ failure received 5 ppm of INO or placebo (nitrogen gas) were included in this study.[5] Problems associated with INO include the rapid inactivation of nitric oxide in a reaction with oxyhemoglobin to form methemoglobin therefore, methemoglobin should be routinely measured in patients receiving INO. Concern also exists regarding the potential of by-products (NO_2) to be directly injurious to the lungs and cause central nervous system toxicity.

In vivo, nitric oxide is synthesized from arginine by nitric oxide synthase. It is a potent vasodilator and bronchodilator.

INO improves oxygenation in ARDS, but improvement in patient survival has not been demonstrated.

Patients receiving INO, especially at high concentrations, are at risk of developing methemoglobinemia.

Despite the evidence that INO improves oxygenation in many patients with ARDS, a clear improvement in patient survival has not been shown. The cost of INO and the need for INO delivery systems to precisely deliver the drug and monitor the development of a toxic byproduct have restricted the widespread use of this adjunctive therapy.

INO has been used in the treatment of hypoxemic respiratory failure of the newborn caused by persistent pulmonary hypertension, respiratory distress syndrome, aspiration syndromes, and sepsis. Persistent pulmonary hypertension of the newborn is a syndrome characterized by increased pulmonary vascular resistance, significant extrapulmonary shunting through a patent ductus arteriosus, foramen ovale, or both, and severe hypoxemia. It is the result of several different entities, including meconium aspiration, surfactant deficiency, and primary pulmonary hypertension. In several randomized trials, INO has been shown to improve oxygenation, stabilize the newborn before ECMO, and reduce the need for ECMO therapy in persistent pulmonary hypertension of the newborn. Recently, in light of the results of randomized-controlled trials, the U.S. Food and Drug Administration approved the use of INO for the treatment of hypoxic respiratory failure of the term and near-term newborn due to persistent pulmonary hypertension.

INO has been shown to improve oxygenation and reduce the need for ECMO in persistent pulmonary hypertension of the newborn.

Helium is less dense than air; its use thus promotes laminar flow and decreased turbulence in the airway.

Heliox has been used in the treatment of upper airway obstruction caused by tumor, edema, fibrosis, and laryngospasm.

Inhaled Heliox

Heliox is a gas mixture composed of 20–30% oxygen and 70–80% helium. Because of its lower density, helium allows laminar flow and decreased turbulence in the airway, resulting in lower intraluminal pressure generation and reduced frictional resistance. Heliox has been used in the treatment of upper airway obstruction caused by laryngospasm, tumor, edema, fibrosis, and obesity. In patients with asthma, the use of heliox has been associated with improved oxygenation and a faster improvement in forced expiratory volume (FEV_1) and peak expiratory flow rate, when compared with controls in nonintubated patients.[6] Heliox may be useful as a bridge until the effect of systemic glucocorticoids and bronchodilators becomes apparent. Heliox has been studied as an adjunctive therapy in patients intubated for COPD exacerbation. Diehl et al has shown that during spontaneous breathing trials and immediately following extubation, heliox can reduce the work-of-breathing primarily by lowering airways resistance.[7] Additionally, heliox has been shown to reduce intrinsic PEEP from 13 ± 4 cm H_2O to 5 ± 2 cm H_2O, which improved cardiac output in patients intubated secondary to severe COPD exacerbation.[8] One of the major disadvantages of heliox is the inability to provide high levels of inspired oxygen concurrently with its use. If the proportion of helium is decreased below 70% of the mixture, the gas density increases and loses its laminar flow properties; therefore, patients with high FiO_2 requirements are not suitable candidates for heliox administration.

Heliox has been shown to reduce the work-of-breathing and $PEEP_i$ in patients intubated secondary to COPD exacerbations.

Tracheal Gas Insufflation

Tracheal gas insufflation (TGI) is a technique whereby a low flow of fresh gas is delivered to the distal end of the ETT through a small-diameter catheter. The flow can be continuous or delivered only during exhalation. Gas can be delivered by a stand-alone catheter or by a catheter embedded in the ETT, positioned approximately 1 cm above the carina. $PaCO_2$ and endotracheal pressures must be carefully monitored while using TGI. The desired level of $PaCO_2$ determines the TGI flow that is given in addition to the ventilator's minute ventilation. TGI will result in a tracheal PEEP that is higher than the circuit PEEP; careful monitoring of tracheal pressures is necessary to avoid pressure-related complications.

In one study in mechanically ventilated patients, TGI reduced $PaCO_2$ and increased pH; it also increased tracheal PEEP and mean airway pressure, thereby reducing cardiac filling. In a study in trauma patients who developed ARDS, TGI was shown to be effective in reducing $PaCO_2$ and increasing pH, although the reduction was small and its clinical relevance is debatable. It was also shown to decrease the intracranial pressure resulting from permissive hypercapnia. Although studies have not clearly shown a survival benefit from TGI in mechanically ventilated patients in whom permissive hypercapnia is employed, it may have a role in selected patients with a relatively high deadspace.

COMPLICATIONS OF MECHANICAL VENTILATION

Most of the complications associated with mechanical ventilation are related to its duration; therefore, daily assessment of weaning should be done.

Mechanical ventilation is a dynamic process that requires close monitoring and alteration of ventilatory parameters to prevent complications and improve patient comfort. Assessment of weaning capability should be performed daily. Most complications are related to the duration of mechanical ventilation.

Ventilator-Induced Lung Injury

Traditional ventilatory support of patients with acute respiratory failure included the use of higher tidal volumes (10–15 mL/kg). In 1974, Webb and Tierney were the first investigators to recognize that rats ventilated with high-pressure mechanical ventilation (>45 cm H_2O) developed ventilator-induced parenchymal injury, manifested by alveolar edema, hypoxemia, and decreased lung compliance.[9] Death occurred in less than 1 h. Dreyfuss and colleagues saw histologic changes similar to those seen in humans with ARDS when they

subjected rats to high-pressure mechanical ventilation.[10] To discern whether high alveolar pressures or alveolar overdistension caused VILI, the same group conducted a study using five different ventilator strategies in rats. The control group received low-volume/low-pressure ventilation, the second group received high-pressure/high-volume ventilation, the third group received high-pressure ventilation with limited volume by means of thoracoabdominal strapping, the fourth group had high-volume/low-pressure ventilation with an iron lung, and the last group received high-pressure/high-volume and extrinsic PEEP. There were no differences between controls and the group that received high-pressure ventilation with thoracoabdominal strapping. The remaining groups developed high-permeability edema regardless of the way of administering high-volume ventilation.

These findings were substantiated by other investigators, who found a decrement in the incidence of high-permeability edema in rats ventilated with chest wall restriction. Other factors, such as inflammation, may also have an important role, as is supported by studies that failed to show a progression to ARDS in neutropenic animals ventilated with large tidal volumes. In humans, protective lung ventilation has been associated with decreased levels of IL-6, a marker for inflammation.

Ventilator-delivered volume and concomitant inflammation are believed to be closely related to the development of VILI.

Barotrauma

Pneumothorax, subcutaneous emphysema, pneumomediastinum, and other forms of extraalveolar air are generally referred to as barotrauma. This name may be a misnomer because the expansion of lung tissue or volume displacement appears to be the most important cause of extraalveolar air formation in patients receiving mechanical ventilation.

Although extraalveolar air formation is usually the result of the disruption of the pulmonary parenchyma, other causes are also possible. Pneumomediastinum and pneumothorax can result from traumatic tracheal intubation, retropharyngeal abscess, blunt or penetrating chest trauma, as a complication from bronchoscopy, or perforation from a foreign body in the airway. Pneumomediastinum can be seen in patients with traumatic or iatrogenic perforation of the esophagus, or in patients with spontaneous rupture of the esophagus due to vigorous retching (Boerhave's syndrome). Most commonly, in patients on mechanical ventilation, the source of the extraalveolar air lies in the pulmonary parenchyma. Although traditionally associated with elevated pressures, extraalveolar air in mechanically ventilated patients is more likely to result from ventilation with large tidal volumes. Additional factors such as lung and chest wall compliance, underlying lung disorder, inflammation, and ventilatory mode also appear to influence the development of pneumothorax and pneumomediastinum.

In mechanically ventilated patients, the most common source of extraalveolar air is the lung parenchyma.

Because of the lack of physical signs and symptoms in ICU patients, daily chest radiographs are important. The new onset of high peak pressures in a mechanically ventilated patient should raise the suspicion of pneumothorax, especially if associated with hemodynamic instability (tension pneumothorax). The treatment of pneumothorax and BPF in these patients entails chest tube placement. The routine application of suction is customary in the United States, but not in other countries where suction is employed only if the lung does not fully expand. The incidence of barotrauma ranges from 6 to 20% in ventilated patients. Interestingly enough, according to a recent trial, the presence of barotrauma in patients with ARDS does not appear to be an independent predictor of mortality.

The incidence of barotrauma in mechanically ventilated patients ranges from 6 to 20%.

Oxygen Toxicity

The effects of normobaric hyperoxia have been known since the eighteenth century when Lavoisier recognized that "when there is an excess of vital air (oxygen) animals undergo a severe illness." The effects of normobaric hyperoxia on the respiratory system have been extensively studied. Normobaric hyperoxia has been associated with depression of the respiratory drive, pulmonary vasodilatation, ventilation–perfusion mismatch, hypercapnia, absorption atelectasis, acute tracheobronchitis, diffuse alveolar damage, ARDS, and bronchopulmonary dysplasia. The depression of the respiratory drive is primarily due to decreased stimulation of the hypoxia-sensitive chemoreceptors at the carotid and aortic bodies.

Hyperoxia has been associated with the development of diffuse alveolar damage, hypercapnia, tracheobronchitis, absorption atelectasis, and respiratory drive depression.

Oxygen may promote atelectasis formation by interfering with the production of surfactant.

Absorption atelectasis occurs in alveolar units with low ventilation–perfusion ratio. In these units, the absorption of oxygen exceeds its replenishment. Oxygen may also stimulate the formation of atelectasis by interfering with the normal production of surfactant.

The syndrome of acute tracheobronchitis and mucociliary dysfunction was described initially in normal volunteers breathing 100% O_2 for more than 24 h who developed retrosternal discomfort, cough, sore throat, nasal congestion, eye irritation, and fatigue. Bronchopulmonary dysplasia is a syndrome that develops in very low birth weight neonates; it is likely to be the result of hyperoxia, pulmonary edema, and mechanical ventilation-induced trauma. Pathologically, it is characterized by fibrosis and destruction of acinar structures, resulting in scarring and emphysematous changes.

Attempts are made to reduce FiO_2 below 60% as soon as patients tolerate it.

It is still unclear at what level oxygen becomes toxic, particularly in critical care patients. The arbitrary threshold of 60% FiO_2 comes from studies in normal volunteers in the 1950s. The histologic pathology of hyperoxia-induced lung injury can be characterized by the term diffuse alveolar damage. There is abundant evidence supporting the toxic role of hyperoxia in the intensive care unit. Nevertheless, it is extremely difficult to isolate the effects of oxygen amid multiple variables such as mechanical ventilator alveolar over-distension, pneumonia, and sepsis. The combination of oxygen and lung tissue distension or "volutrauma" may be responsible for some of the damage reported.

In general, attempts are made to reduce FiO_2 below 60% as soon as patients tolerate it. Achieving this goal requires a careful approach to diagnosis and treatment of conditions that interfere with adequate oxygenation, such as pneumonia, pulmonary embolism, bronchospasm, excess secretions, pleural effusions, and cardiopulmonary shunts. Decreasing oxygen consumption due to fever, infection, or patient–ventilator asynchrony is also an important step toward decreasing oxygen requirements. Finally, adequate selection of PEEP and protective ventilator strategies may also decrease oxygen requirements and result in less VILI and inflammation. However, it is important to remember that when controversy arises, the immediate effect of hypoxemia is far more devastating than the possibility of oxygen-induced lung injury.

In specific cases, adequate selection of PEEP may aid in decreasing oxygen requirements.

Endotracheal Tube-Related Complications

Complications resulting from ETTs can be divided according to the time in which they occur, that is, complications during ETT placement, complications occurring while the ETT tube is in place, and complications occurring after the removal of the ETT.

Complications Occurring During ETT Placement

Complications during ETT placement include nasal trauma, tooth avulsion, and oral and pharyngeal laceration. Laryngeal injuries, such as glottic contusion and vocal cord laceration and/or hematoma, can occur during ETT placement. Tracheal laceration, perforation, or rupture is extremely uncommon. Endobronchial instead of endotracheal intubation has been reported in 2.5–7% of all adult intubations.[11] The incidence of aspiration during intubation ranges from 1–6% in adult nonanesthetic intubations.[11,12] If the placement of the ETT is difficult and requires more than two attempts, then the risk of aspiration increases four fold.[13]

Endobronchial intubation has been reported in 2.5–7% of all adult intubations.

The incidence of aspiration in adult intubations ranges from 1–6%.

Complications Occurring While the ETT Is in Place

Sinus effusions have been reported to occur in 25–100% of all intubated patients, andprolonged intubation predisposes to the development of sinusitis. It occurs more commonly with nasal intubation. Sinusitis is frequently missed as a cause of fever in the ICU. Up to 25% of all intubated patients will develop sinusitis; these patients frequently present with fever and rarely have purulent drainage. Computed tomography of the sinus is the preferred diagnostic method because physical findings are generally unreliable.

Up to 25% of all intubated patients develop sinusitis.

CASE STUDY: PART 4

The patient gradually improved such that the INO was weaned off, the PEEP was decreased back down to 5 cm H_2O and the FiO_2 was decreased to 40%. By day 6 of her admission, she was about to begin the weaning process when she developed fever and purulent sputum. Sputum was sent for gram stain and culture and the patient was started on empiric broad-spectrum antibiotics to cover hospital acquired infections. Chest X-ray showed a new infiltrate in the left lower lobe with air bronchograms. The gram stain showed many white blood cells and gram negative rods, and the culture grew *Pseudomonas aeruginosa* sensitive to piperacillin/tazobactam. The antibiotic coverage was changed to piperacillin/tazobactam for a total of 2 weeks. She improved slowly and by hospital day 10 she was able to be extubated from the ventilator without difficulty.

The presence of an ETT predisposes patients to tracheobronchitis and ventilator-associated pneumonia (VAP). Endotracheal intubation may also result in laryngeal ulceration, glottic edema, tracheal ulceration, and tracheal necrosis, particularly with an overinflated cuff.

The presence of an ETT strongly predisposes patients to ventilator-acquired pneumonia (VAP).

Complications Occurring After Extubation

Hoarseness is very common following extubation and occurs as much as 32% of the time in patients intubated for a surgical procedure. In the majority of these cases the hoarseness resolves within 7 days.[14] Edema of the vocal cords and stridor can occur early after extubation. Some degree of stridor occurs in about 5% of all extubated patients. In a VA study of 54 men who were intubated for 9.3 ± 5.1 days, the investigators found that 78% had some laryngeal injury on exam at the time of extubation. This injury ranged from mild erythema to severe mucosal edema resulting in narrowing of the airway. Only three patients (6%) did not have resolution of symptoms (hoarseness) and required surgical therapy for granuloma formation. The median time to laryngeal healing was 4 weeks, which was also the median time to resolution of symptoms.[15] Prolonged severe hoarseness may indicate arytenoid dislocation; early diagnosis is essential as there is a better rate of recovery with early treatment.[16] Tracheal stenosis, tracheomalacia, and tracheal dilatation are late complications of ETT placement.

Pneumonia develops in about 30% of all mechanically ventilated patients.

Ventilator-Associated Pneumonia

Pneumonia develops in about 30% of patients receiving mechanical ventilation. VAP refers specifically to bacterial pneumonia that develops in patients on mechanical ventilation. VAP is termed early-onset if it occurs within 48–72 h after tracheal intubation; it may be related to aspiration and the intubation process. VAP that occurs after 72–96 h is referred to as late-onset. The risk of developing VAP is greatest earlier (3% per day in the first 5 days) than it is later (1% per day after day 10).[17] Early-onset VAP is associated with antibiotic-sensitive bacteria, methicillin-sensitive *Staphylococcus aureus, Haemophilus,* and *Streptococcus pneumoniae.* Late-onset VAP is generally caused by antibiotic-resistant pathogens such as methicillin-resistant *Staphylococcus aureus, Pseudomonas aeruginosa,* and *Acinetobacter baumanii.*

Knowledge of local ICU resistance patterns of commonly isolated organisms is essential when choosing empiric antibiotic therapy.

Late-onset VAP is defined as that occurring 72–96 h after tracheal intubation.

Several strategies help reduce the incidence of VAP. Handwashing, elevation of the patient's head more than 30°, oral intubation, avoidance of large gastric volumes, adequate oral hygiene, and continuous subglottic suctioning are some of the nonpharmacological measures that may be useful in preventing VAP.[18] A large randomized controlled trial has shown that the use of a silver coated ETT designed to prevent biofilm development on the ETT resulted in a 35.9% relative risk reduction as well as a delay in the development of VAP.[19] Judicious use of antibiotics is important to avoid the emergence of multiresistant pathogens. Chastre et al has shown that treating documented VAP with 8 days of antibiotics was equivalent to treating with 15 days although there was higher

Late-onset VAP is generally associated with antibiotic-resistant bacteria such as *Pseudomonas aeruginosa* and *Acinetobacter baumanii.*

VAP should be treated with appropriate antibiotics for 8 days unless the *Pseudomonas aeruginosa* or *Acinetobacter baumanii* is the infecting organism, which should be treated for 2 weeks.

relapse rates in patients infected with gram negative fermenting rods such as *Acinetobacter baumanii* or *Pseudomonas aeruginosa.*[20] Current American Thoracic Society guidelines recommend treating for only 8 days as long as there is a clinical response to therapy and the infecting organism is not a gram negative fermenting rod.[18] One of the keys to treating VAP is choosing the appropriate empiric therapy, which requires knowledge of local resistance patterns for commonly isolated organisms in order to develop an antibiogram.

Upper Gastrointestinal Bleeding

Patients on mechanical ventilation and patients with a history of bleeding diathesis or a history of gastrointestinal bleeding (GIB) are at higher risk to develop upper GIB.

Patients on mechanical ventilation are at higher risk to develop upper GIB. Patients are also at risk if they have a previous history of upper GI bleeding, or bleeding diathesis. Significant debate exists regarding which agents to use in mechanically ventilated patients to prevent upper GI bleed. One of the theoretical concerns is that altering stomach acid production leads to bacterial overgrowth, which in turn increases the incidence of VAP. A recent study involving 1,200 patients in the ICU compared ranitidine vs. sucralfate. The group that received ranitidine had a significantly lower incidence of GI bleed. There was no difference within groups in terms of VAP, length of stay in the unit, and mortality.[21] A recent study demonstrated that omeprazole, a proton pump inhibitor, was as efficacious in preventing clinically significant GI bleeding as cimetidine.[22] Current guidelines continue to favor using H2 receptor blocking agents for the prevention of stress ulcers in mechanically ventilated patients.

Hemodynamic Alterations

Extrinsic PEEP increases intrathoracic pressure and may decrease venous return and cardiac output.

Because the lungs and heart share a common space in the thorax, multiple interactions between organs are evident. Mechanical ventilation will affect the autonomic tone, pulmonary vascular pressure, heart rate, preload, afterload, and contraction. High tidal volumes have been shown to induce bradycardia. Extrinsic and intrinsic PEEP can cause a decrement in pulmonary venous return, therefore decreasing ventricular preload and cardiac output. Furthermore, because the heart is situated in the cardiac fossa, increments in pulmonary volumes and/or pressures (PEEP or hyperinflation) may lead to significant mechanical interactions resembling pericardial tamponade. Finally, lung inflation can also release humoral factors such as prostaglandins that may have a cardiodepressant effect.

SUMMARY

Monitoring of basic respiratory mechanics is essential to reduce complications related to mechanical ventilation and to monitor recovery from respiratory failure. A large proportion of the advances in mechanical ventilation are the direct result of better understanding of the underlying pathophysiology of the disorders causing respiratory failure. Some of the most important accomplishments in mechanical ventilation are the result of applying new ventilatory strategies while using conventional ventilatory modes, such as low tidal volumes and PEEP titration in ARDS. Although the use of adjunctive therapies in mechanical ventilation appears to be promising, further research is needed in order to clarify their role in respiratory failure. Finally, we have come to recognize that there is a direct relationship between the rate of complications and the duration of mechanical ventilation, which makes daily weaning assessment of utmost importance.

REVIEW QUESTIONS

1. **A 62-year-old patient with a long-standing history of COPD presents to the emergency department complaining of severe shortness of breath and wheezing that did not respond to several albuterol nebulizer treatments. He is a thin (65-kg) male, using accessory muscles of respiration, and is visibly agitated. His vital signs include respiratory rate of 28, heart rate of 112, blood pressure of 138/85, temperature of 37.1°F, and oxygen saturation of 92% on room air. He is rapidly intubated for respiratory distress. The initial settings on AC ventilation include a respiratory rate of 15, FiO_2 of 1.0, an inspiratory flow rate of 50 L/min, and a V_T of 700 mL. The patient received 4 mg lorazepam for sedation. Measured peak and plateau pressures are 35 and 25 cm H_2O, respectively. Twenty minutes later, the patient develops hypotension. His peak and plateau pressures remain unchanged. The more likely cause for hypotension in this patient is:**
   - **A.** Overt sepsis secondary to pneumonia
   - **B.** Hypotension secondary to sedating agents
   - **C.** Tension pneumothorax
   - **D.** Increased intrinsic PEEP

2. **In the patient in question 1, all the following maneuvers are likely to decrease intrinsic PEEP, except:**
   - **A.** Decreased inspiratory flow rate
   - **B.** Decreased tidal volume
   - **C.** Decreased respiratory rate
   - **D.** Decreased inspiratory time

3. **All the following statements regarding complications of mechanical ventilation are incorrect except:**
   - **A.** Late-onset ventilator-associated pneumonia is defined as pneumonia occurring 48–72 h after endotracheal intubation and is generally caused by infection with *Streptococcus pneumoniae*
   - **B.** Sinusitis may be a cause of fever in the ICU, but its incidence is low
   - **C.** Prophylaxis for upper gastrointestinal bleed can be accomplished with H2-blockers or sucralfate
   - **D.** In patients with ARDS, the development of pneumothorax carries a very high mortality

4. **A 32-year-old-woman with a past medical history significant for seizure disorder is admitted to the emergency department after having a witnessed tonic-clonic seizure. Her weight is 60 kg and her height is 158 cm. In the emergency department, she suffers a second seizure and has to be intubated for airway protection. Upon intubation, gastric content is evidenced in the posterior pharynx and trachea. She is treated with lorazepam and phenytoin intravenously. A chest radiograph taken 6 h later showed a right lower lobe pneumonia. She remains intubated, and appropriate antibiotic coverage is initiated. The next day she develops increasing FiO_2 requirements, her compliance is significantly decreased, and a chest radiograph reveals bilateral alveolar infiltrates. Her current ventilator settings include FiO_2 of 90%, tidal volume of 700 mL, and respiratory rate of 12 with no extrinsic PEEP. Her vital signs are stable. An arterial blood gas reveals pH of 7.37, PaO_2 of 69 mmHg, $PaCO_2$ of 38 mmHg, and bicarbonate of 22 mEq/L. Which of the following ventilator strategies is more likely to improve the patient's outcome?**
   - **A.** Adding PEEP of 5 cm H_2O, increasing tidal volume to 10 mL/kg, and increasing FiO_2 to 100%
   - **B.** Tidal volume 6–8 mL/kg, titrating PEEP up to improve oxygenation while maintaining cardiovascular stability, maintaining plateau pressure <35 cm H_2O
   - **C.** Adding PEEP of 5 cm H_2O, increasing tidal volume to 15 mL/kg, and increasing FiO_2 to 100%
   - **D.** Pressure-control ventilation with high PEEP and inverse ratio (2:1) ventilation
   - **E.** High-frequency jet ventilation

5. **All the following statements regarding INO are correct, except:**
   - **A.** It reduces mean pulmonary artery pressure and pulmonary vascular resistance
   - **B.** It is indicated for persistent pulmonary hypertension of the neonate
   - **C.** It is associated with the development of methemoglobinemia in a small percent of patients
   - **D.** It significantly decreases systemic vascular resistance

6. **All the following statements regarding intrinsic PEEP ($PEEP_I$) are correct, except:**
   - **A.** $PEEP_I$ may occur in patients with severe airway obstruction
   - **B.** Static $PEEP_I$ is measured by occluding the expiratory port at end-inspiration
   - **C.** It can decrease venous return and cardiac output
   - **D.** Dynamic $PEEP_I$ is determined by measuring the drop in intrathoracic pressure that is required for inspiratory flow to begin

7. **A 72-year-old patient with a history of idiopathic pulmonary fibrosis develops pneumonia and has to be intubated and placed on mechanical ventilation. Taking into consideration his underlying lung pathology, you expect to find which of the following lung mechanics:**
   - **A.** Increased peak pressure, decreased plateau pressure, increased compliance
   - **B.** Increased peak pressure, increased plateau pressure, increased compliance
   - **C.** Increased peak pressure, increased plateau pressure, decreased compliance
   - **D.** Decreased peak pressure, decreased plateau pressure, decreased compliance

8. **"Permissive hypercapnia" is a ventilatory strategy that is thought to decrease mean airway pressures and consequently the incidence of VILI. Hypercapnic acidosis can be seen in this instance and is associated with which of the following conditions:**
   - **A.** Improved myocardial contraction
   - **B.** Decreased sympathetic activity
   - **C.** Cerebral vasodilation and cerebral edema
   - **D.** Peripheral vasoconstriction

9. A large difference between peak and plateau pressure can be seen in all the following conditions, except:
- **A.** Tension pneumothorax
- **B.** Right mainstem bronchus intubation
- **C.** Excessive secretions and mucus plugging
- **D.** Use of small-diameter ETT

10. In COPD patients intubated for an exacerbation of COPD heliox has been shown to:
- **A.** Reduce the work-of-breathing during spontaneous breathing trials
- **B.** Improve survival by improving FEV_1
- **C.** Lower intrinsic PEEP
- **D.** A and C

ANSWERS

1. The answer is D. The patient in question 1 is intubated for COPD exacerbation. His initial settings include a high tidal volume, a low inspiratory flow, and a relatively rapid respiratory rate. All these parameters result in a decreased inspiratory time, which does not allow him to completely empty each tidal volume, in addition to the expiratory flow limitation imposed by his underlying disease. The end result is positive pressure at the end of expiration or intrinsic PEEP, which has the same hemodynamic consequences as extrinsic PEEP. Tension pneumothorax is unlikely in this patient because his peak and plateau pressures remained unchanged. The patient has been afebrile and hemodynamically stable until that point, which makes overt sepsis unlikely.

2. The answer is A. A decrease in flow rate, that is, the amount of volume that is delivered per unit of time, is likely to increase inspiratory time and decrease expiratory time, predisposing a patient like this to develop intrinsic PEEP.

3. The answer is C. H2-blocking agents (ranitidine, famotidine) have been shown to be as effective as sucralfate in prophylaxis for upper GIB in mechanically ventilated patients. Furthermore, recent studies failed to reveal an increased incidence of ventilator-associated pneumonia in patients treated with H2-blockers. Although late-onset ventilator-associated pneumonia is defined as occurring 48–72 h after endotracheal intubation, it is generally associated with gram negative organisms. Sinusitis is frequently seen in intubated patients. Finally, in a large randomized trial, the occurrence of pneumothorax in mechanically ventilated ARDS patients did not significantly increase their mortality.

4. The answer is B. Protective mechanical ventilation strategies using low tidal volumes, high PEEP, and maintaining plateau pressures <35 cm H_2O have been shown to significantly decrease mortality in ARDS patients. Pressure-control ventilation with inverse I:E ratio has not been shown to be superior in these cases and generally requires sedation and paralysis. High-frequency jet ventilation works with very small tidal volumes and may, theoretically, reduce the incidence of VILI; until now there has not been enough evidence to support its use in ARDS.

5. The answer is D. INO has been shown to decrease mean pulmonary artery pressure and pulmonary vascular resistance. It has a very short half-life, and its effects on systemic vascular resistance are very small or absent. The development of methemoglobinemia is one of its complications; therefore, serial arterial blood gas determinations are made. Methemoglobinemia is infrequently seen <20 ppm. The use of INO was recently approved by the U.S. Food and Drug Administration in term and near-term neonates with persistent pulmonary hypertension, where randomized, controlled trials showed an improvement in oxygenation and a decrease in the need for ECMO.

6. The answer is B. Intrinsic PEEP ($PEEP_I$) can be seen in patients with severe airflow obstruction, such as asthma and COPD. Its hemodynamic consequences are similar to those caused by extrinsic PEEP. Dynamic $PEEP_I$ measurement requires placement of an intraesophageal balloon and determining the drop of intrathoracic pressure required before inspiratory flow begins. Plateau pressure is measured at the end of inspiration; static $PEEP_I$ is measured at the end of expiration.

7. The answer is C. The patient in question 7 has an underlying disorder that is associated with decreased compliance, namely, pulmonary fibrosis. The presence of purulent secretions, debris, and inflammation caused by pneumonia will worsen compliance. The expected findings include elevated peak and plateau pressures, reflecting the altered compliance of the respiratory system.

8. The answer is C. Permissive hypercapnia is frequently used in the setting of ARDS and asthma exacerbation to decrease mean airway pressure. It can result in hypercapnic acidosis, which has been associated with direct myocardial depression, increased sympathetic activation, and peripheral and cerebral vasodilatation. These effects are less likely to occur if pH is maintained >7.20.

9. The answer is A. Tension pneumothorax is associated with a decreased compliance; a large difference between peak and plateau pressure is not an expected finding in this condition.

10. The answer is D. Heliox converts turbulent flow to laminar flow resulting in reduced frictional resistance as well as lower intraluminal airway pressures. The use of heliox therapy in intubated patients has been shown to decrease the work-of-breathing in patients undergoing a spontaneous breathing trial, and this decrease persisted even after extubation. Multiple studies have also shown that heliox can be used to decrease the level of intrinsic PEEP when ventilating patients with a COPD exacerbation. At least one study showed that there was an increase in cardiac output as well. The main limitation to using heliox is that patients require high levels of FiO_2 that are above 30%.

Noninvasive Ventilation

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Know the indications and contraindications of noninvasive ventilation.
- Understand the physiologic effects of noninvasive ventilation.
- Know how to apply different techniques of noninvasive ventilation, that is, negative pressure vs. positive pressure ventilation.
- Understand the relative advantages and disadvantages of different types of patient–ventilator interfaces during noninvasive ventilation.
- Review the evidence of the use of noninvasive ventilation in specific disease categories.
- Review and learn to manage complications associated with noninvasive ventilation.

The use of noninvasive ventilation in acute respiratory failure has received much attention in recent years because of the recognition of the important complications that result from translaryngeal intubation and also the recent development of new and different devices to perform noninvasive ventilation. Although noninvasive ventilation techniques in the form of negative pressure ventilation (e.g., tank ventilators, cuirass, rocking beds) have been used since the 1930s for the treatment of acute respiratory failure, the development of more responsive devices providing negative pressure ventilation, coupled with the recent development of noninvasive positive pressure ventilation (NPPV), have facilitated the increased use of noninvasive ventilation. Moreover, recent awareness that avoidance of translaryngeal intubation preserves upper airway function (e.g., speech, swallowing), enhances patient comfort, decreases the incidence of nosocomial respiratory infections, and appears to improve morbidity and mortality in some individuals (Table 46-1) has led to greater emphasis on noninvasive ventilation.

CASE STUDY 1

A 55-year-old man presents with worsening shortness of breath over 1 week. He has a past history of chronic obstructive pulmonary disease (COPD). He is visibly dyspneic and has difficulty speaking full sentences. His temperature, blood pressure, and respiratory rate is 98.9°F, 124/88 mmHg, and 30 breaths/min respectively. His oxygen saturation is 92% on 6 L/min of supplemental oxygen via nasal cannula. The emergency room physician wants to start noninvasive ventilation. What modalities of noninvasive ventilation are available?

TABLE 46-1

ADVANTAGES AND DISADVANTAGES OF NONINVASIVE POSITIVE PRESSURE VENTILATION (NPPV) COMPARED TO INVASIVE MECHANICAL VENTILATION

	ADVANTAGES	DISADVANTAGES
NPPV	Comfort Preservation of upper airway functions (speech, swallowing) Decreased risk of nosocomial pneumonia and sinusitis Portable	Requires cooperative patient Air leaks Variable tidal volumes Facial skin breakdown Nasal bridge skin necrosis
Conventional mechanical ventilation	Patient cooperation not required Control over volumes and pressures being delivered Fewer air leaks	Complications of endotracheal tube Increased risk of nosocomial pneumonia and sinusitis Ventilator-induced lung injury

In this chapter, we discuss the different techniques of noninvasive ventilation, selection of appropriate candidates, the role of noninvasive ventilation in specific diseases, and possible complications associated with its use. We focus on the use of noninvasive ventilation in the intensive care unit (ICU), specifically, in the management of acute, or acute or chronic respiratory failure.

MODALITIES OF NONINVASIVE VENTILATION

Negative Pressure Ventilation

Lung inflation with negative pressure ventilation occurs as a result of a pressure gradient between the alveoli and the atmosphere.

Negative pressure ventilation is a form of noninvasive ventilation that mimics spontaneous ventilation by applying subatmospheric pressure around the thorax during inspiration, creating a pressure gradient between the atmosphere and the patient's alveoli that results in airflow and lung inflation. There are three different types of devices, each with specific advantages and disadvantages. The prototypical negative pressure ventilator is the tank ventilator, also referred to as the "iron lung," a large cylindrical tank-like device with side portholes to provide nursing care and limited procedures. The patient's body is encased in the tank, but the head and neck protrude through an opening at one end. A neck collar provides an airtight seal (see Fig. 46-1a). The "poncho-wrap" is an airtight body suit using a rigid metal framework that surrounds the torso that is covered with an airtight nylon parka. This provides negative pressure over a larger body surface than the cuirass and is more portable than the tank ventilator (see Fig. 46-1b). The cuirass is a third type of negative pressure ventilator, comprised of a rigid fiberglass shell fitted to cover the chest wall and upper abdomen (see Fig. 46-1c).

The tank ventilator applies negative pressure to the whole body. The cuirass and the airtight body suits apply negative pressure to the thorax and upper abdomen.

The larger the area covered by the negative pressure device, the greater the tidal volume generated.

Settings for negative pressure ventilation are usually established by matching the patient's spontaneous respiratory rate and then progressively increasing the amount of delivered negative pressure until the targeted tidal volume is achieved. With the tank ventilator or iron lung, negative pressure is applied to the whole body except for the head and neck, whereas with the cuirass or the poncho-wrap ventilators, negative pressure is applied to the thorax and upper abdomen. The larger the area covered by the negative pressure device, the greater

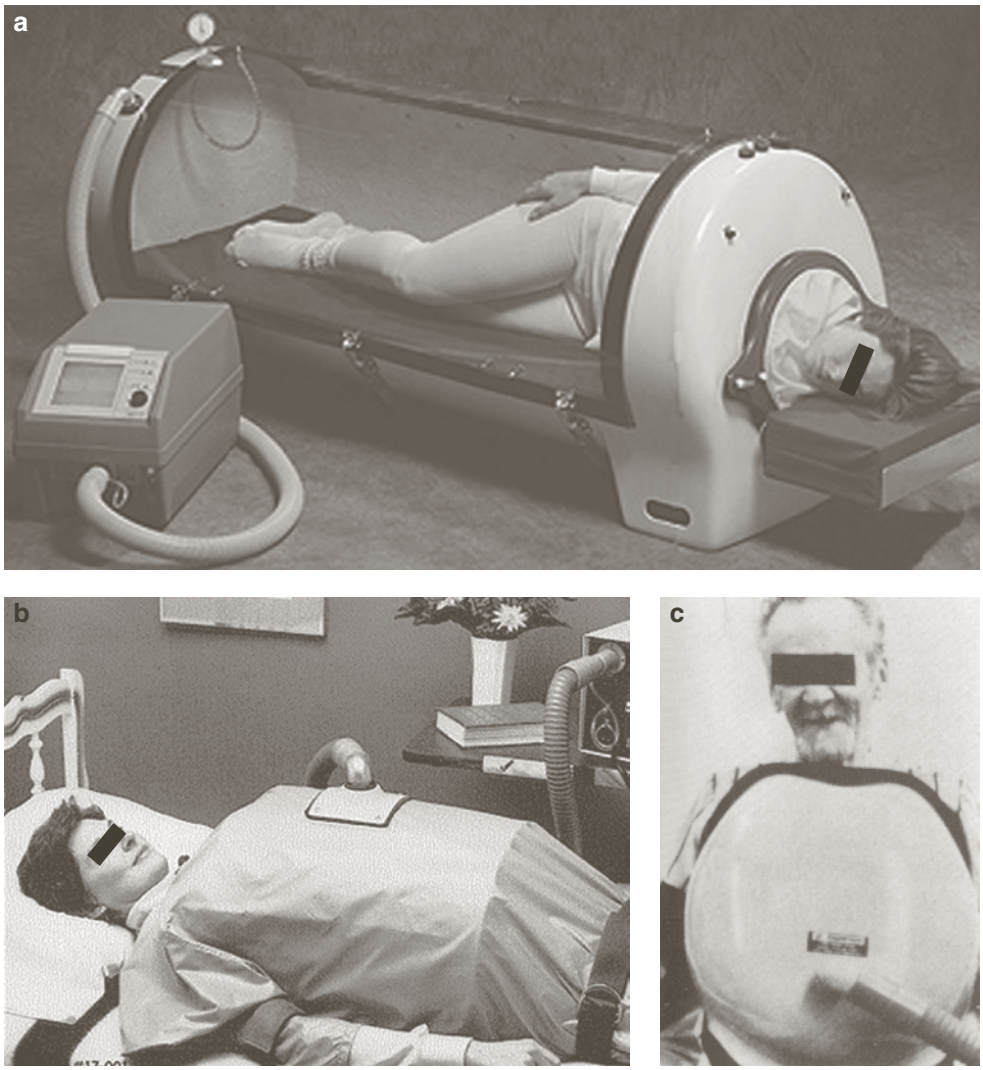

FIGURE 46-1

Negative pressure devices. The Porta-Lung® is an example of a modern noninvasive ventilating chamber. It is made in three different sizes and weighs from 33 to 53 kg. It can be interfaced with the NEV-100® (Lifecare) ventilator or the Emerson 33-CR® to provide negative pressure ventilation (**a**). The poncho-wrap consists of an airtight body suit that surrounds a rigid frame (**b**). The cuirass shell applies negative pressure to the chest and upper abdomen (**c**).

the tidal volume generated. Accordingly, tank ventilators produce greater tidal volumes than body suits, which produce greater tidal volumes than a cuirass. Recently developed devices incorporate the capability for the patient to trigger the ventilator's application of negative pressure, thereby improving patient–ventilator synchrony.

Negative pressure ventilation has been used in several disease categories: the neonatal respiratory distress syndrome, chronic respiratory insufficiency due to neuromuscular and chest wall diseases, and acute and chronic respiratory failure due to COPD. Negative pressure ventilation can therefore be used as full ventilatory support in acute respiratory failure or as intermittent support during sleep in patients with chronic respiratory failure resulting from progressive neuromuscular or chest wall diseases.

Negative pressure ventilation can provide adequate ventilatory support in patients with chronic respiratory failure due to progressive neuromuscular diseases or chest wall diseases.

Complications such as back pain and potential worsening of upper airway obstruction, in addition to the limitations imposed on providing nursing or medical care (such as placing central lines and invasive monitoring) and constraints on patient posture, may limit the widespread application of negative pressure ventilation.

Back pain, potential worsening of upper airway obstruction and limitations on providing nursing care are complications of negative pressure ventilation.

Noninvasive Positive Pressure Ventilation

NPPV is being used more frequently. Compared to invasive mechanical ventilation, NPPV is more comfortable and preserves upper airway function. Invasive mechanical ventilation also has complications such as the following: nosocomial pneumonia, ventilator-induced

NPPV preserves upper airway function, improves patient comfort, and has less nosocomial pneumonias as compared to invasive ventilation.

lung injury, and endotracheal tube malfunction. NPPV avoids these complications and in certain clinical situations may provide a morbidity and mortality benefit (Table 46-1).

NPPV can be delivered with either volume- or pressure-preset ventilatory modes. In the volume-preset mode, a tidal volume is set that increases alveolar ventilation until ventilation targets are met and the peak airway pressure becomes the dependent variable. In a pressure-preset mode, an inspiratory pressure boost above the end-expiratory level is chosen to augment ventilation to the chosen target, and in this case, the delivered tidal volume becomes the dependent variable.

Volume-Preset Mode

Volume-preset or volume-limited mode has several advantages. Almost all critical care ventilators or portable home ventilators are able to provide volume-preset ventilation, and it is therefore readily available. Volume-preset ventilators have the capability to deliver large tidal volumes over a wide range of inspiratory flows. In this case, the volume delivered to the patient is guaranteed on a breath-to-breath basis. The built-in blender permits the delivery of high concentrations of oxygen. However, volume-preset ventilation can be associated with significant air leaks and cannot compensate for them by increasing the delivered volume. The presence of air leaks may result in prolonged inspiratory times, thereby leading to patient–ventilator dysynchrony and limiting patient tolerance.

During noninvasive volume-preset ventilation, delivered tidal volumes are set higher (8–10 mL/kg) than during invasive mechanical ventilation to compensate for air leaks.

Setting the ventilator in the volume-limited mode to deliver noninvasive ventilation is similar to setting the ventilator for invasive ventilation (see Chap. 44). Respiratory rate is generally set at the patient's spontaneous respiratory rate. Delivered tidal volumes should be set higher than in invasive mechanical ventilation, ranging from 8 to 10 mL/kg. Minimal trigger sensitivity should be used to allow easy triggering through the interface. Volume-limited noninvasive ventilation delivered through a critical care ventilator has several advantages, including the presence of alarms, the ability to use higher inspiratory fractions of O_2, and monitoring of ventilatory variables (airway pressure, inspired and expired flows, and tidal volumes).

Pressure-Preset Mode

Pressure-preset ventilation has been shown to decrease the work of breathing, increase tidal volume, and decrease respiratory rate in patients with respiratory failure.

Pressure-preset ventilation has been widely used to deliver noninvasive ventilation. This mode has been shown to decrease the work of breathing, increase expired tidal volume, and decrease spontaneous respiratory rate. Pressure-preset ventilation can compensate for air leaks by increasing ventilator flow to achieve the targeted inspiratory pressure. Two forms of pressure-preset ventilation are generally used: pressure-support ventilation (PSV) and pressure-control ventilation (PCV). With PSV, the patient must trigger every breath, and the delivered tidal volume is a result of the set pressure, patient effort, and individual pulmonary mechanics. A PSV breath is terminated after a predetermined flow has been reached, usually 25% of the initial flow. With the occurrence of air leaks during noninvasive ventilation, the ventilator's inability to appropriately sense flow decay may result in an abnormally prolonged inspiration.

Pressure-preset ventilation can compensate for air leaks by maintaining a constant inspiratory pressure.

With PSV, the patient must trigger every breath.

A pressure-support breath is terminated after a predetermined flow has been reached, usually 25% of the initial flow.

During PCV, the physician determines not only the pressure to be delivered but also the inspiratory time and respiratory rate. In contrast to PSV, the patient does not need to trigger each breath during PCV; moreover, if the ventilator is unable to sense a decrement in flow during pressure support, resulting in a prolonged delivery of the ventilator breath (i.e., prolonged inspiratory time), PCV can be used to set a specific inspiratory time and therefore improve patient–ventilator synchrony.

During PCV, the physician determines the delivered pressure, inspiratory time, and respiratory rate.

Bilevel Positive Airway Pressure

Bilevel positive airway pressure (BiPAP®) is a patient-triggered, pressure-limited, and flow- or time-cycled mode of delivering noninvasive ventilation. BiPAP® is a small, simple, portable device specifically designed for NPPV (Fig. 46-2). Similar to conventional ventilators used in the ICU, BiPAP® can be set in a spontaneous mode (equivalent to the assist mode in

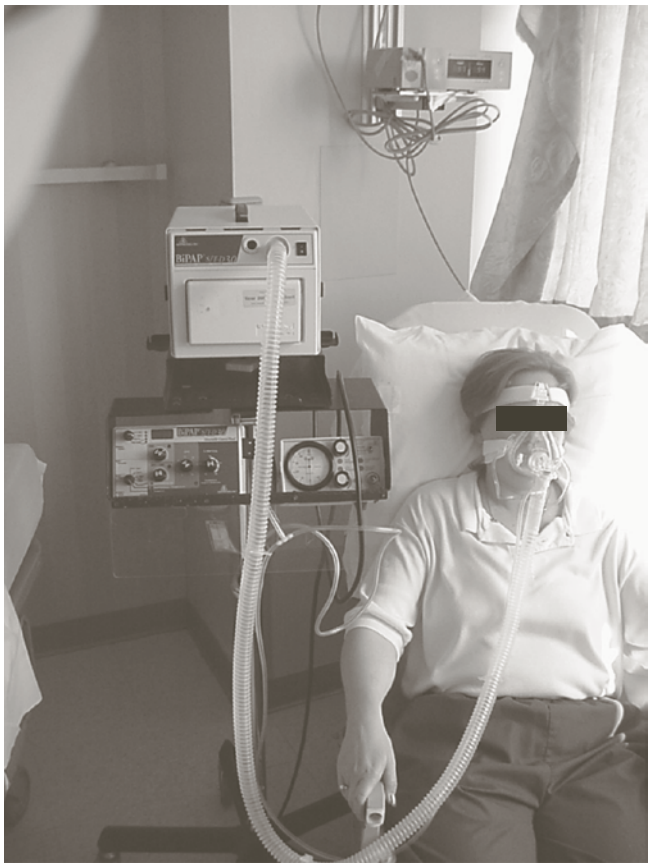

FIGURE 46-2

BiPAP® ventilator.

conventional ventilators), spontaneous/time mode (equivalent to assist/control mode), or time mode (equivalent to control). The latter two modes are used to provide a backup rate and ensure minimum mandatory minute ventilation. The spontaneous/time mode is used in patients who tend to hypoventilate during sleep, such as patients with obesity hypoventilation or severe neuromuscular disease. Both the inspiratory positive airway pressure (IPAP) and the expiratory positive airway pressure (EPAP) can be preset to specific physiologic targets. It is important to realize that the preset level of IPAP with the BiPAP® apparatus is absolute and includes the expiratory pressure. In contrast, when conventional ventilators are used to provide bilevel pressure ventilation, the IPAP is set above the EPAP, so that the total end-inspiratory pressure is the sum of the IPAP and EPAP values.

When BiPAP® is used, 3–5 cm H_2O EPAP provides a constant gas flow that prevents CO_2 rebreathing through the single limb ventilator circuit.

If pressure support delivered by a critical care ventilator is selected, initial ventilator settings should be started low, such as 8–12 cm H_2O of IPAP; EPAP is generally initiated at 3–5 cm H_2O. IPAP should be increased by 2–3 cm H_2O every 3–5 min and adjusted following parameters such as respiratory rate, exhaled tidal volume, and use of accessory muscles. Critical care ventilators are able to deliver high pressures and precise oxygen mixtures. If BiPAP® is used, it is important to remember that it consists of a single circuit for both inspiration and exhalation, which may result in rebreathing of carbon dioxide. A one-way exhalation valve is placed as close as possible to the patient, and the application of EPAP at a level of at least 3–5 cm H_2O allows a continuous flow of gas to flush CO_2 from the line and prevent significant CO_2 rebreathing. EPAP can be slowly titrated upward to increase end-expiratory lung volume and recruit collapsed alveolar units, thereby improving oxygenation. If supplemental oxygen is required, oxygen tubing can be connected to the ventilator circuit using a T-tube or bled in at a mask port.

In most clinical studies, BIPAP® was administered intermittently throughout the day, but in acute respiratory failure caused by parenchymal disease, ventilatory assistance is usually required for more than 20 h/day during the first day. The duration of NPPV is gradually reduced

CASE STUDY 2

A 54-year-old male with a past medical history of nonischemic cardiomyopathy and congestive heart failure (CHF) presents with increasing orthopnea, dyspnea, and lower extremity edema. He is triaged to the ICU and noninvasive ventilation is begun. What are the physiological effects of the different modes of noninvasive ventilation on the cardiopulmonary system?

over subsequent days, depending on the patient's clinical status. In most studies, the overall duration of ventilatory support when treating acute respiratory failure has been relatively short.

Continuous Positive Airway Pressure

CPAP does not provide a pressure boost during inspiration to augment ventilation.

CPAP increases end-expiratory lung volume and decreases intrapulmonary shunting.

CPAP improves respiratory system compliance and decreases the work of breathing.

Acutely, CPAP should be started at 3−5 cm H_2O, within the range of the normal transpulmonary pressure.

Continuous positive airway pressure (CPAP) is the application of a preset positive pressure throughout the entire respiratory cycle. It does not provide a pressure boost during inspiration to augment ventilation. Nevertheless, CPAP has been shown to improve oxygenation by increasing end-expiratory lung volume, therefore decreasing intrapulmonary shunting. CPAP has been shown to improve respiratory system compliance, which results in a decrease in the work of breathing and improved patient comfort. This technique is useful in maintaining upper airway patency in patients with obstructive sleep apnea (OSA), in whom it is widely used.

In the acute setting, CPAP should be initiated at 3–5 cm H_2O, within the range of the normal transpulmonary pressure. The pressure may then be titrated upward in 2-cm H_2O increments every 3–5 min while assessing patient comfort, respiratory rate, accessory muscle use, and the level of oxygenation. The optimal CPAP level reported in pulmonary edema is about 10 cm H_2O. In the setting of severe emphysema, the goal is to set the CPAP level approximately 1–2 cm H_2O below the measurable "auto-PEEP" or intrinsic PEEP (positive end-expiratory pressure). In these cases, the usual level of CPAP required is 5–8 cm H_2O.

PHYSIOLOGIC EFFECTS OF NONINVASIVE VENTILATION

Noninvasive ventilation has been shown to improve gas exchange, normalize $PaCO_2$, increase PaO_2, increase pH, increase tidal volume, and decrease respiratory muscle work in acute and chronic respiratory failure. Additionally, noninvasive ventilation has been reported to stabilize metabolic parameters such as heart rate, respiratory rate, and blood pressure.

Negative pressure ventilation and NPPV have both been shown to assist each spontaneous breath, thereby reducing respiratory muscle work as measured by swings in transdiaphragmatic pressure, inspiratory muscle pressure–time index, or diaphragmatic electromyographic activity. The reduction in respiratory muscle work and patient effort is associated with a change in breathing pattern, towards a deeper, slower pattern, and an overall increment in minute ventilation. Both of these changes, deeper slower breathing and overall increase in total ventilation result in an increase in alveolar ventilation and oxygenation while simultaneously lowering carbon dioxide tension.

Negative pressure ventilation causes a decrease in mean intrathoracic pressure, which results in increased venous return and consequently increased cardiac output.

Negative pressure ventilation lowers intrathoracic pressure, which may result in increased afterload due to increased transmyocardial pressure.

NPPV increases intrathoracic pressure, thereby decreasing venous return, preload, and cardiac output.

Negative pressure ventilation closely mimics spontaneous respiration, and its hemodynamic effect is generally viewed as favorable when compared to positive pressure ventilation (Table 46-2). Negative pressure ventilation applied to the chest wall decreases the mean intrathoracic pressure, which results in increased venous return and consequently increased cardiac output. However, negative pressure ventilation may also have a detrimental cardiovascular effect; lower intrathoracic pressures can also increase left ventricular afterload by increasing transmyocardial pressure. In some patients, the increase in venous return may lead to right ventricular dilatation and a reduction in left ventricle dimension due to the shift of the interventricular septum, ultimately resulting in left ventricular diastolic dysfunction. It is clear that the cardiovascular effects of negative pressure ventilation depend on the type

TABLE 46-2

HEMODYNAMIC EFFECTS OF NONINVASIVE POSITIVE PRESSURE VENTILATION (NPPV) COMPARED WITH NEGATIVE PRESSURE VENTILATION

	NPPV	NEGATIVE PRESSURE VENTILATION
Left ventricular afterload	Decreased	Increased
Right ventricular preload	Decreased	Increased
Venous return	Decreased	Increased

of negative pressure apparatus (and degree of body surface exposed to negative pressure), the patient's intravascular volume, and underlying left ventricular compliance and ejection fraction. In contrast to the hemodynamic effects of negative pressure ventilation, NPPV increases the intrathoracic pressure, thereby decreasing venous return, preload, and cardiac output. In addition, because NPPV exerts an effect on transmyocardial pressure opposite to that of negative pressure ventilation, a reduction in left ventricular afterload can be seen.

In patients in whom breathing against high resistive or high elastic loads has precipitated respiratory muscle fatigue, effective use of noninvasive ventilation provides respiratory muscle resting and eventual recovery. In other scenarios, noninvasive ventilation stabilizes gas exchange (increases PaO_2, decreases $PaCO_2$, increases pH) and ensures stabilization of the patient's medical status until the event precipitating respiratory failure can be treated. Noninvasive ventilation does not cure the disorder precipitating respiratory failure, but is rather an adjunctive aid to provide patient stability until the precipitating disorder causing respiratory failure can be appropriately treated.

APPLICATION OF NONINVASIVE POSITIVE PRESSURE VENTILATION

The goals of noninvasive ventilation are to improve gas exchange, decrease work of breathing, and alleviate patient dyspnea.

The goals of noninvasive ventilation, regardless of the device being used, are to improve gas exchange, decrease work of breathing, and alleviate the patient's dyspnea. Success in achieving these goals may obviate the need for endotracheal intubation. Successful application of noninvasive ventilation is based on appropriate patient selection, adequate sizing of the apparatus and fitting to ensure patient comfort, and proper selection of ventilatory mode (Table 46-3).

To maximize patient safety, it is recommended that the initial treatment of patients with severe forms of acute on chronic respiratory failure should begin in the ICU to ensure adequate vigilance by medical, nursing, and respiratory personnel. Expertise in properly providing noninvasive ventilation depends not only on the physician but also on the support staff (nurses, respiratory therapists), who continuously interact with patients while they are being evaluated for or are being maintained on noninvasive ventilation. Plant et al studied patients admitted for COPD exacerbation and found that those patients with more severe acidosis and hypercapnea at admission were at higher risk for intubation.[1] These patients needed closer monitoring given the severity of condition and possible need for advanced airway management. In another study, Plant found that those with less severe exacerbations could be managed on medical floors.[2] It should be noted that these studies pertain only to COPD exacerbations, and less data exist regarding other disease processes to help risk stratify patients. We advocate that all severe forms of disease exacerbations be managed in an ICU setting. Less severe exacerbation should be managed in a setting that is dedicated and experienced in pulmonary care. This is further elucidated in the patient selection section below.

Noninvasive ventilation for acute respiratory failure should be conducted in a monitored area such as the ICU.

Several preliminary steps must be implemented before NPPV can be instituted for severe exacerbations (Table 46-4). The patient should be placed in a monitored setting. Monitoring should include ECG, respiratory impedance, pulse oximetry, and frequent measurement of vital signs. The patient should be sitting in bed or a chair at an angle greater than 30°. A mask should be selected and properly fit with the appropriate headgear. Ideally, several mask sizes and types should be readily available to minimize air leaks and increase patient comfort.

Selection of device type depends on minimizing side effects while simultaneously augmenting ventilation in the most efficient manner.

Both negative pressure ventilation and NPPV have distinct advantages and disadvantages (Table 46-5). Selection of a device and settings depends on minimizing side effects while

CASE STUDY 3

A 64-year-old female presents to the emergency department with shortness of breath. Her past medical history is significant for COPD, and hypertension. She has difficulty speaking. Her respiratory rate is 30 breaths/min and her oxygen saturation is 91% on 4 L/min of supplemental oxygen. The rest of her vital signs are within normal limits. She states that she is claustrophobic. Is this patient a candidate for NPPV? If so, what hospital setting is most appropriate for the management of this patient? What mask interfaces are available for NPPV? How do we know that NPPV is working?

TABLE 46-3

IMPORTANT FACTORS TO CONSIDER DURING APPLICATION OF NONINVASIVE VENTILATION

- Patient selection criteria
  - Awake and cooperative
  - Able to sustain short period of spontaneous ventilation
  - Intact upper airway function
  - Stable cardiovascular function
  - Absence of facial trauma
  - No excessive secretions
- Interface
  - Negative pressure ventilation
    - Tank ventilator
    - Cuirass
    - Airtight body suit
  - Noninvasive positive pressure ventilation
    - Types of facial mask
      - Nasal: advantages include less risk of aspiration and claustrophobia; disadvantages include leakage from the mouth and poor fit in edentulous patients
      - Oronasal: advantages include absence of leak from the mouth; disadvantages include increased risk of aspiration, claustrophobia, and aerophagia
    - Proper fit of mask is important in avoiding air leak
    - Chinstrap may be used to decrease mouth leaks (nasal mask)
- Modes of ventilation
  - Negative pressure ventilation
    - CPAP: initial indication for patients with cardiogenic pulmonary edema
    - BiPAP
    - Pressure support: may enhance patient's comfort
    - Assist/control mode
    - Volume-preset
    - Pressure-preset

CPAP continuous positive airway pressure; *BiPAP* bilevel positive airway pressure

TABLE 46-4

PRELIMINARY STEPS BEFORE INSTITUTING NONINVASIVE POSITIVE PRESSURE VENTILATION IN THE ACUTE SETTING

- Select an appropriately monitored location (intensive care unit, step down unit, ventilatory rehabilitation unit)
- Baseline vital signs and arterial blood gas
- Continuous EKG, blood pressure monitoring, continuous pulse oximetry, respiratory impedance
- Patient in bed or chair sitting at ≥30° angle
- Select and fit interface
- Apply headgear
- Select ventilation
- Connect interface to ventilator tubing and turn on ventilator

Source: modified with permission from Mehta and Hill[21], Official journal of the American Thoracic Society [3]American Thoracic Society

simultaneously augmenting ventilation in the most efficient manner. The choice of negative pressure ventilation rather than NPPV as the mode of delivering noninvasive ventilation depends on the expertise of the prescribing physician combined with the different ventilatory techniques, the available equipment, and goals of ventilation, patient comfort, and unique patient factors.

	ADVANTAGES	DISADVANTAGES
Negative Pressure Ventilation	No airway cannulation Significantly augments ventilation Rare hemodynamic concerns Simple devices	Cumbersome Induces upper airway obstruction Limits nursing care Controlled ventilation
Noninvasive Positive Pressure Ventilation	Averts upper airway obstruction Patient-initiated breaths Portable	Bothersome interface Leaks Aerophagia Skin breakdown

TABLE 46-5

NONINVASIVE POSITIVE PRESSURE VENTILATION COMPARED WITH NEGATIVE PRESSURE VENTILATION: ADVANTAGES AND DISADVANTAGES

Positive Pressure Ventilation Interfaces

Several different interfaces are currently available (Fig. 46-3). Although designs vary greatly from manufacturer to manufacturer, four main types of masks are used to deliver NPPV: nasal prongs, and nasal, oral–nasal, or full-face masks. To optimize fit and comfort, the type

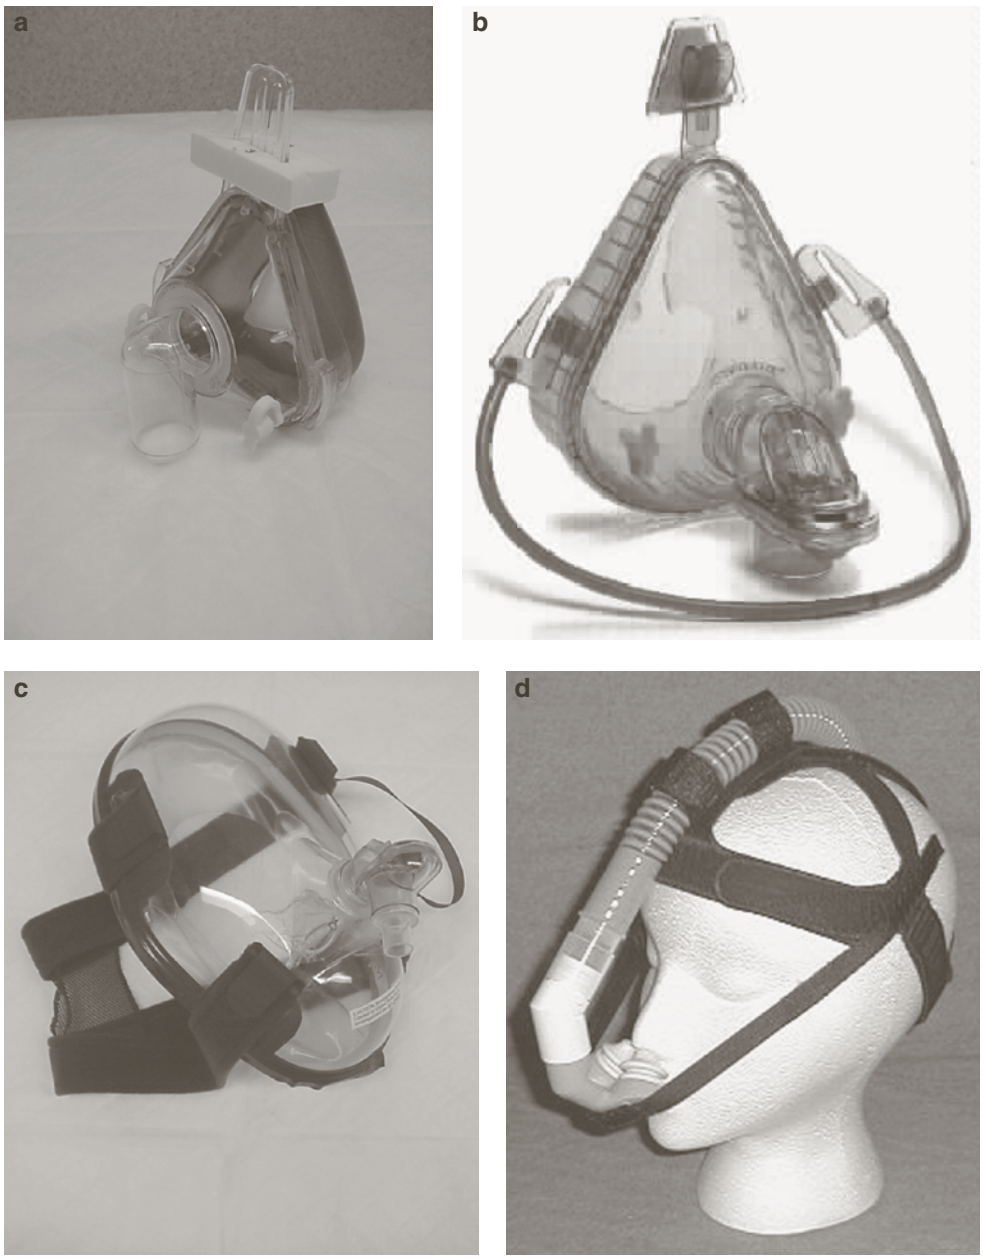

FIGURE 46-3

Noninvasive positive pressure masks. (**a**) A nasal mask. (**b**) A nasal–oral mask. (**c**) This total face mask may increase patient's comfort. (**d**) Nasal prongs, also known as an Adams circuit.

of mask used should be based on the patient's facial features. The masks are secured by an elastic headgear system.

A proper mask fit is essential in maximizing the efficacy of NPPV.

Nasal masks tend to be more comfortable, allow speech and eating, and decrease the incidence of claustrophobia, whereas nasal–oral masks improve gas exchange more quickly. Our group has previously shown that the total face mask improved dyspnea more effectively than nasal or nasal–oral masks, perhaps due to stimulation of facial receptors of the trigeminal nerve and subsequent decrease in central respiratory drive. Previous studies failed to detect significant differences in physiologic parameters between different devices. Others have shown that the mask type may have varying effects on patient comfort and CO_2 elimination. Each type of mask has advantages and disadvantages, but proper fit is crucial in minimizing air leaks and maximizing NPPV efficacy. It is recommended that several mask types and sizes should be evaluated when initiating NPPV to choose the optimal interface to the individual patient.

A chinstrap is useful in reducing mouth air leaks in patients ventilated through a nasal mask.

If a nasal mask is chosen, a chinstrap may help decrease mouth air leaks. Air leak around the mouth is not only uncomfortable for the patients but may result in inefficient triggering and/or a prolonged inspiratory time, ultimately leading to patient–ventilator asynchrony or ineffective ventilation. Masks that fail to fit properly are also more likely to cause facial skin breakdown and nasal bridge skin ulcers. The total face mask that covers the entire face (see Fig. 46-3c) has recently been shown to increase comfort and significantly increase expired tidal volume, decrease $PaCO_2$, and decrease air leaks when compared with nasal and nasal–oral masks.

Patient Selection

Successful application of noninvasive ventilation is based on appropriate patient selection.

The first step in selecting patients for NPPV is to establish which patients are at risk of requiring mechanical ventilation and who may benefit from ventilatory assistance.

Current criteria to select patients for NPPV are based on outcome indicators and previously published entry criteria from several clinical studies. A two-step approach has been recommended (Table 46-6). The first step is to identify those patients who are at risk of requiring intubation and who are likely to benefit from ventilatory assistance. The criteria are clinical as well as gas exchange parameters. Clinical criteria include moderate to severe dyspnea, tachypnea, use of accessory muscles, and paradoxical abdominal breathing. A respiratory rate greater than 24 breaths/min is generally considered as a relative indication for NPPV in patients with COPD, although higher respiratory rates have been used in hypoxemic respiratory failure and acute pulmonary edema. The gas exchange criteria include an elevated $PaCO_2$ and worsening pH, and hypoxemia marked by a $PaO_2/FiO_2 < 200$. Patients who benefit from NPPV often have $pH < 7.35$ or a $PaCO_2 > 45$ mmHg. Keenan et al performed a metanalysis of patients receiving NPPV for COPD exacerbation.[4] They found that those with more severe exacerbations ($pH < 7.30$) had a greater reduction in hospital mortality, rates of intubation, and length of hospital stay. Those patients who were hemodynamically stable and had normal blood gas values did not benefit from acute use of NPPV over standard therapy (Fig. 46-4). NPPV should be considered in moderate to severe respiratory failure, and conventional therapy may be more appropriate for mild COPD exacerbations.

Patients with imminent or actual cardiorespiratory arrest are not candidates for NPPV.

Shock, life-threatening arrhythmias, myocardial ischemia, and hemodynamic instability are contraindications to the use of NPPV.

After identifying patients who are likely to require ventilatory support, the second step consists of excluding patients in whom the use of NPPV would be considered unsafe. NPPV is not recommended in patients likely to experience imminent respiratory or cardiac arrest, and these patients should be promptly intubated. Patients with unstable conditions, such as shock, gastrointestinal bleeding, myocardial ischemia, or life-threatening arrhythmias should not be managed with NPPV. In addition, readily reversible causes such as drug overdose may respond to antidotes, which may obviate the need for either NPPV or intubation. Facial trauma or facial deformities may prevent adequate fitting of a mask and are relative contraindications to the use of NPPV. The upper airway should be intact; patients with upper airway stenosis or tumors are unlikely to benefit from NPPV. Ideally, patients being considered for NPPV should be able to manage their secretions. Although it has been recommended that patients should be awake and cooperative, patients with CO_2 narcosis may benefit from NPPV. Although several studies have enrolled patients with various degrees of altered consciousness, most of these patients presented with hypercapnic encephalopathy.

TABLE 46-6

SELECTION GUIDELINES: NONINVASIVE MECHANICAL VENTILATION FOR PATIENTS WITH ACUTE RESPIRATORY FAILURE

Step 1:Identify patients in need of ventilatory assistance
Symptoms and signs of acute respiratory distress
Moderate to severe dyspnea
RR>24
Gas exchange abnormalities
$PaCO_2$>45 mmHg, pH<7.35
PaO_2/FiO_2<200
Step 2:Exclude those at increased risk with noninvasive ventilation
Respiratory/cardiac arrest
Unstable clinical condition (shock, severe myocardial ischemia, life-threatening arrhythmias, status asthmaticus)
Compromised upper airway (impaired cough or swallowing function, tracheal stenosis, upper airway tumors)
Recent oral, esophageal, or gastric surgery
Excessive secretions
Agitated or uncooperative
Facial trauma, burns, surgery, or anatomic abnormalities interfering with mask fit
Tracheostomy in place
Central nervous disorders unrelated to hypercapnic encephalopathy or hypoxemia (stroke, meningitis)

$PaCO_2$ partial pressure of arterial carbon dioxide; *RR* respiratory rate; *PaO_2/FiO_2* partial pressure of arterial oxygen to inspired oxygen fraction ratio

Patients with an altered mental status caused by conditions other than hypercapnic encephalopathy or hypoxemia (such as meningitis, subarachnoid hemorrhage, or stroke) should not receive NPPV.

The next decision that the clinician must make is whether to use negative pressure ventilation or NPPV (Fig. 46-5). Each mode has specific advantages and disadvantages (see Table 46-5). Negative pressure ventilation has been successfully used in patients with chronic respiratory failure caused by severe neuromuscular disease, in acute exacerbations of COPD, and may be especially suited for patients with chronic or acute on chronic respiratory failure who have no need for invasive monitoring or invasive procedures, such as central venous

Negative pressure ventilation may be especially suited for patients who have no need for invasive monitoring or invasive procedures.

Negative pressure ventilation may be an alternative for patients with facial deformities such that a mask cannot be properly fitted.

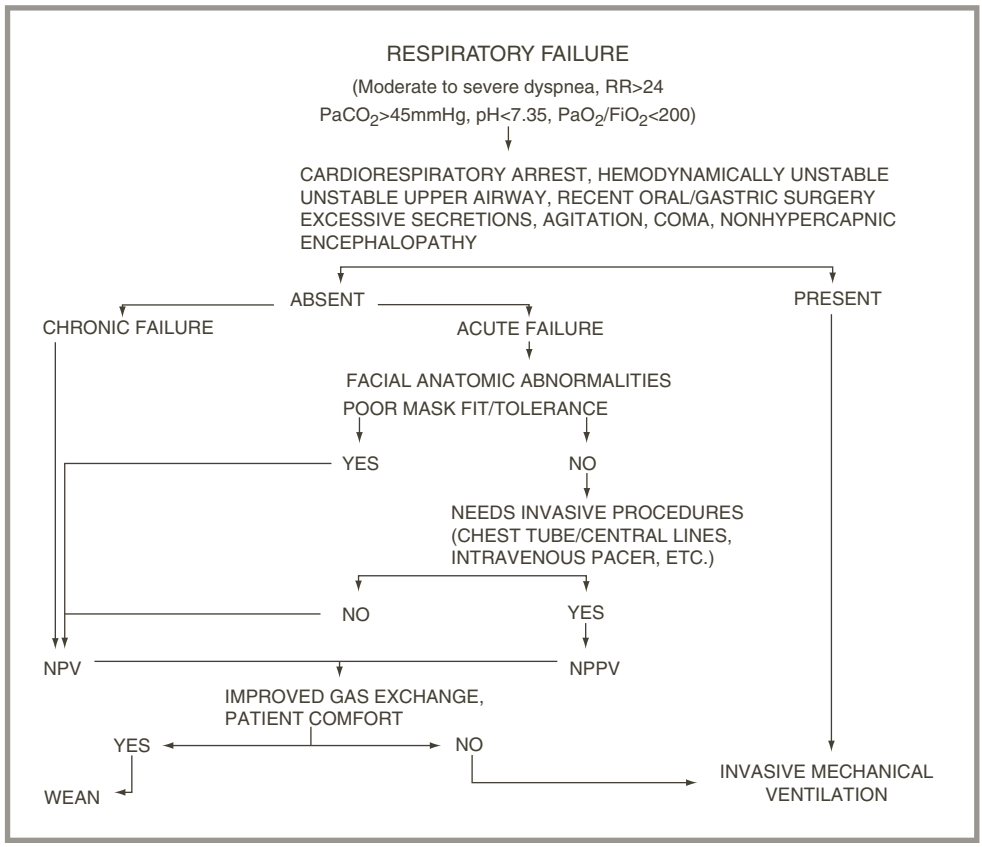

FIGURE 46-5

Selection of noninvasive ventilation in acute respiratory failure. *NPV* negative pressure ventilation; *NPPV* noninvasive positive pressure ventilation.

pressure measurement, pulmonary artery catheter placement, or chest tube insertion. In addition, negative pressure ventilation may be an alternative in those patients with facial deformities and a patent upper airway in which a face mask cannot be properly fitted. NPPV may be more suited for those who require invasive procedures. Frequently, it is uncertain whether patients with acute respiratory failure will require invasive monitoring. As the patient ventilator interfaces with NPPV interfere less with nursing care, it is implemented more frequently in current practice.

Outcome Predictors

Patients with hypercapnic respiratory failure who undergo NPPV have a greater treatment success than patients with hypoxemic respiratory failure.

An increase in pH and decrease in $PaCO_2$ in the first 2 h are associated with a better outcome in NPPV.

NPPV should be promptly instituted, ideally before acidemia and hypercarbia develops or worsens.

Several retrospective studies have found similar determinants of success, defined as avoidance of intubation, in patients receiving NPPV. Overall, hypercapnic patients appear to have better outcomes than hypercapnic patients with concomitant hypoxemia. COPD patients have a worse prognosis if they have an associated illness, especially pneumonia. Successful outcomes with NPPV occur in those who are younger, have intact dentition (improves mask seal), and the ability to coordinate breathing with the ventilator settings. Baseline $PaCO_2$ and pH, as well as a decrease in $PaCO_2$, increase in pH, and improvement in mental status during the first 2 h of NPPV strongly correlate with treatment success. This finding should prompt physicians to institute NPPV expeditiously before worsening acidemia and elevated levels of $PaCO_2$ occur. A study done by Ambrosino et al showed that those likely to succeed with NPPV had an arterial $pH > 7.1$, $PaCO_2 < 92$ mmHg, better baseline neurological scores, and adequate tolerance to the device being used.[5]

Monitoring Efficacy

Monitoring is essential to optimize patient comfort and tolerance of NPPV.

Patients with acute respiratory failure or an acute exacerbation superimposed on chronic respiratory failure who undergo NPPV should be carefully monitored, ideally in the ICU or a similarly equipped unit. Monitoring is essential to optimize the patient's comfort and

tolerance of NPPV, as well as facilitate improvements in subjective, physiologic, and gas exchange parameters.

Subjective Parameters

NPPV relieves symptoms of respiratory distress. It is therefore important to establish that the patient is comfortable by periodic clinical examination and direct questioning. Because the success of NPPV is directly related to the patient's ability to tolerate it, an effort must be made to make the patient comfortable by adjusting the mask and positioning the patient.

Physiologic Parameters

Reduction in respiratory rate and accessory muscles use, coupled with an improvement in thoracoabdominal synchrony, signal a favorable response to NPPV. An improvement in these parameters in the first 2 h portends a good prognosis.[4] Exhaled tidal volumes are difficult to interpret because of the presence of air leaks. Most of the bilevel portable ventilators measure tidal volume by integrating the flow signal. These ventilators report the inspiratory volume accurately, but only estimate exhaled tidal volume. Blood pressure monitoring is important, especially in volume-depleted patients who may have a further decrease in cardiac output if NPPV reduces preload. Continuous ECG monitoring should be available. Additional parameters (i.e., FEV_1, PEFR) may need to be monitored in specific entities.

Gas Exchange Parameters

Gas exchange is monitored using continuous pulse oximetry and arterial blood gas determinations.

Arterial blood gas determinations are useful in assessing the efficacy of a particular ventilatory mode.

In the acute setting, gas exchange is monitored using continuous pulse oximetry and arterial blood gas determinations. Arterial blood gas determinations should be performed at baseline and once patients are stabilized. An initial determination should be performed 2–4 h after initiating noninvasive ventilation; thereafter, arterial blood gas sampling should be based on clinical need. Arterial blood gas determinations are useful in assessing the efficacy of a particular ventilatory mode. A decrease in $PaCO_2$, an increase in PaO_2, and an increase in pH are considered as markers of successful outcome.[4] These parameters can also be used to titrate ventilator settings in specific conditions.

Complications

Complications associated with mask pressure include nasal pain and nasal bridge skin ulceration.

Upper airway obstruction is a well-recognized complication of negative pressure ventilation, particularly in patients with neuromuscular disease. Although OSA is not a common occurrence, the presence of nocturnal desaturation due to obstructive episodes should prompt the physician to consider the addition of CPAP or switching the patient to NPPV. Back pain, neck pain, and claustrophobia have also been reported to occur in patients receiving negative pressure ventilation. Negative pressure ventilation has also been reported to decrease lower esophageal sphincter tone in both normal and COPD patients. This problem may lead to regurgitation of gastric contents and an increased risk of aspiration; however, this condition generally responds well to agents that enhance gastric motility, such as metoclopramide. Patients with a history of gastroesophageal reflux disease and those with a prior history of gastric aspiration should be placed on promotility agents before implementing negative pressure ventilation.

The most frequently encountered complications of CPAP/NPPV are minor in magnitude and are generally related to intolerance of the mask or the degree of applied pressure. Major complications are infrequently seen (Table 46-7). A large proportion of the reported complications are related to mask pressure and include nasal pain (mucosa and over the bridge of the nose), and nasal bridge erythema and/or ulceration; these can be managed by minimizing strap tension, alternating different types of masks, applying artificial skin to the bridge of the nose, or selecting an alternate device. Common adverse effects related to airflow or applied pressures include conjunctival irritation and ear and sinus pain. Refitting the mask and decreasing pressure can treat these problems. Nasal dryness is a common complaint, but so are increased nasal discharge and congestion. The former may improve by decreasing leak

TABLE 46-7

COMPLICATIONS OF NONINVASIVE VENTILATION

Negative pressure ventilation	Noninvasive positive pressure ventilation	Major complications
Neck pain	Minor complications	Hypotension
Back pain	Nasal pain	Aspiration
Claustrophobia	Nasal bridge skin erythema	Pneumothorax
Upper airway obstruction	Nasal bridge skin ulceration	
Gastrointestinal reflux	Conjunctival irritation	
Gastric content aspiration	Ear pain	
	Sinus pain	
	Nasal passage dryness	
	Nasal congestion	
	Gastric distension	

around the mouth and using emollients; the latter may benefit from intranasal decongestants or inhaled steroids. Gastric distension may also occur, but it is rarely reported with peak pressures less than 20 cm H_2O. Distension may respond to simethicone or providing NPPV with the patient lying on the left side, which decreases gastric compliance and thereby limits the development of gastric distension.

APPLICATION IN SPECIFIC DISEASE GROUPS

Noninvasive ventilation has been successfully applied in a wide variety of clinical scenarios (Table 46-8). The level of supportive evidence varies among different disease entities (Table 46-9). Although noninvasive ventilation is currently used in the management of both chronic and acute respiratory disorders, we will focus on those indications that pertain to the acute setting.

TABLE 46-8

CLINICAL SCENARIOS WHERE NONINVASIVE POSITIVE PRESSURE VENTILATION MAY BE USEFUL

Acute respiratory failure	Postoperative respiratory failure
Cardiogenic pulmonary edema	Obesity hypoventilation syndrome
Community acquired pneumonia	Facilitate weaning
Acute respiratory distress syndrome	COPD
Acute on chronic respiratory failure	Neuromuscular diseases
COPD	Bridge to lung transplantation
Asthma	Cystic fibrosis
Neuromuscular diseases	COPD
Chest wall diseases	

COPD chronic obstructive pulmonary disease

TABLE 46-9

USE OF NONINVASIVE POSITIVE PRESSURE VENTILATION (NPPV) IN SPECIFIC DISEASES AND THE TYPE OF SUPPORTIVE EVIDENCE

DISEASES	EFFECTIVENESS OF NPPV DURING ARF	LEVEL OF EVIDENCE
Neuromuscular and chest wall diseases	Effective	Nonrandomized, concurrent-cohort comparisons
COPD	Effective to avoid endotracheal intubation; may decrease mortality and hospital length of stay	Randomized, controlled trials
Asthma	May prevent endotracheal intubation	Nonrandomized, concurrent-cohort comparisons
Acute hypoxemic respiratory failure	Possibly effective	Randomized, controlled trials
Cardiogenic pulmonary edema	Effective	Randomized, controlled trials

COPD chronic obstructive pulmonary disease; *ARF* acute respiratory failure

CASE STUDY 4

A 63-year-old male presents with a past history of amyotrophic lateral sclerosis (ALS) and increasing shortness of breath. He is visibly dyspneic. His respiratory rate is 22 breaths/min and his oxygen saturation is 91% on 4 L/min of supplemental oxygen. What disease states can noninvasive ventilation be used in and how strong is the evidence for its use in specific disease group?

Chronic Obstructive Pulmonary Disease

Negative pressure ventilation and NPPV have been used in the management of acute COPD exacerbations. Several studies suggest that negative pressure ventilation is as effective as positive pressure ventilation in providing adequate ventilatory support in COPD patients with acute respiratory failure; however, because these studies lacked adequate controls and enrolled relatively small numbers of patients, further randomized controlled trials comparing negative pressure ventilation and invasive or NPPV are needed.

Negative pressure ventilation for acute COPD exacerbations is infrequently used in the United States where NPPV is the preferred ventilatory mode for this condition.

CPAP decreases the work of breathing in some patients with severe COPD caused by emphysema. With severe emphysema, a loss of lung elastic recoil leads to premature airway collapse because of loss of external traction on the conducting airways. In these patients, CPAP acts as a pneumatic stent by maintaining patency in the conducting airways and diminishes the effort required to generate intrathoracic pressure and to initiate airflow.

The largest body of evidence supports the use of NPPV in the acute setting. In uncontrolled trials, the success rate in avoiding intubation in acute COPD exacerbation ranges from 60 to 90%. Randomized control trials showed improvements in gas exchange and in dyspnea scores and a significant reduction in the need for intubation.[4] Moreover, several studies showed a decrement in mortality and ICU length of stay when patients received NPPV in addition to conventional therapy for COPD exacerbation in comparison to those treated with conventional therapy alone.

Patients with severe COPD exacerbation are more likely to benefit from NPPV than those with mild or moderate exacerbations.

A metaanalysis by Keenan et al showed an overall 28% decreased risk of endotracheal intubation, a 4.57-day reduction in hospital length of stay, and a 10% reduction in hospital mortality (see Fig. 46-4).[4] The authors also found that only patients who had moderate to severe exacerbations (pH < 7.3) benefited from NPPV and those with less severe exacerbations did not. Similar reductions in mortality, intubation rate, and length of hospital stay were found in a metaanalysis performed by Lightowler et al.[6] In addition, after 1 h of NPPV, there was a significant improvement in pH and respiratory rate over controls. It is important to note that in these trials, NPPV was used to prevent, not to substitute, endotracheal intubation.

Hypercapnic Respiratory Failure in Diseases Other than COPD

Chest Wall Deformities and Neuromuscular Disease

NPPV is now considered the first-line of therapy in respiratory failure with restrictive diseases such as neuromuscular disease and chest wall deformities. Most of the data regarding these disorders involve chronic respiratory failure. One trial showed that NPPV also corrected gas exchange abnormalities and prevented intubation in kyphoscoliosis patients who had acute respiratory failure. The acute on chronic respiratory failure was related to pneumonia or upper airway infection. This highlights the need for finding immediately reversible causes and the benefit of mechanical aids that assist cough and expectoration as an adjunct to NPPV.

Another trial studied the use of NPPV and respiratory failure secondary to ALS. They studied patients with new orthopnea, new hypercapnea, or both due to ALS. Only 39 patients were studied; a survival benefit was seen amongst patients who tolerated NPPV (defined as the

ability to sleep 4 h nightly with machine use). Those who did not establish tolerance had worse outcomes. The group that could not tolerate NPPV had a significantly larger portion of patients with bulbar symptoms (oropharyngeal dysfunction). Patients with neuromuscular-related respiratory failure do benefit from the use of NPPV. However, a careful multidisciplinary approach to patient selection and implementation of NPPV is key to successful treatment.

Obesity Hypoventilation Syndrome

Obesity hypoventilation syndrome (OHS) is a clinical entity defined as obesity (BMI > 30 kg/m^2) combined with hypercapnea during wakefulness. Peres de Llano et al studied both the long and short-term effects of NPPV on OHS.[7] A subset of their population developed acute hypercapnic respiratory failure (pH < 7.34 in the setting of hypercapnea) secondary to OHS. A significant improvement in gas exchange and symptoms were shown at discharge in comparison to values obtained at admission. Overall, PaO_2 increased by 12 mmHg, $PaCO_2$ decreased by 7 mmHg, and pH increased by 0.07. Most importantly, none of these patients required endotracheal intubation. Interestingly, several patients remained hypercapnic at discharge. Many of these patients could not tolerate positive inspiratory pressure (PIP) levels greater than 20 cm H_2O and also required supplemental O_2. These patients eventually tolerated higher PIP levels and had resolution of hypercapnea as outpatients. Thus, patients who are started on noninvasive ventilation for OHS as inpatients should achieve clinical stability and adequately understand how to use the noninvasive equipment (e.g., face mask and device) prior to discharge.

Acute Hypoxemic Respiratory Failure

There is currently no evidence to support the use of negative pressure ventilation in patients with acute hypoxemic respiratory failure (PaO_2/FiO_2 ratio <200, RR > 35, and non-COPD diagnosis). Clinical studies evaluating the efficacy of NPPV in acute hypoxemic respiratory failure have yielded conflicting results.

Antonelli et al compared the use of NPPV and mechanical ventilation in acute,severe hypoxemic respiratory failure.[8] Using similar ventilator settings, they found that NPPV was as effective as conventional mechanical ventilation at improving gas exchange. Success with using NPPV was associated with decreases in the length of ICU stay, rate of pneumonia, and sinusitis compared with conventional mechanical ventilation. They also performed a subgroup analysis using the simplified acute physiologic score (SAPS) as a measure of severity of illness. Patients with scores greater than or equal to 16 showed no difference in gas exchange between NPPV and conventional ventilation. In those with scores less than 16, NPPV was superior to invasive ventilation.

Ferrer et al conducted a randomized trial with 105 patients with acute hypoxemic respiratory failure.[9] They found that compared to oxygen therapy, NPPV decreased the need for endotracheal intubation. Other outcomes measured were the following: incidence of septic shock, ICU mortality, and 90-day survival. NPPV was superior in each of these categories compared to control. Interestingly, most of the patients in this study had pneumonia or cardiogenic pulmonary edema (discussed below) as the cause of respiratory failure. They also found a statistically significant benefit to using NPPV for pneumonia in a subgroup analysis.

Keenan et al performed a metaanalysis of acute hypoxemic respiratory failure and the use of NPPV.[10] They included only randomized controlled trials and measured the following outcomes: need for endotracheal intubation, hospital length of stay, and ICU or hospital mortality. The metaanalysis favored the addition of NPPV to standard therapy over standard therapy alone with all three outcomes. This analysis included patients with diverse diseases but excluded those with COPD and cardiogenic pulmonary edema. Although the analysis reported an overall benefit with the use of NPPV in the treatment of hypoxemic respiratory failure, these results should be interpreted with caution. The significant heterogeneity of the included studies prevents definitive conclusions from being made about the use of NPPV in this setting. Patients should be selected carefully based on the clinical parameters described earlier and closer monitoring should be implemented.

Cardiogenic Pulmonary Edema

NPPV is best applied in conditions in which the underlying cause of respiratory failure can be reversed in 24–48 h. In acute cardiogenic pulmonary edema, NPPV provides partial ventilatory support, thereby improving gas exchange and relieving dyspnea. Additionally, NPPV unloads the respiratory muscles and prevents or delays the onset of respiratory muscle fatigue. Both CPAP and NPPV have been shown to decrease the work of breathing and intubation rates in patients suffering from cardiogenic pulmonary edema.

CPAP and NPPV have been shown to decrease the work of breathing and intubation rates in patients with acute cardiogenic pulmonary edema.

In a large controlled study by Lin et al, 100 patients with acute pulmonary edema were randomized to receive CPAP and oxygen vs. oxygen alone.[11] The CPAP group demonstrated an improvement in PaO_2 with a concomitant reduction in intrapulmonary shunt fraction and the alveolar-arterial tension gradient. The CPAP group also showed a higher cardiac stroke volume. The incidence of tracheal intubation was lower in the CPAP group (8 of 50 patients) compared to the control group (18 of 50 patients). The improvement in cardiovascular function during CPAP was speculated to be caused by a reduction in left ventricular afterload.

NPPV has also been used in the treatment of cardiogenic pulmonary edema. A single randomized controlled trial in cardiogenic pulmonary edema patients compared NPPV to CPAP and showed that NPPV produced a significant decrement in respiratory rate, $PaCO_2$, and dyspnea score when compared to CPAP at 30 min.[12] Both modalities showed a similar incidence of endotracheal intubation, but the NPPV group had a higher incidence of myocardial infarction (71 vs. 31%). This disparity could be partially explained by a trend toward the enrollment of more patients with chest pain in the NPPV group. The difference in myocardial infarction incidence may therefore have reflected baseline characteristics and not whether NPPV or CPAP was used. More recently Ferrari et al have studied this disparity.[13] Their trial included 52 patients comparing CPAP with NPPV in acute cardiogenic pulmonary edema. An increase in troponin within first 24 h with associated chest pain or EKG changes were found in four patients in the CPAP group and four in the NPPV group ($p=0.244$). There were also six patients in the CPAP group and four patients in the NPPV group who had an increase in troponin levels without any other signs of the acute coronary syndrome ($p=0.738$). There were no statistically significant differences in vital signs, ventilatory assistance, death, and hospital length of stay. Based on the current level of evidence, CPAP is considered the initial noninvasive ventilatory modality to be used in patients presenting cardiogenic pulmonary edema.

CPAP is recommended as the initial ventilatory mode to be used in patients with acute respiratory failure due to cardiogenic pulmonary edema.

Immunocompromised Patients

Immunocompromised patients, regardless of the etiology of their immune disorder, are at high risk for developing complications such as ventilator-associated pneumonia and alveolar hemorrhage during invasive mechanical ventilation. Thus, significant interest has been generated in treating these patients with NPPV to avoid endotracheal intubation. In an initial study, there was a 67% success rate in avoiding intubation in patients with AIDS and *Pneumocystis jirovecii* pneumonia.

Immunosuppressed patients, regardless of the etiology of immunosuppression, are at high risk for developing complications during invasive mechanical ventilation.

Hilbert et al conducted a controlled trial and randomized patients with fever, pulmonary infiltrates, and respiratory failure to receive NPPV or conventional therapy.[14] The patients randomized to receive NPPV had a decreased rate of endotracheal intubation and serious complications and an increased likelihood of survival to hospital discharge. Thus, it appears that NPPV can be used as first-line therapy in selected immunocompromised patients, so long as patients are carefully monitored and promptly intubated if needed.

Antonelli et al studied the use of NPPV in solid organ transplants with hypoxemic respiratory failure, defined as PaO_2/FiO_2 ratio <200, respiratory rate of >35 and accessory muscle or paradoxical abdominal muscle use.[15] Patients who required immediate intubation, had contraindications to NPPV, or had multisystem organ failure were excluded from the trial. Compared to oxygen therapy, NPPV decreased the rates of intubation, septic complications, and ICU mortality. Although both the groups had similar demographics, hemodynamics, and laboratory data, the etiologies causing respiratory failure varied greatly between the groups. In addition, almost a quarter of the patient population consisted of patients with cardiogenic pulmonary edema. The use of NPPV for this cause of hypoxemic respiratory failure has a considerable

amount of supportive evidence, and may have accounted for the favorable trial results. However, given the multiple potential complications attributable to prolonged mechanical ventilation in the immunesuppressed population, a trial of NPPV in a controlled setting may be warranted.

Postoperative Patients

Several studies have considered the use of NPPV in the perioperative setting. One study showed NPPV averted intubation in more than 70% of patients who developed respiratory failure within 36 h of surgery. Other authors have found similar results after cardiac surgery, coronary artery bypass, and pneumonectomy. NPPV appears to improve gas exchange and decrease the need for reintubation in postsurgical patients, but most of these studies have involved few patients. A randomized study comparing CPAP and oxygen therapy in postoperative hypoxemia found that CPAP prevented endotracheal intubation, decreased the length of ICU stay, reduced the rate of pneumonia and postoperative sepsis. This trial, however, excluded patients with a prior history of COPD, recent MI or revascularization, pH < 7.3, and $PaCO_2$ > 50 mmHg. They also excluded those meeting the criteria for acute respiratory distress syndrome (ARDS), hemoglobin levels <7 g/dL, and serum albumin <3 g/dL. Therefore NPPV may be attempted in select postoperative patients, while a careful search for the cause of respiratory failure takes place.

EXPANDED INDICATIONS FOR NONINVASIVE VENTILATION

Weaning from Mechanical Ventilation

Because noninvasive ventilation has been successfully used to provide ventilatory assistance in several groups of patients with acute and acute on chronic respiratory failure, its use has been expanded to provide ventilatory assistance to patients who have been recently extubated. This subject is discussed at length in Chap. 47.

Postextubation Respiratory Failure

Reintubation is required in 13–19% of those patients extubated after a successful spontaneous breathing trial, and is associated with higher mortality. NPPV has been shown to decrease the need for reintubation in several nonrandomized trials, but recent randomized single center and multicenter trials have not produced optimistic results.

In a prospective, multicenter randomized controlled trial conducted by Esteban et al, patients who were extubated based on strict criteria were followed for 48 h after extubation.[16] Those who developed respiratory failure were randomized to standard therapy vs. NPPV unless there was a need for urgent reintubation. More number of patients who required reintubation in the NPPV group died compared to those who required reintubation in the standard therapy group, and the delays in reintubation after the development of acute respiratory failure correlated with worsened survival rates. The need for reintubation and length of ICU stay was similar in both the groups. A small subgroup of COPD patients actually had lower rates of reintubation in the noninvasive group but the sample size was too small to draw any other significant conclusions. Therefore, clinicians should have a low threshold for reintubation in patients with postextubation respiratory failure, and delays in reintubation may contribute to an increased risk for mortality. It may be advisable to attempt only noninvasive ventilation with postextubation respiratory failure in COPD patients, but only under conditions of close observation.

Prevention of Postextubation Respiratory Failure

The use of NPPV should be considered for the prevention of postextubation respiratory failure in carefully selected patients.

Although the evidence for the use of NPPV in postextubation respiratory failure is not favorable, its use in the prevention of post extubation respiratory failure may be warranted. One study used NPPV to prevent postextubation respiratory failure in obese individuals

(BMI ≥ 35 kg/m^2). Sixty-two obese patients were placed on NPPV after weaning from mechanical ventilation and were compared to historically matched controls. They found a 16% absolute risk reduction in the rate of respiratory failure in the NPPV group, as well as decreased ICU and hospital lengths of stay. NPPV also conferred a reduction in hospital mortality in those patients who were hypercapnic while weaning from mechanical ventilation.

Ferrer et al conducted a prospective randomized trial on using NPPV to prevent postextubation respiratory failure in patients at risk for reintubation (age >65, APACHE II score >12 at extubation, cardiac failure as a reason for initial intubation).[17] The NPPV group, compared to usual care, had statistically significant decrease in respiratory failure and decreased ICU mortality, but 90-day mortality was unchanged between the two groups. A subset analysis of patients who were hypercapnic during weaning showed an improvement in 90-day mortality when NPPV was used. NPPV should be used postextubation in patients who are obese or hypercapnic during weaning. It may also benefit a select group of patients who have underlying conditions causing chronic respiratory failure and are deemed at risk for reintubation.

Status Asthmaticus

The use of NPPV in status asthmaticus is controversial with little prospective data.. Meduri et al prospectively followed 17 patients with severe asthma exacerbations treated using standard medical treatment plus NPPV.[18] At admission, their pH and PCO_2 were 7.25 ± 0.01 and 65 ± 2 mmHg respectively. They showed that NPPV improved gas exchange with only two of the 17 patients requiring intubation. In a randomized control trial, thirty patients with severe asthma attacks were selected from a larger group of 124 patients who presented to the emergency department. The thirty patients were randomly assigned to either NPPV or to a sham device in addition to conventional therapy. Eighty percent of patients in the NPPV reached the primary endpoint (50% improvement in forced expiratory volume in one second (FEV_1)) as compared to 20% in the control group. NPPV also significantly decreased the need for hospital admission. No patients required endotracheal intubation and invasive ventilation in either group.

Use of NPPV in severe asthma exacerbations still remains controversial. Most trials have only selected patients with severe asthma exacerbations. It is likely that those with mild exacerbations would not benefit. We advocate the use of NPPV in severe asthma exacerbations only when ICU level care is available and by a team that is intimately familiar with noninvasive ventilation management.

NPPV may be attempted in severe asthma exacerbations in a controlled setting where advanced airway management is available.

Severe Community Acquired Pneumonia

Severe community acquired pneumonia (CAP), defined by having three of the following criteria ($PaO_2/FiO_2 \leq 250$, multilobar infiltrates, hypothermia, uremia, leukopenia, thrombocytopenia, mental confusion, or hypothermia) is often associated with respiratory failure and high mortality rates. Avoidance of intubation and the use of noninvasive ventilation is preferable in order to minimize the risks associated with intubation, improve patient comfort, and preserve oropharyngeal function. Unfortunately, efficacy data to support the use of noninvasive ventilation is sparse in severe CAP. Confalonieri et al evaluated the use of CPAP for severe CAP in a randomized trial.[19] They found that CPAP was associated with decreases in respiratory rate, the need for endotracheal intubation, and ICU length of stays. In a subgroup analysis, patients with an underlying diagnosis of COPD had similar results with improved survival at 2 months compared to those in the control group. Although Confalonieri's results support the use of CPAP in severe CAP, its use should be limited to the ICU setting.

Acute Respiratory Distress Syndrome

ARDS represents a severe form of hypoxemic respiratory failure. For this reason most trials for NPPV have excluded patients with ARDS. Antonelli et al conducted a prospective multicenter cohort study to investigate the use of NPPV as first-line treatment in ARDS.[20] Their study evaluated a total of 479 patients, but 332 were excluded because of the need for

emergent intubation. Overall, they found that NPPV averted intubation in 54% of treated patients. They also found that a higher Simplified Acute Physiology Score (SAPS) II at enrollment and a lower $PaO_2/FiO_2 \leq 175$ after 1 h of NPPV predicted the need for intubation. They also noted that 70% of NPPV failures were intubated within the first 48 h of therapy. Avoidance of intubation, however, was associated with a lower mortality rate. According to the authors, it is unclear whether the delay in the use of mechanical ventilation affected mortality. Although this data is promising, it should be interpreted with caution. A vast majority of the patients demonstrated an immediate need for invasive mechanical ventilation and were excluded from the study. If NPPV is attempted, it should be done in an ICU setting where immediate advanced airway management is available, and a low threshold for intubation should be maintained.

Noninvasive Ventilation in Supporting the Terminally Ill

The use of NPPV has been reported in several studies in patients who are not to be intubated but are found to have a reversible cause of respiratory failure. One trial studied 30 elderly COPD patients (mean age, 76 years) for whom intubation was contraindicated or had been refused by the patients in accordance with their advance directives. Despite the severity of respiratory failure (mean $PaO_2 < 45$ mmHg), successful avoidance of intubation was reported in 60% of patients. Another study included 114 patients with acute respiratory failure, who agreed to NPPV but refused intubation. There was a 43% survival to hospital discharge. A diagnosis of CHF was associated with improved survival. Patients with higher baseline $PaCO_2$, stronger cough, and alert mental status had better outcomes. Though the results were somewhat favorable, it should be noted that many of the patients presented with reversible causes of respiratory failure.

In a consensus statement on NPPV in critical and palliative care settings, the Society of Critical Care Medicine supported a three category approach to the use of NPPV: NPPV without preset limits on the level of life support, NPPV for patients who decline intubation, and NPPV as comfort measures for patients who decline intubation.[21] It should be noted that the aforementioned studies represent patients who fall into the second category. The patients had do not intubate wishes; however, NPPV was not being used as palliation for work of breathing or sense of dyspnea. Evidence to support the use of NPPV as a palliative treatment is sparse. In theory, NPPV could be used as an adjunct to pharmacological therapy and it may be helpful to provide time for family affairs to be settled. However, there are no studies to date that evaluate the efficacy and safety of NPPV for this purpose, and no trials compare NPPV with traditional pharmacological approaches to palliation. Therefore, the use of noninvasive ventilation in the palliative care setting remains controversial. Overall, a careful discussion that involves the patient and family must take place to determine the patient's desired level of care. The clinician must realize that the patients and families may transition from one category to another as the level of care is discussed. The physician should describe the use of NPPV, including the risks and benefits. The goals of using NPPV, and a clear plan of treatment that is agreed upon between the patient, family, and clinician if NPPV fails should be established.

SUMMARY

Several options are currently available to deliver noninvasive ventilation. The choice between negative pressure ventilation and NPPV should be made based on physician and supporting staff expertise, equipment availability, patient comfort, and individual patient conditions. Negative pressure ventilation is an alternative mode of noninvasive ventilation in patients with chronic neuromuscular and chest wall diseases. It also appears to be useful in patients with acute exacerbations of chronic respiratory conditions, including COPD. In patients who require partial ventilator assistance, NPPV has been shown to improve patient

comfort and decrease intubation rate and hospital length of stay. Careful attention must be paid to patient selection, proper fitting of interface devices, and adequate monitoring to increase success and the patient's tolerance of NPPV.

REVIEW QUESTIONS

1. **A 78-year-old woman presents to the emergency department with respiratory distress; her respiratory rate is 36, and she is using accessory muscles. She has a long-standing history of COPD and emphysema. Her daughter, who lives with her, states that her mother's mental status has worsened over the past 2 h, and that she is less alert than usual. On her arrival to the emergency department, she develops ventricular tachycardia, and her blood pressure is measured at 60/- mmHg. The most important reason to avoid noninvasive ventilation in this patient is**
   - **A.** Age greater than 65
   - **B.** Use of accessory muscles
   - **C.** Respiratory rate greater than 35 breaths/min
   - **D.** Change in mental status
   - **E.** Lethal arrhythmia and hemodynamic instability

2. **CPAP is thought to be useful in cardiogenic pulmonary edema because**
   - **A.** It increases preload
   - **B.** It increases afterload
   - **C.** It decreases end-expiratory lung volume
   - **D.** It decreases afterload

3. **Complications of negative pressure ventilation include all the following, except**
   - **A.** Upper airway obstruction
   - **B.** Claustrophobia
   - **C.** Gastric distention
   - **D.** Back pain
   - **E.** Neck pain and discomfort

4. **All the following statements regarding patient–ventilator interfaces are correct, except**
   - **A.** Nasal masks are more likely to be associated with air leaks
   - **B.** The use of a chinstrap may decrease air leaks in patients ventilated with nasal masks
   - **C.** Nasal–oral masks are less effective than nasal masks in improving gas exchange
   - **D.** Appropriate mask fitting is one of the most important steps determining successful NPPV

5. **The greatest amount of evidence for NPPV's efficacy in preventing intubation has been shown in which group with acute respiratory failure?**
   - **A.** Hypercapnic patients with COPD
   - **B.** Hypoxemic patients with ARDS
   - **C.** Status asthmaticus
   - **D.** Cardiogenic pulmonary edema

6. **All of the following are complications of NPPV except**
   - **A.** Mask intolerance
   - **B.** Nasal pain
   - **C.** Conjunctival irritation
   - **D.** Upper airway obstruction

7. **NPPV should be used in which group of patients to prevent postextubation respiratory failure?**
   - **A.** Hypoxemic patients with ARDS
   - **B.** Patients with kyphoscoliosis
   - **C.** Patients intubated for asthma
   - **D.** Patients with morbid obesity

ANSWERS

1. The answer is E. When considering the use of NPPV, a two-step approach has been suggested. The first step consists of determining which patients are likely to require future intubation based on respiratory signs, symptoms, and gas exchange parameters. In this case, the respiratory rate and the increased use of accessory muscles are signs consistent with respiratory distress, which would make this patient a candidate for noninvasive ventilation. The second step involves determining in which patients it would be unsafe to use NPPV. In this case, the patient develops a potentially serious arrhythmia and hemodynamic instability (low blood pressure); these, along with other reasons to intubate emergently, are contraindications to the use of NPPV. The change in mental status is likely to be secondary to hypercapnic encephalopathy and is not a contraindication to NPPV. Age should not preclude the use of noninvasive ventilation.
2. The answer is D. CPAP has been shown to decrease afterload and increase stroke volume. In animal models, it has also been shown to cause increased sympathoadrenal stimulation.
3. The answer is C. Gastric distension is a relatively frequent complication in patients undergoing NPPV via facial mask. Back pain, neck pain, and claustrophobia have been reported in patients on negative pressure ventilation. Upper airway obstruction is a consequence of the effect of negative pressure on the pharyngeal tissue and may sometimes result in nocturnal hypoxemia in patients undergoing negative ventilation.
4. The answer is C. Most studies have shown that nasal and nasal–oral masks are equivalent in improving gas exchange. Factors such as patient comfort and proper fit are more important in determining successful NPPV. A chinstrap may be helpful in patients ventilated with a nasal mask who have persistent air leak through the mouth.

5. The answer is A. The greatest body of evidence for NPPV's efficacy in preventing intubation has been shown in patients with hypercapnic respiratory failure and COPD. The evidence is less compelling for patients with acute hypoxemic respiratory failure from other causes. There are no randomized, controlled studies suggesting that patients with status asthmaticus benefit from NPPV. Although NPPV has been used in cardiogenic pulmonary edema, the largest trial available showed an increased incidence of myocardial infarction in patients undergoing NPPV when compared to similar patients treated with CPAP. Although this trial may have introduced an imbalanced sample of patients, CPAP remains the first-line treatment for cardiogenic pulmonary edema, unless patients present with hypercarbia.
6. The answer is D. Upper airway obstruction is a common complication of negative pressure ventilation. NPPV should be considered for those who develop upper airway obstruction with the use of negative pressure ventilation.
7. The answer is D. Studies have shown that obese patients who are being extubated have a decreased need for reintubation and an improved ICU mortality. This is especially true for those who are obese and hypercapnic during weaning. NPPV should be carefully considered for all patients being extubated. In particular, those with increased risk for reintubation, obesity, and chronic respiratory conditions should be considered good candidates for NPPV to prevent reintubation.

CHAPTER 47

VICTOR KIM AND GERARD J. CRINER

Weaning from Mechanical Ventilation

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Determine when a patient is ready to begin the weaning process, based on clinical history, physical examination, and routine laboratory data.
- Use bedside weaning parameters to predict weaning outcome.
- Postulate a differential diagnosis of common and uncommon causes of weaning failure.
- Understand the advantages and disadvantages of the various weaning techniques.
- Realize that certain techniques, such as noninvasive ventilation after extubation and daily interruption of sedatives, can increase your likelihood of liberating the patient from mechanical ventilation.

During the past 25 years, there has been a significant increase in the number of patients who receive mechanical ventilation as a means of life support during surgery or life-threatening medical illness. Although mechanical ventilation has clear-cut benefits, it is also associated with a significant number of complications, such as decreased cardiac output, increased intracranial pressure, ventilator-associated pneumonia (VAP), and ventilator-induced lung injury (VILI). In addition, mechanical ventilation is expensive and hinders efficient patient movement through the intensive care unit.

CASE STUDY

A 70-year-old nursing home resident was intubated for aspiration pneumonia and respiratory distress. He was treated with antibiotics and clinically improved over the period of 5 days. During that time, he required 100% FiO_2 and needed sedatives to maintain patient comfort and patient ventilator synchrony, and frequent endotracheal tube suctioning for purulent secretions. He is now awake and alert with normal oxygen saturation on 40% FiO_2 and PEEP of 5 cm H_2O. Minute ventilation (MV) is 10 L/min. He appears cachectic and has lower extremity contractures. He has no fever and is hemodynamically stable off all vasopressor support. When the patient is placed on CPAP of 5 cm H_2O and pressure support (PS) of 0 cm H_2O, the patient's respiratory rate increases to 40 breaths/min and tidal volume (V_T) drops to 250 mL within 1 min.

Weaning patients from mechanical ventilation remains one of the most challenging aspects of intensive care. Despite the advent of new and promising weaning indices, the skills to determine which patients should be weaned and when patients are ready for weaning remain a mix of art and science. These skills appear to be greatly enhanced by experience. About 20–25% of ventilated patients fail an initial attempt at discontinuing mechanical ventilation and will require more concentrated and prolonged attempts for discontinuance (i.e., weaning). For patients requiring prolonged mechanical ventilation, about 40% of the time spent on the ventilator is devoted to the weaning process. This percentage is even higher in patients with specific diseases such as chronic obstructive pulmonary disease (COPD), who may be undergoing active weaning attempts for as much as 60% of their total time spent receiving mechanical ventilation.

In this chapter, we review the clinical parameters that determine which patients are ready to begin the weaning process, the interpretation of bedside parameters used to predict weaning outcome, and the merits and disadvantages of specific weaning techniques to successfully discontinue mechanical ventilation.

DETERMINING THE CAUSE OF RESPIRATORY FAILURE

Before withdrawing mechanical ventilation, the cause of respiratory failure must be identified.

Before mechanical ventilation can be safely withdrawn, the abnormality causing respiratory failure must be identified and show favorable signs of responding to treatment. To identify the physiologic causes of respiratory failure, it is useful to separate the causes into three major categories: (1) hypoxemic respiratory failure, (2) ventilatory pump failure, and (3) psychologic factors (47-1).

Hypoxemic respiratory failure can result from hypoventilation shunting, impaired pulmonary gas exchange, or decreased mixed venous blood oxygen content. The chest radiograph, physical examination, and alveolar-arterial oxygen gradient are useful in distinguishing among intrapulmonary shunting, increased physiologic deadspace, and alveolar hypoventilation as possible causes of hypoxemic respiratory failure (see Chap. 15).

Respiratory pump dysfunction is considered the most common cause of failure to wean.

Ventilatory pump dysfunction is considered by some authors to be the most common cause of failure to wean from mechanical ventilation. Failure of the respiratory system to sustain adequate ventilation to meet the demands imposed by the illness may occur whenever respiratory demand exceeds ventilatory pump capacity. Ventilatory pump failure may occur because of an increased ventilatory load (even in patients with normal respiratory system), resulting from increased deadspace, hypermetabolism due to sepsis and/or fever, or increased CO_2 production due to increased carbohydrate load. In contrast, normal or only slightly elevated respiratory loads may not be sustained by subjects with decreased ventilatory pump capacity due to impaired central respiratory drive, phrenic nerve dysfunction, thoracic wall abnormalities, or severe derangements of respiratory muscle function (e.g., underlying neuromuscular disease, electrolyte disturbances).

Abnormalities of central respiratory drive can be seen in patients with structural injury to the central nervous system, overuse of sedative agents, and metabolic alkalosis. Diaphragm

TABLE 47-1

CAUSES OF RESPIRATORY FAILURE

Hypoxemic respiratory failure
Impaired pulmonary gas exchange (shunt, *V/Q* mismatch)
Pneumonia
Congestive heart failure
Pulmonary embolism
ARDS
Decreased mixed venous oxygen content
Congestive heart failure
Ventilatory pump failure
Decreased minute ventilation with a relatively normal respiratory workload
Thoracic wall abnormalities (flail chest, rib fractures)
Peripheral neurologic disorder (phrenic nerve damage, critical care illness polyneuropathy)
Muscular dysfunction (neuromuscular blocking agent-associated weakness/myopathy)
Central respiratory depression (drug overdose, brainstem infarction)
Severe metabolic alkalosis
Increased respiratory workload with poor ability to maintain adequate ventilation
Increased minute ventilation requirements (sepsis, fever, hyperthermia, increased CO_2 production)
Increased deadspace
Increased elastic workload (decreased lung and/or chest wall compliance, dynamic hyperinflation)
Increased resistive workload (airway obstruction, secretions, endotracheal tube, ventilator circuit)
Psychologic factors
Anxiety
Depression

dysfunction can be seen in patients with cold-induced phrenic nerve injury or direct diaphragm injury that may occur during cardiothoracic surgery. Diaphragm dysfunction has also been reported in patients following upper abdominal surgery. Impaired respiratory muscle function can also result from various underlying medical conditions.

Hyperinflation is a frequently overlooked cause of weaning failure.

Hyperinflation occurs in patients with acute exacerbations of severe asthma or COPD and is frequently overlooked as a cause of weaning failure. It causes a shortening in the diaphragm's precontraction length, which causes the diaphragm to work on a disadvantageous portion of its tension–length curve. Hyperinflation also alters the orientation of the diaphragmatic fibers medially inward, and decreases the length of the zone of apposition, factors that further decrease the diaphragm's force-generating capacity.

Other disorders commonly encountered in the intensive care unit may cause abnormal respiratory muscle function, thereby hindering weaning. These include undernutrition, electrolyte disturbances (hypophosphatemia, hypokalemia, hypocalcemia, hypomagnesemia), and thyroid dysfunction. Recently, diaphragm muscle atrophy has been shown to occur as a consequence of inactivity in previously healthy brain-dead organ donors receiving fully assisted mechanical ventilation for periods of only 24–96 h.[1]

WHEN IS THE PATIENT READY TO WEAN?

Resolution or significant improvement in the underlying cause of respiratory failure is the most important prerequisite before weaning is attempted.

Before an attempt is made to wean a patient, certain prerequisites should be met (Table 47-2). The most important prerequisite appears to be resolution or significant improvement in the underlying cause of respiratory failure. Patients should be hemodynamically stable, with minimal or no need for vasopressor agents. The absence of sepsis or hyperthermia should be confirmed. Sedative drugs and neuromuscular blocking agents should be discontinued. Patients should be awake, alert, and able to manage secretions and protect their airway. Significant fluid, electrolyte, and metabolic disorders should be corrected before weaning attempts are made. Adequate gas exchange marked by a PaO_2 to FiO_2 ratio greater than 200, FiO_2 requirements of 50% or less, and positive end-expiratory pressure 5 cm H_2O or less are desirable. Adequate respiratory muscle strength needs to be ensured (maximum inspiratory pressure [MIP] or negative inspiratory force at least −25 cm H_2O).

TABLE 47-2

NECESSARY CONDITIONS TO DECIDE WHEN A PATIENT IS READY FOR WEANING

Resolution or significant improvement of the underlying cause of respiratory failure
Stable hemodynamic state
Absence of sepsis or hyperthermia
Cessation of sedative drugs
Cessation of neuromuscular blocking agents
Cessation of vasopressor agents
Patients should be awake, alert, and able to manage secretions and protect their airway
Correction of metabolic and electrolyte disorders
Adequate gas exchange
PaO_2 to FiO_2 ratio greater than 200
FiO_2 requirements less than 50%
PEEP requirements equal to or less than 5 cm H_2O
Adequate respiratory muscle strength

PaO_2 partial pressure of arterial oxygen; *FiO_2* inspired fraction of oxygen; *PEEP* positive end-expiratory pressure

PREDICTORS OF WEANING OUTCOME

Determining when a patient is ready to wean from the ventilator is a complicated task. Considerable research has been devoted to finding variables that predict weaning outcome.

Pulmonary Gas Exchange

The adequacy of pulmonary gas exchange must be assessed before initiating weaning. In the past, several indices derived from arterial blood gas analysis have been used to predict weaning outcome. These indices are derived from retrospective studies and, consequently, have limitations. An arterial blood to inspired O_2 ratio (PaO_2/FiO_2) greater than 238 has a positive predictive value of 90%, yet its negative predictive value is only 10%.[2] In another study, an arterial/alveolar O_2 tension of 0.35 had positive and negative predictive values slightly greater than 0.5.[3] Although adequate arterial oxygenation is essential to initiate weaning, it is clear that the predictive value of this index by itself is insufficient to predict weaning outcome.

Adequate oxygenation is essential to initiate weaning, but its predictive value regarding weaning outcome is poor.

Respiratory Muscle Strength

The strength and endurance of the respiratory system seem to be major determinants of weaning outcome. Sahn and Lakshminarayan were among the first to describe the use of simple bedside criteria to assist decisions in discontinuing ventilatory support.[4] In a study involving 100 patients, these investigators measured resting MV, maximum voluntary ventilation (MVV) (i.e., maximum sustainable ventilation over 15 s... times 4, MVV), and MIP with a spirometer. Of these, 76 patients who had an MV less than 10 L/min, MIP of −30 cm H_2O or less, and MVV twice their resting MV who were able to complete a 2-h spontaneous breathing trial via an endotracheal tube were successfully extubated; seven more patients with a MIP of −25 cm H_2O or less and a mean MV of 10.2 L/min and able to successfully complete at least a 2 hours weaning trial were able to be extubated, although they were not able to double their resting MV. By contrast, 17 patients with an MIP greater than −22 cm H_2O who could not complete a spontaneous breathing trial could not be extubated.

Respiratory muscle strength and endurance are important determinants of weaning outcome.

Application of these criteria in subsequent studies, however, did not yield comparable results. When evaluating 47 patients on mechanical ventilation, Tahvanainen et al found that using a MIP less than −30 cm H_2O as a weaning predictor produced a false-negative result in 11 of 11 patients and a false-positive result in 8 of 23 patients.[5] Similarly, other authors reported poor negative and positive predictive values when evaluating other weaning parameters such as vital capacity (VC), minute ventilation (V_E), and MVV.

Factors that may account for the variability in bedside respiratory mechanics to predict weaning outcomes include different patient populations, variability in the duration of mechanical ventilation, different techniques used in measuring respiratory mechanics, and

inability of the measurements to accurately assess the true cause of ventilatory dependency. For example, no matter what respiratory parameters are measured, if a patient develops an acute severe episode of heart failure, or bronchospasm post-extubation, respiratory failure will recur, and thus, weaning will fail. Because of the poor and variable results of bedside parameters to predict weaning outcome, investigators turned to more complicated measurements of respiratory mechanics, such as $P_{0.1}$, gastric tonometry, and measurements of the work of breathing and mixed venous oxygen content.

$P_{0.1}$

The airway pressure generated 100 ms after initiating an inspiratory effort against an occluded airway ($P_{0.1}$) is believed to reflect central respiratory drive and has been proposed as a useful predictor of weaning outcome. The values for normal, healthy individuals are 2 cm H_2O or less. Herrera et al observed that 89% of patients with a $P_{0.1}$ greater than 4 cm H_2O failed weaning attempts.[6] In patients with COPD, Sassoon and Mahutte found that patients with a $P_{0.1}$ greater than 6 cm H_2O were unable to wean from ventilatory support, but patients with a $P_{0.1}$ less than 6 cm H_2O were successfully extubated.[7] Several studies have shown a large variation in outcome when $P_{0.1}$ is used, possibly because of its inability to predict endurance or its application to patient groups with different diseases causing respiratory failure. This technique also requires special equipment and trained personnel, which makes it less appealing.

Work of Breathing

Work of breathing can be measured by plotting the transpulmonary pressure against V_T. Transpulmonary pressure is calculated from the difference between pleural pressure (estimated with an endoesophageal balloon catheter) and the airway pressure. One study found that mechanical ventilation was necessary when work of breathing exceeded 1.8 kg/m^2/min. A similar study found a discriminating value of 1.34 kg/m^2/min to separate ventilator-dependent from ventilator-independent patients. At this level, the rate of false-negative and false-positive results was 13.8%. An additional study evaluated work of breathing in a group of 17 patients, six of whom required prolonged mechanical ventilation. A work index less than 1.6 kg/m^2/min was observed in all patients who had a successful weaning trial; this was more accurate than conventional weaning parameters in determining weaning outcome. Furthermore, patients who went from unsuccessful to successful weaning did not show significant improvement in conventional weaning parameters, but did show improvement in work of breathing measurements. There are no large prospective studies comparing this parameter against more conventional weaning parameters. The relative invasiveness and complexity of data acquisition and analysis, and the requirement for dedicated staff and equipment to perform the test make it unappealing as an effective clinical tool.

Gastric Tonometry

It has been proposed that measurement of gastric pH during weaning can help predict weaning success. A fall in gastric pH during weaning from mechanical ventilation would indicate mucosal ischemia from hypoperfusion as a result of blood flow diverted toward the respiratory muscles to meet their increased metabolic demands. Mohsenifar et al measured gastric pH before and during weaning attempts in 29 patients who were intubated for respiratory failure.[8] All patients were ventilated for more than 48 h and were treated with ranitidine. Despite similar hemodynamic parameters, changes in respiratory breathing pattern, and gas exchange during weaning, those successfully liberated from the ventilator had no change in gastric pH, whereas those that failed had a fall in gastric pH. The authors concluded that this technique can help predict weaning success. However, it is unclear if these results are applicable to other disease states or to those not treated with gastric acid suppressive therapy. Additionally, the technique requires the placement of an orogastric or nasogastric tube. These drawbacks limit the routine utility of this technique.

Mixed Venous Oxygen Content

Mixed venous oxygen saturation ($S\bar{v}O_2$) has also been measured during attempts at weaning from mechanical ventilation. In one study, the $S\bar{v}O_2$ progressively fell during weaning in eight patients who failed a spontaneous breathing trial, compared to 11 patients who were successfully extubated and had no significant change in $S\bar{v}O_2$. The fall in $S\bar{v}O_2$ was hypothesized to result from an increased oxygen cost of breathing and increased oxygen extraction. Measurement of mixed venous oxygen content needs prospective validation prior to recommendation for routine use.

Respiratory Pattern during Spontaneous Breathing

Multiple studies have reported the role of breathing pattern in the outcome of weaning from mechanical ventilation. The development of rapid shallow breathing, the presence of asynchronous or paradoxical thoracoabdominal movements, and marked accessory muscle recruitment during a spontaneous breathing trial are physical exam findings that herald an unsuccessful weaning trial.

Based on the premise that patients who fail weaning trials rapidly develop a high respiratory rate and a drop in V_T, Yang and Tobin combined measurements of frequency (f) and V_T into the rapid shallow breathing index, f/V_T.[3] They obtained data in 36 patients and noticed that an f/V_T ratio of 105 breaths/min/L best differentiated patients who weaned successfully from those who failed. They subsequently validated the rapid shallow breathing index in 64 patients, comparing it against conventional weaning indexes (Table 47-3). An f/V_T ratio less than 105 predicted a successful weaning trial (Fig. 47-1). The positive and negative predictive values were 0.78 and 0.95, respectively. The predictive power of the f/V_T ratio was better than any of its components, supporting the use of this index. The f/V_T ratio is attractive because it is relatively easy to obtain and the determinant value (i.e., ≈100) is easy to remember. It is important to recognize that this test is most accurate in patients who have received mechanical ventilation for less than 7 days.

An f/V_T ratio less than 105 predicts a successful weaning outcome in about 80% of patients.

Patients who fail a weaning trial frequently exhibit a rapid respiratory rate and a drop in V_T.

In a subsequent study, Epstein attempted to define the cause of extubation failure in patients whose f/V_T predicted weaning success.[9] He analyzed 94 consecutive patients whose f/V_T before the weaning trial predicted successful extubation. The f/V_T was measured while patients breathed unassisted for 1 min. Of the 94 patients extubated, 84 had an f/V_T less than 100 and 10 had an f/V_T of 100 or more. Extubation failure, defined as the need to reintubate within 72 h, occurred in 14 of 84 patients in the group with f/V_T below 100 and 4 of 10 patients with f/V_T above 100 (Table 47-4). When the cause for respiratory failure was analyzed, the underlying respiratory process was responsible for extubation failure in all four patients with f/V_T of 100 or more. In contrast, the initial respiratory process was the cause for extubation failure in only 1 of 14 patients with an f/V_T less than 100; new problems, such as

The f/V_T ratio is more accurate when an underlying respiratory process is responsible for mechanical ventilation.

heart failure and upper airway obstruction, were the most common causes (Table 47-5). When the author further analyzed the 57 patients in whom a respiratory process was the original cause for mechanical ventilation, the positive predictive value for their f/V_T index approached unity (Table 47-6). This study confirmed the high positive predictive value of the f/V_T index in predicting weaning outcome.

It is important to recognize that successful weaning from ventilatory support does not ensure that a patient will successfully remain extubated. These are two distinct phases in the process of liberating a patient from mechanical ventilation. This realization is particularly important because reintubation carries an increased risk of nosocomial pneumonia. Currently, there are no objective measurements to determine the outcome of extubation; therefore, clinical assessment is paramount in establishing which patients can be safely extubated. Important factors include the patient's level of consciousness, which should be adequate for airway protection, the presence of a gag reflex, and the ability to cough and clear the airway. Upper airway patency is one of the most difficult aspects to evaluate. Postintubation laryngeal edema can lead to respiratory failure, especially in patients with decreased respiratory reserve. Some investigators advocate the use of the "cuff-leak" test, ensuring the presence of an air leak around the endotracheal tube when the cuff is deflated and the tube is occluded. The presence of an air leak is reassuring and relatively sensitive in predicting a positive outcome from extubation, but the specificity of the test is very low. Despite this, it is clear from most studies that about 80% of patients will be extubated after a spontaneous breathing

If patients exhibit satisfactory weaning parameters, 80% will wean after a spontaneous breathing trial on a T-piece circuit.

trial and the remaining 20% will require more concentrated weaning efforts; however, the majority will eventually be successfully extubated.

SPECIFIC WEANING METHODS

Trials of Spontaneous Breathing

Once patients show an improvement or resolution of the underlying cause of respiratory failure and fulfill the previously mentioned criteria, weaning attempts can be initiated. Placing the patient on a T-tube system and allowing them to breathe spontaneously is probably the simplest method of assessing the patient's ability to wean from mechanical ventilation. A T-tube system is a continuous high flow source of oxygen delivered by corrugated tubing that is attached to the distal end of the endotracheal tube, with an additional 6-in. tail of tubing that limits the entrainment of room air oxygen. Patients who have spent relatively short periods on mechanical ventilation (less than 7 days), or in whom no problems with the resumption of unassisted breathing is expected, can be placed on a spontaneous breathing trial on a T-tube circuit. Traditionally, patients are placed on T-tube circuit for anywhere from 30 min to 2 h. If they do not develop signs of respiratory distress, such as nasal flaring, tachypnea, abdominal ribcage paradoxical movements or tachycardia, arrhythmias, oxygen desaturation, or hypo- or hypertension during this time, they can be extubated. If signs of intolerance occur, mechanical ventilation is resumed, and weaning attempts are resumed in 24 h. About 75% of the patients who undergo a T-tube weaning trial can be extubated. The 2-h duration of the spontaneous breathing trial had been the prior dogma, but has been recently challenged. In a study of more than 500 patients, patients underwent a traditional 120-min spontaneous breathing trial compared to a 30-min trial. There was no significant

difference within groups in the percentage of patients who were extubated, the percentage of patients who remained extubated at 48 h, and in-hospital mortality.

In difficult-to-wean patients, mechanical ventilation is gradually discontinued. Short trials of spontaneous breathing are followed by periods of rest on the ventilator in the assist-control mode. The duration of the trials is slowly increased; when patients are able to tolerate 2 h of spontaneous breathing, the weaning process is completed and the patient can be extubated. The importance of careful observation of the patient during T-piece trials cannot be overemphasized. Resistance of the endotracheal tube imposes an additional load and increases the work of breathing during spontaneous breathing; therefore, T-piece trials are also thought to test endurance of the weaning patient.

Intermittent Mandatory Ventilation

During intermittent mandatory ventilation (IMV) or synchronized IMV (SIMV; synchronous with inspiratory effort), a specified number of volume-preset breaths are delivered to the patient each minute by the ventilator. In addition, the patient is allowed to breath spontaneously between machine-delivered breaths. As a weaning method, the backup respiratory rate is gradually reduced until the patient is able to tolerate a minimal backup rate (i.e., 2–4 breaths/min) for 2 h. IMV is frequently criticized because patients are generally subjected to an additional inspiratory load imposed by breathing through a demand valve. Most importantly, this mode has also been shown to prolong the weaning process over all other modalities (see following). It is difficult, therefore, to encourage the use of this mode as an appropriate weaning alternative.

Pressure-Support Ventilation

Pressure-support ventilation (PSV) is a pressure-targeted ventilatory mode that provides support to the patient's inspiratory effort with a preset inspiratory pressure. During PSV, the patient determines the respiratory rate. The patient's effort and the level of PS determine the delivered volume. Initial settings are aimed at achieving tidal volumes from 8 to 10 mL/kg and a respiratory rate between 20 and 28 breaths/min. Weaning can be accomplished by gradually reducing the level of PS by 3–6 cm H_2O, titrated on the basis of respiratory rate. In two prospective, randomized trials, extubation was considered when patients were able to comfortably tolerate 5–8 cm H_2O for 2 h. PSV has been shown by several authors to decrease the work of breathing imposed by the endotracheal tube and the ventilator circuit, which suggested that patients who tolerate a weaning trial at this "compensatory" pressure are ready to sustain spontaneous ventilation.[10] There appears to be great variability in the compensatory level of PS between patients, and there is no reliable method to determine it. Occasionally, patients with severe obstructive disease or COPD may have problems with PSV. PSV is set to cycle at a predetermined flow, usually 25% of peak inspiratory flow; patients with COPD may require more time to reach this preset level during expiration, causing ventilator inflation during neural expiration and patient–ventilator asynchrony.

The SIMV mode results in a prolonged weaning process when compared to all other weaning modalities.

Efficacy of Different Weaning Techniques

Daily spontaneous breathing trials lead to extubation twice as quickly as PSV weaning and 3 times more quickly than SIMV.

Two recent rigorously controlled studies have prospectively compared the efficacy of three different weaning techniques: IMV, PS, and spontaneous breathing trials (Table 47-7). Brochard et al found that a significantly greater number of patients could be weaned successfully after 21 days with PSV than with the other methods.[11] This group also reported that weaning time was significantly shorter with PS (5.7 days) than with spontaneous breathing trials (8.5 days) or IMV (9.9 days). In contrast, Esteban et al found that a once-daily trial of spontaneous breathing led to extubation twice as quickly as PSV and about 3 times more quickly than IMV.[12] There was no difference between a once-daily spontaneous breathing trial and multiple daily spontaneous breathing trials (attempted at least twice daily). Some of the differences in these studies are the result of different criteria to assess tolerance to

TABLE 47-7

COMPARISON BETWEEN BROCHARD AND ESTEBAN STUDIES EVALUATING DIFFERENT WEANING TECHNIQUES

weaning and weaning completion, and therefore, the aggressiveness of utilizing PS or T-piece as weaning techniques. Esteban's group considered extubation if patients tolerated 5 cm H_2O of PS for 2 h compared to 8 cm H_2O in Brochard's study. During application of SIMV, Esteban and colleagues extubated patients once they were able to tolerate a backup rate of 5 breaths/min for 2 h; in contrast, Brochard's group's criteria required patients to tolerate 24 h at 4 breaths/min (a significant ventilatory challenge). Both studies similarly concluded that SIMV was less efficient in weaning patients, but differed as to whether PS or T-piece was the superior weaning method. Overall, either PS or T-piece weaning techniques can be successful if patients are properly selected and the method is appropriately implemented.

TECHNIQUES TO AID WEANING

Tracheostomy

A small percentage of all patients placed on mechanical ventilation fail to wean and require more prolonged and concentrated efforts. The medical and respiratory status of these patients should be carefully reevaluated, and efforts should be made to correct any abnormalities. Additionally, tracheostomy placement should be contemplated. After several days, the endotracheal tube becomes coated with a biofilm comprised of secretions, denuded mucosal epithelial cells, and most likely pathologic bacteria. This not only decreases the effective diameter of the tube, thereby making efforts at spontaneous respiration more difficult, but also puts the patient at increasing risk for nosocomial infection. In addition, as the endotracheal tube warms to body temperature, it elongates and the curvature of the tube in the posterior oropharynx becomes more acute, resulting in greater airway resistance at the point of greatest inflection. Tracheostomy has been shown to reduce the resistive work of breathing over the continued use of an endotracheal tube[13] (see Fig. 47-2).

Tracheostomy has been shown to reduce the resistive work of breathing compared to an endotracheal tube.

The question regarding the appropriate timing for tracheostomy remains unanswered. It has been suggested that patients who are likely to require mechanical ventilation for more than 21 days should have a tracheostomy. Evidence regarding the advantages of early vs. late tracheotomy and the relative advantages of tracheostomy over endotracheal tube is controversial. Besides decreasing airways resistance and avoiding laryngeal injury, tracheotomy enhances the potential for improved patient mobility, improves secretion clearance, facilitates the patient's transfer to a lower level of care, and improves oral hygiene and patient comfort. Overall, the most common practice is to perform a tracheostomy if a patient has been on mechanical ventilation for at least 10–14 days.

Daily Interruption of Sedatives

The use of continuous infusions of sedating medications is common in the intubated patient. The concern about continuous sedation is the prolonged duration of action which unnecessarily extends the duration of mechanical ventilation. Moreover, continuous sedation

Daily interruption of continuous sedative infusions can decrease the duration of mechanical ventilation.

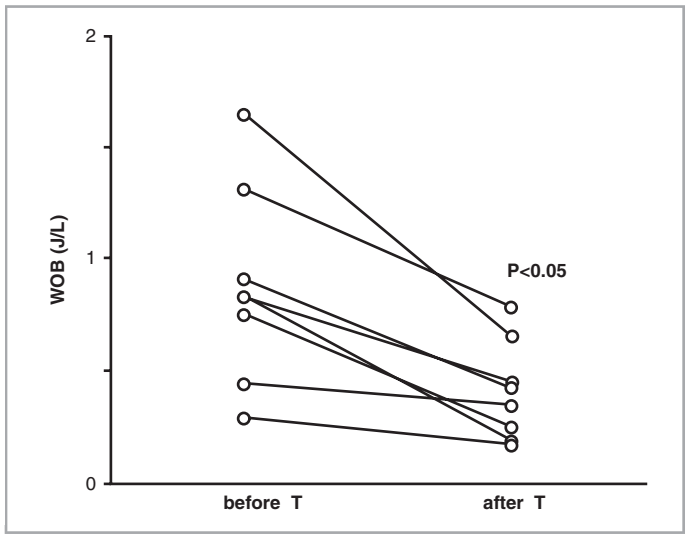

FIGURE 47-2

Work of breathing (WOB), expressed as joules/liter, at the beginning of pressure-support weaning in eight patients, before and after tracheostomy (T). The results were statistically significantly different ($p<0.05$) and show decreased WOB following tracheostomy. complicates the assessment of the neurological status of critically ill patients and may lead to the performance of unnecessary tests. Kress et al tested the hypothesis that daily interruption of sedatives would expedite recovery and decrease ICU length of stay.[14] They randomized 128 mechanically ventilated patients who were receiving continuous sedative infusions, to daily interruption of sedative infusions, until the patient was awake or to usual care (UC) (control of the sedative infusion was left to the discretion of the treating physician). The median duration of mechanical ventilation was significantly less in the group where continuous sedation was interrupted daily, as was ICU length of stay. By comparison, more patients underwent diagnostic testing to assess changes in mental status in the UC group. The authors concluded that daily interruption of sedatives can decrease the duration of mechanical ventilation.

Noninvasive Ventilation

Noninvasive positive pressure ventilation (NPPV) appears to facilitate the weaning process in patients with acute on chronic respiratory failure, particularly in those with COPD.

Because NPPV has been successfully used to avoid the need for intubation in patients with acute and acute on chronic respiratory failure, its use has been expanded to facilitate early extubation. Udwadia et al were the first to report the usefulness of NPPV in facilitating the weaning process.[15] The causes for respiratory failure included neuromuscular disease, primary lung disease (i.e., COPD), or postoperative respiratory failure following cardiac surgery. Patients were placed on NPPV once they met the following criteria: intact upper airway function, minimal airway secretions, low oxygen requirement, hemodynamic stability, ability to sustain spontaneous ventilation for 10–15 min, and functional gastrointestinal tract. NPPV was initially used for 16–20 h/day and was gradually decreased. In this study, 18 of 22 patients were successfully converted to NPPV and discharged home in a mean of 11 days. The results of this study have to be carefully interpreted, because the majority of these patients had acute on chronic respiratory failure, a significant percentage were discharged with nocturnal noninvasive ventilation, and all the patients had a tracheostomy in place, which made resuming invasive ventilatory support relatively easy.

In a study by Nava et al, 40 patients with severe COPD who required mechanical ventilation and failed a T-piece trial 48 h postintubation were randomized to extubation and application of NPPV or weaning by PS via endotracheal tube.[16] At 60 days follow-up, 22 of 25 patients were successfully weaned in the NPPV group compared to 17 of 25 patients in the invasive ventilation group. Patients in the NPPV group had shorter duration of mechanical ventilation, shorter ICU stay, and improved mortality at the time of discharge. None of the patients receiving NPPV developed pneumonia, compared to 7 of 25 patients in the invasive mechanical ventilation arm of the study. Girault et al randomized 33 patients with acute on chronic respiratory failure to conventional PS weans or extubation and NPPV after they

failed a 2-h T-piece trial.[17] The NPPV group had a shorter course of mechanical ventilation and a trend toward fewer complications, but mortality, hospital length of stay, and ICU length of stay were similar among groups. The results of these trials indicate that there may be a role for NPPV in patients who fail a T-piece wean in reducing mechanical ventilation duration and its associated complications. It is important to notice that these trials enrolled patients with chronic or acute on chronic respiratory failure (Table 47-8), and that, in some cases, noninvasive ventilation was continued beyond the hospital admission. The results are, therefore, more likely to be applicable in patients with acute exacerbations of chronic respiratory failure, especially in those with COPD. Whether these results can be extrapolated to other patient populations is unclear at this time, and further studies are needed.

The use of NPPV has also been used in both the prevention and treatment of postextubation respiratory failure. The efficacy of NPPV in this setting, however, is not as great as in others. In a recent large prospective randomized trial, NPPV was no better than UC in the prevention of reintubation. In addition, there was a suggestion that those receiving NPPV had a higher mortality, perhaps related to a delay in intubation. However, NPPV may be of benefit in select patient groups. NPPV in postextubation respiratory failure is described at length in Chap. 46.

Protocol or Computer-Based Strategies

It has been proposed by many that protocol-based strategies for weaning patients shorten time to extubation and decrease ICU cost. This hypothesis is based on the theory that a regimented daily screening of all intubated patients will more rapidly identify those ready to be weaned and that weaning is initiated before the patients are seen by their physicians. There have been several randomized trials addressing this issue, unfortunately with different results.

Protocol-based weaning strategies have been shown by some, but not all, studies to decrease time to extubation and ICU length of stay.

In a randomized, prospective trial, Ely et al studied 300 consecutive medical and coronary care unit ventilated patients.[18] The intervention group ($n = 149$) underwent daily screening of respiratory function to identify those patients capable of spontaneous breathing. Patients had to satisfy five criteria to be considered for a spontaneous breathing trial (e.g., PaO_2/FiO_2 ratio <200, PEEP < 5 cm H_2O, adequate coughing during suctioning, f/V_T ratio <105, and no need for sedative or vasopressor agents). Intervention patients meeting these criteria underwent a 2-h T-piece spontaneous breathing trial. Physicians were notified if patients successfully completed the trial (Fig. 47-3). Control patients received daily screening, but no other interventions. Patients assigned to the intervention group received mechanical ventilation for a median of 4.5 days vs. 6 days in the control group ($p = 0.003$). The group assigned to the intervention had a significant reduction in the incidence of self-extubation, reintubation,

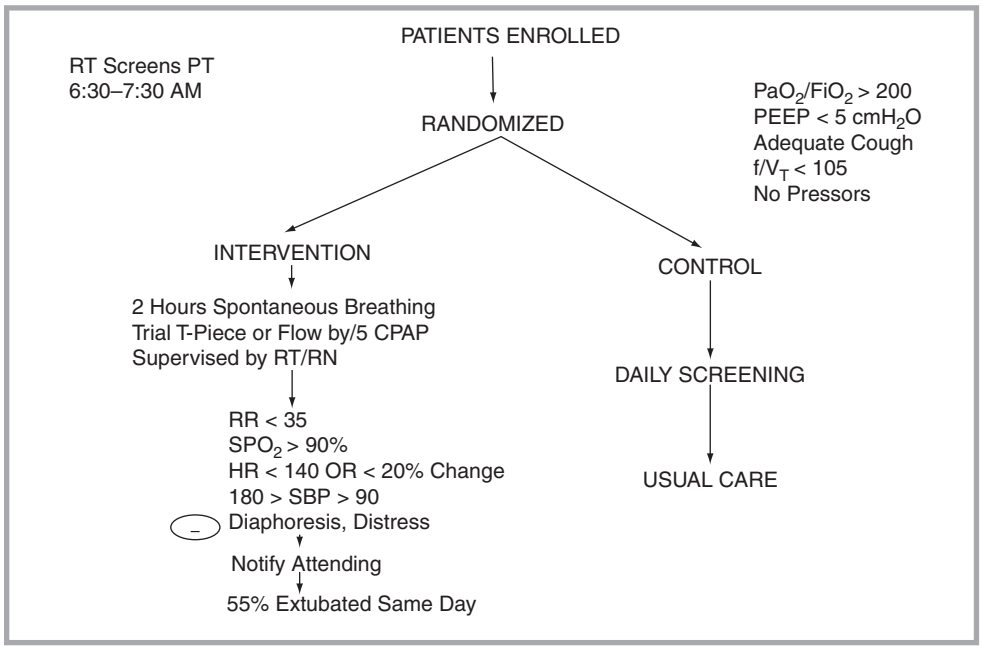

FIGURE 47-3

All rights reserved).

tracheostomy, and mechanical ventilation for more than 21 days. ICU costs were significantly reduced in the intervention group. A more recent multicenter trial (2006) that randomized 144 patients to UC or a computer driven weaning protocol found similar results, with a decrease in weaning duration, total duration of mechanical ventilation, and ICU length of stay, without an increase in reintubation rate or adverse events.

These studies suggest that protocol-based weaning strategies do indeed improve care and decrease cost. However, the implementation of weaning protocols by nursing and respiratory care staff requires significant resources, and the replacement of physician scrutiny by protocol or computer-based practices is not without flaws. Another trial by Krishnan et al had less optimistic results than Ely's study.[19] Two hundred and ninety-nine intubated patients were randomized to a protocol-based weaning strategy (PW) or UC, where eligibility for weaning and weaning technique were determined by the treating physician team. The baseline patient characteristics and protocol for weaning were similar to the Ely study. In contrast to the study by Ely, the patients in the PW group needed to tolerate 1 h of spontaneous breathing in order to be considered ready for extubation. There were no differences in duration of mechanical ventilation, ICU or hospital mortality, ICU length of stay, and rates of reintubation between the two groups. The authors concluded that a rigorous protocol-based weaning strategy may not be necessary as long as the team of physicians carefully and frequently scrutinized each patient for signs of respiratory failure reversal and ventilator weaning is performed in a judicious fashion.

Protocol-based weaning strategies require significant resources to implement and sustain, and cannot replace physician judgment for weaning eligibility.

Adjunctive Therapy

It has become increasingly apparent that supportive therapy, not only for medical illnesses but also for malnutrition, deconditioning, and psychiatric disorders, is essential for managing patients who are difficult to wean from mechanical ventilation. Critical illness requiring mechanical ventilation is associated with malnutrition secondary to increased metabolic demands relative to the provided nutritional supplementation, muscle wasting related to systemic inflammatory response and being bedridden, and finally anxiety from numerous factors including sleep deprivation, ventilator dependence, and the severe medical illness. These comorbidities increase difficulty in weaning from mechanical ventilation.

Malnutrition, deconditioning, and psychiatric disorders are commonly seen in ventilator-dependent patients and treatment of these comorbidites should be included in the treatment plan.

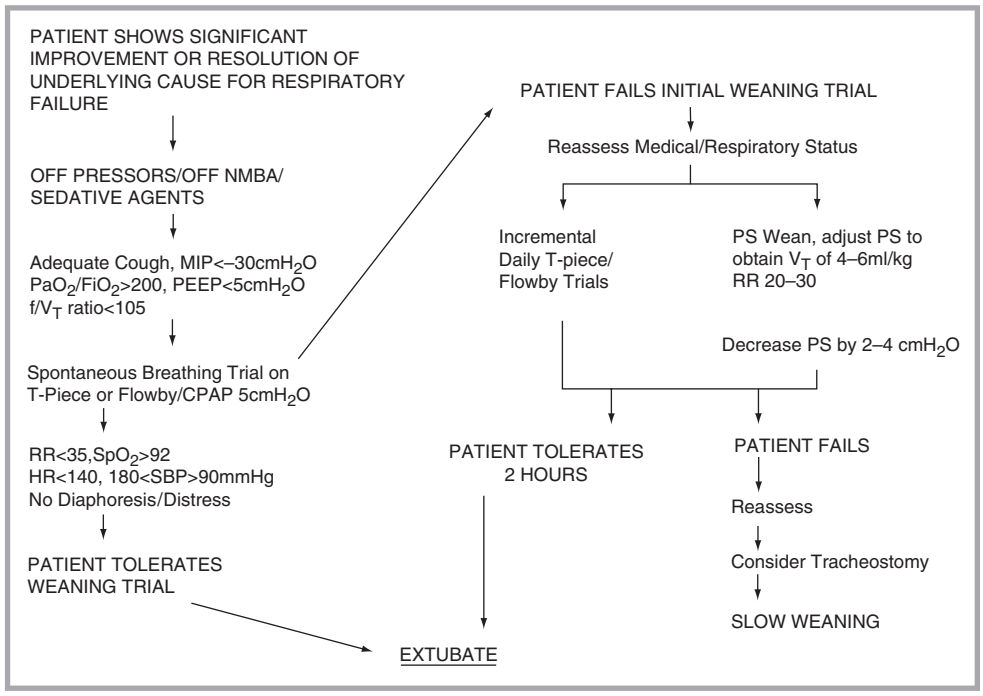

FIGURE 47-4

Weaning algorithm. *NMBA* neuromuscular blocking agents; *PaO_2* arterial oxygen tension; *FiO_2* inspired fraction of oxygen; *MIP* maximal inspiratory pressure; *f/V_T* rapid shallow breathing index; *CPAP* continuous positive airway pressure; *PS* pressure support; *RR* respiratory rate; *HR* heart rate; *SBP* systolic blood pressure.

Treatment of these comorbidities is associated with improved outcome in several small studies, and the clinician should have a heightened suspicion for them in all ventilated patients and include treatment regimens for them as part of a comprehensive treatment plan. Malnutrition and deconditioning may decrease respiratory muscle strength and endurance and may increase the ventilatory response to hypoxia. Aggressive nutritional support in patients with prolonged mechanical ventilation has been shown in small studies to increase the likelihood of successful liberation from mechanical ventilation. The patient should be mobilized out of bed as soon as medically possible. Physical rehabilitation should begin as soon as the patient is medically stable to improve muscle strength and mobility. A retrospective analysis of 49 patients with prolonged mechanical ventilation found that whole body rehabilitation was associated with improvement in muscle strength and conditioning and was associated with liberation from mechanical ventilation. In addition, a case series of ten ventilator-dependent patients revealed that inspiratory muscle strength training, in addition to usual medical care, allowed them to become ventilator independent. Finally, techniques such as anxiolytics, hypnosis, and biofeedback may decrease anxiety associated with the process of weaning, thereby increasing chances of success.

SUMMARY

Weaning from mechanical ventilation blends the art and science aspects of pulmonary and critical care medicine. Successful weaning requires knowledge of the cause of the patient's respiratory failure, a certain degree of clinical stability for the patient, and interpretation of some easily obtainable respiratory function bedside tests (Fig. 47-4). These assessments, in addition to careful observation of a patient's breathing pattern and tolerance of a spontaneous breathing trial on T-piece or PS, can successfully enhance weaning from mechanical ventilation.

REVIEW QUESTIONS

1. **Regarding weaning on PS, all the following statements are true EXCEPT**
   - **A.** As a weaning mode, PSV has been shown to be more efficient than IMV
   - **B.** Pressure-support weans should always be started with a support level of 20 cm H_2O
   - **C.** Patients with severe obstructive disease may exhibit ventilator–patient asynchrony while weaning on PS
   - **D.** PS has been shown to decrease the work of breathing secondary to the additional resistive load of the endotracheal tube

2. **Regarding spontaneous breathing trials via T-tube system, all the following statements are correct EXCEPT**
   - **A.** More than 70% of the patients who are placed on a spontaneous breathing trial have a successful weaning trial
   - **B.** Once-daily spontaneous breathing trials are as efficacious as intermittent spontaneous breathing trials (at least twice daily)
   - **C.** Spontaneous breathing trials via T-piece are associated with increased work of breathing
   - **D.** The rate of reintubation is higher in patients undergoing a 30-min spontaneous breathing trial vs. the conventional 120-min spontaneous breathing trial

3. **Regarding the frequency/tidal volume (f/V_T), all the following are correct EXCEPT**
   - **A.** It should be measured while the patient is breathing spontaneously through a T-piece
   - **B.** A discriminate value less than 100 has a high positive predictive value for successful weaning
   - **C.** The positive predictive value of the f/V_T index is less when a respiratory process is the cause for mechanical ventilation
   - **D.** The limitations of the f/V_T index include its inability to predict outcome if a new condition arises after it was measured (i.e., heart failure)

4. **A frequently overlooked cause of weaning failure in mechanically ventilated patients with severe COPD is**
   - **A.** Electrolyte disturbances
   - **B.** Critical care polyneuropathy
   - **C.** Malnutrition
   - **D.** Silent cardiac ischemia
   - **E.** Hyperinflation

5. **All of the following are true regarding the use of noninvasive ventilation (NPPV) in the facilitation of weaning EXCEPT**
   - **A.** NPPV should be used in all patients who fail conventional weaning methods
   - **B.** NPPV should only be applied for a few hours after removal of the endotracheal tube
   - **C.** Decreased mortality, ICU length of stay, and time to extubation have been shown in all studies involving the use of NPPV as a weaning method
   - **D.** The patient population that is best served with the use of this modality is comprised of those with an acute exacerbation of a chronic respiratory illness

6. **Which of the following statements regarding techniques to facilitate weaning is true?**
   - **A.** Tracheostomy should be contemplated only in those who fail to be liberated from the ventilator within 14 days
   - **B.** Daily interruption of continuous sedative infusions is useful only for daily neurologic assessments
   - **C.** Protocol-based weaning strategies have been shown to decrease time to extubation in several studies compared to UC
   - **D.** Weaning from mechanical ventilation should be driven in all ICUs by protocol-based strategies, as they are easy to implement and maintain, and predict with greater accuracy than physician judgment

ANSWERS

1. The answer is B. The amount of PS at the beginning of a weaning trial should be titrated to obtain a desired V_T (6–8 mL/kg) and respiratory rate (20–28 breaths/min). The PS required to achieve these parameters will vary depending on the respiratory system's compliance and resistance. In several studies, patients on PSV weaned twice as fast as patients on IMV. PSV decreases work of breathing due to the endotracheal tube.
2. The answer is D. A recently published study demonstrated that the rate of reintubation and mortality were not significantly different between patients who underwent a 30-min compared to a 120-min spontaneous breathing trial before extubation. The T-piece circuit is associated with an increase in work of breathing, which is why some authors believe that this weaning method also reflects the patient's endurance. In Esteban's study, no difference was found between patients doing intermittent (at least twice daily) vs. once-daily spontaneous breathing trials. About 70–80% of all patients who meet basic prerequisites (resolution of underlying cause, absence of electrolyte abnormalities, and absence of overt sepsis) will be successfully extubated after a spontaneous breathing trial on a T-piece circuit.
3. The answer is C. The accuracy of the f/V_T index to predict weaning is very high in patients who have an underlying respiratory disturbance requiring mechanical ventilation. It diminishes when the index is not able to reflect the underlying pathophysiologic disorder (new-onset heart failure). The index should be measured while the patient is breathing spontaneously.
4. The answer is E. Although all options listed may be present in a patient with severe COPD and may be implicated in the failure to wean, a frequently overlooked (and very likely under diagnosed) cause of weaning failure in this group of patients is hyperinflation. By altering the orientation of the diaphragm fibers and decreasing the area of apposition, hyperinflation leads to a decrement in the diaphragm's force-generating capacity.

5. The answer is D. What can be concluded from the studies examining NPPV to facilitate weaning is that it is a modality that best facilitates weaning in those with acute exacerbations from chronic respiratory illnesses, such as COPD. It should not be generally applied to all of those who fail weaning attempts. It has been associated with decreased time to extubation in select groups, but mortality and ICU length of stay have not been uniformly decreased in those who receive NPPV. Finally, it is likely that patients extubated and then placed on NPPV require prolonged use to maintain the ventilatory demands imposed by their illness.

6. The answer is C. Protocol-based weaning strategies have been shown to decrease time to extubation in many (but not all) studies, thereby providing supportive evidence that they improve patient care. However, they require significant resources to implement and maintain, and do not replace physician judgment. Tracheostomy has been shown to decrease the work of breathing and should be contemplated in those who fail weaning attempts within 2 weeks or if the anticipated duration of mechanical ventilation is expected to be prolonged. Daily interruption of sedatives is useful for neurologic examination, but also has been shown to decrease time to extubation.

CHAPTER 48

SCOTT A. SCHARTEL AND SHEELA S. PAI

Mechanical Hemodynamic Support

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Discuss the indications for intra-aortic balloon counterpulsation (IABC).
- Formulate a plan for the evaluation and management of ischemic limb complications related to IABC.
- Discuss the use of VAD therapy in the management of failing ventricular function.
- Compare and contrast a variety of VADs with regard to indications, contraindications, and complications.
- Discuss the technique of extracorporeal membrane oxygenation in the treatment of acute respiratory failure.

The mainstay of treatment for patients with inadequate hemodynamic performance is achieving appropriate intravascular volume (preload), vascular tone (afterload), and myocardial pump function (contractility), most commonly accomplished by volume administration or diuretic therapy, pharmacologic manipulation of the vascular tone with vasodilators or vasopressors, and administration of inotropic agents. When these measures result in an inadequate response in hemodynamic performance, mechanical circulatory support may be indicated. This chapter discusses the major mechanical circulatory support techniques currently available for use in critically ill patients, including intra-aortic balloon counterpulsation (IABC) therapy, ventricular-assist devices (VADs), and extracorporeal membrane oxygenation (ECMO).

Most of the coronary artery blood flow to the left ventricle occurs during diastole, not systole, unlike the flow in all other vascular beds.

INTRA-AORTIC BALLOON COUNTERPULSATION

Analysis of blood flow to the heart during the cardiac cycle reveals that the majority of the coronary artery blood flow to the left ventricle occurs during diastole, not systole, unlike the flow in all other vascular beds. This phenomenon can be explained by the increased

CASE STUDY 1: PART 1

A 56-year-old man arrives in the emergency department 1 h after the onset of substernal chest pain radiating to his left arm. He is short of breath and diaphoretic. His blood pressure is 95/45 mmHg with a heart rate of 112 beats/min. An electrocardiogram is consistent with an acute ST segment elevation anterior wall myocardial infarction. He is taken emergently to the cardiac catheterization laboratory where he is found to have multivessel coronary artery disease. Percutaneous coronary intervention with angioplasty and stent placement is performed in the left anterior descending artery and the left circumflex coronary artery. Ten hours later, the patient has recurrent chest pain, his blood pressure decreases to 79/42 mmHg with a heart rate of 119 beats/min. During the preceding four hours his urine output has been less than 20 mL/h.

resistance to blood flow in the small intraventricular arterial branches caused by the force of ventricular contraction. In 1953, using a canine model, Kantrowitz and Kantrowitz[1] demonstrated that delaying the systemic arterial pressure peak until diastole could augment coronary artery blood flow. This finding led to the development of intra-aortic balloon catheters that could be used in humans. In 1968, they reported the use of IABC in three patients in cardiogenic shock.[2] Additional research and improvements in the technical aspects of IABC therapy have proved this to be a valuable therapeutic intervention in a variety of conditions.

Therapeutic Uses

IABC is usually considered as the first choice for mechanical hemodynamic support in patients who have failed to respond to pharmacotherapy and the manipulation of intravascular volume. Intra-aortic balloon catheterization can be performed with a percutaneous insertion technique whether the patient is in the ICU, cardiac catheterization laboratory, or operating room. It is less invasive and less expensive than the ventricular assist devices VADs discussed later in this chapter and does not require a surgical incision or general anesthesia for placement.

IABC is usually the first choice for mechanical hemodynamic support when pharmacotherapy and the manipulation of intravascular volume are ineffective.

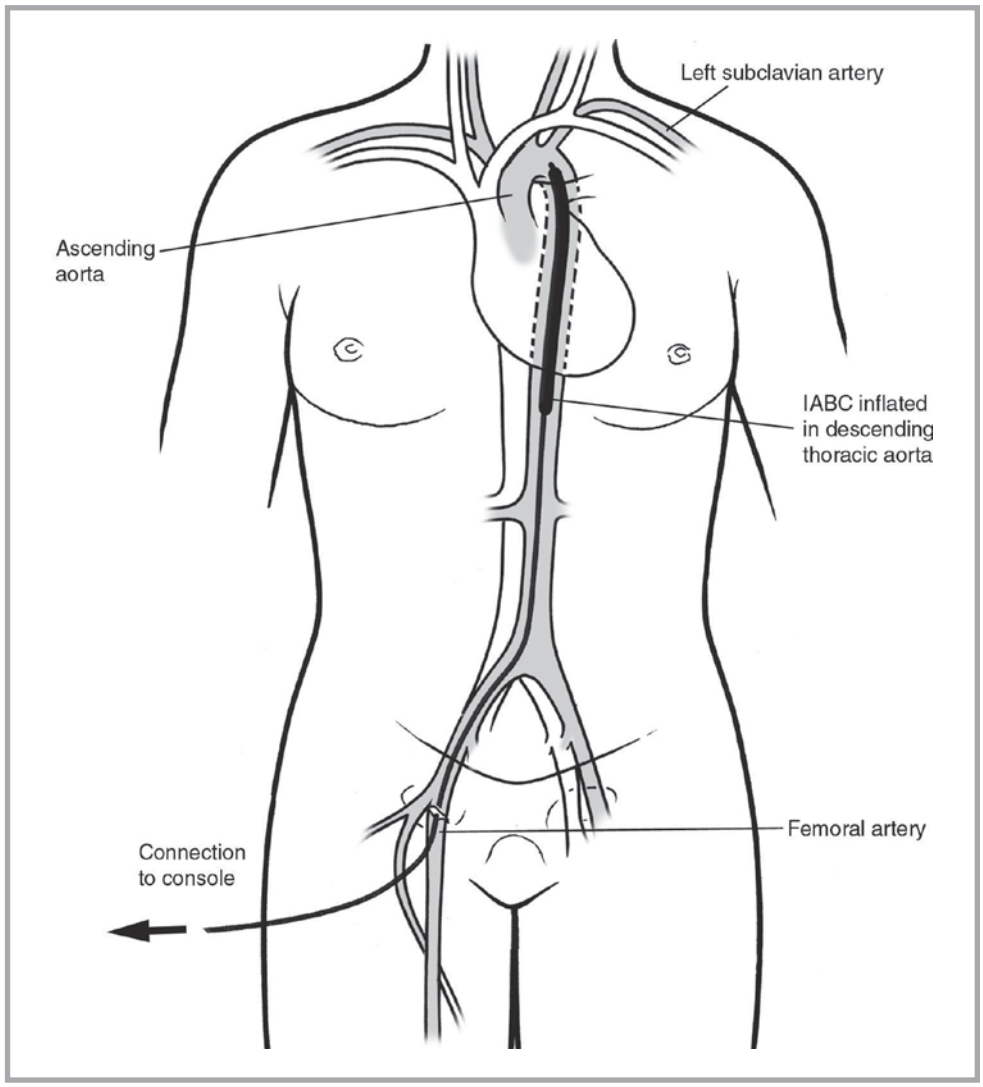
IABC therapy requires two components that work together: the intra-aortic balloon catheter, which must be placed into the patient's aorta, and an electronically controlled pumping device. The intra-aortic balloon catheter has a lumen that communicates with the balloon affixed to the catheter, which is then attached to the pumping device. Most modern intra-aortic balloon catheters also have a central lumen terminating at the distal end of the catheter. This central lumen is used to measure the blood pressure in the proximal aorta (Fig. 48-1). Helium is used to inflate the intra-aortic balloon because its low density allows the gas to move rapidly in and out of the balloon. Rapid shuttling of gas in and out of the balloon is necessary for the correct timing of balloon inflation and deflation with the cardiac cycle. Pumps within the control console provide the driving pressure necessary to inflate the balloon and vacuum to assist in balloon deflation. Balloon inflation is timed to occur with the onset of diastole and deflation to occur with the onset of systole. Information from an electrocardiographic (ECG) signal or an intraarterial pressure waveform is used to identify the specific stages of the cardiac cycle when the intra-aortic balloon will be inflated or deflated by the controller. The controller allows the adjustment of the volume of balloon inflation, the frequency of balloon inflation (every beat, every second or third beat, etc.), and the trigger source (ECG, pressure waveform, fixed rate) that the controller uses to identify the inflation and deflation times.

Balloon inflation is timed to occur with the onset of diastole and deflation with the onset of systole.

Early control devices required the operator to set the inflation and deflation points manually and did not function well when the patient's underlying cardiac rhythm was irregular or rapid. Currently available control consoles have sophisticated electronic circuitry that can automatically set the timing of inflation and deflation and can compensate for irregular cardiac rhythms and premature beats. This increased automation makes the operation of the console easier, but the operator must still evaluate the arterial pressure waveform to ensure that the automatically set timing is appropriate. The control console allows the operator to make adjustments in the inflation and deflation points. The balloon inflation should occur at the dicrotic notch of the aortic pressure tracing, and deflation should be seen just before the onset of the next systolic pressure upstroke. Figure 48-2 shows examples of both correct and incorrect timings.

FIGURE 48-1

Intra-aortic balloon catheter (IABC) proper positioning.



Indications for IABC can be divided into three broad categories: inadequate cardiac pump function, myocardial ischemia, and prophylactic uses.

The indications for IABC therapy can be divided into three broad classes: inadequate cardiac pump function, myocardial ischemia, and prophylactic uses. While IABC predominantly provides support for the left ventricle, some studies have suggested a role in right ventricular dysfunction. When IABC was first introduced into clinical practice, most patients who received this therapy were in cardiogenic shock. Increased experiences with IABC and technologic advances have led to an increase in the use of IABC for the treatment of myocardial ischemia and to support high-risk cardiac interventions. The Benchmark Registry, a database of patients who received IABC therapy at 243 centers in 18 countries, has reported data in 16,909 patients collected between 1996 and 2000.[3] The patients in the database were predominately male (68.8%) and older (mean age of 65.9 years). The indications for IABC in the database population included hemodynamic support during or after cardiac catheterization (20.6%), cardiogenic shock (18.8%), weaning from cardiopulmonary bypass (16.1%), preoperative high-risk patients (13%), refractory angina (12.3%), refractory heart failure (6.5%), mechanical complication of acute myocardial infarction (5.5%), cardiac support for high-risk noncardiac surgery (0.9%), and other or unspecified indications. Table 48-1 provides a more detailed list of indications for IABC.

The most significant contraindications to IABC are aortic insufficiency (AI) and aortic dissection or disruption.

The contraindications to IABC are mostly relative. The most significant contraindications include hemodynamically significant aortic insufficiency (AI) and aortic dissection or transection. Severe peripheral vascular disease, abdominal aortic aneurysm, prior aortoiliac-

TABLE 48-1

INDICATIONS FOR INTRA-AORTIC BALLOON COUNTERPULSATION

Cardiogenic shock (failure of the heart as a pump) refractory to conventional therapy
Ventricular failure following myocardial infarction
Acute myocarditis
Acute mitral regurgitation with pulmonary edema and hemodynamic compromise
Acute ventricular septal defect
Cardiomyopathy (including bridge to transplant)
Postcardiotomy (inability to separate from cardiopulmonary bypass)
Myocardial ischemia unrelieved with medical therapy
Prophylactic uses
Support for patients with significant coronary artery disease, not amenable to revascularization, undergoing noncardiac surgery
Support for patients with severe valvular heart disease undergoing cardiac or noncardiac surgery
Left main coronary artery disease awaiting revascularization
Cardiomyopathy undergoing surgery (cardiac or noncardiac)
Support during high-risk cardiac catheterization and angioplasty

femoral surgery or bypass, sepsis, coagulopathy, or limited life expectancy related to terminal illness or malignancy are some of the relative contraindications. A decision about the use of IABC must weigh the risks of the procedure against its benefits, the risks and benefits of any alternative treatments, or no treatment.

The inflation of the intra-aortic balloon during diastole is associated with an increase in diastolic blood pressure in the proximal aorta and thus an increase in coronary artery perfusion pressure (diastolic blood pressure minus left ventricular end-diastolic pressure). The deflation of the balloon just before the onset of systole is equivalent to the removal of a volume of blood from the aorta equal to the volume of gas removed from the balloon. This decrease in central aortic volume with the onset of systole can facilitate left ventricular

IABC inflation during diastole is associated with an increase in diastolic blood pressure in the proximal aorta and thus an increase in coronary artery perfusion pressure.

ejection into the aorta by reducing the left ventricular afterload. Balloon counterpulsation may also be associated with a decrease in left ventricular end-diastolic pressure. IABC is commonly associated with a small decrease in systemic systolic arterial pressure, an increase in systemic diastolic pressure, and variable changes in mean arterial pressure. In some patients, the mean arterial pressure changes little while in others it increases. The net effect of IABC on systemic blood pressure is, to some extent, dependent on the reasons for the institution of therapy. In hypotensive patients with cardiogenic shock, improvement in cardiac performance by IABC may result in an improvement in the systemic pressures. The elevated pulmonary artery and pulmonary capillary occlusion pressures seen in cardiogenic shock and severe myocardial ischemia may decrease if IABC improves the patient's ventricular performance or myocardial oxygen supply–demand balance. Cardiac output may increase between 500–800 mL/min. The overall beneficial effects of IABC may be limited by hypovolemia, a large aorta, an underfilled or undersized balloon, incorrect timing of balloon inflation and deflation, or frequent arrhythmias.

In theory, augmentation of diastolic blood pressure should lead to an increase in diastolic coronary artery blood flow. However, animal studies and clinical studies in humans have led to variable results. Experimental evidence that regional myocardial function improves in zones of marginal myocardial ischemic following experimental coronary occlusion has led some authors to suggest that this was an indirect evidence of improvement in coronary perfusion. However, other authors using more direct measurements of coronary artery blood flow have not consistently been able to demonstrate an increase in coronary artery blood flow. The methods used to measure or estimate coronary artery blood flow during counterpulsation therapy have included measurement of coronary artery blood flow velocity by Doppler techniques (epicardial or endovascular) and the use of xenon washout techniques. In many studies, the coronary blood flow distal to coronary artery lesions did not increase with IABC. One study reported that Doppler blood flow velocity distal to coronary artery lesions was not changed by IABC before coronary angioplasty, but did increase following successful angioplasty reduction in the coronary artery obstruction.[4] Most studies support the theory that the relief of the signs and symptoms of myocardial ischemia by counterpulsation therapy is primarily a function of decreased myocardial oxygen demand secondary to afterload reduction induced by the counterpulsation therapy.

The relief of signs and symptoms of myocardial ischemia by IABC is primarily a function of decreased myocardial oxygen demand secondary to afterload reduction induced by balloon deflation.

Myocardial ischemia refractory to maximum medical therapy is one of the major indications for the use of IABC. Institution of counterpulsation therapy frequently results in relief of the ischemia. As noted, it is likely that the reduction in myocardial oxygen demand is the most important reason for this improvement. Counterpulsation therapy alone cannot provide definitive treatment for obstructive coronary artery disease, but it can be an important adjunct therapy. The use of IABC may allow patients to undergo diagnostic catheterization and revascularization by thrombolysis, coronary angioplasty, or surgical revascularization.

In cardiogenic shock, counterpulsation therapy can provide hemodynamic support while treatment of the underlying pathophysiologic causes is instituted.

Another important indication for counterpulsation therapy is cardiogenic shock. Cardiogenic shock has many etiologies, including acute myocardial infarction, cardiomyopathy (idiopathic, ischemic, etc.), acute mitral regurgitation, acute ventricular septal defects, and other pathologic conditions leading to severe impairment of myocardial pump function. For patients with ventricular dysfunction who cannot be separated from cardiopulmonary bypass following cardiac surgery or who develop cardiogenic shock following a cardiac surgical procedure, IABC therapy has proved beneficial.

IABC may be beneficial in the setting of acute MI complicated by cardiogenic shock when thrombolytic therapy is used for revascularization.

IABC therapy is not a definitive treatment for cardiogenic shock. Counterpulsation therapy is a support modality that can provide hemodynamic support while treatment of the underlying disease process is instituted. For patients who have transient myocardial dysfunction following cardiac surgery, IABC can provide support while the myocardium recovers. In an observational study[5] using the database from a multiinstitutional study of emergent coronary revascularization in patients with acute myocardial infarctions and cardiogenic shock (SHOCK trial), in-hospital mortality was the lowest in the group receiving IABC and thrombolytic therapy (47%). The in-hospital mortality was 52% for IABC only, 63% for thrombolytic therapy only, and 77% when neither therapy was used. This observational portion of the study was not randomized. Patients who received IABC with or without thrombolytic therapy were more likely to undergo revascularization. Nonrevascularization was a

strong predictor of in-hospital mortality. The authors commented that these data may support the benefits of a combination of thrombolytic therapy and IABC in the treatment of patients with acute myocardial infarction and cardiogenic shock in hospitals without revascularization capabilities, prior to transfer to a center with advanced cardiac care capabilities. Patients in the *National Registry of Myocardial Infarction 2* study who had acute myocardial infarction and cardiogenic shock treated with thrombolytic therapy had a reduced mortality if IABC was used (adjusted OR 0.82).[6] Patients treated with primary angioplasty did not show a benefit from IABC. This study had several limitations. It was not randomized and treatment decisions were left to patient's individual physicians.

IABC may be beneficial as a support modality for some patients undergoing noncardiac surgery, such as those with inoperable coronary artery or valvular disease and those with cardiomyopathy.

IABC therapy can also be employed prophylactically. Certain patients undergoing noncardiac surgical procedures may benefit from the application of IABC. Included among these patients are those with significant ischemic heart disease who are not able to undergo coronary artery revascularization before their noncardiac surgery, those with very poor ventricular function (cardiomyopathy), or those with advanced valvular heart disease. The reasons that would prevent coronary revascularization before noncardiac surgery include inoperable coronary artery disease, emergent noncardiac surgery, and other factors precluding coronary artery bypass, such as severe coexisting disease. No controlled studies have reported on the prophylactic use of IABC in noncardiac surgery, but there are numerous case reports of such use. While IABC is an invasive procedure that carries with it the potential for significant complications, in selected high-risk patients it seems to be of benefit.

There have also been studies on the benefit of prophylactic use of IABC in the setting of coronary angioplasty. The *Second Primary Angioplasty in Myocardial Infarction (PAMI-II) Trial* investigators[7] reported on the results of the prophylactic use of IABC in patients with acute myocardial infarction who underwent acute coronary artery catheterization and percutaneous transluminal coronary angioplasty (PTCA). The high-risk patients, based on angiographic data, were randomized to receive either IABC for 36–48 h or no IABC therapy. Only patients who had no contraindication to IABC were randomized. In this study, IABC following PTCA did not decrease the rate of infarct-related coronary artery reocclusion or reinfarction, did not promote myocardial recovery, and did not change the overall clinical outcome.

IABC can also be used as a short-term bridge to heart transplantation in patients with hemodynamic dysfunction not responsive to less invasive therapies. The use of IABC can allow time to titrate pharmacologic therapies with subsequent separation from counterpulsation. Patients who cannot be separated from counterpulsation without deterioration in their condition may need VAD support as a bridge to transplantation. Given that most patients will wait weeks to months for a heart transplant, the necessity for patients to remain immobile and at bed rest during counterpulsation therapy is a significant disadvantage.

Intra-aortic Balloon Catheter Placement

In evaluating patients for IABC, the history and physical examination should pay careful attention to signs and symptoms of peripheral vascular disease, AI, or coagulation system abnormality.

Balloon counterpulsation therapy requires the placement of the balloon catheter into the descending thoracic aorta, usually accomplished by introducing the catheter via a femoral artery. Alternative sites for insertion have been described and are briefly discussed here. As with any other invasive procedure, it is important to carefully review the patient's history, physical examination, and pertinent laboratory studies. For patients who are about to undergo intra-aortic balloon catheterization, the history and physical examination should focus on signs and symptoms of peripheral vascular disease (i.e., claudication, foot ulcers, prior vascular surgical procedures, aortic aneurysm, dissection, or disruption), significant aortic regurgitation, and coagulation system problems. The pulses in the femoral, popliteal, dorsalis pedis, and posterior tibial arteries should be evaluated and the results recorded in the medical record.

Balloon catheters are available from a variety of manufacturers and in a variety of sizes. The catheters used for adults generally range in size from 8 to 11 Fr in diameter and have balloon volumes of 30–40 mL. The inflated balloon should, ideally, occupy 80–90% of the aortic diameter. The size of the catheter chosen is based on the size of the patient.

A complete discussion of the placement of an intra-aortic balloon catheter is beyond the scope of this chapter, but a brief description of the technique is presented. Strict adherence

to aseptic technique is essential to minimize infectious complications. The puncture site should be disinfected with an appropriate agent such as chlorhexadine solution. Full barrier precautions should be used, with all operators wearing a surgical cap, mask, and sterile gown and gloves. Sterile drapes should be used to create a large working field. The procedure is most commonly performed under local anesthesia using a percutaneous approach to the common femoral artery. Care should be taken to ensure that the arterial puncture occurs inferior to the inguinal ligament (common femoral artery). Superior to the inguinal ligament, the artery is the external iliac artery, and bleeding from the puncture site at this level may result in retroperitoneal hemorrhage.

The common femoral artery is punctured with a needle, and a flexible guidewire is placed through the needle and advanced into the descending thoracic aorta. Fluoroscopic guidance is commonly used to identify the position of the guidewire. During intraoperative or bedside placement without fluoroscopic guidance, an external measurement of the distance from the femoral artery puncture site to the sternal notch is used as an estimate of the distance to insert the guidewire and subsequently the balloon catheter. Transesophageal echocardiography (TEE) can also be used to guide catheter placement. After the placement of the guidewire, the needle is removed and a series of vessel dilators are passed sequentially over the wire into the artery to enlarge the puncture site. The catheter can be placed via a sheath introducer or using a sheathless approach. If a sheath introducer is used, a sheath with a dilator through the central lumen is advanced into the artery over the guidewire, the dilator is removed (leaving the guidewire behind), and the balloon catheter is placed over the guidewire through the introducer sheath. In a sheathless insertion, the balloon catheter is placed over the guidewire after the last dilator is removed. For both types of placement, the balloon catheter is advanced until the tip of the catheter is positioned just below the aortic knob on fluoroscopic examination or below the origin of the left subclavian artery on TEE examination. Confirmation of the presence of an arterial pulse in the left arm indicates that the tip of the catheter is not occluding the origin of the left subclavian artery. On chest X-ray, the tip of the catheter should be seen 1–2 cm distal to the aortic knob. The femoral puncture site should be routinely checked for signs of bleeding or local infection.

When correctly positioned, the tip of the balloon catheter should be 1–2 cm below the aortic knob on radiographic examination of the chest.

The neurovascular integrity of the limb distal to the balloon catheter insertion site must be frequently evaluated. If there is evidence of limb ischemia, further evaluation is required and evaluation by a vascular surgeon should be considered.

Following catheter placement, the neurovascular integrity of the limb distal to the insertion site must be frequently evaluated. Periodic neurovascular checks should include palpation of peripheral pulses or assessment of the pulses by the use of Doppler ultrasound, determination of the temperature, color, and capillary refill in the extremity, and demonstration of intact sensory and motor function. The evaluation should include the limb distal to the insertion site and a comparison with the examination of the contralateral limb. This determination should be made every hour for the first several hours after insertion and then every 1–2 h for the duration of counterpulsation therapy. If there is any indication of ischemia, the patient should undergo further evaluation including evaluation by a vascular surgeon. Low cardiac output, hypothermia, and high-dose vasopressor therapy may also lead to decreased limb perfusion. Correcting these contributing factors may improve perfusion of the limb.

It is a standard practice to administer intravenous heparin to the patient by continuous infusion to prevent clot formation on the surface of the balloon or in the arterial tree distal to the balloon insertion site. The dose is adjusted to maintain an activated partial thromboplastin time (APTT) 1.5–2 times higher than the control value. Heparin is commonly not given to surgical patients in the early postoperative period because of the associated risk of bleeding from the surgical sites. The benefit of heparin therapy during IABC has been questioned by a randomized trial comparing heparin therapy to no anticoagulation.[8] In this group of 153 patients, no significant difference in the occurrence of minor limb ischemia or hematologic parameters was seen. There was no major limb ischemia in either group. No macroscopic clot was seen on any catheter. There was an increased incidence of bleeding complication seen in the heparin group. Some clinicians believe that lower counterpulsation ratios (counterpulsation less than every second beat) may predispose to clot formation because the increased time that the balloon is motionless may facilitate clot formation on its surface.

In patients in whom femoral artery placement is not possible, usually because of peripheral vascular disease, alternative sites can be considered. In the operating room, following cardiac surgery, several techniques for the placement of an intra-aortic balloon pump via the ascending

aorta into the descending thoracic aorta have been described. In one technique an end-to-side anastamosis is created between a synthetic graft and the ascending aorta. The distal end of the graft is brought through the anterior chest or abdominal wall and the balloon catheter is inserted through the graft into the aorta. This technique allows percutaneous removal of the catheter under local anesthesia. In many patients, this percutaneous removal can be accomplished in the critical care unit. The axillary artery has also been used as an alternative site for intra-aortic balloon catheter placement. Axillary artery placement is generally performed with a surgical approach that allows the cannulation of the artery under direct vision.

Following successful positioning of the intra-aortic balloon catheter, counterpulsation therapy is instituted. The timing of the counterpulsation is adjusted as previously described. While undergoing IABC, the patient must remain at bedrest. If the catheter was placed into a femoral artery, the leg on the side of the cannulation must remain straight to prevent kinking of the catheter and injury to the artery. The head of the bed should be kept flat or elevated slightly. A small degree of reverse Trendelenburg position, if tolerated hemodynamically, may provide an alternative to raising the head of the bed. The patient requires careful nursing care to prevent the development of pressure ulceration due to immobility.

Weaning from Counterpulsation Support

When IABC has been instituted to treat hemodynamic instability, it is common to wait until the need for pharmacologic support has substantially decreased before weaning the counterpulsation.

Weaning from IABC can begin when the underlying disease process that led to the institution of IABC has improved. When IABC has been instituted to treat hemodynamic instability, it is common to wait until the need for pharmacologic inotropic support has substantially decreased. Different criteria are used by physicians when determining a patient's readiness for weaning. Some physicians advocate waiting until the patient is receiving, at most, a moderate dose of a single inotropic agent; others allow a combination of inotropic agents, but require that the infusion rates be below a specific target range. Common to all approaches is the appraisal that myocardial function has improved and a demonstration that the level of pharmacologic inotropic support has been successfully reduced. This allows a margin of safety in the event of hemodynamic deterioration after the removal of the balloon catheter since pharmacologic support can be rapidly increased. In patients in whom IABC has been instituted to treat myocardial ischemia, decisions about weaning are related to the institution of medical therapy aimed at preventing or treating myocardial ischemia or interventions that improve coronary artery blood flow (percutaneous intervention or coronary artery bypass surgery).

IABC therapy can be weaned by either decreasing the frequency of balloon inflation or by decreasing the volume of balloon inflation.

When the patient meets the criteria for weaning from IABC, two alternative strategies are available. In the first method, the frequency of balloon inflation is decreased from inflation with every heartbeat to every second, third, or fourth beat; some balloon pump consoles allow counterpulsation ratios as high as 1:8. In the second method, balloon inflation continues with every heartbeat, but the volume of balloon inflation is decreased to provide less blood displacement with each inflation. Advocates of the later technique (reducing the volume within the balloon with each inflation) believe that this provides a physiologically more appropriate trial of weaning. It is the practice in the cardiothoracic surgical intensive care unit at Temple University Hospital to wean by decreasing the assist frequency from 1:1 to 1:2–1:3. Assist ratios of 1:3 or greater do not provide significant hemodynamic support, and therefore trials beyond a ratio of 1:3 are not believed to be necessary. The rate at which weaning proceeds is based on the patient's overall status and the initial indications for this therapy. During the period of weaning, the patient's clinical condition should be frequently assessed to identify any deterioration associated with reduction in IABC support. If there is deterioration (hemodynamic or cardiac ischemia), counterpulsation support should be increased. With lower pumping frequencies (1:3 and above), there is an increased likelihood that thrombus will form on the surface of the catheter. It is our practice to limit the time to 1–2 h at a pumping frequency of 1:3; this may be of greater concern in patients not receiving systemic anticoagulation (see above).

Catheters that were placed surgically should be removed surgically. If the balloon catheter was placed percutaneously without problems and if the puncture site is below the inguinal ligament, it can usually be removed safely at the patient's bedside. Before removal, coagulation parameters (APTT, prothrombin time, and platelet count) should be in

Before the removal of an intra-aortic balloon catheter, the patient's coagulation parameters should be in an acceptable range to assure adequate hemostasis.

an acceptable range to ensure adequate hemostasis. For patients who have been receiving heparin therapy, the heparin should be discontinued before the assessment of the APTT. Counterpulsation is stopped and the balloon catheter is deflated following the manufacturer's recommendations. Immediately before removal, if an introducer sheath is in place, the balloon catheter can be pulled back until it engages the sheath. No attempts should be made to pull the balloon catheter into the introducer sheath because this could result in shearing off a portion of the balloon. Pressure is applied over the femoral artery distal to the puncture site in an attempt to prevent debris or thrombus from entering the distal arterial tree; then the balloon catheter is gently withdrawn from the artery. Blood is allowed to spurt briefly from the puncture site in an attempt to flush out debris. Pressure is then applied at the puncture site, and the distal pressure is released. The pressure should be firm enough to provide hemostasis at the puncture site, but not so firm as to completely occlude the femoral artery. Continuous pressure is maintained for 30–45 min. If after 30–45 min hemostasis has been achieved, a sandbag is placed over the puncture site for an additional 6–8 h, during which time the patient must remain supine and keep the leg straight.

Before placement of the sandbag and periodically during the time it is in place, the puncture site should be inspected for evidence of bleeding or hematoma formation. The distal arterial pulses in the leg should be assessed at regular intervals during and after balloon catheter removal. In the event that bleeding persists after the initial 30–45-min period, pressure should be held over the site for an additional 30–45 min. If a hematoma forms or there is recurrent bleeding, consideration should be given to obtaining a noninvasive vascular assessment (duplex ultrasonography) of the involved femoral artery to identify pseudoaneurysm formation. If bleeding is persistent or if a pseudoaneurysm is noted, a vascular surgery evaluation should be obtained. Several mechanical devices can be used to provide compression of the artery after balloon catheter removal. These devices can be effective and time-saving, but careful attention to the manufacturer's recommendations for safe use is mandatory.

Complications of Balloon Counterpulsation

IABC is a beneficial therapy in appropriate conditions, and in many patients, may be a life-saving intervention; however, it is an invasive procedure and carries with it the potential for complications. The overall rate of complications ranges from approximately 10–30%, with most complications being vascular in nature, especially ischemic complications of a lower limb. Table 48-2 lists the types of complications that have been associated with IABC.

The rate of complications may be 15% or more in high-risk patients.

Cohen et al.[9] reported a prospective study of complications in 1,119 patients who received IABC at a single institution from 1993 to 1997. Complications occurred in 15% of patients, with major complications occurring in 11%. Major complications were defined as limb ischemia or bleeding prompting surgical intervention or blood transfusion, systemic embolism, systemic infection, balloon rupture or failure requiring reinsertion, and death from an IABC-related complication (see Table 48-3). The rates of occurrence of various complications included: major bleeding, 4.6%, major ischemia 3.3%, balloon rupture 2.8%, surgical repair

TABLE 48-2

COMPLICATIONS OF INTRA-AORTIC BALLOON COUNTERPULSATION

Vascular
- Limb ischemia
- Amputation
- Arterial dissection or rupture (femoral, iliac, aortic)
- Embolism of atheromatous material (limb, kidney, gut, etc.)
- Mesenteric ischemia
- Pseudoaneurysm formation

Bleeding
- Insertion site
- Retroperitoneal
- Ruptured major vessel

Balloon rupture
- Balloon catheter entrapment
- Helium embolism

Neurologic
- Paraplegia
- Stroke
- Neuropathy

Thrombocytopenia

Infection
- Localized
- Sepsis

TABLE 48-3

RISK FACTORS FOR COMPLICATIONS OF BALLOON PUMP THERAPY

Peripheral vascular disease
Female gender
Diabetes mellitus
Small size (BSA <1.8 m^2)
Low cardiac index
Hx of stroke/TIA
Other factors may include
Duration of therapy
Use of introducer sheath
Catheter size

0.5%, amputation 0.15, and aortic rupture 0.09%. Independent risk factors for major complications were peripheral vascular disease (relative risk (RR) 4.1), female gender (RR 2.3), and body surface area (BSA) less than 1.8 m^2. In a subset of patients whose data included cardiac index (CI), an index less than 2.2 L/min/m^2 was identified as an independent risk factor. The authors identified a high-risk group defined by the presence of peripheral vascular disease, female gender, BSA <1.8 m^2, CI <2.2 L/min/m^2, history of stroke or transient ischemic attack, and/or diabetes mellitus. In this subgroup, the risk of major complications was 15% compared to 3% in the nonhigh-risk patients. The risk factors described above had an additive effect. Complications rates were 6.4, 18.6, 23.1, 39.5, and 75% with 0, 1, 2, 3, or 4 risk factors.

Risk factors for complications from IABC may include peripheral vascular disease, female gender, lower BSA, diabetes mellitus, lower CI, and history of stroke or transient ischemic attacks.

Complications of IABC have been reported by the Benchmark Registry.[3] Major complications, defined as severe bleeding, major limb ischemia, balloon leak, or in-hospital mortality related to IABC, occurred in 2.6% of patients. Limb ischemia occurred in 2.8% of patients. It was defined as reduced arterial flow characterized by a decrease in pulse distal to the catheter insertion site. Major limb ischemia occurred in 0.9% of patients. It was defined by loss of pulse, loss of sensation, pallor, or abnormal temperature that required surgery, arterial repair, or resulted in amputation of the limb. The incidence of balloon leak was 1%. Severe bleeding occurred in 0.8% of patients. Risk factors for major complications were female gender (odds ratio (OR) 1.96), peripheral vascular disease (OR 1.73), BSA <1.65 m^2 (OR 1.45), and age ≥75 years (OR 1.29).

The introduction of the balloon catheter without the use of an insertion sheath (sheathless insertion) may be associated with fewer complications because the diameter of the balloon catheter alone is less than the diameter of the introducer sheath and therefore obstruction of the ileofemoral artery may be reduced. However, not all published reports have shown benefit to sheathless insertion. The potential for limb ischemia and the seriousness of the problems that can develop, especially in the presence of peripheral vascular disease, lower BSA, female gender, and/or diabetes emphasizes the need for a careful history and physical examination prior to balloon catheter insertion. Likewise, regular monitoring of the patients for evidence of limb ischemia during IABC is essential to allow early identification and treatment.

In patients with a clear history of severe peripheral vascular disease or physical evidence suggesting its presence in the lower extremities, an alternative site of placement should be considered. An axillary approach can be considered in both medical and surgical patients, but a transthoracic approach is limited to cardiac surgical patients. Hazelrigg et al.[10] published a retrospective review of 100 patients in whom transthoracic catheters were placed during cardiac surgery and reported no episodes of lower limb ischemia. They found that the incidence of mediastinal bleeding and balloon rupture was higher in these patients than in similar patients with femoral artery placement of catheters.

Once ischemia has been identified, it can often be resolved by therapeutic intervention. Naunheim et al.[11] reported that for the 69 patients with limb ischemia in their series of 580 patients, the ischemia resolved in 21 patients with catheter removal alone, in another 21 patients with surgical thrombectomy, and in 13 patients following vascular repair. Two patients required fasciotomy; four patients underwent amputation. The ischemia did not resolve in 10 patients (14%), and 6 patients died with the catheter in place and without intervention. In two patients, the ischemia resolved without intervention. In this study, survival was not affected by the occurrence of IABC-related complications.

If the patient develops ischemic vascular complications, the balloon catheter should be removed if clinical assessment suggests the patient no longer needs IABC.

If a patient develops ischemic vascular complications, the balloon catheter should be removed if clinical assessment suggests that the patient no longer needs IABC; this can be by percutaneous removal at the bedside or by surgical removal under direct vision, with possible thrombectomy of the involved artery. There is no universal approach to this problem. Because many episodes of ischemia will resolve with removal of the catheter, a staged approach with percutaneous removal followed by surgical exploration if the ischemia does not resolve, is common. Because of the serious consequences that can develop from this problem, it is beneficial to consult a vascular surgeon. Some patients, especially those with evidence of significant peripheral vascular disease or severe ischemia, may benefit from surgical removal and thrombectomy as the initial approach.

For a patient with limb ischemia who continues to require IABC, one option is to remove the catheter and place a new one in the opposite femoral artery (or an alternative site). Another alternative is to provide perfusion distal to the catheter insertion site by performing a femoral–femoral arterial bypass using a conduit graft from the contralateral femoral artery to the ipsilateral femoral artery distal to the catheter insertion site.

Bleeding, another complication of IABC, can occur at the insertion site or more proximally, if the catheter has injured the artery. Placement of the balloon catheter above the inguinal ligament (external iliac artery) may lead to hemorrhage into the retroperitoneal space secondary to vessel injury during insertion or removal. It is difficult to apply pressure over the artery at this site, and bleeding into the retroperitoneal space cannot be seen on physical examination. For a patient with an unexplained decline in hemoglobin during or after IABC therapy, a CT scan should be considered. If there is concern that the catheter has been placed into the artery above the inguinal ligament, the catheter should be removed surgically.

Patients who bleed excessively after catheter removal or who develop hematomas at the insertion site are at risk for pseudoaneurysm formation.

Patients who bleed excessively after catheter removal or who develop hematomas at the insertion site are at risk for pseudoaneurysm formation, which can be diagnosed by duplex ultrasound examination. In some cases, it is possible to eliminate the pseudoaneurysm by direct compression with the ultrasound probe. If direct compression is not effective, surgical repair is required.

Neurologic complications that can occur related to IABC include stroke, paraplegia, and peripheral neuropathy.

Neurologic complications can also occur. Stroke has been reported and may be a more common complication with placement via the ascending aorta or aortic arch. A stroke rate of 6.2% and a transient ischemic attack rate of 1.2% were reported for ascending aortic balloon catheter placement in a retrospective review by Hazelrigg et al.[10] Flushing of the central lumen of the catheter, which is located in the proximal descending aorta, can cause cerebral embolism of air, thrombus, or debris. The central lumen should not be used routinely to draw blood samples. Great care should be exercised to ensure that all air bubbles have been removed from the system before the system is flushed, and only gentle pressure should be used during the flush.

Paraplegia has been reported as a complication of IABC. Stavridis et al.[12] found 12 published cases of paraplegia developing during or after IABC. Two main mechanisms of injury were reported: aortic dissection and spinal artery embolism. Aortic dissection or adventitial hematoma can lead to interruption of spinal cord blood supply. Local occlusion of a major anterior spinal artery by the embolism of atheromatous material from the aorta can be induced by the balloon catheter.

Another type of neurologic complication is peripheral neuropathy. Local trauma at the insertion site, either as direct nerve injury during catheter placement or as a result of nerve compression from hematoma formation, can occur. Ischemic neuropathy can develop in patients with impaired limb perfusion.

Infection, either local or systemic, can occur. Similar to other invasive intravascular devices, the likelihood of sepsis developing is related to the duration of catheterization. The use of sterile technique during insertion and good site-care during IABC may limit this complication. Fever or sepsis in a patient with an intra-aortic balloon catheter should prompt examination of the site for evidence of local infection. If there is local evidence of infection at the site or if bacteremia develops, it may be necessary to change the balloon catheter to an alternative site or to remove it.

Rupture of the intra-aortic balloon is another possible complication, usually detected by observing the presence of blood in the helium drive line tubing. The balloon rupture is

usually related to the perforation of the balloon by abrasion against an atherosclerotic plaque in the aorta; this appears to be more common in smaller patients where a portion of the balloon catheter may be located in the distal thoracic or proximal abdominal aorta. The defects detected in the balloons by microscopy are usually small pinhole perforations.

Other complications of IABC include infection, rupture of the balloon catheter, helium embolism, balloon entrapment, thrombocytopenia, and embolism of atheromatous material.

A major concern with the perforation of the balloon is the risk of helium embolism. The characteristics of the balloon and drive mechanism (relatively low gas pressure during balloon inflation and large negative intraballoon pressure during deflation) favor the entrance of blood into the balloon rather than helium escape into the patient. However, helium embolism can occur, and if it travels to the cerebral circulation may result in a stroke.

Balloon rupture can be associated with balloon entrapment within the vascular tree. Numerous cases of balloon rupture and inability to remove the balloon because of entrapment have been reported. Forceful attempts at removing the trapped catheter can result in serious vascular trauma. The entrapment usually occurs because of the presence of clotted or desiccated blood within the balloon. There have been case reports of thrombolytic agents introduced via the drive line to dissolve clots within the balloon that are responsible for the entrapment.

Because of the potentially serious complications of balloon rupture, an aggressive approach to management is necessary. If blood is noted in the drive line tubing, balloon inflation should be stopped immediately and the balloon catheter should be removed. If the patient requires continued IABC, a new balloon catheter can be placed into the opposite femoral artery (or alternative site), or a guidewire exchange of the defective catheter for a new catheter can be performed. If any resistance is encountered when removing the defective catheter, the removal attempt should cease and a surgical removal performed. As noted, intraballoon catheter thrombolytic therapy may be a useful adjunct to surgical removal.

Thrombocytopenia is commonly seen in patients undergoing IABC. Vonderheide et al.[13] published a prospective comparison of patients with acute coronary syndromes treated with heparin, some of whom had IABC. They reported that thrombocytopenia occurred in 47% of IABC patients compared with 12% of non-IABC patients. Platelet counts declined by at least 50 in 26% of the IABC group compared with only 4% of the control group. The platelet counts rose rapidly following discontinuation of the balloon pump, normalizing within 4 days. These authors also noted that in patients with prolonged IABC therapy, the decline in platelet count leveled-off or improved after 4 days. It is believed that increased consumption or destruction of platelets by the balloon catheter accounts for the decline; increased platelet production may explain the leveling-off after 4 days. While thrombocytopenia may be caused by IABC, in patients receiving both IABC and heparin, the differential diagnosis must include heparin-induced thrombocytopenia.

Balloon catheters can precipitate embolism of atherosclerotic material. Patients with mobile atherosclerotic material in the aorta have been found to be at greater risk for these complications. Embolism can involve the peripheral vascular tree, the kidney, intestine, spinal cord, or other organs.

The use of IABC has also been reported to be a risk factor for the development of gastrointestinal complications including mesenteric ischemia, gastrointestinal hemorrhage, pancreatitis, and cholecystitis. IABC was not necessarily the cause of all the gastrointestinal problems reported, but may have served as a marker of critically ill patients.

VENTRICULAR-ASSIST DEVICES

When pharmacologic therapies and IABC are not successful in restoring an adequate hemodynamic condition, circulatory support with a mechanical blood pumping device should be considered.

When pharmacologic therapies and IABC are not successful in restoring an adequate hemodynamic condition, circulatory support with a mechanical blood pumping device can be considered. In current practice, mechanical VADs are used to treat cardiogenic shock, either as a support device until ventricular function recovers and the device can be discontinued, or as a bridge to heart transplantation. Recently, a device has been approved as destination therapy in patients with refractory heart failure who do not meet the criteria for heart transplantation. Patients who cannot be separated from cardiopulmonary bypass following a cardiac surgical procedure (postcardiotomy) because of ventricular dysfunction are the largest group of patients in whom VAD therapy is initiated.

CASE STUDY 1: PART 2

IABC was begun and the patient showed improvement in his hemodynamic status. On the second hospital day, he became suddenly short of breath, had an acute decrease in blood pressure, and was found to have a new holosystolic murmur. Echocardiography revealed severe mitral regurgitation with a flail anterior segment of the mitral valve. The patient is treated with diuretics, afterload reducing agents, and continued IABC. Repeat cardiac catheterization shows occlusion of the stent in the left anterior descending artery. He is taken to the operating room for mitral valve repair and coronary artery bypass surgery. Bypass grafts are placed to the left anterior descending, first diagonal, and obtuse marginal coronary arteries and a mitral valve repair is performed. TEE shows severe global hypokinesis of the left ventricle. Inotropic support with epinephrine and milrinone are begun. Despite increasing doses of inotropic therapy and continuation of IABC, the patient cannot be separated from cardiopulmonary bypass.

VADs can be divided into those with pulsatile flow and those with continuous nonpulsatile flow

The choice of mechanical cardiac assist device depends on the type of ventricular support needed, the expected duration of support anticipated, and patient characteristics, such as size, weight, and concomitant diseases.

The pneumatically powered Abiomed BVS 5000 and Abiomed BS 5000 can be used as an LVAD, RVAD, or BiVAD.

VADs can be divided in to two main types based on whether flow is pulsatile, or continuous and nonpulsatile. Some devices provide support for the left, right, or both ventricles, while others can support only the left ventricle. The choice of VAD depends on the type of ventricular support needed, the expected duration of support anticipated, and patient characteristics, such as size, weight, and concomitant diseases. LVAD, RVAD, and BiVAD are used here to refer to assist devices implanted to support the left ventricle, the right ventricle, or both ventricles, respectively.

Pulsatile Devices

Abiomed BVS 5000

The Abiomed BVS 5000 Biventricular Support System (Abiomed Cardiovascular, Inc., Danvers, MA, USA) is a pneumatically powered, pulsatile, VAD that is approved for short-term treatment of reversible ventricular dysfunction. It can be used as an LVAD, RVAD, or BiVAD. The device must be placed surgically and usually requires cardiopulmonary bypass support during placement. Figure 48-3 illustrates the dual chamber design of the blood path within the pump, which consists of an upper collecting chamber (atrium) and a lower pumping chamber (ventricle). The device contains two trileaflet valves that maintain unidirectional blood flow. One valve is between the collecting chamber and the pumping chamber (the inflow valve) and the other valve is between the pumping chamber and the patient (outflow valve).

To configure the device for LVAD support, a cannula is placed into the patient's left atrium; tubing connects the cannula to the upper chamber of the device. Blood returns to the patient through the tubing connected between the pumping chamber and a cannula attached to the patient's ascending aorta. This final connection involves the creation of an anastomosis between the aorta and a polyester graft that is an integral part of the arterial cannula. For use as an RVAD, a cannula is placed into the right atrium with the return connection being an anastomosis between the arterial cannula and the pulmonary artery. The atrial and arterial cannulae are designed so that they exit the body via subcostal stab wounds, allowing for surgical closure of the chest. The cannulae have an external polyester sleeve to aid in hemostasis at the exit site and to decrease the risk of infection. Biventricular support is obtained by placing both an RVAD and an LVAD. A single drive console can control two separate pumps (Fig. 48-4). The drive console functions automatically and requires little operator intervention; it has a variety of alarms to alert the caregivers of problems.

During VAD support, the blood flows from the patient through the atrial cannula and tubing into the upper chamber of the device. Blood collects in this chamber during the VAD systolic phase when the inflow valve is closed. During the VAD diastolic phase, the inflow valve opens when the pressure in the upper chamber exceeds that in the lower chamber and blood fills the pumping chamber. Filling of both the upper collecting chamber (atrium) and lower pumping chamber (ventricular) is passive and depends on the distance between the

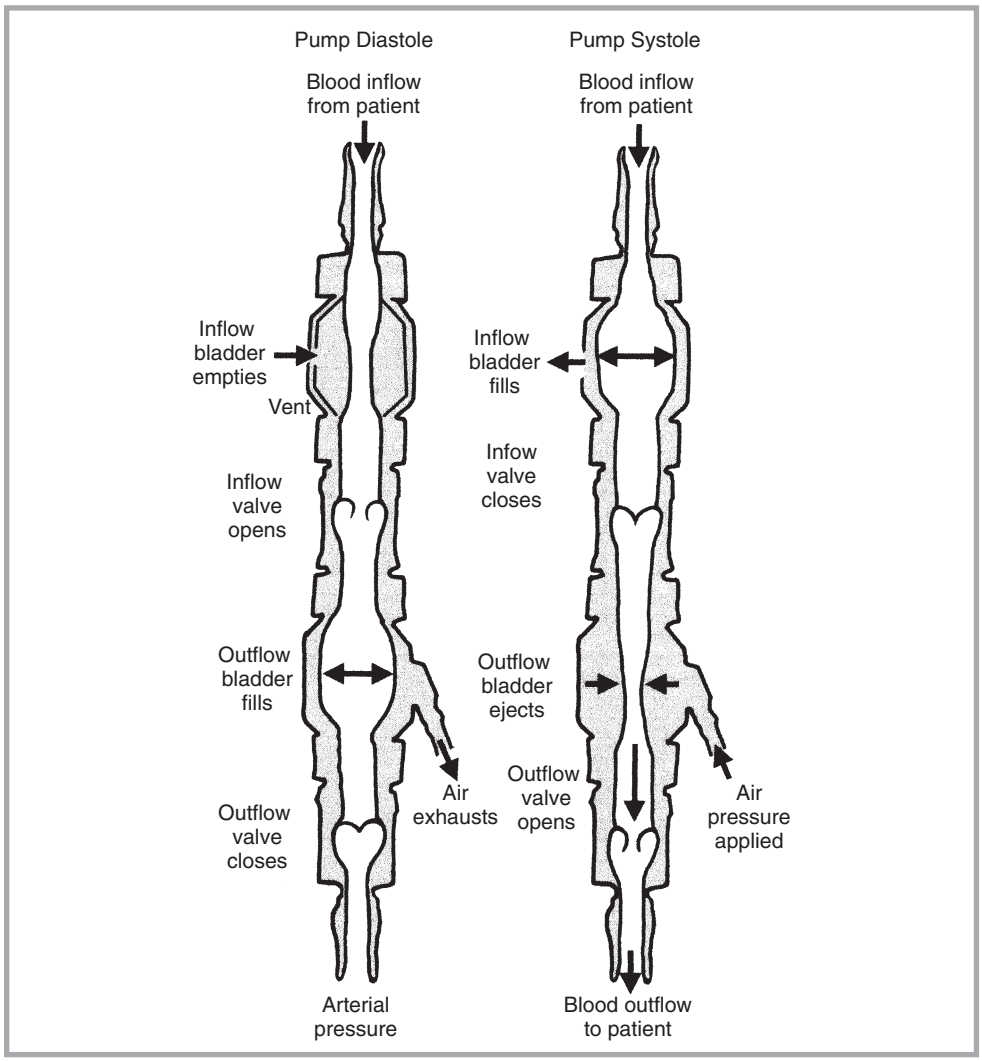

FIGURE 48-3

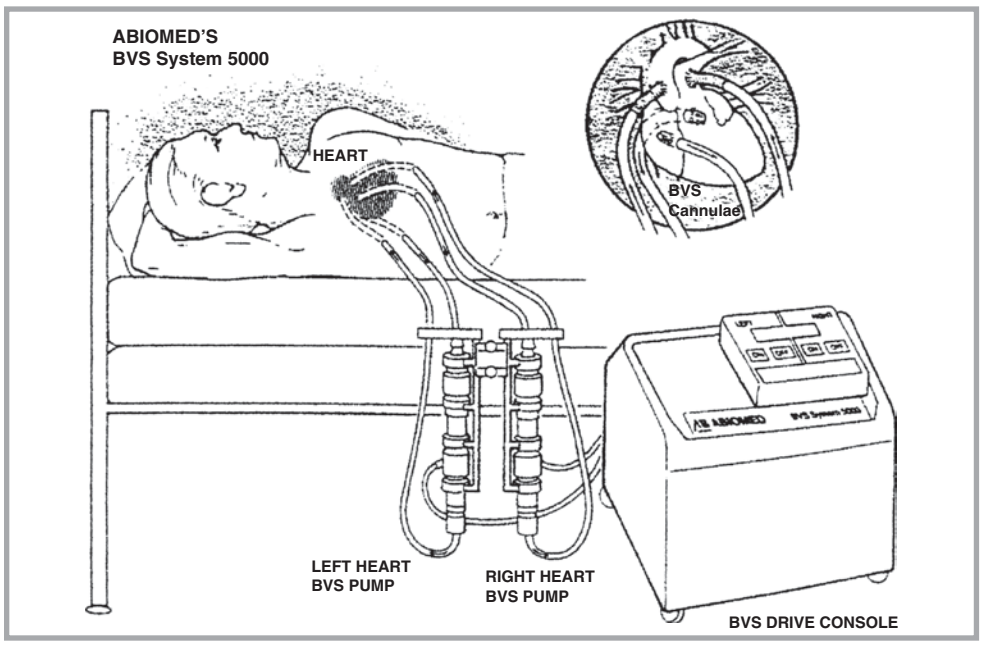

FIGURE 48-4

The Abiomed® BVS 5000® configured for biventricular support (from ABIOMED, Inc.).

patient's atrium and the device. As the pumping chamber fills with blood, air is displaced into the drive console. When the drive console senses that the pumping chamber is full, the displaced air is compressed and pushed back into the rigid shell surrounding the pumping chamber. With pressurization of the lower pumping chamber, the inflow valve closes and the outflow valve opens, and blood is propelled from the device back to the patient through the arterial (aortic or pulmonary arterial) cannula. The rate of pumping is dependent on the rate at which the device fills with blood.

Use of this device can result in up to 5 L/min of pulsatile flow. The control console attempts to maintain the pump stroke volume between 70 and 80 mL. Because of gravitational forces, the vertical distance between the patient and the pump will effect both the filling of the device (preload) and some of the resistance to pumping blood back to the patient (afterload). If the pump is too far below the patient's atrium, pump filling may be impaired because of the collapse of the patient's atrium around the cannula. Pump function may also be impaired if the height the pump must overcome to return the blood to the patient exceeds the capabilities of the drive console.

This device requires systemic anticoagulation to prevent clot formation in the pump and tubing. Anticoagulation with heparin is instituted postoperatively when bleeding related to implantation of the pump ceases. The manufacturer recommends[14] that anticoagulation therapy not be delayed longer than 24 h and suggests adjusting the heparin dose to keep the activated clotting time (ACT) between 180 and 200 s. If flow rates are less than 3 L/min or if the patient's cardiac rhythm is atrial or ventricular fibrillation, an ACT of 300 s is recommended.

When ventricular function has improved, the device can be weaned and removed. The control console allows the flow rate of the pump to be limited; this allows assessment of the patient's hemodynamic status as the heart assumes more responsibility for circulation of the blood. Removal of the device requires surgical explantation of the cannulae.

Dekker and colleagues[15] reported their 5-year clinical experience with the use of the BVS 5000. During this period, the device was implanted in 47 patients; 38 as a bridge to recovery, 9 as a bridge to transplant. The mean duration of support was approximately 13 days. The maximum duration of support was 61.8 days. In the bridge to recovery group, 66% of the patients were weaned from the device and 42% were discharged from the hospital. In the bridge to transplant group, one patient recovered and was weaned from the device prior to transplant and one patient died prior to transplant. Overall, 77% of the patients in this group received heart transplants with a 66% survival rate following transplant.

In a report of the early experience with the BVS 5000, Guyton et al.[16] found that bleeding was the most common postoperative complication, occurring in 76% of patients. Other complications included respiratory failure (54%), renal failure (52%), permanent neurologic deficit (26%), hemolysis (17%), and embolism (13%). There were no reports of device-related respiratory failure, renal failure, or neurologic deficits. Three-quarters of the neurologic deficits were believed to have occurred before the placement of the device. Because these patients were critically ill prior to the institution of VAD therapy, many of these complications may have been related to postcardiotomy shock and not to the device itself. The patients were all moribund at entry into the study; therefore, the overall outcome was favorable.

Abiomed AB5000

The Abiomed AB5000 (Abiomed Cardiovascular, Inc.) is a single chamber, pneumatically powered device that can be used as an LVAD, RVAD, or BiVAD. It is an ambulatory version of the BVS 5000. The AB5000[17] is approved for short-term use in patients with reversible ventricular dysfunction. Among the requirements to be a candidate for use of the device are a BSA greater than 1.3 m^2, an age less than 76-years, and failure to respond to conventional therapies.

The AB5000 (Fig. 48-5) consists of a flexible pumping chamber (ventricle) contained within a rigid plastic housing. The volume of the pumping chamber is approximately 100 mL. The device has two trileaflet valves, one on the inflow side (atrial) and the other on the outflow (arterial) side, that maintain unidirectional blood flow. The blood chamber and the

FIGURE 48-5

The Abiomed AB5000 (from ABIOMED, Inc.).

valves are made of the same material used in the BVS 5000. It uses the same inflow and outflow cannulas as the BVS 5000. The device is implanted surgically with the pumping chamber placed outside the body on the anterior abdominal wall. The cannulation configuration is the same as described previously for the BVS 5000. The AB5000 uses the same controller as the BVS 5000. Unlike the BVS 5000, which fills by gravity alone, the AB5000 uses vacuum-assist to facilitate the filling of the pumping chamber, allowing the device to function with the patient in an upright position. Therefore, patients with the AB5000 can sit up and ambulate.

The pump chamber of the Abiomed BS5000 is located externally on the anterior abdominal wall. Vacuum-assisted filling allows patients to be upright and ambulate with this device.

As the ventricle (pumping chamber) fills with blood, air is displaced from inside the rigid housing that surrounds the ventricle, back into the controller. When a sensor in the console detects that airflow into the console has stopped (ventricle is full), the air is pumped back into the rigid housing causing the flexible ventricle to collapse, pumping blood into the outflow cannula and then into the patient's aorta. The stroke volume of the device is approximately 95 mL.

The AB5000 also requires systemic anticoagulation. The manufacturer recommends[18] that initiation of intravenous heparin therapy begins, without a bolus, when surgical bleeding has been controlled and mediastinal chest tube drainage is less that 75 mL/h for three consecutive hours. Anticoagulation should be adjusted to maintain an ACT of 180–200 s (APTT 2–2.5 times the control). A higher ACT, 250–300 s, (APTT 2.5–3.5 times control) is recommended in the presence of atrial or ventricular fibrillation or with a pump flow rate less than 3 L/min.

Both the BVS 5000 and the AB5000 work asynchronously with the native heart. The rate of pumping for a LVAD is dependent on the rate at which the device fills, which in turn is dependent on right ventricular function. During BiVAD support, the pump flow is independent of native cardiac function; therefore, during periods of malignant atrial or ventricular arrhythmias the pump flow will not change. Nevertheless, it may be prudent to treat the arrhythmias to decrease myocardial oxygen demand and thereby enhance myocardial recovery. If defibrillation is planned, there is no need to turn-off VAD therapy. The company reports[17] 60 patients with the AB5000 implanted as of March 2004. In 45 patients, the AB5000 was the primary device implanted, and in 15, there was a transition from the BVS 5000. The survival rate was 22%, defined as the patient alive 20 days postexplant. The mean

length of support was 13 days, with the longest period of support being 57 days. There was a better outcome in patients when postoperative bleeding was absent. Adverse occurrences that did not correlate with survival included hemolysis, infection, neurologic events, and reoperation.

HeartMate XVE LVAS

The HeartMate XVE LVAS VAD can only be used as an LVAD. It has textured polyurethane and titanium surfaces to encourage the formation of a pseudoneointima that decreases the risk of thromboembolic events.

The HeartMate extended lead vented electric left ventricular assist system – XVE LVAS – (Thoratec Corporation, Pleasanton, CA) is a pulsatile pump that can be used only as an LVAD (Fig. 48-6). The system is approved[19] for VAD support as a bridge to cardiac transplantation in patients at risk for imminent death from nonreversible left ventricular failure. It is also approved for use as destination therapy in patients with New York Heart Association Class IV left ventricular failure, who have received optimal medical therapy for at least 60 of the preceding 90 days, and who have a predicted life expectancy of less than 2 years. The device is contraindicated in patients with a BSA of less than 1.5 m^2.

The pump, characterized as a pusher plate design, consists of a titanium housing that is divided in half internally by a textured polyurethane diaphragm attached to the pusher plate. The diaphragm divides the blood-containing portion of the pump from the drive portion where an electric motor is located. Unidirectional flow is maintained by porcine xenograft inflow and outflow valves. The surface of the inlet cannula and the housing are covered with sintered titanium microspheres. The textured polyurethane and sintered titanium surfaces encourage the deposition of a fibrin-cellular matrix from the patient's blood; this process leads to the formation of a pseudoneointima on the blood-contacting surfaces and decreases the risk of thromboembolic events.

The HeartMate device must be implanted surgically and requires cardiopulmonary bypass during the implantation. The pump is implanted in the left upper quadrant of the abdomen, either in the preperitoneal space or the intraperitoneal space. The inflow of blood from the patient to the pump is through a cannula placed into the apex of the left ventricle. Blood returns to the patient from the pump through a synthetic graft attached to the outflow valve. An anastomosis is created between the polyester outflow graft and the patient's ascending aorta to complete the circuit. A combination power cable and air vent line is brought externally through a separate skin incision. The entire pump is contained within the body; only

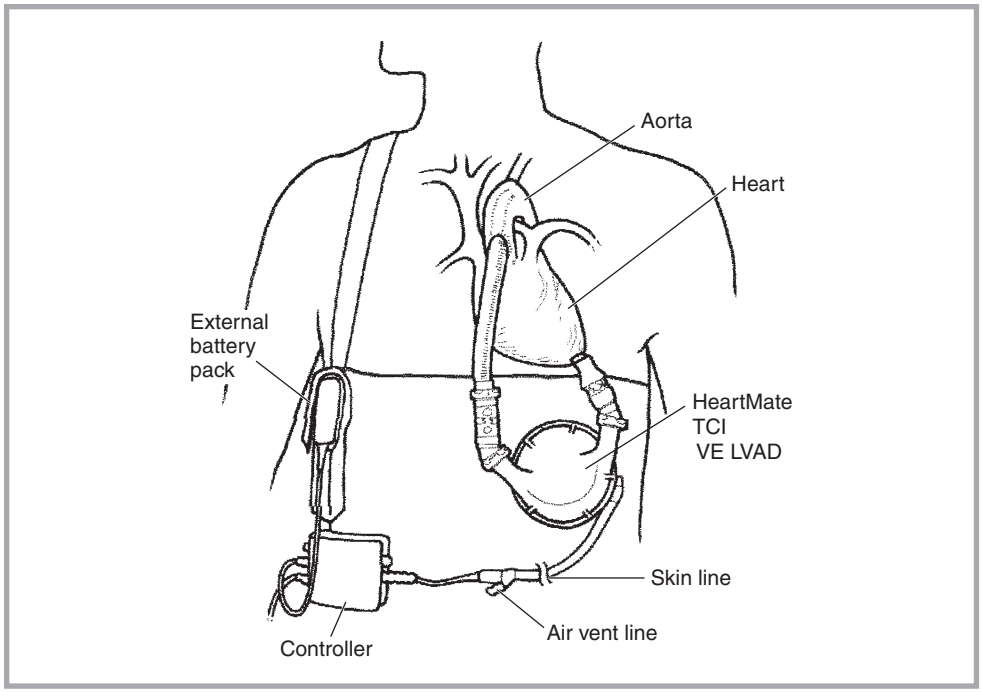

FIGURE 48-6

The TCI HeartMate (vented electric version) (Reprinted with permission from Thoratec Laboratories Corporation).

the power cable and vent line passes externally. The device can generate a stroke volume of approximately 85 mL with a blood flow up to 10 L/min. The device is connected to an external electronic controller and power source. The power source can use household current or batteries.

The HeartMate XVE LVAS can operate on batteries and thus allows the patient freedom of movement.

The device can work in either a fixed rate or automatic mode. The automatic (fill-to-empty mode) mode is most commonly used. In this mode, the pumping chamber is emptied by displacement of the pusher plate when the controller senses that the chamber is full. The two valves ensure unidirectional, antegrade blood flow. The rate of pumping in this mode is determined by the rate at which the pumping chamber fills. The device is not synchronized with the patient's intrinsic heartbeat, but the intrinsic right ventricular cardiac output is responsible for pumping blood through the pulmonary circulation into the left atrium and ventricle, from which it will enter the device. The LVAD rate is therefore indirectly related to the patient's intrinsic right heart function.

Because of the novel design of this device and the formation of the pseudoneointima, systemic anticoagulation is not required. The manufacturer recommends[19] administration of dipyridamole, 75 mg 3 times daily and aspirin, 80 mg daily. Some centers administer low molecular weight dextran intravenously until the patient can take oral medications. Systemic anticoagulation is not recommended unless the stroke volume of the device is persistently less than 30 mL or there is another medical indication for anticoagulation.

With the HeartMate XVE LVAS patients can ambulate. Battery operation expands the range of patient movement. The batteries and controller are relatively small and can be placed in a harness worn by the patient. The XVE LVAS can also be actuated manually or using a pneumatic drive in the event of a controller or motor failure. Patients may be discharged home when they have recovered from the surgical implantation procedure. The patient and support personnel (family and friends) are trained to provide routine care for the cable exit sites and to deal with VAD malfunction. Patients with this device can return to most activities of daily living, including work, school, and social activities.

The manufacturer has reported adverse events from clinical trials of the XVE LVAS.[19] In the Phase II study ($N=160$ patients), the reported adverse occurrences (independent of cause) included: infection events (29%), reoperation (23%), bleeding (13%), thromboembolic (7%), and neural dysfunction (8%). When only those adverse occurrences that were device-related were considered, the incidences were: infection events (28%), reoperation (11%), bleeding (8%), thromboembolic (4%), and neural dysfunction (3%). A potential problem with the XVE LVAS is device reliability with long-term therapy. The manufacturer reports the probability of reoperation, to repair or replace the device, as 7.2% for the first 6 months, 29.8% at 12 months, and 77.6% between 12 and 24 months.

The HeartMate XVE LVAD has been shown to have a low risk of thromboembolic events.

The HeartMate XVE LVAS is the only device currently approved as destination therapy in the treatment of end-stage heart failure in patients who are not candidates for heart transplantation. A multicenter, randomized trial (REMATCH)[20] found a survival advantage for patients receiving device therapy. The 1-year survival in the device group was 52% compared with 25% in the medical-therapy group. However, serious adverse events (most commonly infection, bleeding, and device malfunction) in the device therapy group was 2.35 times higher than in the medical therapy group.

The HeartMate XVE LVAS is the only device currently approved for use as destination therapy for patients who are not candidates for heart transplantation. However, device failure requiring replacement is significant 12–24 months after implantation.

Thoratec PVAD and IVAD

The Thoratec PVAD and IVAD can be used as an LVAD, RVAD, or BiVAD. The PVAD drive chamber rests externally on the patient's upper abdominal wall while the IVAD is implanted in the preperitoneal space.

The Thoratec PVAD (paracorporeal VAD) and IVAD (implanted VAD) Systems (Thoratec Laboratories Corporation, Pleasanton, CA, USA) share the same basic design and operating principles, but differ in the location of the pump. For the PVAD, the pump rests externally on the anterior abdominal wall, while for the IVAD, the pump is implanted in the preperitoneal space of the anterior abdomen. Both versions are pneumatically driven, pulsatile VADs that can be used as an LVAD, RVAD, or BiVAD. The PVAD and IVAD are approved for use as a bridge to transplant or as a bridge to ventricular recovery in postcardiotomy patients who cannot be weaned from cardiopulmonary bypass. The IVAD has not been used in patients with a BSA <1.3 m^2. Both versions of the device must be placed surgically, usually with the use of cardiopulmonary bypass (Figs. 48-7 and 48-8).

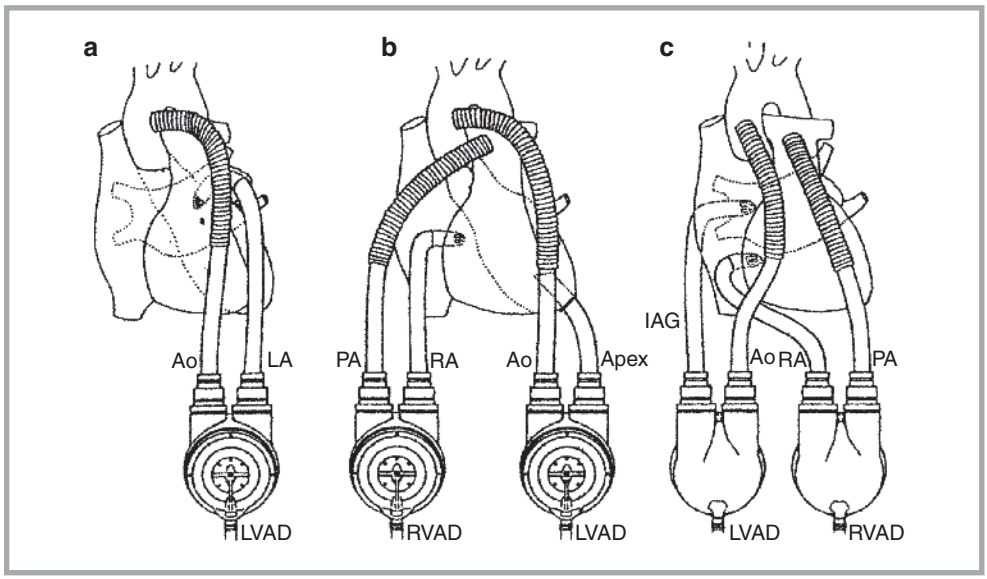

FIGURE 48-7

Configuration of the Thoratec PVAD System. (**a**) The device is placed as an LVAD with outflow from the patient via a left atrial cannula. (**b**) The device is configured for BiVAD support with outflow to the LVAD via a left ventricular apex cannula. (**c**) The outflow to the LVAD is through a cannula placed into the left atrium through the intraatrial groove (this view is from behind the heart) (Reprinted with permission from Thoratec Laboratories Corporation).

FIGURE 48-8

Thoratec IVAD (Reprinted with permission from Thoratec Laboratories Corporation).

The PVAD[21] and IVAD[22] both have a seamless blood pumping chamber (sac) housed within a rigid case. In the PVAD, the housing is a hard plastic polymer, while for the IVAD, the housing is made of a titanium alloy. The blood pumping sac is made from a proprietary polyurethane polymer. Unidirectional, antegrade blood flow is maintained by two mechanical cardiac valves located in inflow and outflow positions. Both pumps have an effective stroke volume of approximately 65 mL and can achieve a flow rate of 6.5 L/min with a pumping rate of 100 beats/min.

The PVAD rests on the external upper abdominal wall. The cannulae that carry blood from the patient to the pump and return blood from the pump to the patient are brought externally through small incisions. Synthetic cuffs on the subcutaneous portion of the cannulae are designed to decrease the risk of infection. For the IVAD, the device is implanted in the preperitoneal space of the anterior abdomen. The blood flow from the patient to the VAD is through a cannula placed in the left ventricular apex or left atrium (LVAD) or in the right atrium (RVAD). Cannulation of the left ventricular apex is usually performed when the device is placed as a bridge to transplant. Cannulation of the left atrium may be used when the device is placed as a bridge to recovery, since the goal is to remove the device following ventricular recovery. Blood is returned to the patient through a cannula that terminates in a synthetic graft. An anastamosis is created between this graft and the ascending aorta (LVAD) or pulmonary artery (RVAD). As with the Abiomed device described earlier, biventricular support requires placement of two devices.

For both the PVAD and IVAD, the device is connected to an external drive console that monitors the filling of the pumping chamber and controls the pumping actions. Blood is pumped by pressurizing the space within the rigid housing that surrounds the blood pumping sac with compressed air. This results in compression of the flexible blood pumping sac, propelling blood out of the blood sac, into the outflow cannula and then into the patient's aorta. Filling of the pumping chamber with blood is assisted by the application of vacuum to the pneumatic chamber during pump diastole. Both positive and negative pressure can be adjusted using controls on the drive console to ensure optimum pump function. A single drive console can control two VADs. A portable drive console is available that allows for increased patient mobility.

While the device can function in several different control modes, most commonly, it is set to function in a full-to-empty mode. In this mode, the pump will empty when the sensor detects that the pumping chamber is full. This mode has a fixed stroke volume with the rate of pumping determined by the rate of filling. A fixed rate mode and an external synchronized mode are used primarily to wean patients from VAD support.

Both the devices require the use of systemic anticoagulation[21,22] because of the mechanical valves. Heparin is usually started in the early postoperative period when bleeding has ceased or decreased significantly. The goal of therapy is to maintain an APTT 1.5 times control. Long-term anticoagulation is achieved by the administration of warfarin to maintain an international normalized ratio (INR) of 2.5–3.5. Some clinicians use concomitant antiplatelet therapy.

The Thoratec PVAD and IVAD devices require the use of systemic anticoagulation.

Slaughter et al. [23] reported on the results of a multicenter study of the IVAD. One hundred patients from the Food and Drug Administration submission for the approval of the PVAD served as a comparative group. The survival rate for IVAD support, all indications, was 69.2 % and for PVAD support, all indications, 63%. In the bridge to transplant group, the IVAD survival statistics were better for the LVAD group (81.3%) than for the BiVAD group (57.1%); a similar pattern was noted with the PVAD. The average duration of support for the IVAD group was 101 days (range 9–597 days). For the PVAD group, the average duration of support was 28 days (range 0–247 days).

For both versions of the device, the most common adverse events were infection, bleeding, and neurologic dysfunction. Ischemic or hemorrhagic stroke occurred in 7.7% of the IVAD group and 12% of the PVAD group. Transient ischemic attacks occurred in 20.5% of the IVAD group and 5% of the PVAD group. Neurologic dysfunction, expressed as the rate per 30 patient days, was 0.16 in the IVAD group and 0.43 in the PVAD group. The rate of adverse outcomes in the IVAD group compared to the PVAD group was lower or similar. Some of the improvements in the IVAD group may be attributable to the changes in experience and patient management that occurred during the 10 years that separated data collection for the two groups.

Novacor LVAS

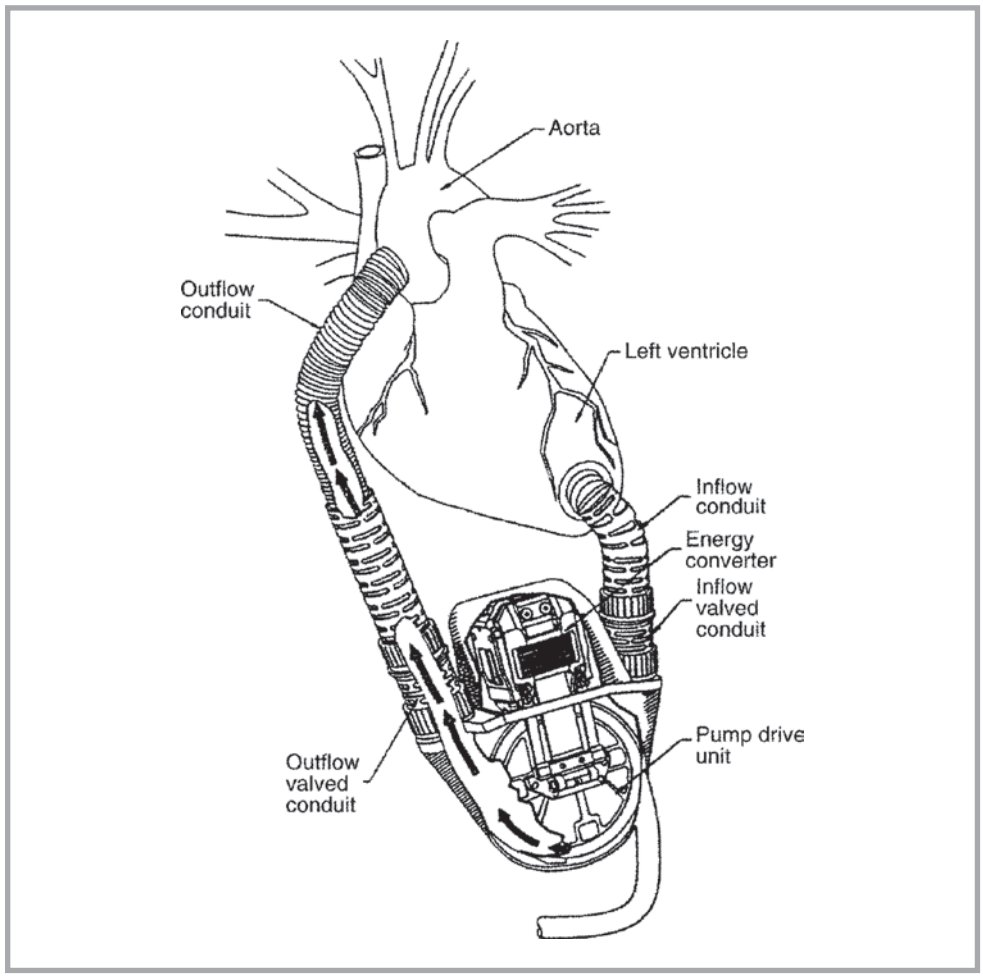
The Novacor LVAS (World Heart, Inc., Oakland, CA) is a pulsatile LVAD system that is approved for use as a bridge to heart transplantation.[24] The device is contraindicated in patients with a BSA less than 1.5 m^2 or greater than 2.5 m^2. It is also contraindicated in patients with primary coagulation or platelet disorders. The device must be implanted surgically, usually with the use of cardiopulmonary bypass. The pump has a seamless polyurethane pumping chamber connected to two pusher plates housed within a rigid shell. The pump has a volume of approximately 70 mL. The pumping action is provided by a pivoting solenoid (electromagnetic device) that is coupled to the pump by springs. Application of an electrical current to the solenoid causes it to pivot and flex the springs, applying pressure to the blood-containing pumping chamber and causing the ejection of blood from the pumping chamber (Fig. 48-9).

The electrically powered Novacor LVAS can only be used as an LVAD. The device is implanted in the anterior left upper quadrant of the abdomen.

The device is implanted in the anterior left upper quadrant of the abdomen. An inflow cannula is placed through the apex of the left ventricle to deliver blood to the pump. Blood returns to the patient through an anastomosis between a polyester outflow conduit and the patient's ascending aorta. Unidirectional blood flow is maintained by two bioprosthetic

FIGURE 48-9

The Novacor LVAS.



valves that are located at the inflow and outflow connections to the pump. Position sensors within the pump monitor the position of various pump components and are used to control the timing of the pump and monitor its function. An electrical lead from the pump exits percutaneously and is used to connect the device to the external controller and power source. A control unit regulates the operation of the pump. The electrical power for pump operation can be provided by a connection to a power base connected to an electrical outlet or by a connection to a rechargeable battery pack. There is also a reserve power pack to provide a backup power supply. The device can be triggered by monitoring the fill rate (pumping will be initiated when the rate of filling decreases, indicating that the pumping chamber is full), by use of an ECG signal, or in a fixed rate mode. The first method is used most commonly. Systemic anticogaulation, initially with heparin and then with conversion to warfarin, is required with this device.

The most common complications reported with the Novacor LVAD were bleeding, infection, and clinically significant cerebrovascular events.

A major concern with the Novacor LVAS has been the incidence of stroke. Since its introduction, several modifications have been made to the cannulae. It was reported that these modifications resulted in a decrease in the incidence of stroke. Tsukui et al. [25] reported on the occurrence of stroke in patients with a variety of VADs at a single institution. Only data from 2000 onward was included to reflect the most recent modifications in the Novacor cannulae. Actuarial freedom from stroke at 6 months was 75% for the HeartMate LVS, 64% for the Thoratec BiVAD, 63% for the Thoratec LVAD, and 33% for the Novacor LVS. All VAD patients, except those with the HeartMate LVS received systemic anticoagulation. The HeartMate patients received aspirin therapy alone unless atrial fibrillation was present.

The Novacor LVAS has shown excellent durability during long-term support and there is a case report of a patient whose device functioned for 1,487 days (4.07 years) before

requiring replacement.[26] A randomized, prospective multicenter study comparing the Novacor LVAS to the HeartMate LVS as a destination therapy device was begun; however, the study was not completed because the manufacturer chose to focus its attention on other product development.

Continuous Flow Devices

HeartMate II LVAS

The HeartMate II is an axial flow pump that can be used as an LVAD. It provides continuous, nonpulsatile flow.

The HeartMate II LVAS (Thoratec Corporation) is an axial-flow rotary pump that produces a continuous flow of blood[27] (Fig. 48-10). The small size of the device makes it suitable for a wide range of patients. It has recently been approved for use as a bridge to transplant. It is contraindicated in patients who have conditions that preclude anticoagulation. The device has no chambers or valves and has a single moving part, a spinning rotor, which contains a magnet and is rotated by electromotive forces generated by the pump's motor. The spinning of the rotor results in blood flow across the pump. The internal surfaces of the pump have a smooth titanium surface. Portions of the inflow and outflow conduits have a textured titanium surface similar to that in the HeartMate LVS. The inflow cannula is placed into the left ventricle through the apex. The outflow cannula, a polyester graft, is connected to the ascending aorta with an end-to-side anastamosis. The pump is implanted in the left upper abdomen, either in the preperitioneal space or within the peritoneum. The choice of location is guided by patient characteristics (size, prior surgery, etc.) and surgical preference. A percutaneous lead carries an electrical cable to an electronic controller. Power is provided either from a power base that is connected to an electrical outlet or by batteries that can be worn in holsters.

The pump can generate blood flows up to 10 L/min. Pump flow is dependent on the speed of rotation and the pressure difference across the pump. The pressure difference is, in turn, determined by the left ventricular pressure, aortic pressure, and the pressure loss across the inflow cannula and outflow graft.

Systemic anticoagulation is required. The manufacturer recommends institution of intravenous heparin therapy 12–24 h after implantation or when chest tube drainage is less than 50 mL/h. The goal is an APTT 1.5–1.8 times control. Antiplatelet therapy with aspirin and dipyridamole is recommended on postoperative day 2–3. Conversion from intravenous heparin to oral warfarin is the final step. The goal is an INR in the range of 2.0–3.0.

Miller et al. [28] reported the results of a study of the use of the HeartMate II as a bridge to transplant. The survival rates were 75% at 6 months and 68% at 12 months. The median duration of support with the device was 126 days. The longest duration of support was 600 days. Patients showed a significant improvement in functional status with device support. Among the more common adverse events, expressed as a percentage of patients with the adverse

FIGURE 48-10

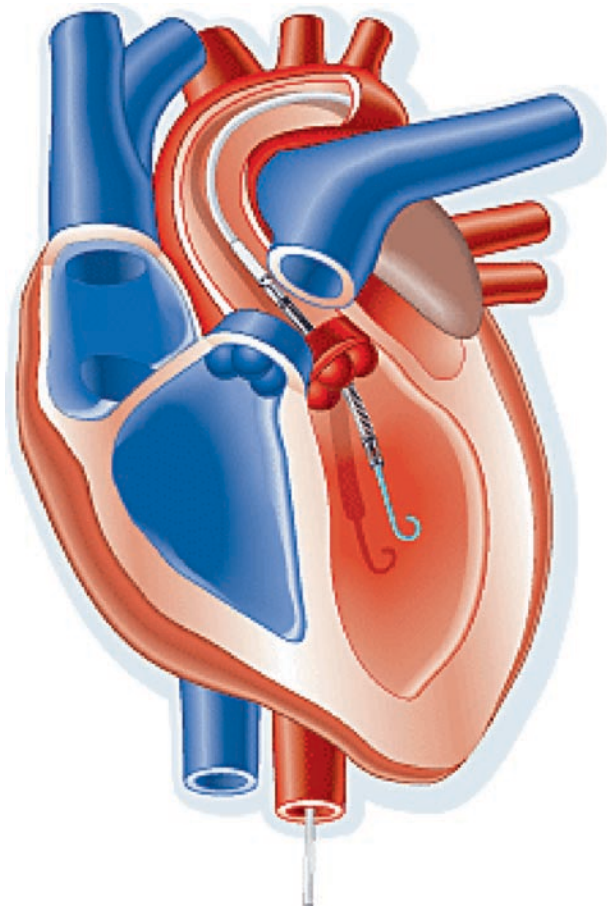
FIGURE 48-11

Impella 2.5 (from ABIOMED, Inc.).



event, were bleeding requiring surgery (31%), local infection (28%), respiratory failure (26%), and sepsis (20%). Neurological events included ischemic stroke (6%), hemorrhagic stroke (2%), transient ischemic attacks (4%), other (6%), and spinal cord infarction (1%).

The small size of the device makes the support available to a larger spectrum of patients. Also, the design of this continuous flow pump offers the potential for better pump durability and longer pump life. Long-term effects of nonpulsatile flow remain to be determined.

Impella 2.5

The Impellas 2.5 is an axial flow device that is placed percutaneously using a femoral artery approach. It can provide 2.5 L/min blood flow.

The Impella 2.5 (Abiomed, Danvers, MA)[29] is an axial flow VAD that is inserted percutaneously, via the femoral artery, and positioned across the aortic valve so that the inflow portion is in the left ventricle and the outflow portion is in the ascending aorta (Fig. 48-11). Percutaneous insertion allows the device to be placed in the cardiac catheterization laboratory. It is approved for up to 6 h to provide partial circulatory support, including partial circulatory support during procedures not requiring cardiopulmonary bypass. Contraindications to placement include a mechanical aortic valve or heart constrictive device, moderate to severe aortic stenosis, and severe peripheral vascular disease that would prevent safe placement of the device via a femoral artery. The axial-flow pump has a diameter of 12 Fr and is mounted on a 9 Fr pigtail catheter. A spinning propeller in the pump creates a continuous flow of blood. The performance of the pump depends on the pressure difference between the ascending aorta and left ventricle (pressure head) and the rotational speed of the propeller. The rotor has a pressure sensor, which continuously monitors this pressure difference. The device can generate a blood flow of 2.5 L/min. Administration of intravenous heparin to achieve an ACT of 250–500 s is recommended by the manufacturer during the placement of

the device followed by maintenance of an ACT between 160 and 180 s until the device is explanted.

The Impella has been shown to unload the left ventricle, decrease myocardial oxygen consumption, increase coronary flow, and decrease infarct size in acute myocardial infarctions. As with all rotary devices, hemolysis is a concern, but this has not been a significant problem in device trials.

Centrifugal Pumps

Centrifugal pumps, although generally not FDA approved for use as VADs, have been used to provide VAD support. These devices provide nonpulsatile blood flow.

Centrifugal pumps have also been used to provide VAD support, especially in postcardiotomy cardiogenic shock. These pumps use a rotating pump head to produce blood flow. Pump design varies among manufacturers, but generally rotation of the pump head is caused by magnetic coupling between a control console and the pump head. The Bio-Medicus Bio-Pump (Medtronic, Inc., Minneapolis, MN) uses a series of concentric rotating cones to propel blood through the pump (Fig. 48-12). The Sarns Centrifugal System (Terumo Cardiovascular Systems, Elkton, MD) uses a fin-like impeller to achieve blood flow. The Cobe Revolution (Cobe Cardiovascular, Arvada, CO) has an impeller with multiple fins. In the CentriMag pump (Thoratec Corporation), the spinning impeller is magnetically levitated, eliminating the need for bearings and seals. Centrifugal pumps use a sensor to determine the actual pump flow because the flow at any given speed (revolutions per minute) depends on the preload and afterload of the system; blood flow with centrifugal pumps is nonpulsatile. Centrifugal pumps are commonly used in cardiac surgery as the arterial blood pump in the cardiopulmonary bypass circuit. They are also used as a part of the circuit for ECMO (see below). While most centrifugal pumps are approved for short-term use (6 h) as part of an extracorporeal circuit, they have been used to provide short-term ventricular support, especially in the era before the approval of the VADs.

Tandem Heart PTVA

The Tandem Heart certifugal pump can be placed percutaneously to provide left atrial to femoral artery bypass support. The support can be used during high-risk percutaneous interventions.

The Tandem Heart Percutaneous Ventricular Assist Device System (Cardiac Assist, Inc., Pittsburgh, PA) is a centrifugal pump that is designed to be used with cannulae inserted percutaneously into a femoral artery and vein in the cardiac catheterization laboratory or operating room.[30] The device is approved for use as a short-term (up to 6 h) extracorporeal support system for procedures not requiring complete cardiopulmonary bypass. The typical circuit involves a left atrial to femoral artery bypass circuit (Fig. 48-13). A specially designed cannula is introduced through a femoral vein into the right atrium and then across the intraatrial septum into the

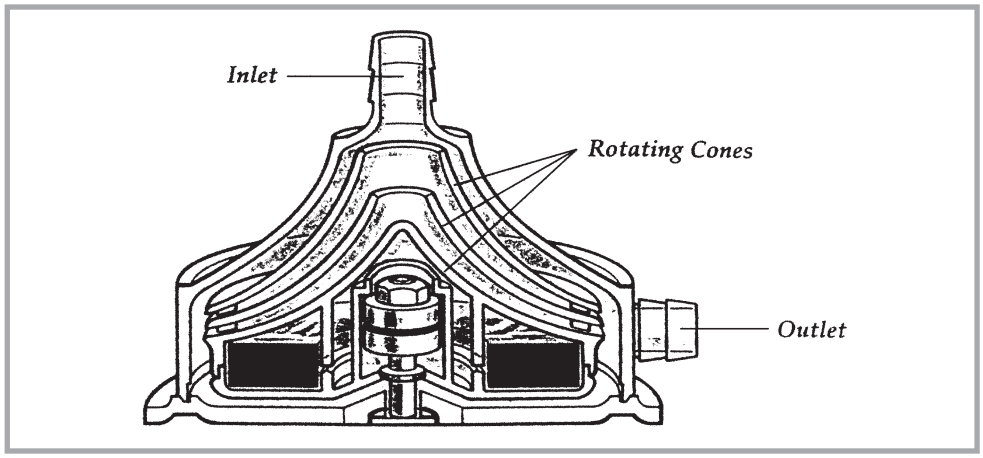


FIGURE 48-12

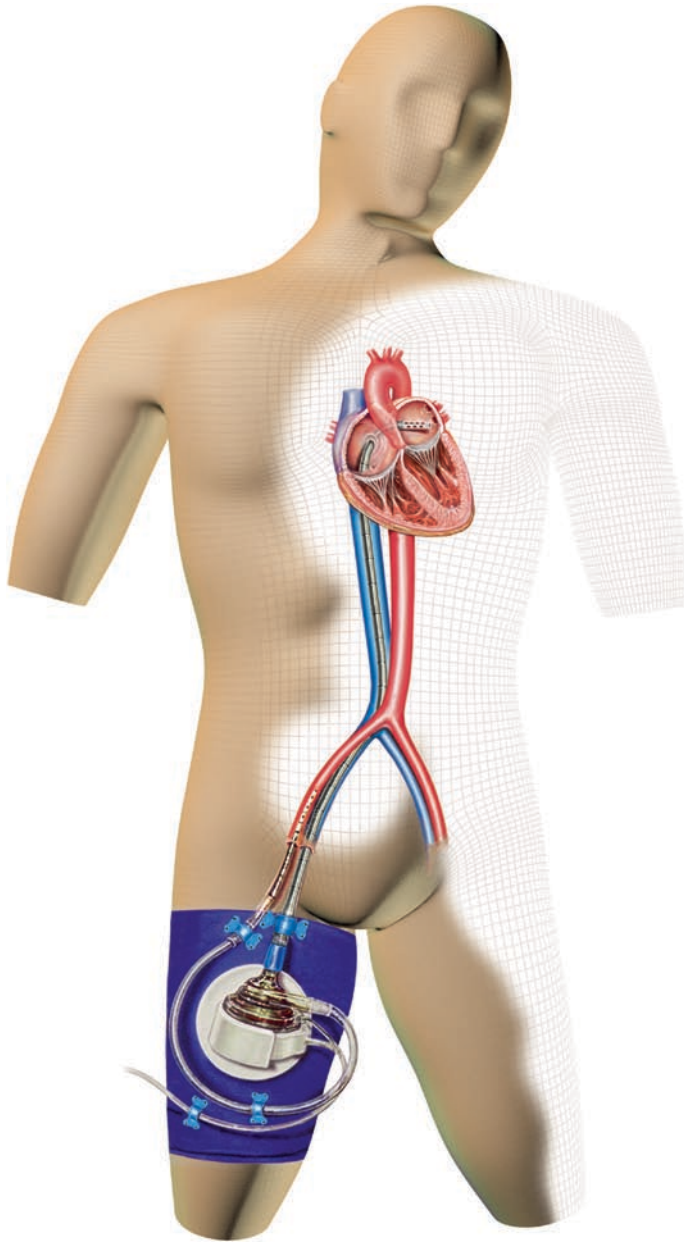
Bio-Medicus centrifugal pump (from © Medtronic, with permission).

FIGURE 48-13

Tandem Heart Centrigual Pump. (From Cardiac Assist, Inc., with permission).



left atrium. This cannula is connected to the Tandem Heart centrifugal pump. The outflow from the pump is returned to the patient through a cannula placed into a femoral artery. The pump is able to generate flows up to 5 L/min. The design of the pump incorporates a hydrodynamic fluid bearing to support the spinning rotor instead of conventional roller bearings; heparinized saline is continuously infused into the pump housing for this purpose. The manufacturer recommends anticoagulation to an ACT of 400 s for insertion of the device. During the support phase, an ACT ≥200 s or an APTT 2.5–3 times the normal range (65–80 s) is recommended. The device has been used to support patients during high-risk interventions in the cardiac catheterization laboratory, following acute myocardial infarction, and for postcardiotomy pump failure. It has also been used to provide a temporary support prior to the placement of a long-term VAD. During support with this device, the patient must remain immobile to prevent movement of the transseptal left atrial cannula and the femoral artery cannula. Sedation may be required to ensure patient compliance and comfort. Bleeding, left atrial cannula migration, leg ischemia (femoral artery cannulation site), and arterial cannula dislocation are all potential complications.

CASE STUDY 2

A 32-year-old female with idiopathic pulmonary fibrosis has undergone bilateral lung transplantation. Two hours following reperfusion of the second transplanted lung, the patient's oxygen saturation decreases to 82% despite an FiO_2 of 1.0 and PEEP of 15 cm of water. Large quantities of frothy fluid are suctioned from the endotracheal tube. A chest X-ray reveals severe bilateral pulmonary edema. The pulmonary capillary occlusion pressure is 6 mmHg.

EXTRACORPOREAL MEMBRANE OXYGENATION

ECMO therapy can provide blood oxygenation and carbon dioxide elimination when conventional management strategies have been unsuccessful.

ECMO therapy is a technique that can provide blood oxygenation and carbon dioxide elimination for patients in whom conventional management strategies have been unsuccessful. A membrane oxygenator is used to deliver oxygen to, and remove carbon dioxide from, the blood. Venous blood is removed from the patient through a cannula connected to an extracorporeal circuit that includes a pump and membrane oxygenator. Oxygenated blood is returned to the patient through a second cannula. A centrifugal pump (as described earlier) is commonly used in this circuit. A veno-venous extracorporeal circuit is most often employed, with the placement of a cannula into the right atrium either through the right internal jugular vein or a femoral vein. A second cannula is placed into a femoral vein. The most common pattern of flow for veno-venous ECMO involves removal of blood from the right atrium with reinfusion of the oxygenated blood into a femoral vein. There is some evidence that the reverse flow pattern (femoral vein to right atrium) could result in better flow rates and oxygenation.

Ventilator management during ECMO is aimed at providing lung rest to limit further lung injury and barotrauma. Low-frequency positive pressure ventilation (either pressure-controlled or volume-controlled with low tidal volumes) with an FiO_2 between 0.3–0.5 and positive end-expiratory pressure (PEEP) less than or equal to 10 cm H_2O is common. Peak airway pressures are reduced to prevent barotrauma. Routine respiratory care with bronchodilators, bronchoscopy, and, in some patients, tracheostomy is used to limit the development of atelectasis and inspisated pulmonary secretions. Fluid management is aimed at achieving the patient's dry weight by the use of diuretics or ultrafiltration. Other care is continued with attention to nutritional support, cardiac function, and antibiotics as indicated. Flow-directed pulmonary artery catheterization and mixed venous oxygen saturation monitoring may provide additional information to help guide management.

Veno-venous ECMO does not provide circulatory support; therefore, in patients who also require circulatory support, a cannulation technique involving veno-arterial ECMO must be used. The arterial return can be into a femoral artery or into a carotid artery. Some centers prefer the carotid artery site to ensure that well-oxygenated blood is delivered to the proximal aorta for distribution to the major organs.

Complications of ECMO include bleeding, cannulation-related vascular problems, renal failure, multisystem organ failure, infection, neurologic problems including brain death and seizures, mechanical problems with the ECMO circuit, and liver dysfunction. It is not always possible to differentiate between ECMO and the underlying disease process as a cause for many of these complications.

ECMO in Respiratory Failure

An international registry of ECMO therapy has reported an overall survival of 77% for neonatal respiratory distress and approximately 50% for adult respiratory distress.

The Extracorporeal Life Support Organization (ELSO), which maintains a voluntary international registry of information from more than 100 centers, has reported the results of nearly 29,000 patients treated with ECMO.[31] The majority of the patients (66%) were cases of neonatal respiratory failure. For neonatal respiratory failure treated with ECMO, the overall survival to discharge or transfer was 77%. The registry contains fewer cases of ECMO used in the treatment of adult respiratory failure (1,005 patients), with an average of 93 cases per year (range 82–112) for the years 1996 through 2003. The average survival rate reported from the

registry has been approximately 50% and has remained relatively stable. Survival was better for adult patients with non-ARDS respiratory failure (64%), viral pneumonia (62%), and aspiration pneumonia (56%). The lowest survival rate, 49%, was in the category *OTHER*.

The role of ECMO in the management of adult respiratory failure refractory to conventional medical therapy remains unclear. Preliminary data from a recent randomized study suggests that it may provide a survival advantage in severe ARDS.

The role of ECMO in the management of respiratory failure refractory to conventional medical therapy remains unclear. Only two prospective randomized trials of extracorporeal treatment for adult respiratory failure have been published; neither demonstrated an outcome benefit. The first trial, published in 1979, was a multicenter, prospective, randomized trial of ECMO for the treatment of severe respiratory failure. The authors reported survival rates of 9.5% in the ECMO group and 8.3% in the conventionally treated group.[32] The difference in outcome was not statistically significant. The second prospective randomized trial,[33] published in 1994, compared pressure-controlled inverse ratio ventilation to low-frequency positive pressure ventilation with extracorporeal carbon dioxide removal. It also showed no significant difference between treatment groups in 30-day survival, the primary outcome measure. Survival rates were 42% in the control group and 33% in the treatment group. The difference was not statistically significant.

There are numerous nonrandomized studies and case series published on the use of ECMO in adult respiratory failure. One of the largest single-center experiences is from the University of Michigan. Hemmila et al.[34] reported their experience from 1989 through 2003. Of the 405 patients that were placed on extracorporeal life support, 255 had severe ARDS. In this group, 67% were weaned from extracorporeal support and 52% survived to discharge. Of those who survived to discharge, none required mechanical ventilatory support or supplemental oxygen therapy. A standard protocol for the management of ARDS was used, with ECMO instituted for patients refractory to conventional therapy. The standard treatment protocol included inverse ratio pressure-controlled ventilation, limiting peak inspiratory pressure to a maximum of 35–40 mmHg, titration of PEEP and FiO_2 to maintain SaO_2 greater than 90% and SvO_2 greater than 70%, and the use of prone positioning. For patients receiving ECMO, most were supported with a veno-venous circuit. During ECMO, a lung protection ventilation strategy was used, which included inverse ratio ventilation with low peak pressures, an FiO_2 ≤0.5, and respiratory rates of 6–10 breaths/min.

The *Conventional Ventilatory Support vs. ECMO for Severe Adult Respiratory Failure* (CESAR) trial was recently completed in Great Britain. The CESAR trial[35] was a randomized, prospective study comparing conventional management for ARDS with ECMO. All patients who received ECMO were treated in a single center, while the conventional therapy patients were treated in various hospitals throughout Great Britain. The conventional treatment arm of the study did not use a single protocol; each center followed its standard practice. The study protocol recommended a low tidal volume strategy (plateau pressure ≤30 cm H_2O). Veno-venous ECMO was used for patients who did not require cardiac assist, and veno-arterial for those who did. In the veno-venous circuit, blood was drained from the right atrium (internal jugular or femoral vein cannulation) and returned to a femoral vein. During ECMO, mechanical ventilation aimed to achieve lung-rest with peak inspiratory pressures ≤20 cm H_2O, PEEP 10 cm H_2O, and FiO_2 0.3. The results of this trial, which enrolled 180 patients (90 in each arm) from 2001–2006, were recently published.[36] Of the 90 patients randomized to ECMO therapy, 68 patients received ECMO, 5 patients died before or during transport to the treatment center, and 17 responded to conventional therapy during the first 12 hours after arrival at the treatment center. Sixty-three percent of patients randomized to the ECMO treatment group were alive without severe disability 6 months after randomization, while this occurred in only 47% of those randomized to the conventional treatment group (p=0.03). The economic analysis suggested that ECMO could be cost effective in this setting.

Veno-venous ECMO is the most common pattern of support with veno-arterial cannulation being used for patients who also require cardiac assist.

The ELSO registry data on the use of ECMO in the treatment of primary graft failure following lung transplantation was reported by Fischer et al.[37] There were 151 patients in this group. Sixty-two percent of the patients survived ECMO, 19% died from multisystem organ failure, 15% from other causes, and in 4% the outcome was unknown. Even though more than 60% of the patients survived ECMO, only 42% survived to hospital discharge. Veno-arterial ECMO was used in 56% of patients, veno-venous ECMO in 17%, and other or unknown type in 27%. The use of veno-arterial ECMO was much higher in this group than in the total adult ECMO population in the registry, where veno-arterial ECMO was used only 16% of the time.

With the publication of the results of the CESAR trial, the role of ECMO in the treatment of adult respiratory failure refractory to conventional treatment may become clearer. To be successful, ECMO therapy requires an experienced team of physicians, nurses, and perfusionists. It is not likely to be a treatment that can be provided at every hospital. However, in the CESAR trial, all patients receiving ECMO were treated at a single institution, suggesting that regional treatment centers can be used effectively to provide this advanced therapy.

Use of TEE in Mechanical Hemodynamic Support

As discussed above, TEE can be used to assist in the placement of an intra-aortic balloon. During and after placement of the balloon catheter, TEE can demonstrate that the tip of the catheter is just distal to the origin of the left subclavian artery.

Chumnanvej et al.[38] published a detailed review of the use of perioperative echocardiography in VAD implantation. The discussion below highlights the more common uses they identify, including a search for intracardiac defects, assessment of cardiac valve function, assessment of the ascending aorta, assessment of right and left ventricular function, assessment of VAD components and cannulas, assessment of the presence of ventricular air after implantation and deairing of the heart, and assessment and diagnosis of various complications of VAD therapy.

Intracardiac defects such as patent foramen ovale (PFO) or atrial septal defect (ASD) can result in profound hypoxemia after cardiopulmonary bypass due to right-to-left shunting. A PFO cannot always be diagnosed prior to LVAD therapy because high right and left atrial pressures may prevent significant shunt being seen on examination. In the presence of right ventricular failure and pulmonary hypertension, the initiation of LVAD therapy, with its attendant unloading of the left ventricle and decrease in left atrial pressure, can result in a significant right-to-left shunt through the PFO. PFOs are common and may be seen in 25–30% of patients. A careful search for an ASD and/or PFO is important prior to the insertion of the device since their presence may require an alteration in surgical technique. Ventricular septal defects can also cause problems following VAD placement.

In evaluating the cardiac valves it is essential to exclude significant AI. Proper functioning of a pulsatile LVAD requires a competent aortic valve. The presence of severe AI will require oversewing of the aortic valve or valve replacement. AI may also develop after the implantation of the device due to distortion of the valve by the cannula. In patients with prior aortic valve replacement, the type of artificial valve needs to be identified. A mechanical aortic valve may need to be replaced by a bioprosthetic one. Mechanical valves have an increased thrombotic risk in these patients due to minimal valve washing during LVAD support. Severe mitral stenosis may interfere with adequate LVAD filling and may require a commissurotomy or valve replacement. Mitral regurgitation will usually improve with LVAD therapy because of the unloading of the left ventricle.

With LVAD therapy, filling of the device is dependent on the right ventricle pumping blood through the lungs into the left atrium. If there is significant RV dysfunction, there may be inadequate filling of the LVAD leading to low pump flow. Volume overload may cause a marginally performing RV to fail. Prediction of significant RV dysfunction or failure following LVAD placement is difficult. Patients with RV failure as a result of LV failure may show improvement of RV function following initiation of LVAD therapy. Assessment of RV function should be a part of the post-LVAD-implantation echocardiographic study.

Prior to device implantation the presence or absence of ventricular thrombi should be determined. An apical thrombus will prevent cannulation of the apex. Following the initiation of VAD therapy, echocardiography can be used to confirm that the ventricle is appropriately decompressed. Incomplete decompression of the ventricle suggests problems with the cannula or device. If the device was placed as a bridge to recovery, echocardiography can be used to monitor the recovery of the ventricular function.

Echocardiography can also be used to assess the various components of the mechanical assist devices. VAD flows should be laminar and unidirectional; the presence of turbulence may identify cannula obstruction or the development of thrombus. Echocardiography can also be used to diagnose VAD valve regurgitation that may result from the deterioration of

the valves over time. Inflow valve regurgitation is more common than outflow valve regurgitation. Echocardiography may also detect thrombus in the cannulas of axial flow devices.

Echocardiography can be used to assess the presence of air in the cardiac chambers following implantation. Thorough deairing is necessary prior to initiating LVAD therapy, in order to prevent systemic air emboli. Other uses include the identification of acute aortic dissection, cardiac tamponade, and device endocarditis.

SUMMARY

Patients who develop inadequate hemodynamic function despite conventional medical therapies may benefit from the use of mechanical cardiac support. IABC is usually considered as the first-line therapy. IABC can also be used to treat myocardial ischemia that is refractory to conventional medical therapy. IABC, although an effective therapy in many patients, can be associated with significant adverse consequences, the most common of which are related to limb ischemia.

Patients with inadequate cardiac pump function who do not respond to IABC or who need long-term support can be considered for VAD therapy. The choice of device depends on the expected duration of therapy, the patient's size, and whether support is needed for the left ventricle, the right ventricle, or both. VAD therapy is most commonly used as a bridge to heart transplantation. However, it can also be used as a bridge to recovery in patients with cardiogenic shock where recovery of myocardial function may occur with prolonged and aggressive support, as in patients who cannot be separated from cardiopulmonary bypass or in whom cardiogenic shock has developed as a consequence of acute myocarditis or myocardial infarction. New devices that can be placed percutaneously can be used to provide support during high-risk percutaneous interventions and to provide short-term support and stabilization in patients with cardiogenic shock. The most common complications of VAD therapy are bleeding, embolism, and infection.

ECMO can be used to provide oxygenation and carbon dioxide removal in patients with respiratory failure refractory to conventional therapy. ECMO has been shown to be a beneficial therapy for the treatment of infant respiratory distress syndrome, but its role in adult respiratory distress remains unclear.

REVIEW QUESTIONS

1. **The indications for IABC therapy include all of the following except:**
   - **A.** Cardiogenic shock following acute myocarditis
   - **B.** Acute mitral regurgitation with pulmonary edema from papillary muscle rupture
   - **C.** Acute ventricular septal defect developing after a myocardial infarction
   - **D.** Acute AI from endocarditis
   - **E.** Angina, refractory to medical therapy

2. **A patient with an intra-aortic balloon catheter placed through the right femoral artery develops evidence of limb ischemia in the right leg. Which of the following is not an acceptable response to this condition?**
   - **A.** Remove the intra-aortic balloon catheter
   - **B.** Do a femoral–femoral artery bypass
   - **C.** Obtain a vascular surgery consultation
   - **D.** No intervention is necessary for the first 12 h
   - **E.** Move intra-aortic balloon catheter to left femoral artery

3. **Advantages of the HeartMate VAD include:**
   - **A.** Can be used as LVAD, RVAD, and bivad
   - **B.** Does not require systemic anticoagulation
   - **C.** Can be used in patients with a BSA $\leq 1.5\ m^2$
   - **D.** Durability exceeds 24 months in most patients
   - **E.** Can be placed percutaneously

4. **What is the major difference between the Abiomed BVS 5000 and AB5000?**
   - **A.** The AB5000 does not require anticoagulation
   - **B.** The BVS 5000 is electrically powered
   - **C.** The AB5000 uses vacuum-assist filling
   - **D.** The BVS 5000 allows patient ambulation
   - **E.** The AB5000 is designed for long-term use

5. **Which pulsatile flow device has the lowest risk of thromembolic events?**
   - **A.** Thoratec IVAD
   - **B.** Thoratec PVAD
   - **C.** Abiomed AB5000
   - **D.** HeartMate XVE LVAS
   - **E.** Novacor LVAS

6. **Which VAD would be the best choice to support a patient in cardiogenic shock during a percutaneous intervention in the cardiac catheterization laboratory?**
   - **A.** Tandem Heart PTVA
   - **B.** HeartMate II
   - **C.** Abiomed BVS
   - **D.** Thoratec PVAD
   - **E.** Novacor LVAS

7. **Which indication for ECMO therapy has demonstrated the BEST outcomes?**
   - **A.** Viral pneumonia
   - **B.** Neonatal respiratory distress
   - **C.** ARDS
   - **D.** Aspiration pneumonia
   - **E.** Postlung transplant graft failure

8. **Following the placement of an LVAD for severe biventricular failure with pulmonary hypertension, a patient demonstrates severe hypoxemia with an FiO_2 of 1.0. Which of the following findings on TEE would BEST explain this?**
   - **A.** PFO
   - **B.** Malpositioned inflow cannula
   - **C.** Aortic insufficiency
   - **D.** Left ventricular akinesis
   - **E.** Air in the left atrium

ANSWERS

1. The answer is D. Significant AI is a contraindication to the use of intra-aortic balloon counterpulsation. Inflation of the intra-aortic balloon during diastole will increase the amount of aortic regurgitation. For the other conditions listed, IABC may be beneficial.
2. The answer is D. Limb ischemia is one of the most serious complications of IABC. Prompt recognition of limb ischemia and intervention to restore distal limb blood flow are required to prevent permanent disability or loss of limb. Each of the other options is an acceptable intervention.
3. The answer is B. The HeartMate VAD does not require systemic anticoagulation. The design of the device, which encourages the formation of a psudeoneointima with the blood pumping chamber, decreases the incidence of clot formation.
4. The answer is C. For the Abiomed AB5000 VAD, the pumping chamber is located on the anterior abdominal wall and uses vacuum-assisted filling. The use of vacuum-assisted filling allows the pump to function when the patient is upright.
5. The answer is D. The HeartMate XVE LVAS has the lowest incidence of thromboembolic events of the devices listed. The design of the device with the use of bioprosthetic valves and the textured surface to the pumping chamber that encourages the formation of pseudoneointima are felt to be the reasons for the low incidence of thromboembolic events.
6. The answer is A. The Tandem Heart PTVA is the only one of the devices listed that can be placed via a percutaneous route. The Impella 2.5 can also be placed percutaneously. The other devices in the list require surgical implantation.
7. The answer is B. The outcome data for ECMO therapy has showed the highest success in the treatment of neonatal respiratory distress syndrome. Success rates for ECMO in adult respiratory failure have been lower.
8. The answer is A. In patients for whom LVAD therapy has been initiated, the presence of a patent foramen ovalae with right-to-left shunting can lead to hypoxemia that is refractory to increased inspired oxygen concentrations. TEE can be used to demonstrate the presence of a patent foramen ovalae.

CHAPTER 49

CHRISTINA ROSE, NEIL W. BRISTER, AND DAVID E. CICCOLELLA

Pharmacologic Hemodynamic Therapy of Shock

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Know the indications and contraindications for each medication.
- Know the clinical hemodynamic effects of each medication.
- Know the potential complications associated with each medication.
- Know the use of these agents in specific shock states.

The pharmacologic support of critically ill patients commonly includes hemodynamic support for hypotension and shock. Pharmacologic therapy is used in conjunction with other treatments such as fluid administration, antibiotics, and, in special situations, mechanical circulatory-assist devices. Within the different categories of shock, the type, dose, and number of drugs vary significantly. We describe here the various categories and causes of shock as well as hemodynamic support drugs and their use in selected causes of shock.

Shock is characterized by persistent hypotension that is unresponsive to fluid challenge and by end organ hypoperfusion[1] defined as the failure of the circulatory system to maintain adequate cellular or tissue perfusion and oxygen delivery to meet current metabolic demands, resulting in organ dysfunction, which if prolonged, results in irreversible cellular damage. Oliguria, hypotension, lactic acidosis, and mental status changes are common findings in patients with shock. Although shock is more likely to exist at a (SBP <90 mmHg or a reduction of SBP >40 mmHg) mean arterial pressure of less than 60 mmHg (or a decrease in premorbid systolic blood pressure (BP) of 40 mmHg), shock is not necessarily defined by a low BP, but rather as an inability to meet the metabolic demands. Therefore, shock may occur at a BP of 95/70 if oxygen delivery does not meet the metabolic demands.

Categories of Shock

Shock can arise from a number of different etiologies and can manifest in several different hemodynamic patterns based upon the underlying pathophysiology. One commonly used general shock classification describes four basic categories: hypovolemic, cardiogenic, extracardiac obstructive, and distributive shock, for which there are multiple possible underlying causes (Fig. 49-1a).

Shock may be divided into four types: hypovolemic, extracardiac obstructive, cardiogenic, and distributive.

Hypovolemic shock results from a loss of circulatory volume due to hemorrhage or extravascular fluid losses. Cardiogenic shock results from inadequate pump function whether

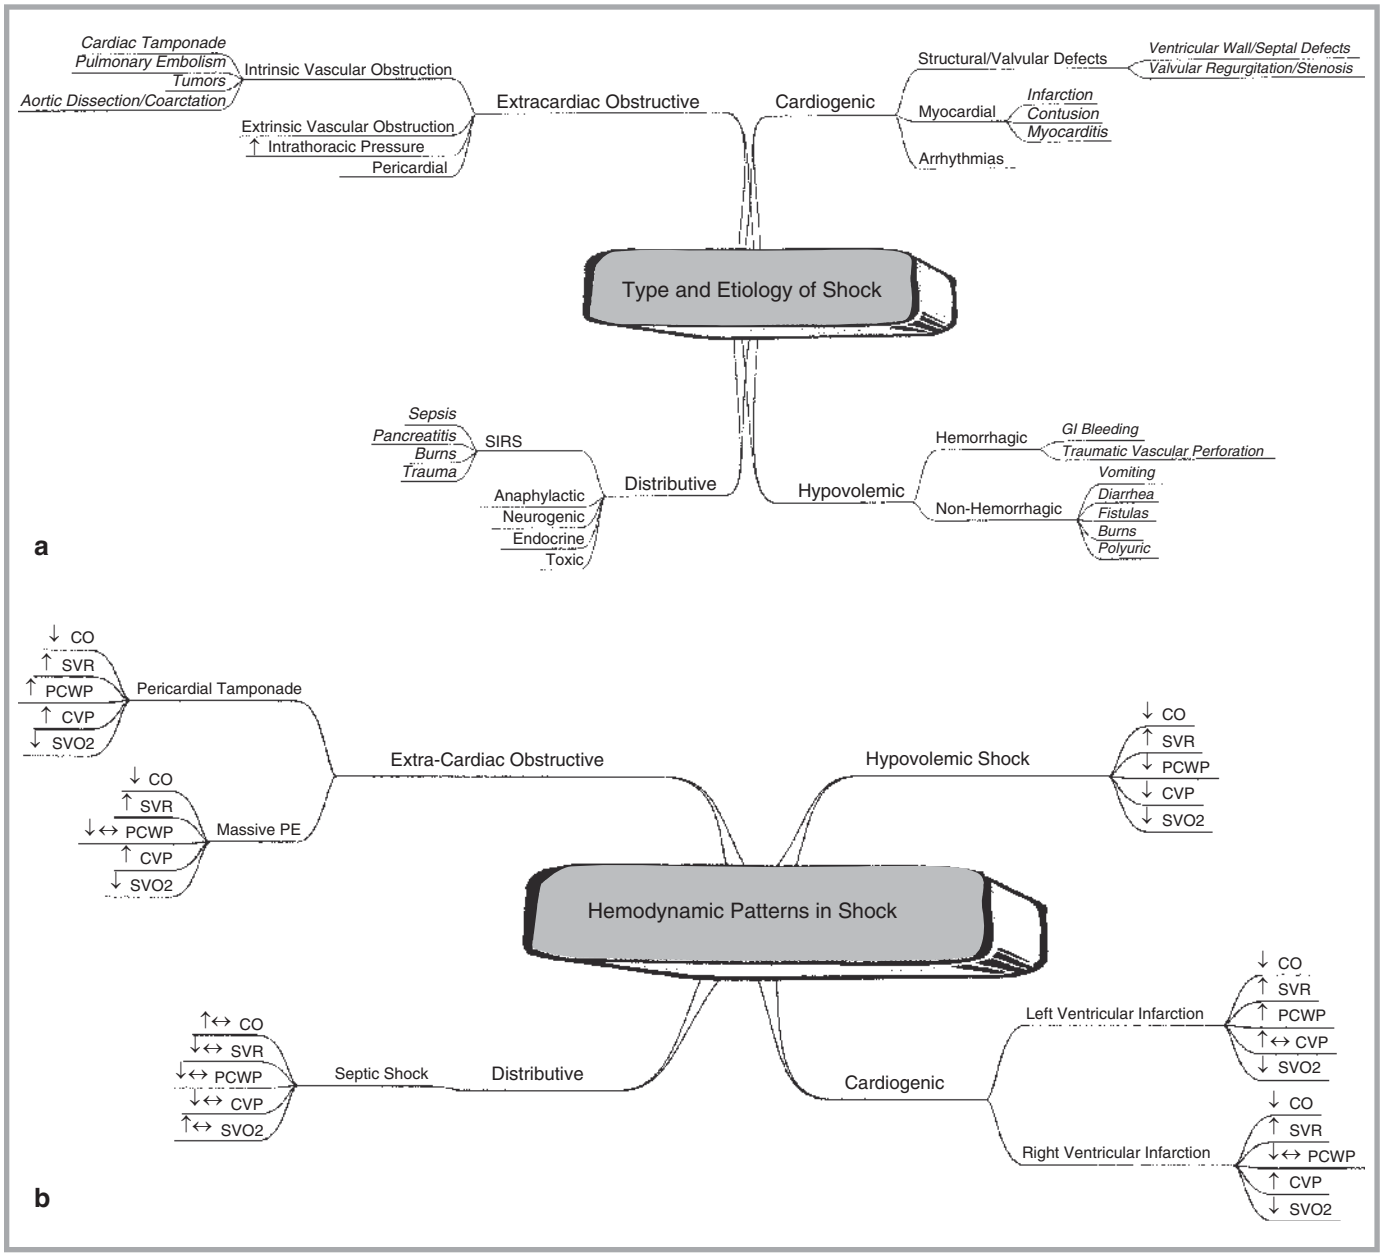

FIGURE 49-1

(**a**) Category and etiology of shock. The four main categories of shock and their etiologies are shown. A single etiology may occur in two or three of the shock types such as septic shock. (Information adapted from Parillo[67]). (**b**) Hemodynamic patterns in shock. The four main categories of shock and the hemodynamic patterns for some of their important causes are shown.

Each of the shock types has multiple different causes.

caused by predominant left or right myocardial infarction, acute valvular disease such as acute mitral regurgitation or aortic regurgitation, dysrhythmias, intracardiac obstruction, or severe cardiomyopathy. Extracardiac obstructive shock results from a mechanical impediment to blood flow caused by diseases such as pulmonary embolism, tension pneumothorax, pericardial tamponade, or aortic dissection or compression. Distributive shock may result from a maldistribution of blood volume in processes such as sepsis, anaphylaxis, spinal cord injury (e.g., spinal shock), and adrenocortical insufficiency.

Some of the specific causes of shock – anaphylaxis, pancreatitis, trauma – have features of more than one of the four shock types.

In this general classification of shock, it should be noted that some of the specific causes (e.g., anaphylaxis, pancreatitis, and trauma) have features of more than one of the four basic shock categories. For instance, septic shock predominantly tends to be a distributive type but may include hypovolemic or cardiogenic categories. Similarly, anaphylactic shock, which is mainly distributive, includes elements of hypovolemic shock due to rapid intravascular volume shifts. Moreover, an acute problem, leading to shock, may occur in the setting of an underlying cardiac dysfunction. For example, severe hemodynamic instability may be the result of the acute occurrence of septic shock in a patient with an underlying ischemic cardiomyopathy. These aspects of the shock classification should be considered when evaluating any patient in the ICU for the specific cause of shock and its treatment(s).

Acute shock may be complicated by an underlying chronic cardiac dysfunction.

These four shock categories and their causes are associated with hemodynamic patterns that may further aid in the identification of the specific cause as well as the type of treatment (Fig. 49-1b). Hypovolemic, cardiogenic, and extracardiac obstructive shock are associated with decreased cardiac output. In contrast, during the initial phase of septic shock, a distributive form of shock, cardiac output (CO) may be increased, and systemic vascular resistance (SVR) decreased. Other causes of increased CO and decreased SVR include cirrhosis of the liver, neurogenic shock, and anaphylactic shock. The pulmonary capillary wedge pressure (PCWP) may help to further differentiate hypovolemic from cardiogenic shock.

Initial Evaluation and Diagnosis of Shock

The patient should be assessed for the etiology of shock by an initial rapid clinical evaluation based on a focused history and physical examination, followed by appropriate initial laboratory studies. Knowing the history of present illness, underlying past illnesses, medications, and other disease risk factors is especially helpful in determining the etiology. The physical examination should be directed toward evaluating traditional vital signs such as heart rate and rhythm, blood pressure, respiratory rate, and temperature, plus the adequacy of tissue or organ perfusion. Physical signs of decreased perfusion include tachycardia, hypotension, decreased pulse pressure, altered mental status, oliguria, tachypnea and cyanosis, and decreased skin capillary refill. Certain constellations of historical information and physical findings may immediately indicate the etiology of shock; other cases may be much less obvious.

Further evaluation for the diagnosis includes laboratory studies such as serum electrolytes and anion gap, creatinine and biliary urea nitrogen (BUN), arterial blood gas (ABG); chest roentgenogram (CXR) and electrocardiogram (EKG) may be very helpful in the initial evaluation.

TREATMENT OF SHOCK

Hemodynamic Goals

The treatment of shock is directed at increasing tissue perfusion and oxygen delivery through the use of fluids, vasoactive drugs, mechanical ventilation, and circulatory-assist devices.

In general, shock may require a combination of fluid resuscitation, specific vasopressor, inotropic, and/or vasodilator agents, or ventricular-assist devices depending upon the etiology and severity of shock. Shock results from inadequate substrate and O_2 delivery, which is necessary to maintain metabolic processes. Therefore, the goals of treatment are to restore tissue perfusion and oxygenation to an adequate level. The main determinants of tissue perfusion are CO and mean arterial blood pressure (MAP). The MAP has been one method used traditionally to help assess tissue perfusion.

Although it has its limitations, especially in certain distributive types of shock, the MAP is a simple measure to roughly determine the adequacy of tissue perfusion. MAP minus the central venous pressure (CVP) is related to CO and SVR as shown in the following equation:

$$MAP - CVP = CO \times SVR, \quad (49\text{-}1)$$

which can be rearranged to

$$MAP = (CO \times SVR) + CVP \quad (49\text{-}2)$$

In this equation, we know that the CO is dependent on stroke volume (SV) and heart rate (HR):

$$CO = SV \times HR \quad (49\text{-}3)$$

The SV, in turn, is dependent on the degree of preload, contractility, and afterload, assuming the absence of regurgitation. The preload is the cardiac chamber volume before contraction, and afterload is the resistance to blood ejection, one component of which is SVR. The main component of SVR is regulated by the systemic arterioles.

Thus, shock may result from problems with one or more of the following: the heart, the heart rate, the intravascular volume or the vascular resistance. Through clinical assessment, echocardiography and/or invasive procedures, such as pulmonary artery catheterization, the volume problem can be evaluated and treated. After assessment and infusion of fluids to correct volume deficits, pharmacologic support of the circulation is directed at maximizing CO through changes in SV, HR, and SVR. Generally, the HR, which also affects preload, is not specifically targeted unless it is significantly too fast or slow due to arrhythmias. An increase in HR may be a manifestation of inadequate preload or secondary to administration of a vasoactive drug. The clinician may choose to use vasoactive drugs that selectively target these components of the circulation in order to improve the patient's hemodynamic status.

Shock may result from problems affecting one or more of the following: heart, heart rate, vascular resistance, or intravascular volume.

Circulatory support is directed at modifying CO through its effects on increasing SV and HR.

Initial Phase of Treatment

The initial phase of treatment involves the establishment of large-bore intravenous catheters, an arterial line for direct and continuous pressure measurement, electrocardiographic monitoring and pulse oximetry. Depending on the presumed etiology of shock (other than cardiogenic shock and pulmonary edema) and clinically assessed volume status of the patient, an intravenous fluid bolus of crystalloid or colloid should be administered. In severe sepsis and septic shock, the Surviving Sepsis Campaign guidelines recommend administering 500–1,000 mL of crystalloids or 300–500 mL of colloids over 30 min.[2] In the 1970s, a dynamic fluid challenge algorithm was proposed for fluid resuscitation in shock.[3] Using a pulmonary artery catheter to measure pulmonary artery wedge pressure (PAWP) or a central venous catheter to measure CVP, the following was recommended 10 min after a fluid bolus: If the change in PAWP is <3 mmHg (for CVP 2 mmHg), fluid administration should be continued; if the change in PAWP is in the 3–7 mmHg range (for CVP 2–5 mmHg), fluid administration should be stopped and then after 10 min, the situation is reevaluated. If there is a change of >7 mmHg (for CVP 5 mmHg), fluid should be stopped.[3,4] This protocol has not been based on trials and modifications of this fluid challenge algorithm have been suggested with regard to the type of fluid, rate of fluid administration, goals, and safety limits.[4] However, the fluid volume or administration rate that constitutes an adequate challenge has not been determined.[5] In general, only half of patients who are given a fluid challenge will respond and in an effort to avoid the risks of fluid challenge in unstable patients (i.e., pulmonary edema) who are not fluid responsive, other dynamic techniques have been investigated such as passive leg raising, and changes in CVP during spontaneous breathing and CO during positive pressure ventilation.[5,6] However, these other dynamic techniques also have their limitations.[4]

Use of Pulmonary Artery Catheter

Placement of a pulmonary artery (PA) catheter should be considered in most cases when an initial trial of fluids is not helpful, the specific cause of shock is not known, or vasoactive drugs are required.[7,8] The risks and benefits of a PA catheter should be carefully weighed. The most useful parameters are cardiac index, PCWP, and SVR for evaluating the cause and the response to treatment. If the patient does not have pulmonary hypertension, severe right ventricular dysfunction, significant tricuspid regurgitation, or severe pulmonary disease, then a central venous catheter may be helpful to monitor and guide fluid management.[9] A more thorough discussion of the use of the PA catheter is provided elsewhere in this book.

PHARMACOLOGIC SUPPORT

Two classes of drugs are used in the treatment of shock: vasopressor/inotropic drugs and, in special situations, vasodilators.

Pharmacologic support of the circulation is possible due to a variety of agents that have different specific effects on the cardiovascular system. Generally, these drugs are broadly classified into two categories: vasopressor/inotropic drugs and vasodilators. In shock treatment, the vasopressor/inotropic drugs are the main pharmacologic agents utilized, whereas the vasodilator drugs are generally used adjunctively and only in special circumstances. These vasopressors/inotropic drugs can be tailored to effect various changes in CO and vascular resistance depending on their mechanism of action, receptor-binding properties (receptor type and potency) and tissue target.

Receptor Type and Actions

The vasopressor/inotropic drugs used in shock treatment use either adrenergic/dopaminergic or nonadrenergic receptor.

The vasopressor/inotropic drugs produce their effects using several different mechanisms of action that can be categorized into adrenergic receptor and nonadrenergic receptor-mediated mechanisms (Fig. 49-2). The adrenergic receptor (AR) drugs mediate their effects through the alpha- and beta-receptors as well as the dopaminergic receptors which are located mainly on the nerve terminals and effector cells of the autonomic nervous system. The ratio of activity varies among the adrenergic agents from predominantly alpha-activity to predominantly beta-activity. The nonadrenergic mechanisms are more diverse and may not be mediated by discrete receptors but by interaction with various messenger systems (e.g., phosphodiesterase (PDE) III inhibitors).

The adrenergic receptor-mediated agents comprise the largest group of medications that are used in the treatment of shock states. These agents can be further subcategorized into the endogenous or natural catecholamines (e.g., norepinephrine) and synthetic catecholamines and the noncatecholamine drugs. In order to use these agents appropriately, it is important to have an accurate understanding of the properties of the different ARs.

The adrenergic-receptor agonists may affect three types of receptors: α, β, and dopamine (DA).

An understanding of the various adrenergic receptors, including the types and effects mediated by them, is the key to using them appropriately. In the sympathetic component of the autonomic nervous system, preganglionic nerves originate in the thoracic and lumbar spinal cord; axons from these cells synapse with the cells located in a nearby chain of ganglia. Usually, this neuron then synapses with another cell in the ganglion (postganglionic neuron). The axon of the postganglionic neuron projects to the effector cell receptors on the target tissue. The adrenergic receptors, identified as α- and β-receptors, or dopaminergic receptors, identified as dopamine-1 (DA1) and dopamine-2 (DA2), are located on the presynaptic terminals and/or the postsynaptic cell.

Generally, stimulation of the α1-AR peripherally mediates arterial and venous vasoconstriction. In the heart, α1-AR also has a minimal inotropic effect and a reflex negative chronotropic effect.

Generally, the α_1-receptors are postsynaptic, whereas the α_2-receptors are mainly presynaptic, but are also present at postsynaptic sites in various tissues. However, the presynaptic α_2-ARs inhibit the release of norepinephrine depending on the stimulatory intensity and can counter the vasoconstriction. The α-AR is primarily located in the eye, venous and arterial blood vessels, gastrointestinal tract, spleen, bladder, and liver. Activation of α-AR in the smooth muscle of the blood vessels leads to significant venous and arterial vasoconstriction. Both α1-AR and α_2-AR mediate positive inotropic responses. However, this inotropic effect

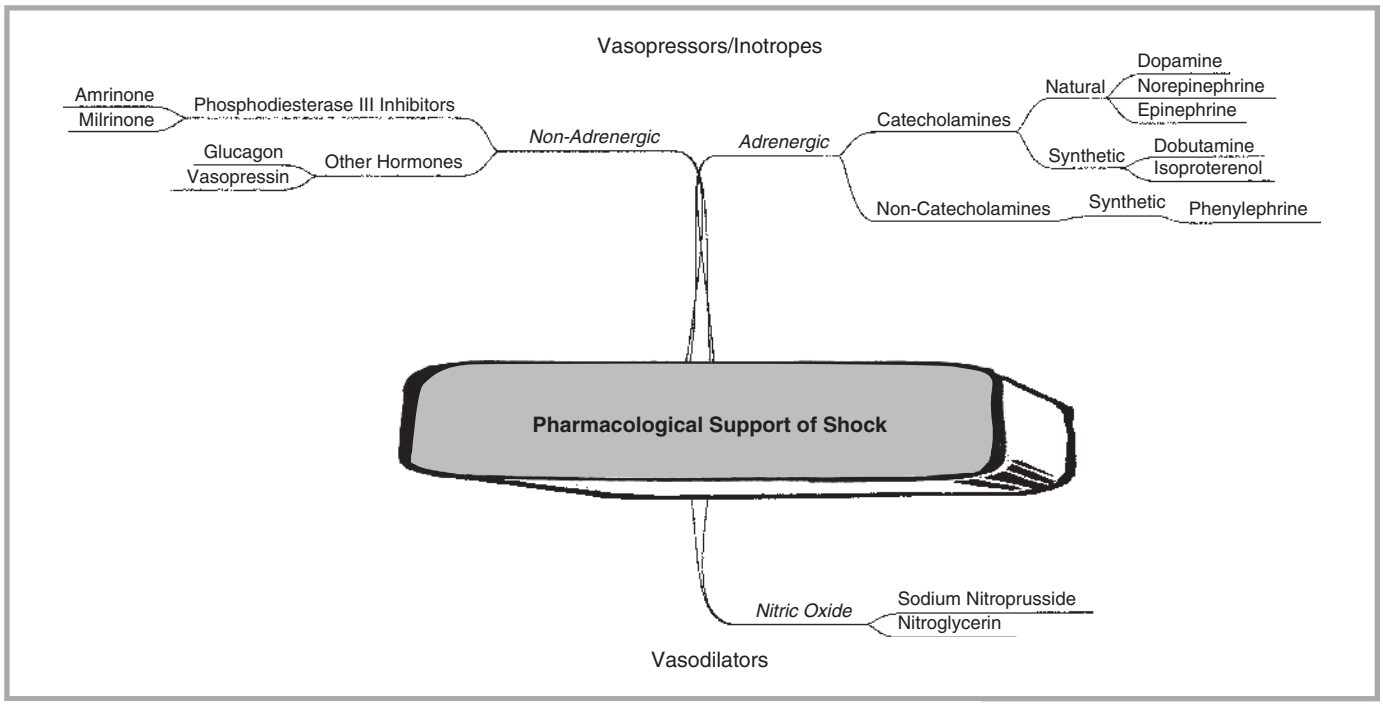

FIGURE 49-2

The drugs used in the treatment of shock are categorized as vasopressors/inotropes or vasodilators according to mechanism of action and type of drug. The vasopressor/inotrope drugs are subcategorized as adrenergic receptor or nonadrenergic receptor mechanisms. The adrenergic receptor drugs are further subcategorized as catecholamines or noncatecholamines, which may be synthetic or natural. The nonadrenergic drugs are subcategorized as phosphodiesterase inhibitors or other hormones. The vasodilators mediate their effects through the release or production of nitric oxide, an endogenous mediator of smooth muscle relaxation.

is believed to be of minor importance in the heart.[10] At high doses, the potency of the agonists at the α_1-AR increases from dopamine to norepinephrine and then epinephrine.

The β_1-ARs are predominantly located in the heart. The β_2-ARs are located in the smooth muscle (bronchial, vascular, gastrointestinal, and genitourinary) as well as skeletal muscle and liver. The β_1-ARs mediate increases in heart rate and cardiac contractility, causing increased cardiac oxygen consumption as well as decreases in atrioventricular time. The β_2-ARs mediate vasodilatation.

The β_1-AR mediates cardiac contractility and rate. The β_2-AR mediates vasodilatation.

Dopamine stimulates both DA1 and DA2 receptors depending on drug concentration. Low-dose stimulation of DA1 receptors, which vary in density according to the vascular bed, causes vascular smooth muscle relaxation and vasodilatation predominantly in the mesenteric and renal vascular beds. Stimulation of the DA2 receptors on the presynaptic sympathetic nerve terminals inhibits norepinephrine release to indirectly induce vasodilatation. The catecholamines are removed by reuptake mechanisms and metabolized by catechol-*O*-methyl transferase (COMT), and to a lesser extent by monoamine oxidase (MAO). The noncatecholamine drugs, such as phenylephrine, are metabolized primarily by MAO. The type of enzymatic degradation affects the duration of drug action. If MAO inhibitors are present they will also have an effect.

Dopamine is an important CNS neurotransmitter that in progressively higher pharmacologic doses has effects on dopamine receptors and α- and β-adrenergic receptors.

The nonadrenergic vasopressor/inotropic drugs and the vasodilators are not catecholamines and do not mediate their effects through adrenergic receptors. These include the hormones vasopressin and glucagon, the phosphodiesterase III inhibitors amrinone and milrinone and a new class of inotropes, the calcium-sensitizing drug, levosimendan. Glucagon mediates its effects by binding to glucagon receptors and increasing cellular cAMP levels. Vasopressin binds to V_1 receptors on the vascular smooth muscle, causing vasoconstriction

Glucagon mediates its effect through the glucagon receptor.

Vasopressin mediates its vasoconstrictive effects by the V_1 receptor on vascular smooth muscle.

Milrinone mediates its effects by selectively inhibiting the class III phosphodiesterases and increasing cAMP levels.

Levosimendan mediates its effects through enhanced sensitivity of contracting myofilaments to calcium.

through the contraction of vascular smooth muscle. Amrinone and milrinone are selective inhibitors of the class III phosphodiesterase iso-enzymes that increase cAMP by interfering with the degradation of cAMP to 5'-AMP by phosphodiesterase (PDE). PDE inhibitors produce peripheral vasodilatation, reduce arterial blood pressure and may increase CO through after-load reduction. The calcium-sensitizing drugs mediate their effects through enhanced sensitivity of contracting myofilaments to calcium as well as PDE inhibition. The vasodilators nitroprusside and nitroglycerin are considered nitro-vasodilators and mediate their effects through a nitric oxide mechanism.

Specific Vasopressors, Inotropes, and Vasodilators

To use these drugs appropriately in the treatment of shock, a thorough knowledge and understanding of their mechanism of action, indications, therapeutic issues, and potential adverse effects is required. Each of these agents has differing effects on cardiac contractility and rate, and vascular resistance, (Fig. 49-3) which can lead to profound changes in mean arterial pressure, CO, SVR, and PCWP (Fig. 49-4).

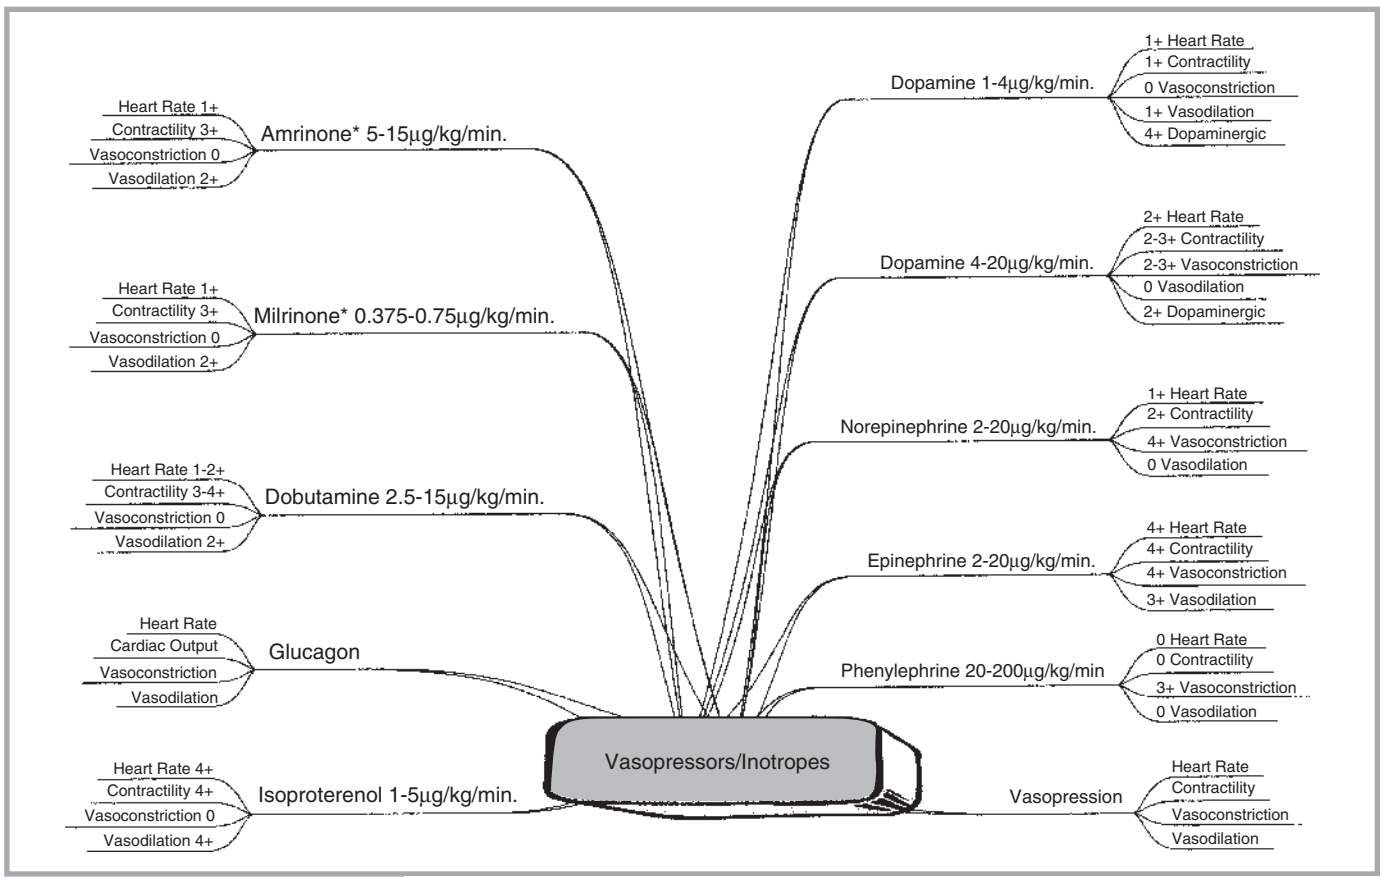

FIGURE 49-3

The effect of vasopressor/inotropic drugs on the components of the cardiovascular system are shown on a scale of 0 to 4+ for heart rate, contractility, vasoconstriction, vasodilation, and dopaminergic effects. This activity is different from the net effect of the drug produced in the patient. For example, norepinephrine has a significant effect (2+) on cardiac contractility through its β_1-adrenergic receptor, but this tends to produce no effect or only a small effect on CO because of its greater vasoconstrictor effect (4+) through its strong α_1-adrenergic activity. Note that only dopamine has dopaminergic effects and a dopaminergic category. The infusion dose is also shown for each drug. The *asterisk* for amrinone and milrinone indicates that a loading dose is needed. (Information adapted from Parillo[67]).

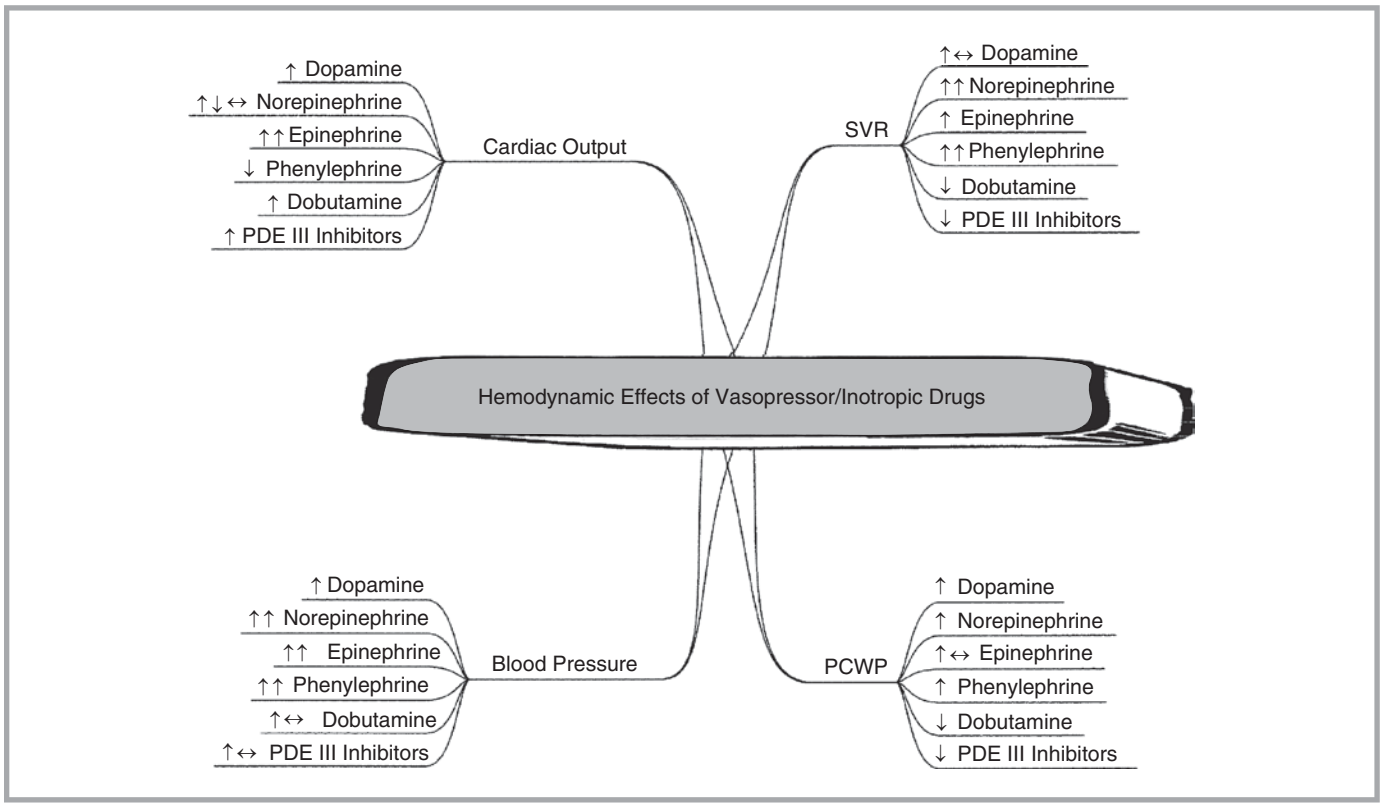

FIGURE 49-4

A general guideline of the net effect of some vasopressor/inotropic drugs on various hemodynamic parameters. The number and direction of the arrows (↑, increase; ↔, unchanged; ↓, decreased) indicate the magnitude of the effect on each hemodynamic parameter. The net effect of each drug is partially dependent on its direct action, derived from its activity at various receptor sites (see text), as seen in Fig. 49-3. For example, phenylephrine, a strong vasoconstrictor (+3) without inotropic effects (0) as seen in Fig. 49-3, tends to cause a net increase in SVR and a net decrease in CO because of its strong α_1-adrenergic vasoconstrictor response. The net effect of each drug will also tend to vary depending on the clinical situation (e.g., cardiogenic shock or septic shock), the volume status, and the presence or absence of hypotension. *SVR* systemic vascular resistance.

Adrenergic Drugs

Dopamine

Dopamine is a catecholamine-like agent, an endogenous precursor of norepinephrine, and an important central and peripheral neurotransmitter. It is present in sympathetic nerve endings as well as the adrenal medulla. At pharmacologic concentrations, it has direct effects on three types of receptors: the β-ARs, (β_1 and β_2), α-ARs (α_1 and α_2), and the dopaminergic receptors (DA1 and DA2) in a dose-dependent manner. The DA1 receptors mediate vasodilatation in the renal, mesenteric, coronary, and cerebral vascular beds. The DA2 receptors inhibit norepinephrine release and also induce the central effects of nausea and vomiting. The DA2 receptors are stimulated at rates of 0.2–0.4 μg/kg/min. The DA1 receptors are stimulated at a concentration of 0.5–3.0 μg/kg/min. An infusion at these doses causes an increase in glomerular filtration rate, renal blood flow, and sodium excretion. A further increase in dose from approximately 5–10 μg/kg/min increases β_1-AR effects causing a positive inotropic effect on the myocardium. At >10 μg/kg/min, predominantly α-AR effects are seen leading to vasoconstriction;[11] the actual dose at which these effects occur varies widely between patients and therefore titration is required.

Low-dose dopamine has been used in the past to maintain or protect renal function but there is no data to support an improved outcome and because of the possibility of dysrhythmias dopamine is no longer recommended in this setting.[12-14]

The cardiovascular response of dopamine is dependent on the dose. Low rates of infusion produce vasodilatation in the renal, mesenteric, coronary, and cerebral vascular beds with minimal effect on other blood vessels or on the heart. Stimulation of the D_1 receptor will result in vasodilatation, natriuresis, and diuresis. D_2 receptor activation results in hypotension, bradycardia, and local vasodilatation.

At moderate doses, approximately 5–10 μg/kg/min, dopamine increases the rate and force of contraction of the heart, thus increasing CO; this is mediated by β_1-receptor activity. The increased CO is mainly due to an increase in SV and less so by an increased HR. Dopamine predominantly increases systolic blood pressure (SBP) without affecting diastolic blood pressure (BP). At higher doses, 10–20 μg/kg/min, dopamine produces α-receptor mediated vasoconstriction, increasing mean arterial pressure (MAP), SVR, and pulmonary vascular resistance (PVR).[11] Furthermore, venous capacity is reduced through vasoconstriction, which increases PCWP, especially at higher dopamine doses.

Indications for dopamine include shock associated hypotension, as a second-line drug for symptomatic bradycardia-associated hypotension, and for right ventricular failure with hypotension.

Indications for dopamine include shock associated hypotension (MAP <65 mmHg), as a second-line drug for symptomatic bradycardia-associated hypotension unresponsive to atropine, and for right ventricular failure with hypotension. After initiating fluid resuscitation, dopamine is recommended as one of the first-line agents for hemodynamic support in septic shock[2]; it may be the preferred agent in patients with systolic dysfunction. However, it causes tachycardia and may be more arrythmogenic than phenylephrine or norepinephrine[2].

Dopamine can be used in cardiogenic shock only after adequate fluid resuscitation unless pulmonary edema is present. Tachycardia and increased peripheral resistance may exacerbate myocardial ischemia. Therefore, dopamine should be titrated to the lowest effective dose in cardiogenic shock to minimize the increases in myocardial oxygen demand.

Hemodynamic effects may be potentiated by MAO inhibitors, requiring dopamine dose reduction.

Dopamine is administered as a continuous infusion because of its short half-life (approximately 1 min). It is metabolized by the MAO and COMT enzymes and the metabolic products are renally excreted.[11] The hemodynamic effects of dopamine may be potentiated by MAO inhibitors, requiring significant dose reduction. Cardiac effects of dopamine are antagonized by beta-blocking agents, and the vasoconstrictive effects of dopamine are antagonized by alpha-blocking agents. Additionally, the concomitant administration of phenytoin and dopamine may cause hypotension due to possible catecholamine depletion by dopamine and cardiac depression caused by phenytoin. Dopamine is contraindicated in patients with pheochromocytoma as it may precipitate a hypertensive crisis. In general, the side effects of dopamine include excessive sympathomimetic-related effects, increased myocardial oxygen consumption leading to myocardial ischemia, hypertension, and increased PCWP. Reduction in urine output, tachycardia or the occurrence of arrhythmias may be indications to decrease or discontinue dopamine. Noncardiac adverse effects associated with dopamine include, nausea, vomiting, and headache. Because dopamine has such a short half-life, any adverse effects should subside within minutes of a dose reduction or discontinuation. Extravasation of dopamine into the tissue can cause ischemic necrosis and sloughing. Therefore, administration of the drug should be through a central line, but in emergency situations, it can be given through a large peripheral vein until central access is obtained. If extravasation occurs, local administration of 10–15 mL of saline and 5–10 mg of the α-receptor blocking agent, phentolamine[11] should be instituted immediately. Sympathetic blockade with phentolamine results in an increase in blood flow if the area is infiltrated within 12 h.

Norepinephrine

Norepinephrine (NE) is a natural precursor of epinephrine and the neurotransmitter of the postganglionic sympathetic nervous system. It is also released by the adrenal medulla. NE exerts its effects predominantly through α_1- and α_2-adrenergic vascular smooth muscle receptors and cardiac β_1-ARs; it has minimal β_2-AR vasodilator effects. NE produces vasoconstriction and augments MAP via its major α-AR activity, but it is a weaker inotrope. At doses less than 30 ng/kg/min, it typically stimulates the β_1-ARs and at higher doses has an increasing α-adrenergic receptor effect.[11]

The effects of NE include increased systolic and diastolic pressures and increased SVR; reflex vagal activity may cause a reduction in HR. The vasoconstrictor action is much more

potent that its effect on cardiac contractility, which could lead to an increased afterload and a reduced CO. However, its vasoconstrictor effects will also act on venous capacitance vessels to increase preload and CO. Thus, there is little net effect on CO. Therefore, the increase in MAP occurs predominantly by elevating peripheral vascular resistance. Because NE receptors are also less abundant in the coronary and cerebral vasculature, NE tends to augment coronary blood flow, especially in shock.

NE increases MAP primarily by increasing SVR.

NE is indicated in patients with hypotensive emergencies requiring a rapid increase in MAP to maintain adequate organ perfusion pressures. Its major use is in patients with hypotensive shock and a low SVR unresponsive to volume resuscitation and other weaker inotropic/vasopressor drugs. It is used in a number of different shock conditions including septic shock, neurogenic shock, severe cardiogenic shock, right ventricular failure and hypotension, and massive pulmonary embolism. The most common use of NE may be in septic shock or in neurogenic shock where a low BP unresponsive to dopamine is typically found associated with a low vascular resistance. NE is more potent than dopamine in reversing hypotension in septic shock and has been recommended as a first-line agent.[2,15] NE is beneficial in septic shock because it reverses vasodilatation and improves myocardial function with an unchanged or increased CO, increased coronary blood flow, and a small decrease or no change in cerebral blood flow.

NE's vasoconstrictor action is much more potent that its effect on cardiac contractility, which could lead to an increased afterload and a reduced CO. However, its vasoconstrictor effects will also act on venous capacitance vessels and increase preload and CO. Thus, there is little net effect on CO.

In severe cardiogenic shock (Fig. 49-5), it is used to reverse hemodynamically significant hypotension (systolic BP <70 mmHg), but is most efficacious if the hypotension is secondary to a low vascular resistance. Otherwise, it acts as a temporizing agent in ischemic heart disease and shock until further mechanical hemodynamic support (e.g., intra-aortic balloon pump) and other treatments can be implemented.

The major use of NE is in patients with hypotensive shock and a low vascular resistance unresponsive to other weaker inotropic/vasopressor drugs.

NE is a systemic vasoconstrictor which has long been thought to cause renal, splanchnic, and pulmonary vascular vasoconstriction. No conclusion can be made concerning the effect of NE on splanchnic blood flow as clinical studies have shown variable results in septic shock patients.[16] Although NE (as well as other α-adrenergic agonists) may impair renal perfusion in the setting of hypotension and hypovolemia, recent clinical data indicate that NE can be used safely in vasodilatory shock states (in association with adequate fluid resuscitation) without compromising renal function.[17,18] NE is not recommended for use in the presence of a decreased intravascular volume nor in the presence of significantly reduced cardiac function associated with an elevated SVR or PCWP. It should also be used with caution in the presence of PA hypertension.

NE may increase PCWP and CVP through its potent vasoconstrictor effects.

NE should be used with caution in the presence of pulmonary hypertension.

The vasopressor effect of NE is enhanced by simultaneous use of tricyclic antidepressants such as amitriptyline or by guanethidine. Unlike dopamine, MAO inhibitors do not have a marked effect on the action of NE, because MAO only metabolizes it at the sympathetic nerve terminals, and COMT metabolizes intravenously administered NE. NE should be administered only by the central venous route because its extravasation may produce severe local tissue damage; this can be treated with liberal infiltration of the tissue with phentolamine.

The potential adverse effects include anxiety, decreased skin, visceral, renal, and muscle blood flow, headache, tremor, reflex bradycardia, and angina. NE should be avoided in pregnant women as it can lead to an increased frequency of uterine contractions.

Epinephrine

Epinephrine (adrenaline) is a naturally occurring catecholamine produced by *N*-methylation of NE in the adrenal medulla.[11] Its production and release are regulated by sympathetic innervation of the adrenal gland. Epinephrine binds and activates β_2-, β_1-, and α-AR in a dose-dependent manner. The effects of epinephrine at lower doses are mediated via the β-AR, causing vasodilatation, whereas higher doses primarily affect the α-AR resulting in vasoconstriction. Epinephrine is one of the most potent vasoconstricting drugs available. It causes increased myocardial contraction, electrical activity, automaticity, and oxygen requirements. In sepsis, the increase in MAP primarily results from a direct effect on myocardial contractility (increased SV) with only moderate increases in HR and SVR. Other important features of epinephrine are its ability to cause bronchial muscle relaxation

Epinephrine is a naturally occurring hormone that activates both α- and β-AR.

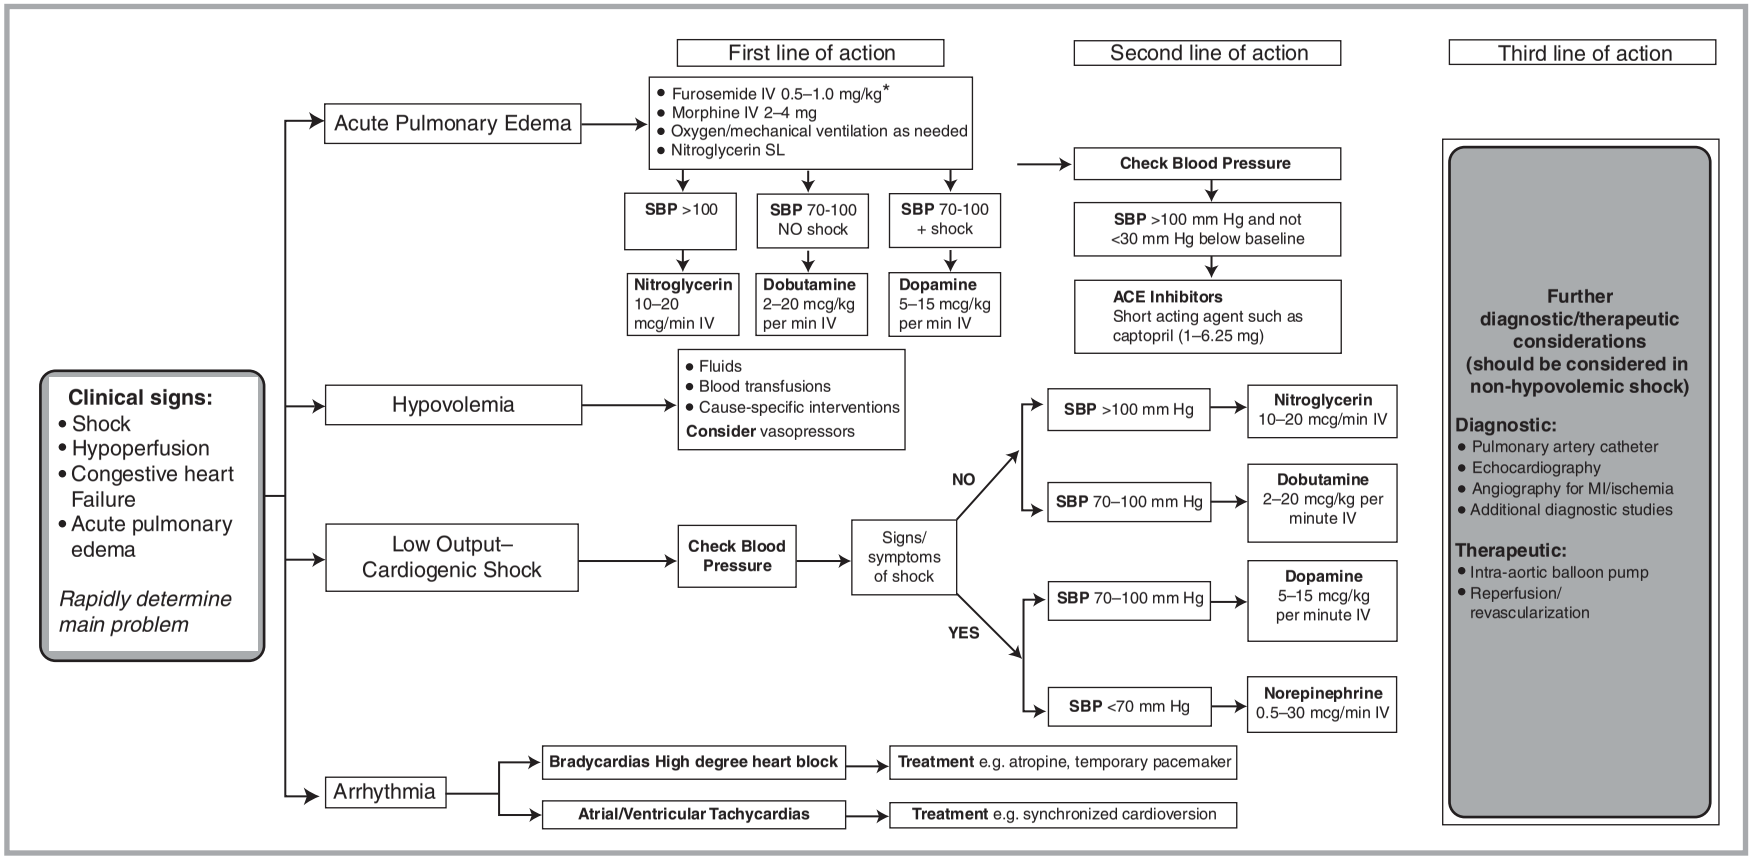

FIGURE 49-5

Algorithm for the initial evaluation and treatment of cardiogenic shock with or without acute pulmonary edema during complicated ST-elevation myocardial infarction. The algorithm starts with the evaluation and rapid determination of the main problem, i.e., acute pulmonary edema, hypovolemia, low output-cardiogenic shock or arrhythmia. Initially, patients with hypotension should be assessed for hypovolemia and if there is no clinical evidence for volume overload or increased filling pressures, then careful fluid challenge should be given. In particular, those with hypotension, clear lungs, and inferior wall MI, suggesting possible right ventricular infarction (assessed by V4R EKG lead and echocardiogram), will usually need to be given fluid challenge as long as jugular venous pressure is not increased. Depending on response, treatment and especially the use of vasoactive/inotropic drugs, is then essentially based on the main problem, blood pressure (BP) and the presence or absence of signs/symptoms of shock. Ongoing evaluation with diagnostic studies may include pulmonary artery catheterization (PAC) and/or echocardiogram and angiography. PAC monitoring is recommended (Class 1) for progressive hypotension unresponsive to fluid or when fluid is contraindicated as well as for suspected mechanical complications (not evaluated by echocardiogram). In pulmonary congestion, oral short-acting ACE inhibitors should be given to normotensive and hypertensive patients unless there are other contraindications. However, those with hypotension or borderline BP with pulmonary congestion frequently need support with inotropic/vasopressor drugs or intra-aortic balloon pump (IABP) or both to treat pulmonary congestion and hypoperfusion. In general, therapeutic considerations are mechanical circulatory support (e.g., IABP), and reperfusion (e.g., fibrinolytic therapy)/revasculization (e.g., percutaneous coronary intervention [PCI]; coronary artery bypass grafting) interventions.[20] IABP use is recommended for cardiogenic shock not quickly reversed with pharmacological treatment. Fibrinolytic therapy is recommended for patients with shock who are not suitable for more invasive care with revascularization. (Data from Antman et al,[20] illustration by Alice Y. Chen).

or dilation, and to inhibit the release of antigen-induced inflammatory mediators from mast cells.

The indications for epinephrine include refractory circulatory shock; anaphylaxis with or without shock; severe allergic reactions; symptomatic bradycardia unresponsive to atropine, dopamine, and transcutaneous pacing. Epinephrine is also indicated in cardiac arrest resulting from ventricular fibrillation (VF), pulseless ventricular tachycardia (VT), asystole, and pulseless electrical activity.[19,20] In cardiac arrest, epinephrine can increase coronary and cerebral blood flow. It is indicated, as a second-line drug (after glucagon) in treating β-adrenergic blocker cardiotoxicity associated with hypotension, shock and/or bradycardia. Although controversial, it has been suggested that epinephrine should be the first alternative agent in septic shock patients not responding to dopamine or NE.[2]

Epinephrine may cause increased myocardial oxygen demand, ischemia, and angina secondary to an increased HR and BP. It may also increase lactate concentrations either by reduction of organ perfusion or its hypermetabolic effects. The chief concern with the use of epinephrine is its potential to decrease regional blood flow, specifically in the splanchnic circulation.[15,21,22] However, a recent study comparing NE plus dobutamine vs. epinephrine for the management of septic shock showed no difference in efficacy and safety between the two regimens.[23] The potential adverse effects of epinephrine include anxiety, headache, tremor, and agitation. More serious reactions include cerebral hemorrhage, tachycardia, arrhythmias, hyperglycemia, angina, and poor cutaneous perfusion.

Phenylephrine

Phenylephrine is a rapid-acting, selective α_1-adrenergic agonist drug that acts as a powerful peripheral and arterial vasoconstrictor.[24] Accordingly, phenylephrine elevates MAP mainly through an increase in SVR. The elevated MAP may produce a reflex bradycardia and a small decrease in CO, which may be more marked in patients with preexisting cardiac dysfunction; renal perfusion may also decrease.

Phenylephrine is a powerful vasoconstrictor that elevates MAP primarily through an increase in SVR.

Because phenylephrine is a vasocontrictor without positive inotropic effects, there have been concerns regarding its potential to reduce HR and CO, especially in hypodynamic states or in the setting of unrecognized cardiomyopathy (e.g., sepsis-induced cardiomyopathy). It can increase MAP in fluid-resuscitated patients in septic shock and may be especially useful in patients with tachyarrhythmias associated with the use of β-adrenergic drugs.

Phenylephrine is probably most useful as an alternative vasopressor for patients who develop tachyarrhythmias.

There is only one study evaluating the clinical effects of phenylephrine in septic shock patients ($n=13$), who remained hypotensive (MAP, 57 mmHg; CI, 3.3 L/min/m^2) despite either low-dose dopamine or dobutamine and fluid administration.[25] Phenylephrine was titrated to a mean dosage of 3.7 μg/kg/min to maintain MAP >70 mmHg, which resulted in increases in MAP, SVR, CI, SI, and urine output. Increases in oxygen consumption and delivery occurred as well. In hyperdynamic septic patients without hypotension, phenylephrine (70 μg/min) increased MAP, CI, SI and slightly decreased HR by 3 beats/min. At the same dosage in normotensive patients with cardiac disease, phenylephrine caused an increase in BP and SVR but decreased CI without change in HR.

Phenylephrine is a powerful vasoconstrictor used to treat hypotension during anesthesia-induced loss of sympathetic tone, spinal cord shock, and for hypotension and shock associated with sepsis. However, phenylephrine has been studied minimally in septic shock, and thus it is difficult to state with certainty its role in septic shock treatment. Phenylephrine has been reported to reduce splanchnic blood flow and oxygen delivery in septic shock patients.[26] It does not have positive inotropic properties and may secondarily decrease SV and CO. As a result, phenylephrine is now recommended as a third-line therapy in the treatment of septic shock.[2] However, it appears to be most useful as an alternative in patients with septic shock who develop β-AR agonist-associated tachyarrhythmias. It was previously used to treat supraventricular tachycardia with hypotension.

Phenylephrine is a noncatecholamine but has a molecular structure similar to epinephrine. Unlike epinephrine, it is metabolized by MAO but not by COMT; it is a short-acting agent. Because the drug is a pure vasoconstrictor, there is a tendency for CO to fall due to an increase in afterload. In patients with impaired myocardial function or in valvular heart

disease (aortic insufficiency or mitral regurgitation), it may significantly decrease CO. In septic shock, it has been used as an alternative to NE. This agent decreases renal and splanchnic blood flow and may increase oxygen consumption and delivery. As a vasoconstrictor, this medication may adversely increase PA pressure and should be used with caution in patients with right heart failure.

Dobutamine

Dobutamine is a catecholamine derivative, synthesized to have potent inotropic activity without peripheral vascular effect. Its salutary effects result from its administration as a racemic mixture with the levo-isomer having a strong α_1-AR effect and the dextro-isomer having strong β_1- and β_2-AR effects.[11]

Dobutamine is a synthetic catecholamine that produces strong inotropic effects and a net mild vasodilatory effect.

Dobutamine produces its strong inotropic effects through stimulation of both β_1- and α_1-ARs in the myocardium. It produces a mild vasodilatation because of the effect of β_2-AR stimulation on the peripheral vasculature and cardiac musculature and is more potent than the vasoconstrictor response produced by α_1-AR stimulation. Therefore, total peripheral resistance is mildly decreased or unchanged. Dobutamine enhances automaticity of the sinus node to a lesser degree than isoproterenol; however, augmentation of atrioventricular and intraventricular transmission is similar for the two agents.[24] Dobutamine does not stimulate dopaminergic receptors, but it does increase renal and mesenteric blood flow through augmentation of CO.

Indications for dobutamine include patients with elevated left ventricular filling (LV) pressures and a low CO state. In conjunction with moderate volume loading, it is the main treatment for patients with hemodynamically significant right ventricular (RV) infarction.

Dobutamine is best used in septic shock patients with left ventricular dysfunction: low cardiac index (CI <2.5 L/min/m^2) and elevated filling pressures.

The indications for the use of dobutamine, which increases ventricular contractility and produces mild vasodilatation, in patients with septic shock are poorly defined; there is concern that the vasodilatory effects of dobutamine may augment the hypotension. In septic shock, cardiac index is usually maintained in fluid resuscitated patients though cardiac contractile function is impaired.[27] Severe cardiac dysfunction (CI <2.5 L/min/m^2) may develop in a small percentage of patients, and if filling pressures are elevated, dobutamine may be helpful. However, no benefit has been shown to increasing CI to achieve supranormal levels of O_2 delivery. Because of its vasodilatory effects, it is used in conjunction with other vasopressors in the management of septic shock.

The conventional infusion rate of dobutamine is 2–20 μg/kg/min and should be titrated according to the desired response without increasing the heart rate to more than 10% above baseline.[19] At doses between 5 and 15 μg/kg/min, there is a greater inotropic effect than chronotropic effect. It characteristically decreases PCWP and CVP with only a mild effect on vascular resistance. Moreover, hemodynamic monitoring is recommended. Avoid dobutamine if the systolic BP is <100 mmHg and there is evidence of shock.[20] It is not indicated for the treatment of congestive heart failure (CHF) due to diastolic dysfunction, and it is contraindicated in obstructive cardiomyopathies (hypertrophic cardiomyopathy, etc), atrial fibrillation, or flutter. In severe aortic stenosis, it may cause or worsen cardiac ischemia with no increase in CO. It is contraindicated in poisoning or drug-induced shock. Allergic reactions in sulfite-sensitive patients may occur from the commercial preparation of dobutamine because it contains sodium bisulfite.

Dobutamine is not indicated in CHF due to diastolic dysfunction.

Dobutamine is contraindicated in poison/drug-induced shock and in hypertrophic cardiomyopathy and other obstructive cardiomyopathies.

Dobutamine and dopamine have been used concomitantly at moderate doses of 5.0–7.5 μg/kg/min.[20,28] Side effects (e.g., increases in PCWP) may be reduced when both are used together. However, this combination does not seem to affect mortality.[20]

Adverse effects of dobutamine include cardiovascular effects and arrhythmias, BP variations, and tachycardia, which may produce myocardial ischemia. Dobutamine doses greater than 20 μg/kg/min tend to consistently produce tachycardia, especially if the patient is hypovolemic, but doses between 2 and 20 μg/kg/min are less likely to produce tachycardia than either dopamine or isoproterenol. Myocardial ischemia may occur, especially if it produces tachycardia resulting in increased myocardial oxygen demand. Miscellaneous adverse effects include headache, tremor, nausea, and hypokalemia.

Isoproterenol

Isoproterenol is a synthetic catecholamine produced by adding an *N*-isopropyl moiety to NE, which provides it with significant nonselective β-AR agonist properties and a very low affinity for the α-AR. The drug has inotropic, chronotropic, and vasodilatory effects. The β-adrenergic properties increase myocardial contractility and rate. Indirectly, it also produces a reflex chronotropic response by decreasing SVR via its vasodilatory properties, causing significant tachycardia.

Isoproterenol is a synthetic β-adrenergic agonist with inotropic, chronotropic, and vasodilatory effects.

Isoproterenol produces a net increase in CO in a euvolemic patient but a decrease in CO may occur in the hypovolemic patient because of reduced venous return from vasodilatation. The improvement in CO is related more to an increase in heart rate than SV. Its β_2-agonist vasodilatory properties decrease diastolic blood pressure and may also redirect blood flow from the splanchnic vasculature to the higher β_2-AR-dense skeletal muscle vascular bed.

The previously broad indications for isoproterenol have been reduced due to the availability of safer and more effective drugs. Currently, the indications for isoproterenol include the temporary control of symptomatic bradycardia or heart block (if an external pacer is not available), for bradycardia in the denervated heart transplant patient, and in *torsades de pointes*[29] unresponsive to magnesium sulfate.

Indications for isoproterenol use have been narrowed by the availability of safer and more effective drugs.

Isoproterenol requires very careful cardiovascular monitoring, especially continuous electrocardiographic monitoring, as it may increase myocardial ischemia by increasing myocardial oxygen requirements. Accordingly, it should be avoided in adults with coronary artery disease. Symptoms of ischemia such as chest pain should lead to a quick reduction in dose. The cardiac effects may also trigger palpitations, sinus tachycardia, and life-threatening arrhythmias. It should *not* be used for the treatment of cardiac arrest, drug-induced shock, except in β-adrenergic blocker and calcium channel blocker poisoning, or conditions where epinephrine is being administered as it may cause VF or tachycardia. It may be safely administered via a peripheral intravenous catheter. MAO inhibitors or tricyclic antidepressants do not alter its effects. Isoproterenol causes less hyperglycemia than epinephrine because insulin secretion is mediated by β-adrenergic activation of pancreatic islet cells.

Isoproterenol requires careful cardiovascular monitoring, especially electrocardiographic, as it may increase myocardial ischemia by increasing myocardial oxygen requirements.

Nonadrenergic Drugs

Amrinone and Milrinone

Amrinone and milrinone are part of a group of synthetic PDE III inhibitors with significant inotropic and vasodilatory effects; they are classified as ino-dilators. Milrinone has replaced the use of amrinone because of the more frequent thrombocytopenia found with amrinone.

Milrinone is a PDE-III inhibitor that has significant inotropic and vasodilatory effects.

The hemodynamic effects of increased CO associated with decreased preload and SVR are dose-related and similar to dobutamine. These agents cause vasodilatation and a subsequent reduction in SVR and BP. At low doses, MAP does not decrease due to a balance between the increase in SV and the reduction in SVR. High doses can cause tachycardia. These drugs decrease right atrial pressure, mean PA pressures, vascular resistance, and dilate coronary arteries. The pulmonary vasodilator effect may help to augment right ventricular function.

Unlike catecholaminergic drugs, the hemodynamic effects of milrinone are secondary to PDE III inhibition causing increased cAMP concentrations. Accordingly, adrenergic-blocking drugs do not reverse its inotropic manifestations.

The indication for milrinone is severe CHF unresponsive to diuretics, vasodilators, and standard inotropic agents.[19] The vasodilatory effects and relatively long half-life makes it difficult to use these agents as monotherapy in patients with cardiogenic shock and its use is not recommended in the ST-segment elevation myocardial infarction.[20] Milrinone can be used with other agents to enhance myocardial contractility. There have been few studies evaluating the effects of milrinone in sepsis and septic shock. In septic shock, the inotropic effects of the drug may improve SV, but its vasodilator effects, which decrease SVR, may worsen or prolong hypotension. These agents cannot be recommended for use in septic shock because of the small number of patients studied and the concomitant use of adrenergic agents.[30]

Indication for milrinone is severe CHF, unresponsive to diuretics, vasodilators, and standard inotropic agents.

Because of its greater selectivity for PDE III, shorter half-life of 30–60 min and fewer side effects, milrinone is the PDE inhibitor of choice for inotropic support. Maximum benefit requires a loading dose and dose–response titration using central hemodynamic monitoring. A milrinone loading dose is usually ≤0.5 μg/kg and a continuous infusion rate of 0.25–0.75 μg/kg/min is recommended.[19] Impaired drug clearance may occur in patients with renal or hepatic dysfunction. Both of these agents need to be initiated at lower doses in patients with renal dysfunction.

Milrinone may cause cardiac ischemia, hypotension, tachyarryhthmia, and thrombocytopenia.

Thrombocytopenia with milrinone is rare (<1%). These agents should be used with caution in patients with hypotension, thrombocytopenia, and restrictive cardiomyopathies. The thrombocytopenia occurs within 2–3 days in small number of patients and is typically reversible (after drug discontinuation), dose dependent, and rarely associated with bleeding. Similar to other inotropic medications, PDE III inhibitors may worsen hemodynamics in hypertrophic obstructive cardiomyopathy and are contraindicated in patients with stenotic valvular lesions.[19] Additional potential adverse effects include gastrointestinal disturbance, liver dysfunction (enzyme elevation) with long-term use, muscle aches, fever, and ventricular or atrial arrhythmias.

Levosimendan

Levosimendan is a new class of inotropic agents, calcium sensitizers, available in Europe. Levosimendan increases cardiac contractility by increasing the sensitivity of the myofilaments to calcium and to a lesser extent due to phosphodiesterase inhibition (PDE-III).[31] This agent has been shown to stabilize the binding of calcium to troponin C, thereby enhancing actin–myosin cross-bridging and augmenting the contractile force. PDE-III inhibition is more pronounced at higher doses and plays a smaller role in the inotropic effects of the drug.[31] CO is increased and PCWP is dose-dependently decreased. Levosimendan has been shown to increase SV and decrease SVR in patients with acute decompensated heart failure. The vasodilatation occurs due to its action of opening of ATP-sensitive K^+ channels.[32] It also causes coronary vasodilatation and improves coronary blood flow.[31]

Levosimendan has been evaluated in patients with left ventricular failure. This agent has also been studied in patients with left ventricular failure due to acute myocardial infarction (patients with a SBP <90 mmHg and need for immediate revascularization were excluded). There have been multiple small studies and case series published reporting the use of levosimendan in patients with cardiogenic shock following MI or cardiac surgery in combination with catecholamines. There is currently a randomized, double-blinded placebo controlled study enrolling patients to assess the safety and efficacy of levosimendan in patients with acute MI complicated by symptomatic left ventricular failure, including patients in cardiogenic shock. The results of this study may help us determine the role of this agent in shock states.

Levosimendan does not appear to impair diastolic dysfunction unlike other inotropic agents. It improves myocardial contractility without increasing the myocardial oxygen demand unlike dobutamine, through its increased contractility and vasodilatation effects.[32] It does not cause diastolic calcium overload thereby impairing diastolic relaxation and increasing energy demand with its associated negative effects. In a comparative study between levosimendan and dobutamine, in patients with severe heart failure, levosimendan improved hemodynamics better than dobutamine with less mortality at 180 days.[32] It has been studied as an intravenous and oral agent but is marketed only as an intravenous infusion. The half-life of levosimendan is approximately 40–60 min; total drug half-life (including metabolites) is approximately 5.5 h. It is metabolized by the liver and a portion is excreted unchanged via the kidneys. Because of the long half-life of the active metabolites, the hemodynamic effects of levosimendan appear to last after the infusion is discontinued. This agent appears to be well tolerated. Dose-dependent decreases in hemoglobin and hematocrit have been seen. This is thought to occur as a result of a dilutional effect induced by peripheral vasodilatation. Levosimendan has also been associated with dose-dependent increases in heart rate, QT prolongation, and ventricular ectopy. Other adverse effects include headache, hypotension, dizziness, and nausea.

Vasopressin

Vasopressin, otherwise known as antidiuretic hormone (ADH), is a small peptide hormone released from the posterior pituitary that has several physiologic actions. It plays a major role in water balance and in the regulation of the cardiovascular system. It is a potent vasoconstrictor that is released in the presence of hypovolemia or hypotension. It has been found to be elevated in patients with some types of shock.[33]

Its effects are mediated through three types of receptors known as V_1, V2, and V_3.[33] The V_1 receptor is found in multiple tissues of the body such as vascular smooth muscle, bladder, liver, spleen, kidney, CNS, testes, and platelets. ADH actions are mediated mainly through renal V_2 receptors found in the renal collecting ducts. The V3 receptors are present in the anterior pituitary and are involved in the secretion of adrenocorticotropin hormone. The vasoconstrictor effects, which require higher vasopressin concentrations than its antidiuretic actions, are mediated through direct stimulation of the V_1 receptors present on vascular smooth muscle. The increase in MAP has been attributable to increases in peripheral vascular resistance. Administered in supraphysiologic doses, vasopressin causes powerful vasoconstrictor effects and is more potent than angiotensin II or NE. In contrast to catecholamines such as epinephrine, the effects of vasopressin are not reduced by acidosis.

Vasopressin produces powerful vasoconstrictor effects by direct stimulation of V_1 smooth muscle receptors.

Vasopressin was introduced by the American Heart Association 2000 guidelines[34] as an alternative to epinephrine for the treatment of adult shock-refractory ventricular fibrillation. The effects of vasopressin have not been shown to differ from epinephrine and in the most recent 2005 guidelines,[19] vasopressin 40 units IV/intraosseous (IO) are recommended to either replace the first or second dose of epinephrine in the treatment of pulseless arrest. Observational studies involving the use of a vasopressin infusion at doses less than 0.1 U/min in patients with vasodilatory shock have shown improvement in blood pressure. In a study of 19 patients with septic shock, it was found that vasopressin plasma levels were inappropriately low; it was concluded that this decrease could contribute to the hypotension seen in vasodilatory shock.[35] It is now thought that patients with vasodilatory shock may have elevated vasopressin concentrations in early septic shock that then decrease at 24–48 h. This has been referred to as a relative vasopressin deficiency. The most recent study published in 2008 (VASST trial) compared NE alone to NE and vasopressin at 0.03 U/min, in patients with septic shock and found no difference in outcome between the two groups.[36] In the most recent 2008 Surviving Sepsis Campaign guidelines, vasopressin is recommended at 0.03 U/min in patients already receiving NE.[2]

Vasopressin is an alternative to epinephrine for the treatment of adult shock-refractory VF.

Vasopressin may be helpful in shock states with a vasodilatory component.

Vasopressin can produce multiple adverse effects related to smooth muscle constriction in vascular, gastrointestinal, uterine, and bronchial smooth muscle. At supraphysiologic levels (>0.04 U/min), potent vascular smooth muscle constriction may cause coronary artery constriction resulting in cardiac ischemia. Therefore, its use in alert patients with coronary artery disease is inadvisable. Other effects resulting from smooth muscle constriction include decreases in cutaneous perfusion, bronchospasm, uterine contractions, and gastrointestinal effects such as nausea and abdominal cramps. However, some clinical studies have not found clinical evidence for cutaneous, liver, gastrointestinal, or myocardial ischemia. The most recent VASST study found that the incidence of adverse events was as high as 10% in each group; therefore, there was no difference in the patients receiving NE vs. norepinephrine plus vasopressin. The investigators did exclude patients who were most likely to experience an adverse event (acute coronary syndrome or severe heart failure).[36] Vasopressin may cause platelet aggregation and increase the potential for small vessel occlusion. Its half-life is longer than that of epinephrine (approximately 10–20 min), which allows less frequent dosing.

Glucagon

Physiologically, glucagon plays a major role in glucose and ketone body metabolism. A polypeptide hormone with multiple metabolic and physiologic effects, glucagon has both inotropic and chronotropic effects on the heart.[37] The cardiovascular effects of glucagon are mediated through two potential mechanisms resulting in increases of adenosine 3'-5'-cyclic monophosphate (cAMP) through adenylyl cyclase stimulation or PDE inhibition. The

Cardiovascular effects are mediated through glucagon receptors and therefore are not affected by α-adrenergic or β-adrenergic receptor blockers.

increased cAMP cause increases in the available intracellular calcium, resulting in increased contractility during depolarization. Glucagon stimulates adenylyl cyclase at a different site than the adrenergic agents and therefore the responses are not affected by adrenergic blockade.[38]

In cardiac insufficiency (CHF or cardiogenic shock), glucagon increases HR, CI, and O_2 delivery with minimal changes in left ventricular end-diastolic pressure (LVEDP) and SVR. Glucagon infusion may increase CO by 20%. Its effects on CI and MAP, however, are less than that of dopamine, dobutamine, amrinone, or epinephrine.

Glucagon is used in the treatment of calcium channel blocker and β-adrenergic blocker toxicity.

Glucagon is used for the treatment of β-adrenergic blocker and calcium channel blocker toxicity.[38,39] It can be used as a secondary agent to epinephrine in anaphylaxis/anaphylactic shock, especially if β-adrenergic blocking drugs are present.[38] Glucagon has not been studied in sepsis and septic shock.

Glucagon has been found to be superior to other drugs in the treatment of β-adrenergic blocker toxicity. Similarly, it is more effective than the PDE inhibitors, which also enhance cAMP levels. Pharmacokinetic studies have shown that cardiac effects of a 5-mg IV bolus of glucagon begin in 1–5 min and last for 20–30 min. Because its half-life is approximately 20 min, therapy is initiated with a bolus dose followed by a continuous intravenous infusion.[40]

Glucagon does not alter heparin effects but it does potentiate the anticoagulant effect of warfarin. The most frequent adverse effects are nausea and vomiting, which may require high-dose antiemetics; hyperglycemia may be observed. Other adverse effects include hypokalemia, vasodilatation and hypotension, and tachycardia.

Vasodilators

Sodium Nitroprusside

Sodium nitroprusside is a rapid-acting, powerful venous and arterial vasodilator. It is one of the most effective afterload-reducing agents.

Sodium nitroprusside is a rapid-acting powerful vasodilator mediated by both arterial and venous smooth muscle relaxation, which results in a reduced arterial resistance and an increased venous capacitance.[11] Thus both preload and afterload will be reduced. It produces these effects on smooth muscle through the generation of nitric oxide (NO), a physiological endogenous vasodilator. NO activates guanylate cyclase in the vascular smooth muscle, which results in increased cellular concentrations of cGMP. Cyclic GMP reduces cellular calcium, causing smooth muscle relaxation and vasodilation.[11]

Sodium nitroprusside is primarily used in hypertensive crises, as an afterload reducing agent in both heart failure and acute pulmonary edema,[20] and in acute mitral or aortic valve regurgitation. It may be used in conjunction with other vasopressor/inotropic drugs and circulatory-assist devices, such as intra-aortic balloon pump (IABP), to maintain coronary blood flow in shock. The use of nitroprusside in the presence of coronary artery disease or myocardial infarction (MI), however, is controversial because it may reduce coronary blood flow and worsen ischemia. A decreased CO may result if the preload is markedly reduced.

Sodium nitroprusside is a vasodilator with both a rapid onset of 1–2 min and a rapid offset of 1–10 min; this allows for tight control of hemodynamic effects. It is rapidly metabolized to cyanide and nitric oxide. It is recommended to initiate therapy at a low dose of 0.10 μg/kg/min because it produces rapid vasodilatation and hypotension, especially in the elderly and in volume-contracted patients. The drug may be rapidly titrated upward to as high as 5–10 μg/kg/min in order to achieve the desired hemodynamic effect. In CHF, a PA catheter may be considered for optimal use and safety. If hypotension does occur, it may be reversed by stopping the infusion and administering volume as necessary. Its vasodilator actions may also cause hypoxemia by impairing hypoxic pulmonary vasoconstriction, especially in patients with pulmonary disease.

Cyanide and thiocyanate are toxic products of nitroprusside metabolism.

Other potential adverse effects may result from its metabolism. Sodium nitroprusside binds to the sulfhydryl groups on hemoglobin, oxidizing it to methemoglobin and releasing toxic cyanide radicals, some of which convert methemoglobin to cyanomethemoglobin. The other cyanide radicals are enzymatically converted by rhodanese to thiocyanate using thiosulfate and cyanocobalamin in the liver and kidney, followed by urinary excretion. However, the reaction is limited by the availability of rhodanese, thiosulfate, and cyanocobalamin.

Cyanide and thiocyanate are both toxic products produced during the metabolism of nitroprusside, thereby limiting the dosage of nitroprusside. The toxicity of cyanide may cause metabolic acidosis, dyspnea, confusion, abdominal pain, headache, and convulsions. The cyanide radicals are rapidly toxic and cause inactivation of the cytochrome oxidase system and impaired oxidative metabolism. This will result in anaerobic metabolism, acidosis, and eventual death if the process is not reversed. Lab assays for thiocyanate and cyanide blood concentrations are available and can be monitored if a patient is at high risk for developing toxicity; however, it may take days to receive the results. If toxicity is suspected, the infusion should be stopped immediately and antidotes (sodium nitrite, sodium thiosulfate, and hydroxycobalamin) administered. Sodium nitrite creates methemoglobin, which binds cyanide radicals, while thiosulfate is a substrate for the conversion of cyanide to thiocyanate; hydroxycobalamin will be converted to cyanocobalmin, effectively removing cyanide from the circulation.

Thiocyanate/cyanide toxicity may occur more frequently in patients with renal or hepatic dysfunction. Nitroprusside should be used with caution in this patient population.

Thiocyanate toxicity is an uncommon complication that may result in lassitude, anorexia, nausea, abdominal pain, miosis, visual blurring, mental status changes, hyperreflexia, and seizures. However, its likelihood increases in the presence of impaired renal function or administration of high-dose (>3 μg/kg/min) or prolonged infusions (greater than 48–72 h). In these situations, monitoring of signs and symptoms and blood thiocyanate levels becomes important. Though early signs of thiocyanate toxicity may occur at 5 mg/dL, patients are usually safe and tolerate levels less than 10 mg/dL. Thiocyanate can be removed by hemodialysis.

Cyanide toxicity may manifest as metabolic acidosis, dyspnea, confusion, and headache.

Nitroglycerin

Nitroglycerin is a powerful vasodilator that acts rapidly by increasing the formation and release of NO from vascular endothelium, causing smooth muscle relaxation. It is primarily a venodilator at low doses and both a venodilator and arteriolar vasodilator at high doses. Its venodilator effects result in mesenteric and hepatic venous pooling and a reduction in ventricular filling pressures and pulmonary congestion.[11,20] Further increases in dose lead to progressive arterial vasodilatation with a resultant increase in CO. Higher doses will result in hypotension.

Nitroglycerin causes venodilation at low doses and both veno- and arterial vasodilation at higher doses.

The hemodynamic effects of nitroglycerin are affected not only by dose, but also by the patients' volume status and cardiac function. If hypovolemia is present, nitroglycerin is likely to cause a significant decrease in preload and CO, resulting in marked hypotension. Its arterial effects are typically lost in this situation. In the setting of CHF, nitroglycerin reduces preload and vascular resistance, leading to a reduction in myocardial oxygen uptake and increased CO.

Nitroglycerin is used in patients with acute MI and CHF, large anterior wall infarction, persistent or recurrent ischemia, or hypertension for the first 24–48 h.

A major potential adverse effect of nitroglycerin is frank hypotension, including postural hypotension. The hypotension responds to volume repletion. Therefore, nitroglycerin should be used with caution in the presence of inferior wall MI and is contraindicated in patients with right ventricular infarction and ventricular filling pressure dependence. Additional adverse effects include headache (possibly severe), faintness, tachycardia, paradoxical bradycardia, and impaired hypoxic pulmonary vasoconstrictor response resulting in hypoxemia. Some side effects may be related to either the alcohol or propylene glycol drug solvent. Hemodynamic tolerance seems to develop after 24–48 h of continuous nitrate infusion. Nitrates are contraindicated with the use of phosphodiesterase-5 inhibitors (sildenafil, vardenafil, tadalafil) due to excessive increases in cGMP leading to a precipitous drop in blood pressure.

Hypotension is a major side effect of nitroglycerin therapy.

THERAPY FOR SELECTED CLINICAL CONDITIONS

Because the mechanisms for specific causes of shock, and therefore the treatment, can vary significantly, this section describes the pharmacologic support for some of the more common clinical disease conditions presenting to the intensivist.

Hypovolemic Shock

Hypovolemic shock can result from hemorrhagic etiologies (e.g., trauma, gastrointestinal) and nonhemorrhagic etiologies (e.g., vomiting, diarrhea, GI fistulas, and third-space fluid accumulation). The etiology of hypovolemic shock is usually apparent from the history of external blood or fluid losses, physical examination, and/or laboratory tests such as hemoconcentration and increased BUN to creatinine ratio. Treatment of hypovolemic shock requires two or more large-bore peripheral lines or a central venous line for rapid infusion of blood products, colloidal solutions, or crystalloid solutions. If blood loss is ongoing, resuscitation and evaluation should be performed simultaneously. Volume resuscitation should result in rapid improvement of clinical parameters of perfusion, such as blood pressure and pulse rate. Other parameters such as increased urine output occur later, and improved mental status may be further delayed. If significant improvement does not occur, there may be either ongoing blood or fluid volume loss or incorrect or additional diagnoses (e.g., adrenal cortical insufficiency). The sites at which blood loss is occurring need to be evaluated and controlled. To rapidly improve tissue perfusion, additional supportive measures include the temporary use of low-dose vasopressor/inotropic agents such as dopamine, NE, or epinephrine, until fluid resuscitation is accomplished. However, the use of vasoactive agents in hypovolemic shock may confound the perfusion endpoints for volume resuscitation and lead to continued instability due to inadequate circulatory volume.

Severe hypovolemic shock may require the temporary use of vasoactive drugs.

Extracardiac Obstructive Shock

Extracardiac obstructive shock can be caused by a wide variety of disorders and grouped into several mechanisms: extrinsic vascular obstruction (e.g., mediastinal tumors), increased intrathoracic pressure (e.g., pneumothorax), intrinsic vascular flow obstruction (e.g., pulmonary embolism, air embolism, and tumors), and pericardial disease (e.g., tamponade).

Pulmonary Embolism

In pulmonary embolism (PE), the pulmonary vascular system is obstructed, causing an impediment to blood flow and, if a massive PE, resulting in hypotension or shock. A massive PE can cause a sudden increase in right ventricular afterload, for which the right ventricle will be unable to provide the SV to the left ventricle thereby reducing preload and leading to hypotension.[41-43] The hemodynamic pattern commonly produced by massive pulmonary emboli includes decreased CO, unchanged PCWP, and an increased CVP.[43] The SVR and PVR are increased, and the SVO_2 is decreased (see Fig. 49-1b).

Massive pulmonary embolism can cause an extracardiac obstructive pattern of shock.

The treatment of massive pulmonary embolism involves hemodynamic support with fluids and vasoactive drugs, thrombolytics, or possible surgical embolectomy. Use of a PA catheter may help guide fluid and vasoactive drug therapy.

Fluid therapy has the potential to improve the right ventricular preload leading to improved hemodynamics. In patients with acute massive pulmonary embolism, a Dextran 40 infusion of only 500 mL improved cardiac index from 1.6 to 2.0 L/min/m^2 and also increased right atrial pressure from 9 to 17 mmHg.[44] The increased CI was highly correlated inversely with baseline RV end-diastolic volume. Similar hemodynamic changes were obtained in acute massive PE using blood volume expansion of 600 mL.[43,45] However, fluid therapy should be very carefully evaluated as it has the potential to further compromise the right ventricular function and cardiac index. In pulmonary embolism, the right-sided filling pressures may already be high, and the addition of fluids may significantly increase these pressures causing further right ventricular distension and hemodynamic compromise.[42,46] Right ventricular distension can cause right ventricular ischemia and decreased left ventricular compliance due to leftward interventricular septal movement; these changes have the potential to significantly compromise CO. Fluid therapy should be initiated with a bolus and, if deemed hemodynamically helpful, carefully titrated while monitoring the resultant hemodynamic changes. The Task Force Report on PE states that fluid challenge is controversial and should not exceed 500 mL.[45] Generally, right atrial pressures should be targeted to 15–20 mmHg while

In shock caused by pulmonary embolism, volume resuscitation may be deleterious and must be carefully titrated.

avoiding pressures greater than 20 mmHg. Fluid loading may cause deleterious increases in the right-atrial pressure (RAP) and PCWP, causing decreased left ventricular end-diastolic pressure or volume due to interventricular septal movement and right ventricular ischemia, thereby compromising CO.

If the patient does not appear to benefit from a fluid bolus, vasoactive therapy can be initiated. Dopamine,[42] Dobutamine,[45] or combined Dobutamine and NE[41,43,47] are possible agents to be considered in massive PE. Dopamine and dobutamine have been recommended in patients with pulmonary embolism, low CI, and normal BP while vasopressors have been recommended in patients with hypotension.[45] Because dobutamine is an inotropic agent associated with a vasodilator effect, it may improve hemodynamics by increasing right ventricular performance or reducing PVR.[48] Since dobutamine may cause vasodilation and lower BP, caution should be exercised when using it without a vasoconstricting agent to maintain adequate BP.[41] NE has been recommended[41] because it appears to improve right ventricular function by a direct positive inotropic effect and by its vasoconstrictor effects that may increase coronary artery blood flow to the right ventricle. In addition, epinephrine has potential vasoconstricting and inotropic effects that may make it useful in shock due to massive PE.[41,45]

If PE is unresponsive to fluid therapy, consider vasopressor/inotropic drugs such as dobutamine or NE.

Distributive Shock

Distributive shock may be caused by a number of different etiologies, including septic shock, anaphylaxis, and neurogenic and toxic (drug overdose) shock.

Septic Shock

Septic shock generally presents as hypodynamic ("cold shock") or hyperdynamic ("warm shock"), depending on the differences in CO and SVR. Typically, the hemodynamic parameters of hyperdynamic shock are associated with a low preload, a high CO, and a low SVR. In contrast, hypodynamic shock is associated with hemodynamic parameters of a low preload and a low CO in association with a high PVR and SVR. Most septic patients present with a suboptimal preload from fluid loss and vasodilatation.

In addition to infection management, the Surviving Sepsis Campaign 2008 recommend evidence-based practice parameters for hemodynamic support of adults with sepsis, recommend titration to clinical endpoints of CVP of 8–12, MAP ≥65 mmHg, urine output ≥0.5 mL/kg/h and $ScvO_2 \geq 70\%$ using fluid, blood, and dobutamine in a early goal-directed protocol.[2] They also recommend using indicators of tissue perfusion such as blood lactate concentrations and mixed venous oxygen saturation (SvO_2). However, titration to supernormal preset clinical endpoints of O_2 delivery and CI is not recommended in the patient with sepsis.

Resuscitative efforts first include volume infusion to promote the development of the hyperdynamic state, followed by vasopressors and inotropes.[2] In those patients with persistent evidence of shock despite volume infusion, vasopressors such as dopamine or NE are considered as a first-line drug to increase MAP.[2] Dopamine increases CI more than NE. NE may decrease or only mildly increase CI due to its potent vasoconstrictor effects. However, dopamine may excessively elevate HR while NE may have significantly less effect. If shock is refractory to dopamine or NE treatment, epinephrine should be considered.[2] Vasopressin has been used for the treatment of septic shock but awaits further evaluation before it can be formally recommended and its place in therapy defined.

In septic shock, rapid fluid resuscitation is a first-line therapy. In severe shock, vasopressors/inotropes should be started simultaneously.

Anaphylactic Shock

In anaphylactic shock, epinephrine is the drug of choice.

A severe, systemic allergic reaction most commonly caused by foods, bee and wasp stings, drugs, and latex,[49] anaphylactic shock results from IgE- and IgG-mediated systemic release of histamine and other mediators.[50] The clinical manifestations of anaphylaxis commonly involve two or more of the following organ systems: skin, respiratory, cardiovascular, and

gastrointestinal.[51] Cutaneous and mucosal manifestations include urticaria, conjunctivitis, and rhinitis. Gastrointestinal signs and symptoms are abdominal pain, vomiting, and diarrhea. Respiratory manifestations include upper and lower airway edema and bronchospasm. Cardiovascular manifestations include circulatory shock, commonly caused by vasodilatation and intravascular volume loss, caused by increased capillary permeability.[52] The hemodynamic findings in anaphylaxis include a decreased or increased preload, associated with a low CO, high PVR, and a low SVR.[52] The multiple differential diagnoses include vasovagal reactions, psychological disorders such as panic attacks associated with paradoxical vocal dysfunction, hereditary and ACE inhibitor-induced angioedema, and scombroid seafood poisoning.

Treatment for the multiple manifestations of anaphylactic shock includes pharmacologic therapy and important supportive measures such as early airway control, high-flow oxygen, mechanical ventilation, and intravenous fluids. Epinephrine is the drug of choice as it has a number of beneficial effects derived from both its β- and α-adrenergic properties.[50] It stimulates β-adrenergic receptors (β-1and β-2) and increases intracellular cAMP levels, leading to inhibition of mast cell and basophil mediator release, bronchodilation, and inotropic and chronotropic cardiac effects. Its α-adrenergic properties cause peripheral vasoconstriction and decreased mucosal edema. It should be administered to all patients who exhibit clinical signs of circulatory shock, airway swelling, or respiratory difficulty. Epinephrine should also be administered in mild anaphylaxis. It is usually administered either intramuscularly or intravenously depending on its severity and the presence of venous access. To treat circulatory shock in adults, administer epinephrine at an initial dose intravenously and then initiate an infusion[50,53-55]; if the patient is unresponsive to epinephrine and fluid, persistent hypotension can be treated with the addition of dopamine, NE, or phenylephrine. Glucagon may be helpful especially if the patient has received beta-blockers. Normal saline, 1–4 L, should be administered rapidly if hypotension is present and the patient does not rapidly respond to epinephrine.

Neurogenic Shock

Neurogenic shock may result from neuraxial or general anesthesia or spinal cord injury.

Neurogenic shock may be precipitated by neuraxial (epidural, spinal, combined epidural-spinal) or general anesthesia or by cerebral or spinal cord injury resulting in impairment of sympathetic vascular tone. Clinically MAP, preload, and CO are decreased, typically without any tachycardia.[56] Hypotensive patients may have warm dry skin because of parasympathetic predominance due to reduced sympathetic outflow from the spinal cord.[56]

Spinal shock, which is usually caused by a traumatic injury, results in the complete blockade of neurotransmission in the spinal cord below the level of the injury.[57] Spinal cord injury due to trauma is frequently associated with hypotension and worse outcomes.[57] The hypotension may be due to the associated trauma and hypovolemia, direct spinal cord injury, or both of these.[57] In acute spinal cord injury, the hemodynamic effects are hypotension, cardiac arrhythmias, decreased peripheral vascular resistance, and decreased CO.[57] In fact, patients with spinal shock from a spinal cord injury above T6 will tend to have bradycardia. Severe cervical cord injuries tend to be associated with the highest risk for cardiac and hemodynamic compromise.[57] The resulting fall in BP places the patient at risk for ischemic injury to the heart and brain and to further ischemic injury to the spinal cord. The hypotension and bradycardia may continue for 2–6 weeks.[58]

Patients with decreased perfusion should be given fluids, and if inadequate perfusion continues, pharmacologic therapy should be considered. In acute spinal cord injury, it has been recommended to keep the MAP >85–90 mmHg for the first 7 days, which may improve spinal cord perfusion and neurologic outcomes.[57] The hemodynamic support of neurogenic shock depends on whether it results from a transient, reversible cause such as autonomic blockade due to anesthesia or from actual damage to the autonomic nervous system such as spinal shock,[57] which also affects cardiac function. In the former, an α-adrenergic agonist such as phenylephrine[59] is commonly used to provide BP support; in the latter, drugs with combined α-adrenergic and β-adrenergic properties, NE or dopamine is used to provide sympathetic tone to blood vessels and chronotropic support to the heart.[58]

Cardiogenic Shock

Cardiogenic shock may result from primary myocardial dysfunction, valvular or structural abnormalities and arrhythmias (see Fig. 49-1a). Acute left ventricular failure resulting in cardiogenic shock occurs most commonly after myocardial infarction[20] with or without ST-elevation. Cardiogenic shock results when approximately 40% or more of the myocardium is damaged.[60] It is seen in <9%[61] of patients with ST segment elevation who suffer a myocardial infarction, but it is associated with a high mortality (approximately 50–60%).[61]

Cardiogenic shock has a high mortality rate, 50–60%, and results when approximately 40% or more of the myocardium is infarcted.

Hemodynamically, SV decreases, causing increased left ventricular volume and dilation. This leads to increased myocardial O_2 consumption and the potential for worsening ischemia (see Fig. 49-1b). The reduced SV results in a decreased CO, unless a compensatory tachycardia occurs, which will further increase myocardial O_2 consumption and ischemia. The decreased CO results in increasing left ventricular pressures, pulmonary congestion, and shock. PA catheter pressures typically show systolic BP <100 mmHg, PCWP >18–20 mmHg, and CI <2.5 L/min/m^2. Usually, evidence for poor perfusion is present at a systolic BP of 90 mmHg and CI of 2.2 L/min/m^2.

The hemodynamic monitoring and therapy of acute pulmonary edema, hypotension, and shock is shown as an algorithm corresponding to the American College of Cardiology/American Heart Association Guidelines(ACC/AHA) 2004 for ST-elevation myocardial infarction (STEMI) (see Fig. 49-5).[20] The guidelines recommend (Class I) that PA catheter monitoring should be performed for:(1) progressive hypotension unresponsive to fluid is contraindicated or (2) suspected mechanical complications of STEMI if no echocardiogram is done. Moreover, insertion of an arterial pressure line for monitoring BP should also be used in patients who are hypotensive (SBP <80), receiving vasopressor/intropic agents or are in cardiogenic shock. One set of goals for hypotensive patients in cardiogenic shock is to restore MAP to at least 60 mmHg, CI to more than 2.2 L/min/m^2, and to optimize CO to the lowest possible PCWP. This algorithmic approach to therapy is based on the most likely type of problem such as volume status (acute pulmonary edema or hypovolemia), LV function, and heart rate, and then stratified by systolic BP. In the presence of pulmonary congestion and an acceptable systolic BP (<100 mmHg or >30 mmHg below baseline), diuresis is recommended while reducing preload and afterload. In a hypotensive patient with cardiogenic shock who has not developed pulmonary congestion, fluid should be cautiously administered to increase the intravascular volume.[20] The clinician should closely monitor the patient for the development of pulmonary edema and/or coronary ischemia due to an increase in ventricular filling pressures. For hypotension (low output-cardiogenic shock) that does not resolve with volume, vasopressors and/or inotropic drugs are indicated according to the systolic BP and presence or absence of signs/symptoms of shock.[20] Generally, for SBP below 70 mmHg and evidence of shock, NE is initially indicated; and after SBP increases to 80 mmHg or more, dopamine replacement (starting at 2.5–5.0 µg/kg/min) should be attempted, and at an SBP of approximately 90 mmHg, dobutamine is added to allow the reduction of the dopamine infusion rate.

STEMI-associated cardiogenic shock is treated with pharmacologic therapy and when it does not reverse quickly, intra-aortic balloon counterpulsation is recommended.[20]

Echocardiogram is recommended in cardiogenic shock to evaluate mechanical complications unless evaluated by invasive procedures.[20]

In general, vasodilators are contraindicated in cardiogenic shock. Vasodilators used in cases of CHF with normal or high systemic arterial pressures are helpful to improve SV and CO, but are not recommended if the systemic arterial pressures or ventricular filling pressures are low because further hypotension may result.[20] These drugs may be considered in cases where shock is caused by mitral (vasopressors contraindicated) or aortic regurgitation, aortic dissection, or in conjunction with other treatments such as IABP or other vasopressor/inotropic drugs. Patients should be considered for intra-aortic balloon counterpulsation therapy (IABP), angiography for acute myocardial infarction or ischemia, and potential therapeutic procedures (percutaneous coronary intervention, revascularization, fibrinolytics).[20]

Right Ventricular Infarction

Right ventricular (RV) infarction can result in cardiogenic shock (see Fig. 49-1b). This entity is more commonly associated with inferior wall infarcts than anterior wall infarcts or as an isolated insult. On examination, the lungs are typically clear but there is jugular venous

In the presence of inferior wall infarction, the association of hypotension with clear lungs and increased jugular venous pressures strongly indicates hemodynamically significant right ventricular infarction.

distension, sometimes associated with a Kussmaul's sign, distention of jugular vein with inspiration.[20] The clinical association of hypotension with the preceding two signs occurs in 25% of patients with RV infarction.[20,62] Typically, laboratory evaluation reveals a clear chest roentgenogram. Hemodynamic parameters commonly show a decreased CO associated with elevated right-sided pressures (RA) relative to PCWP, and an increased RV diastolic pressure. In fact, a rather specific and sensitive marker or measurement for RV ischemia or infarction is a RA pressure of ≥10 mmHg, which is greater than 80% of the PCWP.[20,63] The RV infarction and the resulting dysfunction produces a decrease in left ventricular preload and in turn a decreased SV and CO. In inferior wall STEMI, although only 10–15%[64,65] of the patients show classic hemodynamic abnormalities of clinically significant RV infarction, these patients with inferior STEMI have a higher mortality of 25–30%.[20,64] Moreover, patients with predominant RV infarction and cardiogenic shock have a mortality (53%)[66] that approaches that of LV-associated cardiogenic shock.[20] The most common differential diagnoses include pericardial tamponade and pulmonary embolism. Studies such as right precordial EKG, echocardiography, or ventilation–perfusion lung scanning should be considered to confirm or exclude other possible diagnoses.

Treatment of shock resulting from right ventricular infarct includes fluids initially and vasopressor/inotropic drugs (e.g., dobutamine) as well as coronary reperfusion therapy (e.g., fibrinolytic therapy, percutaneous coronary intervention) and other general supportive measures (e.g., IABP, arterial vasodilators for associated LV dysfunction).[20] Hemodynamic data from the PA catheter are often used to optimize therapy. Initially, fluid therapy in the form of a single bolus should be considered carefully to optimize right ventricular preload based on clinical assessment of volume status. If there is no significant improvement, pharmacologic therapy should be considered, such as dobutamine or NE, to provide inotropy and increased coronary artery perfusion.[20] These drugs should be titrated to clinical as well as hemodynamic indices of perfusion.

SUMMARY

Shock is defined as a failure of the circulatory system to provide adequate cellular or tissue perfusion and oxygen delivery to meet the current metabolic demands, resulting in organ dysfunction and irreversible cellular damage. Shock can be classified into four categories: hypovolemic, cardiogenic, extracardiac obstructive, and distributive. Each of these four categories includes a number of different potential etiologies. The identification of the category of shock and its etiology provides for more specific treatment and potentially a better outcome. To determine the etiology of shock, a clinical (history, physical examination, and directed laboratory studies) and hemodynamic evaluation (pulmonary arterial catheterization, echocardiography) further delineate the cause and treatment.

The goal of shock treatment is to restore tissue perfusion and oxygenation. Tissue perfusion is closely related to CO and SVR. The treatment of shock includes fluid therapy, the use of vasopressor/inotropic medications (classified by adrenergic and nonadrenergic mechanisms) and, in special cases, vasodilators. Each of these therapies may have untoward effects, which include but are not limited to, increased heart rate, splanchnic vascular bed vasoconstriction, or arrhythmias. These interventions are the tools available to restore the patient to a premorbid hemodynamic state. An understanding of their mechanism of action, potency, side effects, drug interactions, and clinical effects in a particular shock state is critical to a successful outcome.

In conclusion, the pharmacotherapy of shock requires identification of the category and etiology of shock, evaluation of the hemodynamics of the shock state, and knowledge and application of the properties of each type of drug to restore tissue perfusion and oxygenation in each disease entity. Currently, new vasoactive drugs for shock are being developed with more specific hemodynamic effects and fewer potential adverse effects.

REVIEW QUESTIONS

1. **After fluid resuscitation, which of the following drugs is recommended for the initial treatment of persistent hypotension in septic shock?**
   - **A.** Dobutamine
   - **B.** Epinephrine
   - **C.** Norepinephrine
   - **D.** Phenylephrine
   - **E.** Milrinone

2. **In a euvolemic patient, administration of dobutamine (dose) generally causes:**
   - **A.** Decreased heart rate
   - **B.** Decreased CO
   - **C.** Decreased or unchanged PAWP
   - **D.** Decreased stroke volume
   - **E.** Increased SVR

3. **A previously healthy 28-year-old man presents to the Emergency Department with spinal cord injury, occurring in the upper thoracic vertebrae (T1–T6), and develops bradycardia and hypotension. After adequate fluid administration and other ongoing treatment, the patient remains persistently hypotensive. The commonly recommended drug to use for further hemodynamic support is:**
   - **A.** Dobutamine
   - **B.** Nitroprusside
   - **C.** Amrinone
   - **D.** Norepinephrine
   - **E.** Milrinone

4. **Which one of the following drugs causes a decrease in pulmonary capillary wedge pressure?**
   - **A.** Dopamine
   - **B.** Norepinephrine
   - **C.** Epinephrine
   - **D.** Phenylephrine
   - **E.** Dobutamine

5. **A true statement regarding norepinephrine use in cardiogenic shock caused by myocardial infarction includes:**
   - **A.** Norepinephrine primarily augments BP by increasing cardiac output
   - **B.** Norepinephrine is not used in hypotension due to ischemic heart disease
   - **C.** It is used for hemodynamically significant hypotension (SBP <70 mmHg) and is more useful when SVR is low
   - **D.** Generally, it causes a marked increase in CO
   - **E.** After fluid resuscitation, norepinephrine is recommended for a patient with a systolic BP of 74 mmHg with signs and symptoms of shock

6. **Which of the following drugs may interact with the vasoactive agent dopamine?**
   - **A.** Phenelzine (Nardil)
   - **B.** St. John's wort
   - **C.** Nefazodone (Serzone)
   - **D.** Nedocromil (Tilade)
   - **E.** Venlafaxine (Effexor)

7. **A 35-year-old woman, who is a hospital administrator, presents to the Emergency Department (accompanied by two coworkers) with a rash, facial swelling, nasal congestion, abdominal pain, and nausea approximately half an hour after lunch. She had a small bowl of tortellini with pesto, an apple, and a caffeine-free diet cola in the hospital cafeteria. She states that she has an allergy to nuts. She appears pale with facial swelling and is tachycardic with a BP of 80/48 mmHg. Her legs are elevated and given high flow oxygen. She is given epinephrine intramuscularly as large bore intravenous lines are being established. A normal saline fluid bolus is administered and continued at a high flow. After 5 min, her BP drops further despite treatment and flagrant shock is present. The next step is:**
   - **A.** Administering glucagon
   - **B.** Starting an epinephrine infusion
   - **C.** Starting a phenylephrine infusion
   - **D.** Starting a dopamine infusion
   - **E.** Starting a norepinephrine infusion

8. **Match the drug to the most appropriate statement:**

1. Phenylephrine	**A.** First-line treatment for anaphylactic shock
2. Amrinone	**B.** Treatment of beta-blocker-induced shock
3. Norepinephrine	**C.** Confusion, metabolic acidosis, seizures
4. Glucagon	**D.** Decrease platelets in dose-dependent fashion
5. Isoproterenol	**E.** Phenytoin-induced hypotension
6. Epinephrine	**F.** Treatment of hypotension after spinal cord injury
7. Dopamine	**G.** Treatment of bradycardia in the denervated heart transplant
8. Nitroprusside	**H.** Pure α_1-adrenergic agonist

9. **A patient undergoes cardiac surgery for aortic stenosis and postoperatively is delivered to the intensive care unit with an elevated blood pressure (150/80), PA pressures of 25/15, and a cardiac index of 1.9. Preoperatively, the history included normal ejection fraction with some diastolic dysfunction and left ventricular hypertrophy. Operating room team would like a systolic BP of <110 and improved cardiac index. Which single treatment may achieve these goals.**
   - **A.** Starting sodium nitroprusside
   - **B.** Starting epinephrine
   - **C.** Starting dobutamine
   - **D.** Starting milirone
   - **E.** Administering fluid boluses

10. **Patients in the intensive care unit on inotropic infusions of Epinephrine, Dobutamine, Isoproterenol, and/or Norepinphrine should be monitored for: Best answer(s)**
    - **A.** Hyperglycemia
    - **B.** Hypernatremia
    - **C.** Hypoglycemia
    - **D.** Hypokalemia

11. Catecholamine extravasation can be treated with intradermal:
- **A.** Phenylephrine
- **B.** Phentolamine
- **C.** Hydralazine
- **D.** Glucagon

12. Which of the following is true regarding low-dose dopamine?
- **A.** It has been shown to decrease the progression of acute kidney injury
- **B.** It stimulates dopaminergic and α-adrenergic receptors at this dose only
- **C.** It causes vasodilation of the renal arteries and oliguria but has not been shown to preserve or improve kidney function
- **D.** It can cause bradycardia

ANSWERS

1. The answer is C. Norepinephrine. After fluid resuscitation, the drug recommended for the initial treatment of persistent hypotension in septic shock is either norepinephrine or dopamine. Norepinephrine is more potent than dopamine and may be better at reversing hypotension in septic shock. Dopamine increases splanchnic blood flow without vasoconstriction and at low doses increases CO, but it can cause more tachycardia and arrhythmias. Dobutamine generally is not indicated as first line in septic shock because it may cause further hypotension. It is generally indicated as an adjunctive treatment when CI is impaired (e.g., <2.5 L/min/m^2). Epinephrine is generally recommended as the first alternative to dopamine or norepinephrine. Phenylephrine has not been well studied in adult septic shock and has a tendency to decrease CI. It is best used when cardiac arrhythmias are problematic because of its lack of direct cardiovascular effects and when CI is greater than 4.0 L/min/m^2. Milrinone has significant vasodilatory properties as well as a long half-life.

2. The answer is C. Dobutamine does have beta-1 and beta-2 agonist properties, which results in inotropy but not vasoconstriction. In a euvolemic patient, dobutamine administered from 5 to 20 μg/kg/min generally results in an unchanged or increased heart rate, increased stroke volume, and cardiac output. Additionally, it causes a decrease in SVR and a decreased or unchanged PCWP and CVP. Because dobutamine does not cause vasoconstriction, its use in septic shock is limited, and it is typically used in conjunction with vasoactive drugs. Furthermore, patients placed on dobutamine who are hypovolemic may experience severe hypotension.

3. The answer is D. Norepinephrine. The patient has developed neurogenic shock resulting from a spinal cord injury and spinal shock, disruption of sympathetic output, and unbalanced parasympathetic input. Spinal shock is a neurologic condition that involves injury to the autonomic system, which affects not only vascular resistance but also cardiac function, thereby requiring a combined α- and β-adrenergic agonist. Phenylephrine, a pure α-adrenergic agonist, can be used for transient, reversible forms of neurogenic shock caused by anesthesia. The other drugs, such as dobutamine, milrinone and amrinone, and nitroprusside, may cause a decreased SVR and further hypotension.

4. The answer is E. Typically, dobutamine causes a decrease in PCWP due to mild peripheral vasodilatation and improved inotropic response. Dobutamine stimulates α_1- and β_1-AR in the heart and α_1- and β_2-AR in the peripheral vascular system. The β_2-AR vasodilatory response is stronger than the α_1-AR vasoconstrictor response which results in some vasodilatation. Moreover, the increased inotropic response and the concomitant increase in CO also result in a decreased vascular resistance. The other drugs have significant vasocontrictor properties, resulting in arterial and/or venous vasoconstriction and causing a decrease in venous capacitance and increased blood return. For example, dopamine stimulates both α_1-AR and β_1-AR, causing an increase in vasoconstriction and increased CO. Higher doses cause further vasoconstriction resulting in more marked peripheral arterial and venoconstriction, augmenting the systemic and PVR and PCWP.

5. The answer is C. Norepinephrine is used for hemodynamically significant hypotension refractory to other sympathomimetic amines and is more useful when SVR is low. Although a low SVR is uncommonly found in cardiogenic shock, norepinephrine is helpful when BP is very low because it has stronger vasoconstrictor effects than dopamine and produces less tachycardia. Furthermore, its strong inotropic properties are helpful to prevent a decrease in CO. For choice A, norepinephrine primarily augments BP by increasing peripheral vascular resistance. Although norepinephrine has potent effects on cardiac contractility, the stronger vasoconstrictor properties may actually result in decreased, unchanged, or only mildly increased cardiac output. Choice B is false because norepinephrine is used in cardiogenic shock without pulmonary edema when dobutamine and dopamine are unsatisfactory, especially in shock at SBP below 70 mmHg. D. As in choice A, typically there is only a modest change in CO, which may be negative or positive due to the balancing of its strong vasoconstrictor effects and less potent inotropic effects. E. For hypotension with a systolic BP less than 70 mmHg and signs and symptoms of shock, volume is given if preload is decreased, and norepinephrine is the recommended temporary vasoactive drug of choice. As treatment continues and blood pressure rises, norepinephrine is then substituted as soon as possible for a less intense vasoconstrictor.

6. The answer is A. Phenelzine (Nardil) is a monoamine oxidase inhibitor used for the treatment of depression. Dopamine is metabolized by the enzymes monoamine oxidase and catechol-*O*-methyl transferase. An inhibitor of monoamine oxidase may significantly potentiate the effects of dopamine, and it has been recommended to use 1/10th or less of the usual dose. Patients still may have exaggerated blood pressure response to dopamine days after stopping nardil. Two other MAO inhibitors used for depression are tranylcypromine (Parnate) and isocarboxazid (Marplan). Choice B is an herbal remedy marketed as a dietary supplement that has not been known to affect the pharmacology of exogenous dopamine. It appears, however, to have some antidepressant effect in controlled trials, but it may also significantly interact with other major drugs. Choices C and E are antidepressants. Serzone is a serotonin antagonist and reuptake inhibitor while Venlafaxine is both a serotonin- and norepinephrine-reuptake inhibitor. Neither of these significantly interacts with the cardiovascular effects of dopamine. However, in stable outpatients,

Venlafaxine has been known to cause a dose-related elevation in diastolic blood pressure. Choice D is a nonsteroidal antiinflammatory agent for the treatment of mild asthma.

7. The answer is B. Administering epinephrine. The first-line pharmacologic treatment of anaphylactic shock is epinephrine because it has a number of beneficial effects in different organ systems derived from both its β- and α-adrenergic properties. It stimulates β-adrenergic receptors (β-1and β-2) resulting in bronchodilation, and inotropic and chronotropic cardiac effects. Stimulation of α-adrenergic properties cause peripheral vasoconstriction and decreased mucosal edema. It should be given immediately in the presence of clinical evidence for airway swelling, respiratory difficulty, or shock as delay in treatment may be fatal. It should be repeatedly administered or given as an epinephrine infusion from 2 to 10 μg/min. Moreover, rapid volume infusion is necessary in all the patients and monitoring especially in those with risk factors for volume overload. If hypotension persists despite epinephrine, a norepinephrine, dopamine or phenylephrine infusion should be given. Additional medications such as H1- and H2-antihistamines, bronchodilators, and corticosteroids can be given after epinephrine. H1-antihistamines help to reduce pruritis and hives but do not help with hypotension or airway obstruction. H2-antihistamines may not be of much help for the immediate treatment of anaphylaxis. In general, albuterol can be added for residual bronchospasm, but it does not treat the airway mucosal edema as with epinephrine. Corticosteroids may be helpful to prevent extended reactions but there is no data that supports this.

8. The correct answers are:

1. Phenylephrine	Pure α_1-adrenergic agonist
2. Amrinone	Decrease platelets in dose-dependent fashion
3. Norepinephrine	Treatment of hypotension after spinal cord injury
4. Glucagon	Treatment of beta-blocker-induced shock
5. Isoproterenol	Treatment of bradycardia in the denervated heart transplant
6. Epinephrine	First-line treatment for anaphylactic shock
7. Dopamine	Interacts with phenytoin causing hypotension
8. Nitroprusside	Confusion, metabolic acidosis, seizures

Phenylephrine is a noncatecholamine with adrenergic properties of α-adrenergic stimulation. Amrinone is associated with a reversible thrombocytopenia, usually developing in 2–3 days and resolving after drug cessation. Norepinephrine is used in neurogenic shock due to spinal cord injury, especially T1–T6, where sympathetic outflow is blocked resulting in bradycardia and hypotension. Glucagon is helpful in β-blocker-induced shock because of its nonadrenergic mechanism of action. It is also used in other forms of shock unresponsive to standard therapy such as anaphylactic shock. Nitroprusside is metabolized to cyanide and then converted to the less toxic product of thiocyanate. These products may accumulate during prolonged infusion, high-dose therapy, or poor renal function and cause significant side effects of anion-gap metabolic acidosis and mental status changes. Liver disease is rarely a significant contributor to the accumulation of these toxic products. In critically ill patients receiving phenytoin, hypotension may occur with the administration of dopamine.

9. The answer is D. A postoperative patient usually needs adjustments in their therapy in the intensive care unit. Sodium nitroprusside can be used to reduce the blood pressure to acceptable levels, but will lower filling pressures and reduce cardiac index further. Epinephrine will increase cardiac index; however, the beta adrenergic vasodilatation is minimal and blood pressure may further increase. Dobutamine is a reasonable option; however, the left ventricular hypertrophy weighs against this option. Use of fluid alone should increase the cardiac index and also blood pressure. Milrinone increases contractility while decreasing afterload with vasodilation, thus an ino-dilator.

10. The answer is A and D. All the inotropic agents listed have beta adrenergic properties with their associated side effect profile. This includes gluconeogenesis with resulting hyperglycemia. Another electrolyte disturbance can be hypokalemia since the Na/K pump is in proximity to the beta receptor. Stimulation of the receptor causes potassium to be moved intracellularly.

11. The answer is B. Extravasation from catecholamine vasopressors such as dopamine, norepinephrine, and epinephrine causes severe tissue injury such as dermal necrosis. If extravasation is suspected, the injected drug should be discontinued immediately and the original needle should be left in place to try and aspirate as much of the infiltrated agent as possible. Phentolamine competitively blocks alpha-adrenergic receptors to produce brief antagonism of circulating epinephrine and norepinephrine to reduce hypertension caused by alpha effects of these catecholamines. In extravasation, phentolamine acts at both arterial and venous sites producing vasodilation and improving blood flow to the affected area, reducing ischemia. Phentolamine 5–10 mg should be diluted in 10–15 mL of normal saline in a syringe and 0.5–1 mg doses should be injected in and around the site of extravasation and elevate the limb.

12. The answer is C. Dopamine acts primarily on the dopamine receptors found in the renal, mesenteric, and coronary beds at doses from 1 to 3 μg/kg/min. Dopamine has been shown to increase the renal blood flow and induce dieresis, but two metaanalyses and a large prospective randomized multicenter trial has failed to show that low-dose dopamine can improve or protect renal function in critically ill patients.

CHAPTER 50

FREDERIC H. KAUFFMAN AND LIZA D. LE

Advanced Cardiopulmonary Resuscitation

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Describe the evolution of various CPR techniques, including open and closed chest resuscitation.
- Describe the epidemiology of sudden cardiac death.
- List the various etiologies of sudden cardiac arrest.
- Describe the research-validated mechanisms by which blood flows in a forward direction during CPR.
- Correlate coronary and cerebral perfusion pressures with survival and clinical outcome.
- Describe several techniques by which CPR can be performed, along with pros and cons for each technique.
- List the techniques for assessment and support of the airway, breathing, and circulation.
- Recite the algorithms for the treatment of asystole, pulseless electrical activity (PEA), ventricular fibrillation, ventricular tachycardia, and bradycardic rhythms.
- Alter properly the resuscitation techniques for victims of cardiac arrest associated with hypothermia, near-drowning, trauma, electrical shock/lightning, and pregnancy.

A BRIEF HISTORY OF BASIC CARDIOPULMONARY RESUSCITATION

Death, an inevitable reality for all of us, has not always been viewed as a potentially reversible event. Before the Renaissance, the views espoused by Galen in the second century A.D. were deemed the final, inviolable authority on all matters related to health, disease, and death. Galen taught that life began with the first beat of the heart and ended with the last beat

(brought about by the cessation of flow of the vital spirit held within breath), never again to be started; death was permanent and irreversible.

The great awakening of intellectual curiosity during the Renaissance included matters related to medicine. However, religion still had a stronghold on all matters of death, and attempts at resuscitation were viewed as against the laws and will of God. By the eighteenth century, the scientific method was established, and the potential reversibility of death began to be explored. The stage was set for the first documented cases of resuscitation, along with the scientific inquiry to support its development.

During the early-mid eighteenth century, when accounts of artificial resuscitation techniques began to surface, common causes of sudden death included trauma, smoke inhalation from fires, drowning, and infectious diseases. Sudden cardiac death was not the norm for the day. One of the initial accounts of mouth-to-mouth resuscitation occurred during this time in a man overcome by smoke inhalation from a coal fire; he had no spontaneous respirations or pulse, but was revived successfully and returned to his job a few days later. Later in that same century, rescue societies were developed in many cities, and a concerted effort began to develop a successful method of resuscitation from sudden death. Recommendations at that time included patient warming, placing the head below the feet, stimulating the abdomen and feet to remove swallowed and aspirated fluids, rectal and oral stimulation via fumigation techniques, mouth-to-mouth or bellows-supported respirations, and bloodletting.[1] By the mid-nineteenth century, the obstructing role of the flaccid tongue during resuscitation became known, along with the need to intervene as soon as possible after arrest. Multiple methods of respiratory support were proposed at the time, but by the beginning of the twentieth century, the American Red Cross endorsed the technique developed by Edward Schafer: intermittent pressure was placed on the back of the prone victim.[2] By the early 1930s, a new method, developed by Holger Nielsen, was endorsed by the Red Cross: with the victim in the prone position, back pressure was alternated with bilateral arm lifts.[3]

In the 1940s, James Elam demonstrated the effectiveness of mouth-to-nose ventilation in supporting patient oxygenation. His experience with polio victims who had suffered respiratory paralysis convinced him that there was a better method of respiratory support than the Nielsen method.[4] By the late 1950s, research by Elam and Peter Safar using postoperative patients and partially paralyzed volunteers with curare conclusively demonstrated the superiority and adequacy of mouth-to-mouth resuscitation in providing ventilatory and oxygenation support in the setting of respiratory insufficiency. The technique of "expired air breathing" was endorsed in the *Journal of the American Medical Association* in 1958, and efforts to disseminate this information began.[5,6]

The first successful accounts of chest compression in the setting of cardiac arrest occurred in the late nineteenth and early twentieth centuries. The technique, however, did not catch-on in the medical community until it was "rediscovered" in the late 1950s by William Kouwenhoven and his team at Johns Hopkins University. It was observed that vigorous application of defibrillator paddles to the chest of a dog in ventricular fibrillation transiently increased arterial blood pressure, and that repetitive chest wall displacement by the paddles significantly prolonged the length of time available to achieve successful defibrillation. Through trial and error it was determined that compression with the heel of the hand could achieve similar results, and that optimal arterial pressures were obtained with compressions over the lower third of the sternum to a depth of 1.5–2 in. at a rate of 60–80/min. In an article in the *Journal of the American Medical Association* in 1960, Kouwenhoven et al reported the use of chest compressions in 20 patients who suffered cardiac arrest, most resulting from complications of anesthesia; 14 survived. Prior to this publication, open cardiac massage was the standard of care. Shortly thereafter, the techniques of mouth-to-mouth respiration and external chest compression were joined, and modern basic cardiopulmonary resuscitation (CPR) was born.[7]

EPIDEMIOLOGY OF SUDDEN DEATH

To understand sudden death and the potential for intervention, you must begin with the collection and analysis of factors associated with sudden death. Such epidemiologic data allow health care providers to better understand initiating events and promote the efficient study of

CASE STUDY: PART 1

A 58-year-old male businessman with a past history of hypertension and diabetes mellitus collapsed suddenly at his office while speaking to a group of business executives. Shortly before the meeting, he complained of an uncomfortable sensation in his chest, but thought that it was "just heartburn." After collapsing, he was attended to immediately by a colleague who was trained in basic life support (BLS). The victim was ashen in color, not breathing, and did not respond to shaking or verbal stimuli. The colleague asked another executive to call 911, then opened the airway with a head tilt and noted no evidence of breathing. He gave two slow breaths to the victim via mouth-to-mouth respiration, and then felt for a carotid pulse. Finding no pulse, he initiated chest compressions alternating with mouth-to-mouth respirations until the ambulance squad arrived and assumed care of the patient.

TABLE 50-1

potentially effective clinical interventions. Table 50-1 lists some traditional epidemiologic data that are collected and studied.

Sudden death is defined as "cessation of cardiac mechanical activity, confirmed by the absence of a detectable pulse, unresponsiveness, and apnea or agonal, gasping respiration."

Epidemiologic study begins with establishing strict definitions of terms. A consensus definition established by the Utstein II International Workshop in 1991 defines sudden death as "cessation of cardiac mechanical activity, confirmed by the absence of a detectable pulse, unresponsiveness, and apnea or agonal, gasping respiration."[8] Ischemic heart disease is the most common cardiac condition predisposing to sudden death.[9,10] Other less common causes in adults include primary dysrhythmias not associated with ischemic disease, pulmonary disease, cerebrovascular disease, electrolyte abnormalities, and toxins.

Ischemic heart disease is the most common cause of sudden death.

Ischemic heart disease increased substantially in the United States in the early twentieth century. By the 1940s, cardiovascular disease was the leading cause of death in adults, but perhaps as a result of diet and lifestyle changes, smoking cessation, and treatment of hypertension, there has been a relatively recent and significant decline in the incidence of cardiac arrest in the United States.[10,11] Annually in the United States, approximately half a million people die of sudden cardiac arrest.[12] This is the leading cause of death in the United States and Canada.[13-15] In developed countries, 50% of cardiac mortality is due to sudden cardiac death.[16] Approximately 50% of these deaths occur in patients older than 65 years of age and nearly half occur in women.[17] Sixty percent of sudden cardiac deaths occur outside the hospital setting. Resuscitation is attempted on two thirds of these patients.[14] Successful resuscitation from sudden death occurring outside the hospital setting is unusual. Nationally, it is estimated that survival of out-of-hospital cardiac arrest reaches just 5–10%,[18] and in some large cities, it is even less. Through intensive educational programs and community training, however, some midsize cities now boast survival rates as high as 18%.[19]

Survival rates for out-of-hospital sudden death range from 0 to 18%.

Exactly why sudden cardiac arrest should occur at a given moment in a given individual is rarely known. Typically, such individuals have identifiable risk factors for the development of cardiac disease that have been present for a significant period of time. Superimposed upon these relatively static factors may be transient factors that can suddenly trigger events leading to sudden death. For example, in a patient with underlying hypertension and coronary artery disease, transient ischemia and reperfusion may be the triggering factor leading to dysrhythmia and death.[20] Table 50-2 lists other potential transient triggering factors leading to sudden cardiac death.

All forms of underlying cardiac disease have been associated with the sudden death syndrome. The most significant risk factors in this category include known coronary artery

disease and a history of sudden death in the family. In addition, the presence of known dysrhythmias represents risk for sudden death. Increasing age increases the rate of cardiac arrest exponentially, and sudden death risk is greater in males than in females for any given age.[20] Race also plays a role in sudden death. African–Americans have a higher rate of sudden death than Caucasians, most likely because of higher rates of hypertension, diabetes mellitus, and renal disease.[17] Fortunately, some risk factors for the development of sudden death can be ameliorated. Obviously, prevention of sudden death is much preferable to treatment. Table 50-3 lists potentially modifiable risk factors for sudden death.

Survival rates from sudden death vary considerably, from nearly 0 to 18% overall.[19] Many factors influence survival rate within a community. Population modification of the foregoing risk factors, in and of itself, can have a positive influence. In addition, community education regarding CPR certification and rapid notification of the emergency medical services (EMS) system, coupled with prompt institution of CPR and defibrillation, can enhance survival.[21] Other factors, not all of which can be modified, that influence survival from sudden death include witnessed vs. un-witnessed cardiac arrest, race, age, sex, initial rhythm, and amplitude of ventricular fibrillation. Lack of uniform reporting of data regarding out-of-hospital cardiac arrest has led to difficulties in evaluating data and comparing resuscitation techniques between communities. The Utstein template for uniform reporting of data from out-of-hospital sudden death, recommended in *Circulation* in 1991 by Cummins et al, has become an accepted mode of data collection and reporting, thereby facilitating overall and subgroup analysis of epidemiologic data and therapeutic modalities.[8]

Positive predictors of successful resuscitation are listed in Table 50-4. Witnessed cardiac arrest consistently has been determined to be a predictor of increased survival, as has the initiation of bystander CPR before EMS arrival.[22-24] Unfortunately, only 20–30% of sudden death victims in most communities have CPR performed by bystanders at the scene.[25] The chance of survival falls precipitously as time passes, emphasizing the need for prompt initiation of basic and advanced life support efforts. Finally, victims who present with ventricular tachycardia or ventricular fibrillation are 2–3 times more likely to survive than patients presenting in pulseless electrical activity (PEA) or asystole.

ETIOLOGY OF SUDDEN DEATH

As noted, approximately 500,000 cases of sudden death occur each year in the United States,[12] and nearly 60% of these deaths are attributable to underlying coronary artery disease.[14] Autopsy studies indicate that 40–70% of victims have evidence of healed myocardial

infarction,[20] and acute myocardial infarction is found in approximately 30% of victims. Other less frequently found cardiac and vascular etiologies of sudden death include coronary artery vasculitis, congenital cardiac abnormalities, left ventricular hypertrophy, congestive heart failure, myocarditis, infiltrative disorders of the myocardium, valvular heart disease, conduction system disease, pericardial tamponade, aneurysm rupture, and aortic dissection.[26]

Various respiratory diseases (e.g., asthma, bronchial obstruction, pulmonary infarction, and pulmonary infections) may be associated with sudden death, with hypoxia and catecholamine excess playing important causative roles. Acute neurologic events may also result in sudden death. The abnormal depolarization and repolarization electrocardiogram (ECG) findings in patients with subarachnoid hemorrhage or large cerebral infarctions are well described and may result from altered autonomic nervous system regulation. Sympathetic overactivity, giving rise to cardiac dysrhythmias, may be the cause of sudden death associated with seizure activity. Electrolyte disturbances associated with various endocrine disorders are also potential culprits for sudden death, giving rise to lethal dysrhythmias. Examples include the prolonged QT syndrome seen with hypothyroidism, hypokalemia in Cushing's syndrome, and hyperkalemia in adrenal insufficiency.[20] Toxins as causative factors in sudden death have received increasing publicity in recent years. Typically, the involved toxins cause lethal ventricular dysrhythmias. Examples include cocaine, and inhalant drugs such as toluene, anabolic steroids, and chloroform. Finally, overwhelming infection may give rise to sudden death within 24 h of presentation; examples include bacterial meningitis, endocarditis, myocarditis, and Chagas disease.

MECHANISMS OF BLOOD FLOW DURING STANDARD CPR

It seems intuitive that if CPR is to be successful, with resumption of cardiac and neurologic function, adequate forward blood flow to the heart and brain must occur. Indeed, optimization of coronary and cerebral perfusion pressures is central to successful resuscitation and is reviewed in the next section. But in order to optimize perfusion of vital organs, we must first understand the forces controlling the forward flow of blood during CPR.

Debate continues as to the nature of the pump during external chest compressions. Three basic theories have evolved: the cardiac compression pump, the intrathoracic pressure pump, and a combination of the first two theories.[27] The standard theory proposed for many years was the cardiac compression pump theory. It states that intrathoracic pressures do not rise during external chest compression. Rather, external compression compresses the heart directly between the sternum and vertebral column, thereby raising intraventricular pressure and squeezing blood out of the heart and forward into the peripheral circulation, including the coronary and cerebral vasculature. In this theory, the cardiac valves remain competent, thereby preventing retrograde flow of blood during compression and decompression. During decompression, the heart refills with blood, and the cycle repeats itself as compression is again instituted. It is presumed that air moves freely in and out of the lungs, thereby preventing a rise in intrathoracic pressure during chest compression and allowing air to return to the lungs during cardiac decompression.[28]

Beginning in the 1960s, suspicion arose regarding the adequacy of the cardiac compression pump theory of forward blood flow. It was noted in dogs that external chest compressions did not result in a pressure gradient between arterial and venous systems. Such a gradient would be required for blood to flow by a direct compressive mechanism.[29] In the 1970s and early 1980s, cyclic fluctuations in intrathoracic and vascular pressures during chest compressions were demonstrated. It was suggested that forward blood flow during CPR was caused by alterations in intrathoracic pressure being transmitted to the vascular system. During chest compression, intrathoracic pressure rises and alveolar collapse occurs. In addition, retrograde venous flow is prevented by the collapse of venous structures at the thoracic inlet.[30] The cardiac valves are neither competent nor necessary to explain forward flow. During chest decompression, there is a fall in intrathoracic pressure with venous return

Changes in intrathoracic pressures account for most, and possibly all forward blood flow during CPR.

of blood to the thoracic structures. The heart, rather than being directly compressed and decompressed as with the cardiac compression pump theory, actually acts as a passive conduit responding to changes in intrathoracic pressure.[31]

Since then, many elegant techniques have been developed to measure intrathoracic pressure during CPR, evaluate cardiac and aortic dimensions, and evaluate competency of the cardiac valves. Currently, most investigators believe that the bulk of evidence supports the intrathoracic pressure pump theory, though direct cardiac compression may play some role, albeit minor, in the generation of forward blood flow during CPR.

CORONARY AND CEREBRAL PERFUSION PRESSURES

Chest compression during CPR is intended to provide vital organ perfusion to sustain viability until native cardiovascular activity is restored. Research has indicated, however, that regional organ perfusion achieved during CPR is substantially less than what occurs with normal sinus rhythm. Standard closed chest CPR techniques provide, at best, only 30–40% of normal cerebral blood flow and only 10–30% of normal myocardial blood flow.[32] In addition, there is almost no perfusion of peripheral structures. It is critical to evaluate the questions of minimal heart and cerebral perfusion required, not only for return of spontaneous circulation, but also for provision of acceptable neurologic recovery. Maximization of cerebral and myocardial perfusion, thereby enhancing survival, is a major challenge to resuscitation researchers.

CPR provides only 10–30% of normal myocardial blood flow, and only 30–40% of normal cerebral blood flow.

Estimation of myocardial perfusion during CPR is best achieved via measurements of coronary artery perfusion pressure. Work by Crile and Dolley in the early 1900s led to the concept that a minimum coronary perfusion pressure in experimental models of cardiac arrest was necessary for successful resuscitation to occur.[33] This concept was reaffirmed by studies done in the 1960s and 1970s, with an understanding that a minimum aortic diastolic pressure of approximately 40 mmHg was necessary for return of spontaneous circulation.[34] As a result, the beneficial action of alpha-adrenergic agents in resuscitation, which increase peripheral vasoconstriction and lead to a subsequent rise in aortic diastolic pressure, was better defined. Selective alpha-blockade resulted in the inability to raise aortic diastolic pressures with epinephrine. With selective beta-blockade, the ability to raise aortic diastolic pressure with epinephrine was retained. Further work refined the concept of coronary perfusion by demonstrating that forward blood flow, more precisely, was related to the difference between aortic diastolic pressure and right atrial pressure, with this difference representing an arteriovenous gradient responsible for organ perfusion. Kern, et al.[35] have elucidated not only what happens during the relaxation, or diastolic, phase of CPR, but also during the compression, or systolic phase. Investigation into the entire cardiac cycle has revealed that diastolic pressure gradients account for the majority of forward blood flow and myocardial perfusion during CPR, and that retrograde coronary flow often occurs during the compression phase. In addition, the correlation between coronary perfusion pressure and myocardial blood flow has been well established, with laboratory-documented increases in myocardial perfusion as coronary perfusion pressure increases. Finally, as would be expected, coronary artery stenoses compromise myocardial perfusion during CPR in experimental animals, and research indicates that stenoses deemed insignificant under normal physiologic conditions play a compromising role in the setting of CPR.[35]

Fortunately, the rises in myocardial perfusion associated with rises in coronary perfusion pressures also translate into increased success in defibrillation, short-term survival, and long-term survival. Thus, maximization of coronary perfusion can be studied objectively and lead to improvements in CPR techniques and pharmacologic interventions.

Unfortunately, most victims of cardiac arrest do not survive. Interestingly enough, most victims of cardiac arrest undergoing external CPR have coronary perfusion pressures less than 10 mmHg. Those victims who do survive typically have much higher coronary perfusion pressures, generally greater than 15 mmHg.[36] This correlation between coronary

Minimum coronary perfusion pressure required for survival is ~15 mmHg.

perfusion pressure and survival persists both in the laboratory and human clinical situations. As such, coronary perfusion pressure seems to be a predictor of survival during CPR, and generation of pressures greater than 15 mmHg is an important goal of research and clinical efforts.

Predictably, much research has occurred in an attempt to develop optimal dosing regimens and newer drugs that further enhance coronary perfusion pressure. Epinephrine has been the standard alpha-agonist used in cardiac arrest and its optimal dosing has been the study of much research. There was great anticipation that high-dose epinephrine would produce an increase in coronary perfusion pressures and survival. However, multiple human trials of high-dose epinephrine in adults failed to demonstrate a survival advantage, perhaps because of a change in the balance between myocardial oxygen demand and consumption as increases in coronary perfusion pressure were achieved.[37] Other alpha-agonists studied in cardiac arrest have included norepinephrine, phenylephrine, and methoxamine; no consensus yet exists as to coronary perfusion pressures and survival data associated with these drugs.

High-dose epinephrine fails to increase survival in adult cardiac arrest. Standard CPR techniques can support cerebral blood flow for ~15 min.

Avoidance of ischemic neurologic injury during CPR and after successful return of spontaneous circulation is necessary to avoid significant morbidity and mortality. Cerebral blood flow is closely correlated to the difference between carotid artery pressure and intracranial cerebrospinal fluid pressure. Initially during CPR, carotid artery pressure equals intrathoracic aortic pressure. With time, however, there is a fall in carotid pressure, known as carotid collapse, which correlates with a parallel fall in cerebral blood flow. Alpha-agonists reverse this decline in carotid pressure.[38,39]

Experimental evidence in dogs suggests that standard techniques of CPR generate cerebral blood flow of 30 mL/min/100 g and that this degree of flow is adequate to maintain cerebral oxygen consumption and ATP levels at prearrest levels for approximately 1 h. Animals resuscitated under such conditions appear to be neurologically intact. For these conditions to be met, cerebral perfusion pressures of approximately 30 mmHg are required,[40] which in turn require mean aortic pressures of 55–60 mmHg.

Clinical data is less readily available due to obvious technical limitations of directly measuring cerebral perfusion pressure and cerebral blood flow during CPR. Typical aortic pressures generated during CPR, however, probably yield adequate mean pressure levels to generate cerebral perfusion pressures up to 20 mmHg.[36,41]

CLOSED CPR TECHNIQUES

Much research has been directed toward improving the results of current standard techniques of CPR in terms of generation of coronary perfusion pressure, rates of return of spontaneous circulation, and overall survival to neurologically acceptable states of function. We briefly discuss some of the alternative methods studied.

Increased force of compression does, indeed, produce an increase in coronary perfusion pressure.[31] Overly aggressive chest compressions, however, are not without hazard. Increasing coronary perfusion pressure comes at the expense of CPR-induced injury and mortality. Thus, chest compression forces that result in depressions greater than the recommended 1.5–2 in. are not warranted.[42]

High-impulse CPR, a technique whereby the rate of chest compression is increased, yields increased mean aortic diastolic pressures and, consequently, increased coronary perfusion pressures.[43] Though true survival data are not available, the increase in coronary perfusion pressure warranted the recommended increase in compression rate from 60/min to 80–100/min.

Interposed abdominal compression CPR is a three-person technique with the proposed hemodynamic advantages of increasing venous return, as well as raising coronary perfusion pressure, myocardial perfusion pressure, and blood flow. A dedicated rescuer provides manual abdominal compression (midway between the xiphoid and the umbilicus) during the relaxation phase of chest compression.[44,45] Most animal studies support the concept, but human clinical experience has been less straightforward. Measurements of coronary

CASE STUDY: PART 2

Upon arrival of the ambulance crew, the executive performing CPR told them what had taken place. He stated he had witnessed a full cardiorespiratory arrest, and that since institution of CPR, no vital signs had returned. The emergency medical technician (EMT) reassessed the airway in the head tilt–chin lift position and confirmed lack of spontaneous air movement. Using a bag-valve-mask device after placing an oral airway, he administered oxygen and confirmed air movement into the lungs. After confirming pulselessness in the victim, the EMT continued with one-person CPR. His assistant placed an 18-gauge needle in the left antecubital fossa without difficulty and began IV administration of normal saline solution as CPR continued.

perfusion pressure have yielded inconsistent results. Preliminary clinical outcome studies have suggested a possible role for in-hospital cardiac arrest. However, the technique has potential for patient injury, especially in the abdomen, along with pulmonary aspiration if the airway is not properly protected. Interposed abdominal compression CPR is a promising technique, but as yet, insufficient data exist as to its safety and efficacy.

No "alternative methods" of closed chest CPR have demonstrated significantly improved survival data compared to standard CPR techniques.

Active compression–decompression CPR is often referred to as the "plunger" technique. This device has a circular suction cup that actively lifts the anterior chest during the relaxation phase of CPR. It helps decrease intrathoracic pressure during the decompression phase, thereby enhancing venous return to the heart.[46] Laboratory models of cardiac arrest suggest an improvement in coronary perfusion pressure using this technique. To date, adequate hemodynamic data in humans are not available, and use of the device is still considered experimental.

Another promising adjunct for CPR is the use of the perithoracic pneumatic vest, which alters intrathoracic pressure in rhythmic fashion in conjunction with asynchronous ventilation. Early clinical studies have demonstrated significant increases in coronary perfusion pressures.[47]

AIRWAY, VENTILATION, AND OXYGENATION

It is not just for purposes of convenience and ease of recall that the initial response to any emergency begins with the ABCs. Failure to manage properly the airway and breathing of a cardiac arrest victim, while doing everything correctly to maintain circulatory support, results in a dead patient. Resuscitation begins with the airway, as does periodic reassessment of the patient during times of clinical change. The importance of the ABCs, in that order, cannot be overemphasized.

Although we continually preach and practice the ABCs, data from animal[48] studies and human studies[20] demonstrate that chest compression-only BLS by the public may be as equally effective as BLS-CPR with rescue breaths. Bystanders may be reluctant to perform mouth-to-mouth ventilations for fear of infectious disease transmission. In the SOS-KANTO study,[20] patients who received compression-only resuscitation were found to have similar or even superior neurological outcome than those who received BLS-CPR with ventilation.

Only airway management in the setting of full respiratory arrest is addressed here. Chapter 1 also discusses in great depth many of the techniques presented here. When an arrest victim is encountered, first rule out the readily reversible causes of respiratory arrest secondary to airway obstruction. Witnesses to the arrest may provide invaluable information. For example, the victim who collapses at a restaurant, after placing their hands to the anterior neck, almost certainly has arrested due to foreign body obstruction. In acute airway obstruction, regardless of cause, the highest priority is to open the airway. In the absence of foreign body obstruction, most likely the flaccid tongue is occluding the posterior pharynx. Loss of tone of the supporting submandibular muscles makes at least partial airway obstruction in this setting almost universal. The head tilt, coupled with the chin lift or jaw thrust, is a simple but

The flaccid tongue is the most common cause of airway obstruction in the victim of sudden death.

The head tilt, coupled with the chin lift or jaw thrust, is the initial airway procedure of choice in the noninjured adult victim of sudden death.

potentially lifesaving technique. These maneuvers displace the mandible and tongue forward to relieve the airway obstruction. In the setting of trauma, the cervical spine must be maintained in a neutral position to avoid cervical injury; thus, the head is not tilted, but the jaw thrust can be used safely.

In the setting of sudden death, if a patent airway and ventilation cannot be achieved, foreign body obstruction must be assumed to be the etiology for respiratory failure.

The airway is inspected to exclude obstruction by a foreign body, and if present, the foreign body should be removed with protected fingers or suction. If spontaneous respirations begin, maintenance of a patent airway is essential. In the absence of return of spontaneous respirations or obvious foreign body, airway adjuncts, such as the oropharyngeal or nasopharyngeal airway, may assist in establishing airway patency. Ventilation is attempted via one of several techniques: mouth-to-mouth, mouth-to-mask, or bag-valve-mask with 100% oxygen. If air does not enter the chest easily and if the chest does not rise, airway obstruction once again must be suspected. The head and neck are repositioned, and ventilation is again attempted. If ventilation still is not achieved, reversal of airway obstruction is attempted utilizing the Heimlich maneuver or back blows. If ventilation is achieved and pulselessness is confirmed, chest compressions should be instituted. Definitive airway support and protection, however, still have not been accomplished. Optimal oxygenation and ventilation are best achieved via endotracheal intubation.[42] The American Heart Association lists the following as indications for endotracheal intubation: cardiac arrest with ongoing chest compressions, inability of a conscious patient to ventilate adequately, inability of the patient to protect the airway (coma, areflexia, or cardiac arrest), or inability of the rescuer to ventilate the unconscious patient with conventional methods.[49] As a matter of course, cricoid pressure should be applied in adults before intubation. This can improve the view of the glottis and may help prevent aspiration of gastric contents; cricoid pressure should be maintained until the endotracheal tube cuff is inflated and proper tube position confirmed.[50,51]

Definitive airway support for the victim of sudden death requires endotracheal intubation.

VASCULAR ACCESS AND CIRCULATORY SUPPORT

Once the airway has been secured and ventilation begun, pulselessness is confirmed, and chest compressions are instituted. Continuous monitoring of all functions, including cardiovascular, is necessary to assess the initial cardiac rhythm and any changes in rhythm. It is essential that cardiac rhythm be assessed at the earliest possible moment because immediate defibrillation is of the highest priority if ventricular fibrillation or pulseless ventricular tachycardia is present.

Atropine, epinephrine, naloxone, and lidocaine can be administered via the endotracheal tube.

Intravenous or intraosseous access should be established as soon as possible for fluid therapy and drug administration, but all is not lost if intravenous access is delayed or difficult to establish. Atropine, lidocaine, naloxone, and epinephrine can be administered via the endotracheal tube in the absence of intravascular or intraosseous access. A 35-mm through-the-needle intracatheter is threaded down the endotracheal tube, and 2–2.5 times the usual drug dose is injected, followed by a 10-mL flush of normal saline down the catheter and several forceful ventilations via the endotracheal tube.[52]

Central lines provide more rapid drug delivery to the central circulation compared to peripheral lines.

It is not surprising that drug delivery to the central circulation from a peripheral venous site of administration is delayed by 1–2 min compared to normal physiologic conditions.[52] Direct central vein cannulation is preferable for drug delivery. There are, however, disadvantages of this approach; central line access takes longer than peripheral vein access and may interfere with airway management and chest compression.[53] Central techniques also are not without hazard due to the potential for pneumothorax, puncture of associated arterial or neurologic structures, and lack of ready access for bleeding control. The American Heart Association balances these issues and recommends that "cannulation of a peripheral venous access site is the procedure of choice, even during CPR, because of the speed, ease, and safety with which it can usually be performed." We agree that peripheral access is the procedure of choice in the field and for many resuscitations in the hospital during the initial phases. However, we view cardiorespiratory arrest as the ultimate complication, which should be managed as aggressively as possible; maximizing drug delivery and effect is essential, in our opinion, and often outweighs the potential disadvantages of central venous cannulation.

CASE STUDY: PART 3

Next, the assistant placed "quick-look paddles" on the victim's chest and determined that the patient's cardiac rhythm was asystole. She proceeded with endotracheal intubation, confirmed the rhythm and that 100% oxygen was being administered, and then administered 1 mg epinephrine intravenously while her colleague continued CPR.

The following are prudent guidelines to follow, in our opinion: (1) begin with easy peripheral intravenous cannulation so that drugs can be administered as rapidly as possible; (2) if intravenous access is unavailable or difficult to obtain, perform intraosseous cannulation; (3) if well-trained personnel with significant expertise are available, proceed quickly with central vein access; and (4) choice of central venous access will depend on the skill of the practitioner. Keep in mind that insertion into a femoral vein does not disrupt CPR; insertion into the subclavian vein may interfere with chest compression, while internal jugular or supraclavicular subclavian vein access may interfere with airway management and chest compression.

ASYSTOLE TREATMENT

When CPR has been initiated, intubation with oxygen administration accomplished along with intravenous access, and the rhythm determined to be asystole, prompt therapy is essential. Possible causes of asystole are listed in Table 50-5.

Asystole should be considered an end-stage arrhythmia and must be treated rapidly. Drug therapy for asystole consists of epinephrine 1 mg IV every 3–5 min, followed by atropine 1 mg IV every 3–5 min to a total dose of 3 mg. An alternative to the first or second dose epinephrine is one dose of vasopressin 40 U IV.[52] Sodium bicarbonate 1 mEq/kg should be considered in known cases of severe preexisting metabolic acidosis or hyperkalemia and in cases of tricyclic antidepressant drug overdose associated with cardiac arrest. Much has been reported recently about the dose of epinephrine and the basic science in support of high-dose epinephrine (generally defined as 0.1–0.2 mg/kg). Suffice it to say that three large randomized clinical trials comparing standard-dose to high-dose-epinephrine failed to demonstrate a significant resuscitation benefit, coupled with a survival benefit with high-dose epinephrine.[37] Its potential role in pediatrics and young adults with primary respiratory arrest has yet to be evaluated by rigorous clinical trial.

Drugs used for the treatment of asystole include epinephrine and atropine.

PULSELESS ELECTRICAL ACTIVITY (PEA) TREATMENT

PEA is defined as the presence of electrical cardiac activity on the monitor in the absence of a palpable pulse or blood pressure via traditional means of measurement. The study of ultrasound during PEA has demonstrated that some cases actually have evidence of mechanical myocardial contraction, but there is not enough forward force to produce a palpable pulse or

Always look for correctable causes of asystole and PEA.

TABLE 50-5

CAUSES OF ASYSTOLE AND PULSELESS ELECTRICAL ACTIVITY

Hypovolemia	Toxins (cyclic antidepressants, digoxin, beta-blockers, calcium channel blockers)
Hypoxia	Massive pulmonary embolism
Hyperkalemia	Massive myocardial infarction
Hypokalemia	Cardiac tamponade
Hypoglycemia	Tension pneumothorax
Hypothermia	Trauma
Severe acidosis	

CASE STUDY: PART 4

Epinephrine therapy resulted in a bradyasystolic rhythm, with ventricular escape beats every 15 s. Atropine 1 mg was administered intravenously with restoration of sinus rhythm at a rate of 60 beats/min. Despite restoration of the rhythm, no pulse was felt, and CPR was continued. Intravenous fluids were run wide open, bilateral breath sounds were confirmed with bag-valve-mask respiratory support, and neck veins were determined to be flat. The IV epinephrine dose was repeated.

blood pressure.[52] As with asystole, causative and potentially correctable reasons should be considered for the development of PEA (Table 50-5). PEA is commonly encountered in the victim of penetrating trauma, and in our experience, this rhythm often can be converted to a more stable rhythm because of potentially correctable causes in trauma patients. The so-called medical patient with PEA is a much more difficult case to stabilize.

Drugs used for the treatment of PEA include epinephrine and atropine.

Drug therapy for PEA is the same as for asystole. Though epinephrine and atropine are the first-line drugs for the management of PEA, determination and treatment of underlying cause(s) provide the cornerstone of therapy without which the patient will not survive.

VENTRICULAR FIBRILLATION TREATMENT

The presence of ventricular fibrillation represents the greatest likelihood for patient survival, assuming that prompt intervention takes place. Time is of the essence in this situation, and immediate defibrillation should take top priority. Chest compressions should be started immediately while a defibrillator is obtained. Defibrillation should be attempted initially with one shock at 200 J with a biphasic defibrillator or 360 J with a monophasic defibrillator. Chest compressions should be immediately resumed for 5 cycles (1 cycle = 30 compressions: 2 breaths, for a goal of 100 compressions a minute with the emphasis on pushing hard and fast) or 2 min, and then stop compressions to check the rhythm. Rhythm checks should be brief.[52] It is important to minimize chest compressions interruptions in order to maintain coronary perfusion.[54] If ventricular fibrillation persists, defibrillation at 200 J (biphasic) or 360 J (monophasic) should be attempted again. CPR should continue while the defibrillator is charging and until the patient is cleared for shock delivery. If the patient remains in ventricular fibrillation after two attempts at defibrillation, CPR should be continued, airway management optimized, and a vasopressor like epinephrine or vasopression administered at the above-noted doses. Defibrillation should then be reattempted for a third time at the same energy level as above, and if unsuccessful, an antiarrhythmic drug should be administered.

Antiarrhythmic medications recommended are amiodarone 300 mg IV once, and then consider an additional 150 mg once; lidocaine 1–1.5 mg/kg IV, repeated in 5–10 min at a doses of 0.5–0.75 mg/kg IV for a maximum of three doses or total dose of 3 mg/kg[52]; procainamide 20 mg/min IV to a maximum dose of 17 mg/kg for refractory ventricular fibrillation[55]; and magnesium sulfate 1–2 g IV for torsades de pointes or severe suspected hypomagnesemia.[52]

The most important aspects to the treatment of ventricular fibrillation are rapid defibrillation and effective chest compressions.

Pulse checks should only be performed with the presence of an organized rhythm during rhythm checks.[52] If spontaneous circulation returns at any point during the above management, airway, breathing, and vital signs should be reassessed and managed as indicated. Ventricular ectopy should be suppressed, unless otherwise contraindicated, by continuous infusion of medication(s) that appeared to be successful in terminating the rhythm in association with defibrillation (see Table 50-6).

TABLE 50-6

CONTINUOUS INFUSION DOSES FOR VENTRICULAR FIBRILLATION AND TACHYCARDIA

Lidocaine: 1–4 mg/min
Procainamide: 1–4 mg/min
Sotalol: 10 mg/min

CASE STUDY: PART 5

Two minutes after the second dose of epinephrine was administered, the cardiac monitor revealed ventricular fibrillation. The patient was immediately defibrillated at 200 J with a monophasic defibrillator without success; a second attempt at defibrillation at 200 J resulted in restoration of a sinus rhythm at 50 beats/min with frequent PVCs; this time, there was a palpable pulse with a blood pressure of 70/40 mmHg.

BRADYCARDIA TREATMENT

Management of bradycardia is dictated by the clinical condition of the patient, not the absolute pulse rate.

The case study indicates that treatment of bradycardias in the prior setting of cardiac arrest is determined by clinical evaluation of the patient. In the presence of any of the serious signs or symptoms noted in Table 50-7 and directly related to the bradycardia itself, heart rate must be increased; this is accomplished via the sequential use of atropine 0.5–1 mg IV every 3 min to a clinical response or a total dose of 3 mg, transcutaneous pacing, dopamine 5–10 μg/kg/min, and epinephrine 2–10 μg/min.[55] Cardiac transplant patients have denervated hearts. Thus, they will not respond to atropine and should be treated initially with transcutaneous pacing or catecholamine infusion. Finally, lidocaine should not be given in bradycardic patients with ventricular escape mechanisms because this may terminate the very electrical activity that is keeping the patient alive.

In the absence of symptomatic bradycardia and in the presence of type II second degree AV block or third-degree AV block, preparation for transvenous pacemaker insertion should be started due to the potential for worsening degrees of heart block. In the absence of such situations, the patient can be monitored and observed without acute intervention.

VENTRICULAR TACHYCARDIA TREATMENT

Unstable ventricular tachycardia is treated in identical fashion as ventricular fibrillation.

As with bradycardic rhythms, the presence of ventricular tachycardia on the monitor requires the clinician to evaluate the patient. Not all patients with prolonged ventricular tachycardia develop unstable vital signs. In the unstable patient, or the patient without vital signs who develops ventricular tachycardia, treatment should proceed identical to the treatment for the victim of ventricular fibrillation. In the stable patient, therapy is initiated with amiodarone 150 mg IV over 10 min, repeat as needed for a total dose of 2.2 g/24 h. Other options include lidocaine 1–1.5 mg/kg IV, followed by lidocaine 0.5–0.75 mg/kg IV every 5–10 min to a maximum dose of 3 mg/kg. If unsuccessful, the next treatment option is procainamide 20 mg/min IV until the arrhythmia stops, hypotension develops, or the QRS complexes prolongs, or to a maximum dose of 17 mg/kg. If still unsuccessful, sotalol can be administered IV at 1–1.5 mg/kg at a rate of 10 mg/min. If the patient remains in ventricular tachycardia, synchronized cardioversion should be considered. As with ventricular fibrillation, continuous maintenance doses of these drugs should be administered, based on which ventricular tachycardia will be terminated (see Table 50-6).[55]

SPECIAL RESUSCITATION SITUATIONS

Hypothermia

Chapter 31 provides an extensive review of the management of hypothermic patients, including caveats of resuscitation in the setting of cardiorespiratory arrest. A few points are worth emphasizing here:

TABLE 50-7

SERIOUS SIGNS AND SYMPTOMS RELATED TO BRADYCARDIA

Chest pain	Hypotension
Dyspnea	Pulmonary edema
Altered level of consciousness	Myocardial infarction

CASE STUDY: PART 6

The patient's pulse decreased to 40 beats/min, and blood pressure of 70/40 is barely audible. Atropine 1 mg IV was administered, and the pulse increased to 75 beats/min. Repeat blood pressure is now 110/60 mmHg. The PVCs continue.

1. Prevention of further heat loss is essential, especially in the wet victim who loses significant heat due to the enhanced conductivity of water compared to air.
2. Excessive jostling of the patient may precipitate ventricular fibrillation.
3. Careful intubation is a safe procedure and should be done by the most experienced person available.
4. Active core rewarming techniques are indicated in the profoundly hypothermic, unstable patient.
5. Drugs and defibrillation techniques rarely work in the profoundly hypothermic patient; emphasis should be placed on rewarming, with reservation of standard procedures until rewarming is achieved.
6. CPR should be withheld in the hypothermic patient with an organized rhythm whose clinical status corresponds to the degree of hypothermia; aggressive rewarming should be the treatment of first priority; chest compressions may convert the bradycardic patient to a patient with ventricular fibrillation.
7. Patients should not be pronounced dead until adequate rewarming has taken place.

Near-Drowning

Victims of near-drowning should be assumed to have associated neck injuries, and airway management should proceed with this caution in mind. It is imperative to restore ventilation and oxygenation as rapidly as possible. Care must always be taken to protect the rescuer(s) during removal of the patient from the water. Once the patient is in shallow water or on land, rescue breathing should be initiated. The Heimlich maneuver should not be used unless upper airway obstruction from a foreign body is suspected. Generally, only a minimal amount of water is aspirated, and laryngospasm prevents aspiration in approximately 10% of victims. The Heimlich maneuver is of little benefit, and in fact, may promote the aspiration of gastric contents, vomiting, and delay of CPR.[56]

Victims of near-drowning should be resuscitated using the basic principles of advanced life support. Many such victims have associated hypothermia due to submersion, which frequently plays a protective function in maintaining organ system viability despite prolonged periods of cardiorespiratory arrest. The principles of hypothermic resuscitation should be followed as outlined in Chap. 31.

Failed Field Advanced Cardiac Life Support Resuscitation

In this age of cost cutting in medical care, it seems reasonable to assess clinical strategies for patients with extremely poor prognoses. One such group comprises those victims of cardiorespiratory arrest who have failed lengthy out-of-hospital resuscitation based upon ACLS guidelines. Depending on the level of sophistication of the local prehospital system, this scenario may or may not be common in a given emergency department.

Data support the concept that failed prehospital advanced cardiac life support (ACLS) resuscitation represents a medically futile state.

Two extensive studies in the past decade have addressed this issue with similar results, the first by Kellerman et al and the second by Gray et al. They described medically futile outcomes in resuscitative efforts performed on victims of cardiac arrest who failed to regain spontaneous circulation after full out-of-hospital resuscitation efforts. Placing the issue of medical student and resident education aside, these studies support the notion that continued resuscitative efforts in these medically futile situations simply increase health care costs and patient agony, without any hope of patient benefit.[57,58] There are, however, important caveats.

CASE STUDY: PART 7

The patient's pulse and blood pressure remained stable over the next 2 min. As an IV drip of lidocaine was being prepared for administration after a bolus of lidocaine, the cardiac rhythm suddenly reverted to ventricular tachycardia. There was no palpable pulse. Immediate defibrillation at 200 J with the monophasic defibrillator restored sinus rhythm, a pulse of 80/min, and blood pressure of 138/70 mmHg. The lidocaine bolus of 1.5 mg/kg was given, followed by a lidocaine drip at 3 mg/min. The victim's pulse and blood pressure remained stable over the next several minutes. There was no return of ventricular ectopy, and the patient was transported to the nearest hospital emergency department for further care.

Victims of hypothermic-induced cardiac arrest must continue to be resuscitated until core rewarming has been achieved; failure to recognize correctable causes of arrest in the field may be amenable to hospital resuscitation; and the pregnant victim of cardiac arrest actually represents two patients, not just one, and aggressive maternal resuscitation, even in the setting of maternal medical futility, is necessary if an attempt at fetal survival is the goal. As such, it is our opinion that strict policies governing cessation of resuscitative efforts for victims of failed out-of-hospital resuscitation are inappropriate; it is our opinion that physicians who employ sound clinical judgment, coupled with a broad knowledge of the principles of resuscitation, should make these decisions.

The Controversy over Closed CPR vs. Open Cardiac Massage

Open cardiac massage clearly provides for marked increases in coronary perfusion pressure, significantly above those produced by closed techniques, although survival advantage declines with increasing time from induction of arrest.[59,60] Case reports describe cardiac arrest victims, unable to be resuscitated by closed techniques, who have survived open chest cardiac massage. Such success appears limited to the first 15–20 min postarrest, after which open chest cardiac massage appears to have little or no value.[61] Finally, before the introduction in 1960 of closed chest CPR, open chest cardiac massage was the standard of care for resuscitation. Successful resuscitation rates were much higher than current values for closed CPR, although most patients studied before 1960 were victims of cardiac arrest associated with surgery.

Why was closed CPR so readily accepted and open cardiac massage discarded? For one thing, the appeal of the closed technique was its universality. Lay persons and health professionals alike could be taught the technique of standard CPR. The open technique was messy, bloody, and poorly applicable to the prehospital setting. Bodies were not judged to be "violated" by the closed technique. Opening the chest and restarting the heart was only the first step; a surgeon needed to be immediately available to complete the resuscitation and operative closure. Finally, worries about bloodborne pathogens now abound, and closed CPR, from that perspective, is less risky.

When the hemodynamics of closed vs. open techniques is compared, open chest cardiac massage is clearly superior. The following have been demonstrated in various models to be significantly superior via the open technique: aortic systolic and diastolic pressures, coronary perfusion pressure, myocardial blood flow, and cerebral blood flow.[59,60] The fundamental question is whether such hemodynamic improvements translate into significant survival advantages.

Open cardiac massage produces significantly better hemodynamic data compared to closed CPR.

Many laboratory models of cardiac arrest have been designed to help address this issue. The overwhelming evidence supports the concept that in animals in which cardiac arrest has been initiated, not only does open chest cardiac massage improve hemodynamics, but also improves immediate resuscitation rates, short-term survival, long-term survival, and neurologic recovery. There appears to be a limited "window of opportunity" after which open cardiac massage still improves hemodynamics, but not ultimate survival; this window appears to be within the first 15–20 min of cardiac arrest.[62]

If open cardiac massage is to be used successfully, it must be initiated early in the resuscitation process (probably within the first 15–20 min of cardiac arrest).

Designing clinical trials of open vs. closed techniques within this time frame represents a major challenge. Animal trials, however, clearly support the importance of such research.

To date, adequate trials based upon what we have learned from animal models of cardiac arrest are quite limited, and there is no definitive answer to the question of the utility in humans. To complicate the issue even further, new technologies, such as cardiopulmonary bypass and ventricular-assist devices, most closely approximate open chest techniques and have the potential to be incorporated into resuscitative efforts.

Finally, should we continue what may be suboptimal closed chest resuscitative techniques? The answer lies within the realm of clinical research, but will require much additional investigation. The newer technologic developments mentioned above are of great interest, but like the emergency thoracotomy required for direct cardiac massage, they can be criticized for lack of universal availability, propensity for increased risk of transmission of bloodborne pathogens, and their monetary expense.

The challenge is in the development and study of limited, readily learned, invasive techniques that can be used in the hospital and perhaps in the prehospital setting as well. One such device, utilizing a small chest incision and a simple piece of equipment for direct cardiac compression within the chest, holds potential promise. It is clear that if open techniques are to be used, they must be used relatively early after cardiac arrest and not as a last-ditch effort. As with many therapies in medicine, we may yet come full circle in our management of cardiac arrest.

SUMMARY

The response to a witnessed cardiorespiratory arrest often involves a single rescuer who begins resuscitation, calls for help, and thus, activates a highly skilled team-approach to the resuscitative effort. Standard protocols exist regarding management of very specific clinical scenarios as pertain to respiratory and cardiac disease processes. Ongoing investigation of currently accepted dogma is essential to continued improvement in resuscitation medicine; significant advancement will likely involve more invasive techniques of cardiac resuscitation.

REVIEW QUESTIONS

1. The definition of sudden death includes which of the following?
- **A.** Absence of a detectable pulse
- **B.** Unresponsiveness
- **C.** Agonal or apneic respirations
- **D.** All the above

2. The most common clinical condition predisposing to sudden death is:
- **A.** Nonischemic-related cardiac dysrhythmias
- **B.** Underlying cerebrovascular disease
- **C.** Ischemic heart disease
- **D.** Hypertension

3. Positive predictors of successful resuscitation from cardiac arrest can be attributed to which of the following factors?
- **A.** Establishment of coronary perfusion pressure of at least 15 mmHg
- **B.** Adequate perfusion pressures to both central and peripheral structures
- **C.** Maintenance of normal levels of cerebral perfusion during CPR
- **D.** None of the above

4. The use of high-dose epinephrine in the setting of cardiac arrest:
- **A.** Has been proven to be of clinical benefit for children but not adults
- **B.** Is defined as 1 mg/kg body weight
- **C.** Is indicated as first-line therapy for both asystole and refractory ventricular fibrillation
- **D.** Has not been proven to be of significant clinical benefit in adults

5. Which of the following statements is/are true regarding cardiac arrest in the setting of profound hypothermia?
- **A.** Excessive jostling of the patient may precipitate ventricular fibrillation
- **B.** Intubation may precipitate ventricular fibrillation and should not be performed
- **C.** Defibrillation rarely is successful
- **D.** Chest compression should be performed in the presence of marked bradycardia, but no palpable pulse

6. **Which of the following statements is true regarding alternative methods of closed chest CPR?**
   - **A.** Chest compression forces resulting in depressions greater than 2 in. increase coronary perfusion pressure and decrease mortality
   - **B.** Active compression–decompression CPR increases intrathoracic pressure during the decompression phase
   - **C.** Interposed abdominal compression CPR has been found to be far superior to standard CPR in hemodynamic evaluations in humans
   - **D.** No alternative methods of CPR have demonstrated significantly improved survival data compared to standard CPR techniques in humans

7. **Which of the following drugs cannot be administered via the endotracheal tube route?**
   - **A.** Amiodarone
   - **B.** Atropine
   - **C.** Naloxone
   - **D.** Epinephrine

8. **Asystole**
   - **A.** Readily responds to nonpharmacologic therapy in most cases
   - **B.** May be treated with sodium bicarbonate in cases of cyclic antidepressant overdose
   - **C.** Tends to respond to the same pharmacologic management as ventricular fibrillation
   - **D.** Should be treated initially with defibrillation 200 J

9. **Frequently encountered causes of PEA include**
   - **A.** Hypovolemia, profound acidosis, and massive pulmonary embolism
   - **B.** Hypovolemia, profound acidosis, and congenital conduction system abnormalities
   - **C.** Hypovolemia, hyponatremia, and massive pulmonary embolism
   - **D.** Hypovolemia, profound acidosis, and SSRI (selective serotonin reuptake inhibitor) overdose

10. **In the bradycardic patient**
    - **A.** Heart rate must be increased immediately
    - **B.** Transcutaneous pacing should be utilized in the patient who has undergone a cardiac transplant
    - **C.** Lidocaine should be used if ventricular ectopy is noted in order to avoid ventricular tachycardia
    - **D.** With type II second degree AV block, higher grade heart block rarely occurs

ANSWERS

1. The answer is D. In 1991, a consensus definition of sudden death was established by the Utstein II international workshop. Such strict definition was necessary for meaningful epidemiologic studies to be performed.
2. The answer is C. Ischemic heart disease is the most common condition that predisposes one to sudden death. Other less common conditions include answers A and B. Since the 1940s, there has been a decline in the incidence of cardiac arrest in the United States, attributable to diet changes, smoking cessation, and the treatment of hypertension.
3. The answer is A. Successful resuscitation from cardiac arrest requires return of spontaneous circulation and avoidance of ischemic neurologic injury. Both experimental and clinical data support the need to generate coronary perfusion pressures of at least 15 mmHg for spontaneous circulation to be restored. Direct measurement of cerebral perfusion in humans has obvious technical limitations, but extrapolation of available data suggests that generation of cerebral perfusion pressures of 20 mmHg is possible during the first 15 min of standard CPR. Peripheral structures receive almost no perfusion during CPR.
4. The answer is D. High-dose epinephrine is defined as 0.1–0.2 mg/kg. Laboratory studies have suggested a possible clinical benefit, but such survival benefits have not been substantiated in large human trials of cardiac arrest. Large trials evaluating its potential use in children have not been done.
5. The answer is A and C. The mainstay of successful resuscitation in the setting of profound hypothermia is core rewarming. Ventricular fibrillation in this setting is exceedingly difficult to treat and may be precipitated by unnecessary jostling of the patient; defibrillation rarely works before adequate rewarming. Careful intubation is a safe procedure, and as in all instances of cardiac resuscitation, airway management is essential to survival. Even bradycardic rhythms may be able to provide adequate levels of coronary and cerebral perfusion in this setting, even if palpable pulses cannot be felt due to peripheral vasoconstriction. The use of chest compressions may convert an organized rhythm into ventricular fibrillation.
6. The answer is D. Chest compression forces resulting in depressions greater than 2 in. do increase coronary perfusion pressure, but at the expense of CPR-induced thoraco-abdominal injuries, and have not been shown to decrease mortality. Active compression–decompression CPR decreases intrathoracic pressure during the decompression phase. Interposed abdominal compression CPR has not yielded consistently superior hemodynamic evaluations and carries a risk of abdominal injury and pulmonary aspiration. Overall, no alternative methods of CPR have yielded consistently superior survival data compared to standard CPR techniques.
7. The answer is A. Atropine, naloxone, and epinephrine can be administered via the endotracheal tube. Amiodarone requires intravenous administration in the CPR setting.

8. The answer is B. The cornerstone of treatment of asystole is pharmacologic, being the same as for PEA. Defibrillation 200 J is utilized for the initial treatment of ventricular fibrillation and not asystole. Cyclic antidepressant overdose is a special situation where sodium bicarbonate may be useful in the setting of asystole; other situations include known preexisting severe metabolic acidosis or hyperkalemia.
9. The answer is A. Hypovolemia, profound acidosis, and massive pulmonary embolism are all known causes of PEA. Congenital conduction system abnormalities and hyponatremia are not known to cause PEA. Various toxins, including cyclic antidepressants, may cause PEA, but SSRI overdose has not been reported to do so.
10. The answer is B. Immediate treatment of bradycardia is not indicated in the otherwise stable patient, and in patients with profound hypothermia. Lidocaine is contraindicated in the bradycardic patient with ventricular escape; suppression of the ventricular focus may lead to cardiac arrest in such patients. In type II second degree AV block, development of higher grade heart block is a significant concern. Transcutaneous pacing should be utilized in a patient who has undergone a cardiac transplant and who is bradycardic due to denervation secondary to the transplant surgery.

CHAPTER 51

HENRY H. HSIA AND KELLY MATSUDA

Antiarrhythmic Drug Management

CHAPTER OUTLINE

LEARNING OBJECTIVES

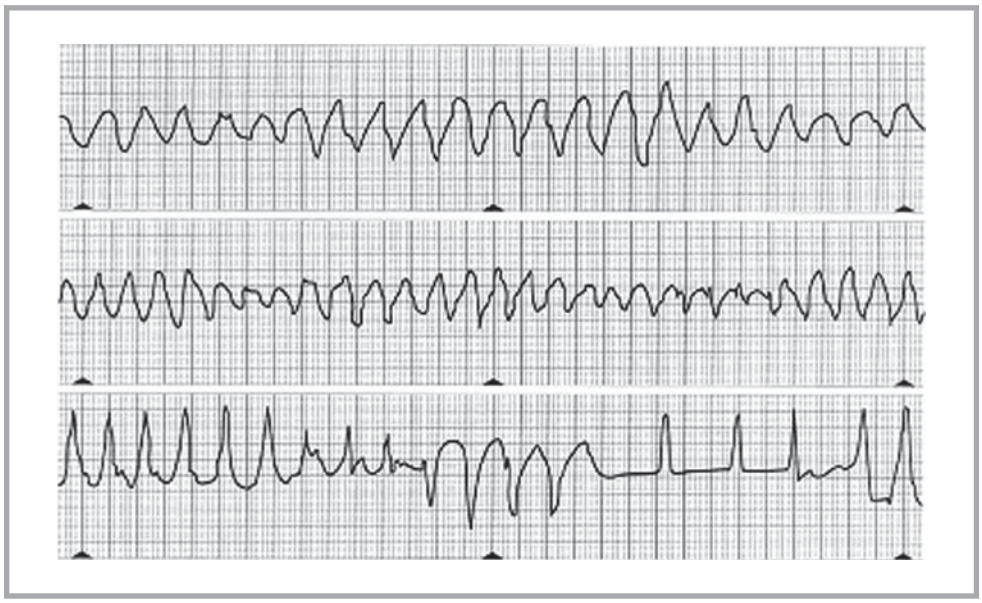
After studying this chapter, you should be able to:

- Understand the basic cellular electrophysiology.
- Know the classification of antiarrhythmic drugs and their electrophysiologic effects.
- Understand the potential mechanisms of clinically relevant arrhythmias.
- Identify potential pharmacologic target sites based on arrhythmia mechanisms.
- Know the side effect profiles of antiarrhythmic drugs.
- Develop a logical approach in the selection of a specific antiarrhythmic drug.

INTRODUCTION

This chapter focuses on the electrophysiologic principles of antiarrhythmic drug management of supraventricular and ventricular arrhythmias. The reader should understand the physiologic actions of antiarrhythmic drugs and mechanisms of arrhythmias. The goal is not to present a comprehensive review of individual antiarrhythmic agents, but to provide a framework for clinical approaches to antiarrhythmic drug selection based on the mechanisms of the target arrhythmia. Antiarrhythmic drugs are agents that exert their effects either directly or indirectly on cellular impulse generation or conduction. They alter cellular membrane potential by interactions with membrane receptors or ionic channels. This chapter presents an overview of antiarrhythmic drug management including (1) a review of cellular electrophysiology, (2) a general classification of antiarrhythmic drugs, (3) a survey of arrhythmia mechanisms, and (4) clinical correlation of antiarrhythmic drug effects on the heart.

CASE STUDY: PART 1



A 68-years-old woman admitted to the emergency room with a syncopal event. She complained of lightheadedness, palpitations, and shortness of breath prior to her fainting. She was in her usual state of health until 4 days prior to admission. The patient had a "cold" and was started on an antibiotic for the upper respiratory infection. The patient has a history of a fast heart beat and is taking medications for the heart problem. She has suffered another syncopal episode while being evaluated in the emergency room.

Her past medical history include: heart failure (EF ~30%), dyslipidemia, and paroxysmal atrial fibrillation.

A rhythm strip shows the following.

Her current medications include: carvedilol 3.125 mg p.o. b.i.d.; pravastatin 40 mg p.o. daily; furosemide 40 mg p.o. b.i.d.; warfarin 3 mg p.o. daily; dofetilide 250 μg p.o. b.i.d.; pantoprazole 40 mg p.o. daily; candesartan 8 mg p.o. daily; aspirin 81 mg p.o. daily; erythromycin 500 mg p.o. q.i.d.

Her physical examination showed an irregularly-irregular rhythm with trace extremity edema. Her laboratory tests were significant for

Hgb 12.1 g/dL, WBC 12,000 cells/mm^3

Na 140 mEq/ L, K 2.8 mEq/L, Serum creatnine 1.4 mg/dL, Mg 1.2 mg/dL

1. What is the diagnosis?
2. What potential management should be considered?

CELLULAR ELECTROPHYSIOLOGY

To optimize the antiarrhythmic drug management, one must understand the basic cellular electrophysiology. You may wish to review Chap. 19 on "cardiac arrhythmias," which discusses the cellular electrophysiology and various arrhythmias in more detail. The resting cellular membrane potential (phase 4) of cardiac cells is predominately determined by the potassium (K^+) electrochemical equilibrium. In the first phase of the action potential, fast-Na^+ influx into the cell mediates the rapid upstroke (phase 0). The slope of the phase 0 upstroke (V_{max}) determines the velocity of impulse propagation. Calcium influx occurs slightly later and lasts longer, accounting for the plateau (phase 2) of the action potential, and mediates myocardial contraction. These are followed by K^+ efflux from the cell, leading to repolarization (phase 3) and back to the resting membrane potential (phase 4) (Fig. 51-1). Cells with this type of Na-dependent "fast-response" action potential comprise most of the heart (atrium, ventricles, His-Purkinje system, and bypass tract fiber). Other cells in the sinoatrial (SAN) and atrioventricular (AVN) nodes have "slow-response" action potentials, in which Ca^{++} influx is more important than Na^+ in mediating the phase 0 upstroke of action potential (Figs. 51-2 and 51-3).

The refractory periods determine the ability of a cell to respond to an external stimulus by depolarizing and forming an corresponding action potential for continued propagation of cardiac impulse, this is also known as excitability. Sodium ion channels are "voltage-sensitive,"

Cardiac action potential:
- *Phase 4*: resting membrane potential (–50 to –90 mV), spontaneous depolarization
- *Phase 0*: action potential upstroke (V_{max}), slope determines the conduction velocity; fast-Na response in atrium, ventricle, and His-Purkinje fibers; slow Ca response in sinus node, AV node
- *Phase 1*: early rapid repolarization inactivation of I_{Na} and K outward current
- *Phase 2*: plateau, Ca inward current determines the duration of AP
- *Phase 3*: repolarization, K efflex determines the refractory periods

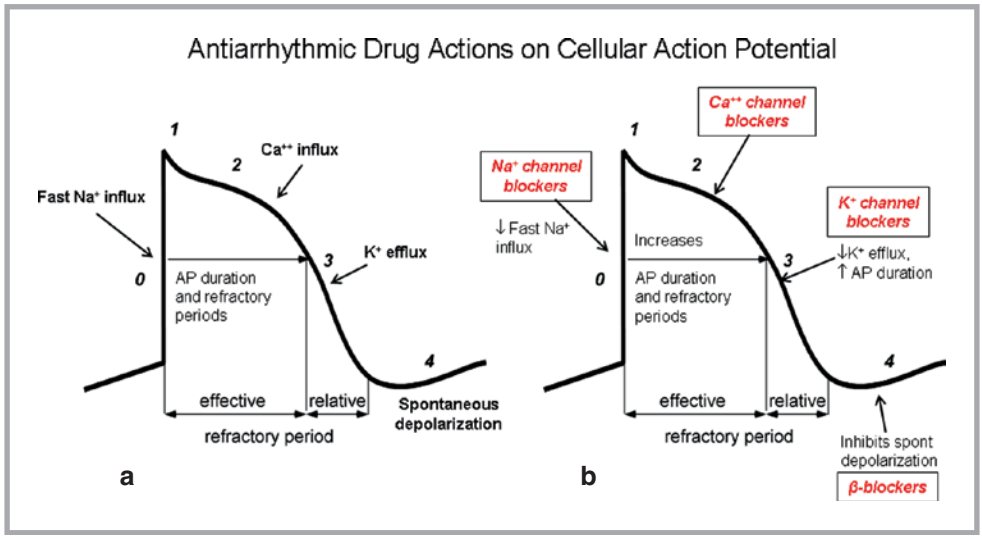


FIGURE 51-1

Antiarrhythmic drug actions on cardiac cellular action potential. (**a**) Cardiac action potential (AP) consists of a rapid upstroke of cellular depolarization referred to as phase 0, mostly due to rapid sodium (Na^+) influx. Repolarization is divided into three phases. Phase 1 represents early and rapid repolarization. Phase 2 is known as the plateau phase, and phase 3 represents the final repolarization of the cell. Calcium (Ca^{++}) influx is essential in maintaining the plateau membrane potential, and potassium (K^+) efflux is predominantly responsible for cellular repolarization. Phase 4 represents spontaneous depolarization with cellular automaticity. Also depicted are the effective (absolute) and relative refractory periods. (**b**) Antiarrhythmic drug actions: class I drugs (sodium channel blockers) block the fast-Na^+ channels of the rapid phase 0 depolarization. Class IV drugs (Ca^{++} channel blockers) inhibit calcium influx of phase 2 (also block phase 0 upstroke in cells of the SA and AV nodes). Class III drugs (potassium channel blockers) inhibit K^+ efflux and prevent repolarization. The action potential duration (APD) and refractory period is prolonged. Class II drugs are β-blockers, which act mostly at phase 4.

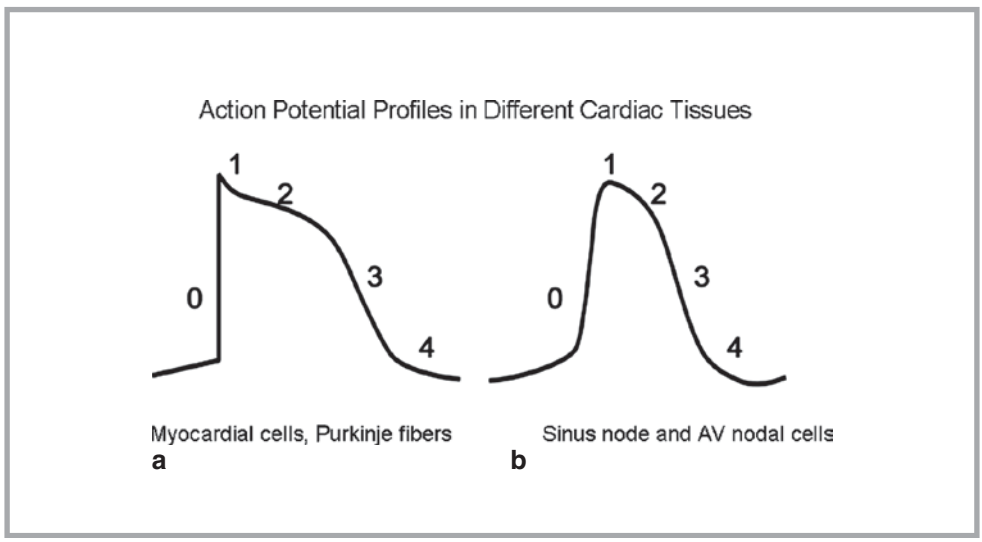

FIGURE 51-2

The cardiac action potentials: (**a**) fast-response Na-dependent action potential in cells of atrium, ventricles, His-Purkinje system, and bypass tract myocardial fibers, (**b**) slow-response Ca-dependent cells of the sinoatrial and atrioventricular nodes.

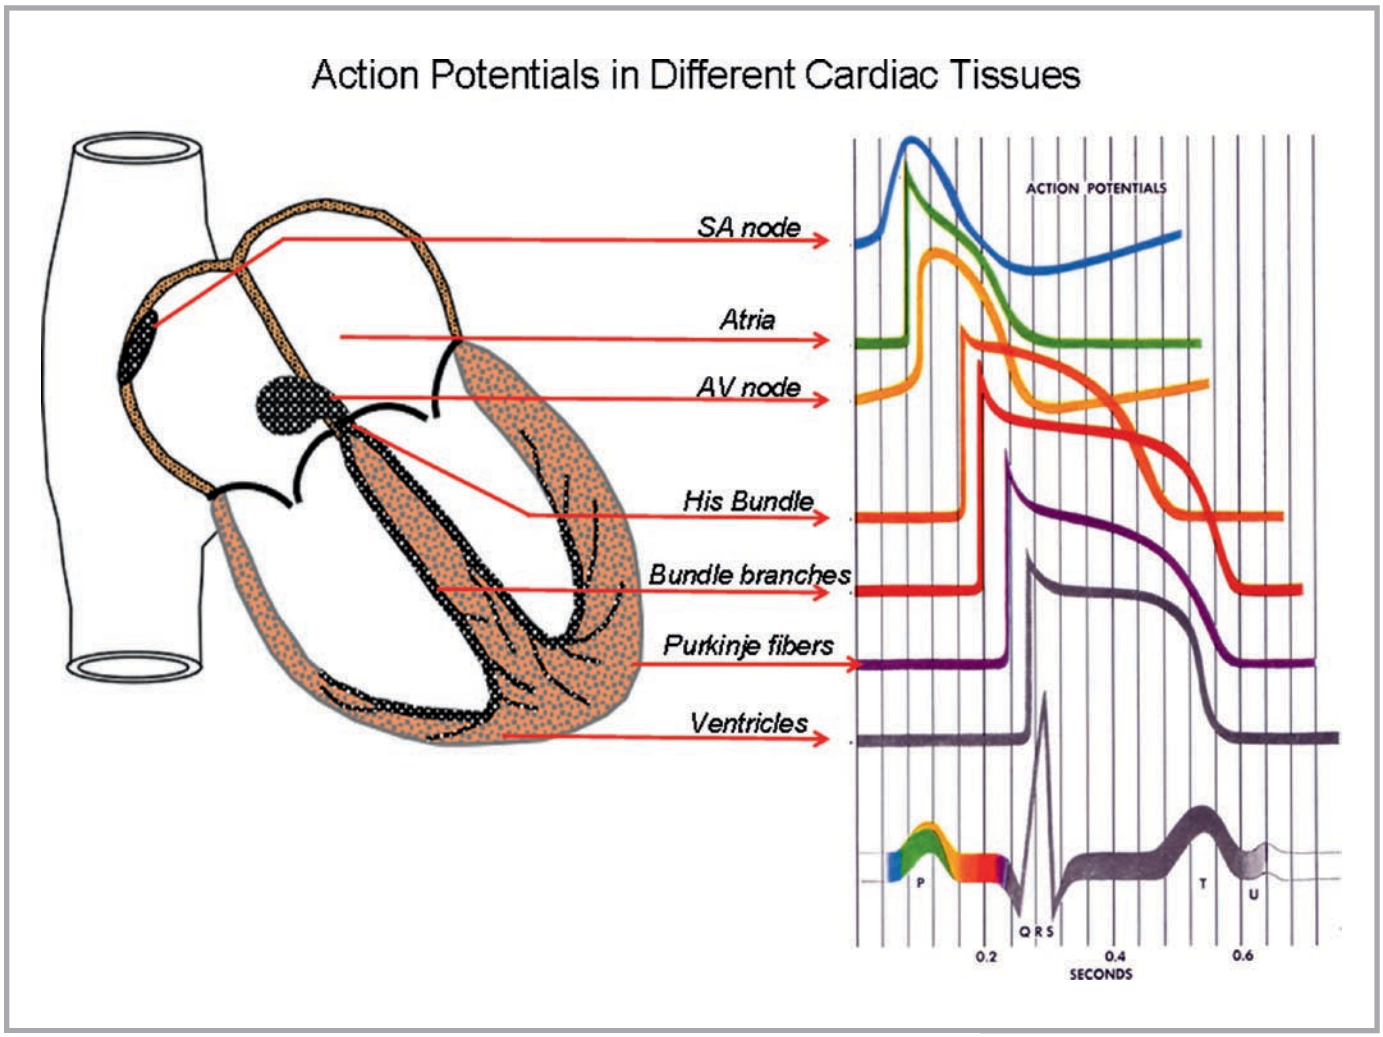

FIGURE 51-3

Action potential (AP) profiles in different cardiac tissues. Impulse propagation, originating from the SA node, through the atrial tissue, and enters the AV node. Conduction continues down the His Bundle that leads to ventricular myocardial activation via the bundle branches and Purkinje fibers. Notice the AP profiles of the SA node and the AV node slow-Ca-dependent, whereas the remaining myocardial tissues, especially the His-Purkinje system, are based on fast-Na-response.

and their behavior and availability are influenced by the level of membrane potentials. During phases 2 and 3 of the action potential, cells gradually resume their ability to respond as the membrane potential recovers toward the resting state. A stimulus applied early in phase 3 cannot open enough Na^+ channels to allow sufficient Na^+ influx that results in a self-sustaining action potential, then the cell is said to be in the absolute refractory period. If a stimulus arrives later, when some Na^+ channels will be activated to conduct some Na^+ current but not a normal amount, this gives rise to a slower upstroke of phase 0 and is termed as the relative refractory period. Stimuli occurring still later encounter essentially all available Na^+ channels and a normal action potential results (fully excitable) (Fig. 51-4).

ANTIARRHYTHMIC DRUG CLASSIFICATION

Antiarrhythmic drug modifies membrane receptors or ionic channels and alters different phases of the action potential at a cellular level. This affects rhythm formation or impulse

FIGURE 51-4

Effects of action potential refractory period on conduction property. A stimulus (*arrow*) applied during the resting membrane potential phase induces a normal action potential (**a**). Progressively earlier stimulations (or longer refractory periods) encounter greater degree of refractoriness as fewer sodium channels are available at higher membrane potentials (**b**, **c**). This result in smaller AP amplitudes and slower phase 0 upstroke and conduction velocity of induced action potentials. No conductive action potential was generated in the absolute refractory period (**d**).

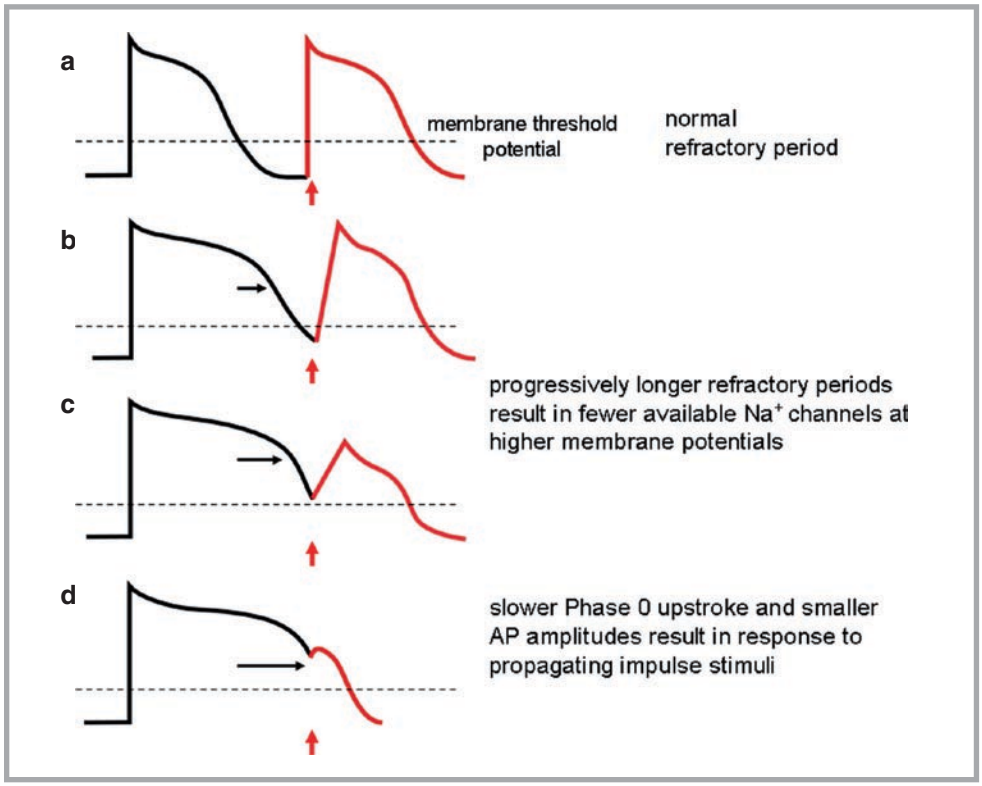

TABLE 51-1

VAUGHAN WILLIAMS CLASSIFICATION OF ANTIARRHYTHMIC DRUGS

Class I: Na^+ channel blockers
- IA Moderate depression of phase 0
  - Slow conduction velocity
  - Lengthen refractory period
  - Vagolytic effects
  - Examples: qunidine, procainamide, disopyramide
- IB Mild inhibition of phase 0 upstroke
  - Shorten APD and refractory period
  - Selective effects on diseased, ischemic tissues
  - Examples: lidocaine, tocainide, mexiletine, phenytoin, ethmozine
- IC Most potent Na channel blockers
  - Marked depression of phase 0 upstroke: very slow conduction
  - Markedly depress His-Purkinje system conduction, widen QRS
  - Little effect on refractory period
  - Examples: flecainide, propafenone, encainide

Class II: sympatholytic agents: β-blockers
- SAN/AVN blockers

Class III: K^+ channel blockers:
- Inhibition of repolarization
- Prolong repolarization
- Increase action potential duration, refractoriness
- Examples: amiodarone, sotalol, bretylium, ibutilide

Class IV: Ca^{++} channel blockers
- Inhibition of slow inward Ca^{++} channel
- SAN/AVN blockers

Classification of antiarrhythmic drugs
- I: sodium channel blockers
  - IA: moderate, prolong refractory period
  - IB: mild inhibition of phase 0 upstroke
  - IC: marked Na channel inhibition
- II: sympatholytic agents: beta-blockers
- III: potassium channel blockers:
- IV: calcium channel blockers

conduction at the tissue level, which translates to clinical antiarrhythmic effects. Traditionally, antiarrhythmic drugs are classified using the Vaughan Williams classification. Singh and Vaughan Williams have categorized antiarrhythmic compounds based on the "predominate" effect on (1) the fast sodium depolarization current, (2) the sympathetic activity of the heart, (3) the repolarization currents, and (4) the slow inward calcium current (Table 51-1).

The class I antiarrhythmic drugs antagonize the fast sodium channel, which is responsible for the initial rapid depolarization of the action potential (phase 0). They inhibit phase 0 of action potentials and slow conduction velocity that causes impulse slowing or block. Class II agents are β-blockers, whose antiarrhythmic effects are probably based on inhibition of formation of the second messenger, cyclic AMP, acting mostly at phase 2 and 4 and suppressing spontaneous depolarizations. Another major category of antiarrhythmic compounds (class III) are the potassium channel antagonists. By inhibiting the potassium efflux and preventing repolarization of membrane potential back to the resting level, the duration of the action potential is increased which translate to a prolonged cellular refractory period (phase 3). The class IV agents (calcium channel blockers) owe their pharmacologic effects by inhibiting the slow calcium current, particularly in the atrioventricular (AV) node (Fig. 51-1).

The Vaughan Williams classification correlates reasonably well with specific membrane effects of the drugs. However, it provides incomplete links among the actions of antiarrhythmic agents, the mechanisms of arrhythmia, and the efficacy of therapy. From the clinical point of view, this classification has a number of shortcomings. First, it does not take into account the presence of multiple pharmacologic effects produced by a single drug. For example, quinidine has effects of both class I and class III drugs, sotalol has effects of both class II and III, and amiodarone has properties of all four classes. Second, poor concordance of response and toxicity between members of a class, and drugs within a given class can produce disparate "secondary" electrophysiologic effects. For example, as described earlier, the kinetics of interactions of class I drugs with sodium channels vary greatly. Although the subdivision of class I drugs corrects for much of these difference, the "secondary" vagolytic effect of class I-A drugs is not intuitively obvious. In addition, the Vaughan Williams classification does not take into consideration the effects of active metabolites, which may have different action from their "parent" drugs. For example, procainamide blocks inward sodium channels and outward potassium channels, making a class I-A drug. Its major metabolite, *N*-acetylprocainamide (NAPA), is a pure potassium channel blocker, making it a class III drug. The final pharmacologic effects of procainamide therapy depends on the relative concentration of the parent drug and the active metabolites, which is influenced by multiple factors such as renal function and genetically determined hepatic metabolism. Finally, many drugs do not fall under any Vaughan Williams classification scheme, such as digitalis or adenosine.

Class I Drugs

The class I antiarrhythmics are further divided into three subcategories based on their relative potency of sodium channel blockade. The class I-C drugs (flecainide, propafenone, encainide) have the most potent sodium channel blocking activity among the class I agents that induce a significant slowing of impulse conduction and depression of phase 0 upstroke (V_{max}). It has a propensity to bind the activated sodium channels with slow dissociation kinetics. As heart rate increases, more "activated" sodium channels are available for drug binding, and greater inhibition of sodium channels results due to slow dissociation. The class I agents (especially I-C drugs), therefore, exhibit considerable "use-dependent" (frequency-dependent) property. The class I-B drugs (lidocaine, mexiletine) are the least potent sodium channel blockers. Class I-B drugs exhibit preferential binding to "inactivated" sodium channels (at slower heart rates) with fast kinetics, and thus, have minimal "use-dependency." Selectivity of lidocaine on ischemic myocardium has also been described and may be particularly useful in prophylactic prevention of ventricular arrhythmia in a setting of acute ischemic syndrome or myocardial infarction. The class I-A agents, such as quinidine, procainamide and disopyramide, demonstrate an intermediate activity and kinetics of sodium channel blockade with a modest depression of V_{max} and conduction. However, the I-A drugs also exhibit potassium blockade activity with prolongation of action potential duration (APD) and cellular refractory period. In addition, the class I-A drugs have variable anticholinergic (vagolytic) activity which tends to facilitate conduction through the AV node and accelerates ventricular rate response during atrial fibrillation or flutter. Such vagolytic effects should be considered in the determination of overall clinical actions of class I-A drugs (Fig. 51-5).

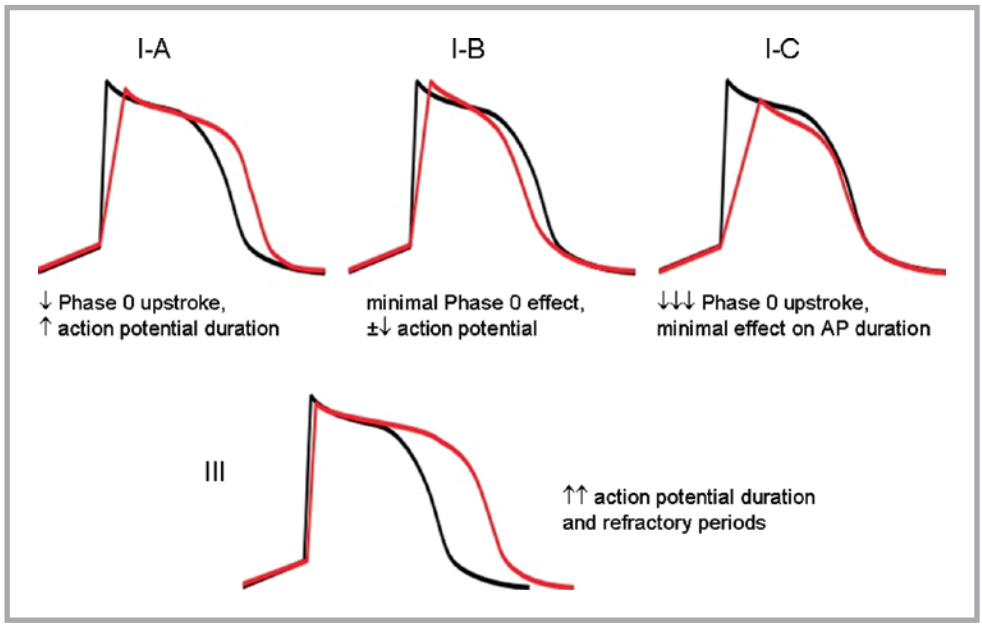

FIGURE 51-5

Differential drug effects of class I and class III antiarrhythmic agents on cardiac cellular action potentials. Class I-A agents demonstrate intermediate potency of sodium channel blockade with a modest depression of phase 0 (V_{max}) and conduction. The I-A drugs also exhibit potassium blockade activity with prolongation of APD and refractory period.

Quinidine is the prototype of class I-A agent. It is a typical fast sodium channel blocker with mild class III effect (prolongs refractoriness). In addition, as a group, the I-A drugs interact with muscarinic receptors that result in anticholinerigc (vagolytic) effect. Quinidine also inhibits peripheral and myocardial α-adrenergic receptors, and thus, induce hypotension with intravenous administration. Its use is associated with frequent subjective side effects such as diarrhea (33%), nausea (18%), headache (13%), and dizziness (8%). The gastrointestinal (GI) effects may be less severe with the gluconate preparations. Central nervous system (CNS) toxicity, referred to as cinchonism, includes tinnitus, hearing loss, confusion, delirium, and visual disturbance which are not uncommon, especially in elderly patients. Immune-mediated reactions, such as rash, fever, hemolytic anemia, leukopenia, hepatic toxicity, and anaphylaxis, have also been reported. Overall, adverse effects preclude long-term quinidine therapy in up to 30% of patients. Significant drug interactions with digoxin, amiodarone, verapamil, and warfarin have been well documented. Prudent dosage adjustment with frequent plasma drug level monitoring is warranted. For quick references, Table 51-2 provides a summary of some important drug interactions.

Procainamide is a very versatile agent that may be given orally, intravenously, and rarely intramuscularly. A good plasma level (8–10 μg/mL) can be achieved after a loading dose of 15 mg/kg administered via infusion (~50 mg/min). This can be followed by a maintenance dose (1–4 mg/min or 0.11 mg/kg/min) before switching over to oral drugs. Hypotension is commonly observed during IV infusion due to its vasodilator effect and the infusion rate must be titrated to hemodynamic tolerance. Contrary to quinidine, procainamide does not increase the serum digoxin concentration. However, its clearance is significantly reduced in patients with diminished renal function. Multiple noncardiac effects have been observed with procainamide that includes the usual GI and CNS symptoms. In addition, fever, rash, myalgia, digital vasculitis and Raynaud's phenomenon have been reported. A potentially life-threatening pancytopenia or agranulocytosis has also been described. This may be an allergic or hypersensitivity reaction that appears days to weeks after starting procainamide. Twenty to thirty percent of patients may develop clinical symptoms of a systemic lupus erythematosis (SLE)-like syndrome with positive serologic tests observed in 60–70% of patients on chronic procainamide therapy. This is a reversible phenomenon and positive serologic tests are not necessarily a reason to discontinue drug therapy.

Disopyramide is comparable to other class I-A drugs in its antiarrhythmic actions. Its elimination is primarily via renal excretion and the dose must be reduced in patients with renal impairment. The most common side effect relates to the drug's potent parasympathetic,

TABLE 51-2

ANTIARRHYTHMIC DRUG INTERACTIONS

DRUGS	INTERACTIONS WITH	EFFECTS
Quinidine	Digoxin	↑ Digoxin level
	Class I antiarrhythmic drugs	↑ Negative inotropic effects with depressed conduction
	β-blockers	Hypotension, negative inotropy
	Amiodarone, sotalol	Torsade de pointe
	Diuretics	Hypokalemia/Torsade de pointe
	Verapamil	↑ Quinidine level
	Nifedipine	↓ Quinidine level
	Warfarin	↑ Anticoagulation
Procainamide	H_2 blockers	↑ Procainamide level
	Captopril	Enhanced immune effects
Disopyramide	Other class I antiarrhythmic drugs	↑↑ Negative inotropic effects with depressed conduction, ↑↑ myocardial depression
	Anticholinergic	Severe anticholinergic effects
Lidocaine	β-blockers, H_2 blockers, halothane	Reduces hepatic clearance, increases toxicity
Mexiletine	Phenytoin	Hepatic enzyme induction, ↓ plasma level
	Disopyramide	Negative inotropic effects
Flecainide	β-blockers, Ca blockers	SA node or AV node conduction depression
	Other negative inotropic drugs	↑↑↑ Myocardial depression
	Class IA or III	↓↓ His-Purkinje conduction
	Amiodarone	Increases flecainide level
Propafenone	Similar to flecainide	Increases digoxin level
	Digoxin	
Sotalol	Diuretics, class IA, amiodarone, tricyclics, phenothiazine	↑↑ Risk of Torsade de pointe
Amiodarone	Similar to sotalol	±↓ Risk of Torsade de pointe
	Digoxin	↑ Digoxin level
	Flecainide	↑ Flecainide level
	Warfarin	~2-fold increase in anticoagulation level
Dofetilide	Similar to sotalol, diuretics, class IA, III, other QT prolonging drugs	↑↑ Risk of Torsade de pointe
	Verapamil	↑ Peak plasma level and Torsades de pointe
Verapamil	β-blockers, digoxin	↓ AV node, His-Purkinje conduction, SA node dysfunction, bradycardia
	Quinidine	Negative inotropic effects, ↑ quinidine level

anticholinerigc property that can cause urinary obstruction (14%), dry mouth (32%), constipation (11%), and should be avoided in elderly patients and those with glaucoma, prostatic hypertrophy, or myasthenia gravis. Disopyramide administration is also associated with substantial suppression of myocardial contractility (negative inotropic effect) compared to others in its class. Acute exacerbation of congestive heart failure may occur as early as 48 h following initiation of the drug, especially in those patients with a past history of heart failure (55%).

Class III Drugs

By contrast, class III antiarrhythmic agents selectively block the rapid component of the delayed rectifier potassium channel (IKr), and produce a progressive prolongation of APD at slower heart rates. Thus, these class III antiarrhythmic agents exhibit "reverse use dependent" prolongation of the APD (reverse use-dependence). This means that the refractoriness increases at lower heart rates.

The class I-C drugs exhibit considerable "use-dependent" (frequency-dependent) property, with greater Na^+ blockade at higher heart rates. The class III drugs exhibit "reverse use dependent" prolongation of the action potential and refractoriness at slower heart rates.

This increases the susceptibility of the myocardium to early afterdepolarizations (EADs) at low heart rates. Antiarrhythmic agents that exhibit reverse use-dependence are more efficacious at preventing a tachyarrhythmia than converting someone into normal sinus rhythm. Because of the reverse use-dependence of class III agents, at low heart rates, class III antiarrhythmic drugs may paradoxically be more arrhythmogenic. Common class III agents include amiodarone, azimilide, dofetilide, ibutilide, dronedarone, and sotalol.

Amiodarone is an iodinated bezofuran derivative with coronary and peripheral vasodilatory properties. Its electrophysiologic and pharmacologic actions are complex. Amiodarone uniformly lengthens APD and refractory periods and is usually classified as a class III antiarrhythmic potassium blocker. However, it also blocks cardiac sodium channels and depresses phase O of action potentials (class I), as well as possessing noncompetitive α- and β-receptor antagonist (class II) and calcium channel blocking (class IV) activities. In addition, amiodarone blocks peripheral conversion of thyroxine (T4) to tri-iodothyronine (T3). It contains a significant amount of iodine (38% of its weight) and many of the effects of the drug are similar to those seen with hypothyroidism. The drug is extensively metabolized by liver with minimal renal elimination. Amiodarone has a large volume of distribution and moderate and erratic bioavailability, with an unusually long half-life ranging from 26 to 107 days (mean ~50 days). It is lipophilic and deposits extensively into various tissues, especially those with high fat content (liver, lung, heart, skin, adipose tissue) and is not dialyzable.

Amiodarone

Amiodarone has been used to suppress a wide spectrum of supraventricular and ventricular tachyarrhythmias, and is the most commonly used intravenous antiarrhythmic drug in an acute setting. Success rates vary depending on patent population, targeted arrhythmia, underlying heart disease, and length of follow-up. In general, amiodarone's efficacy equals or exceeds all other antiarrhythmic drugs. It is effective in approximately 60–80% of most supraventricular tachyarrhythmias and 40–60% of ventricular tachyarrhythmias. Because of its long half-life and large volume of distribution, the ideal loading dose schedule remains controversial, but depends on the nature of the arrhythmia and the underlying cardiac function. In general, for patients with ventricular arrhythmias, an oral loading dose of 800–1,800 mg/day for a minimal 2–3 weeks should be used. The onset of action following oral administration may require several days, and a maintenance dose of 400 mg/day is usually recommended. Due to its multiple side effects, most patients on chronic amiodarone therapy develop intolerable reactions, and dosage reduction is usually required after 12–24 months. Intravenous amiodarone is available for use in life-threatening ventricular arrhythmias refractory to other drugs, as well as atrial fibrillation. The onset of action after IV administration is within several hours. The initial IV loading dose of 150 mg over ~10 min is followed by a maintenance infusion of 0.5–1.0 mg/min. Contrary to its oral route of administration, intravenous amiodarone can cause vasodilatation and has negative inotropic action (antiadrenergic effects) and should be given with caution under close monitoring. For treatment of supraventricular arrhythmias, lower loading dose of 400–800 mg/day are used, with an effective once-a-day maintenance doses of 100–200 mg/day. Given its long half-life, good efficacy, and easy compliance, low dose amiodarone is considered a first-line therapy in elderly with atrial arrhythmias.

Amiodarone pulmonary toxicity:
- Dyspnea, hypoxia, cough, and fever
- Abnormal chest radiographic patterns
- A positive gallium scan
- A reduced diffusion capacity (DLco)
- Abnormal high-resolution chest CT scan

Adverse effects of amiodarone with long-term therapy are common and occur in 50–80% of patients. The frequency of side effects is dose and duration-related, and careful follow-up is mandatory to prevent potentially serious consequences (Table 51-3). Most of the adverse effects are reversible with dose reduction or discontinuation. Fortunately, amiodarone is generally associated with a low incidence of proarrhythmia, even in high-risk patients with life-threatening arrhythmias, significant structural heart disease, and ventricular dysfunction. Of all the noncardiac adverse reactions, pulmonary toxicity (up to 15%) is the most serious, usually occurring within the first 30 months of treatment and occasionally as early as 2–3 weeks. The mechanism is unclear but may be related to a hypersensitivity reaction and/or extensive drug/iodine deposits in the lungs. Pulmonary toxicity is associated with an approximately 10% mortality and is uncommon in patients receiving less than 400 mg/day of amiodarone. A high degree of suspicion is essential for early diagnosis in patients who presented with dyspnea, hypoxia, cough, and fever. Abnormal chest radiographic patterns of diffuse interstitial changes or alveolar infiltrates may be seen, as well as a positive gallium scan, a reduced diffusion capacity with abnormalities on a high-resolution chest CT scan. Treatment requires drug withdrawal and supportive care, but the use of steroid is controversial.

TABLE 51-3

ADVERSE EFFECTS OF AMIODARONE THERAPY

Ocular	Corneal microdeposits (95%), mostly asymptomatic
	Visual blurring (6–14%)
	Possible optical neuritis
Dermatologic	Photosensitivity (25–75%)
	Blue–gray skin discoloration (5–8%)
	Rash
Gastrointestinal	Abnormal liver function tests (50%)
	Hepatitis (3%)
	Nausea, anorexia, constipation
Neurologic	Peripheral neuropathy (5%), tremor (30%)
	Sleep disturbance (25%), myopathy, headache (14%)
Cardiovascular	Symptomatic bradycardia (6%), AV block
	Heart failure (4%)
	Proarrhythmia (1%)
Thyroid	Elevated TSH, T3 and T4 abnormalities (25%)
	Symptomatic hypothyroidism (1–22%), hyperthyroidism (1–12%)
Pulmonary	Interstitial pneumonitis (3–15%)
	ARDS

Ibutilide

Ibutilide is considered a class III antiarrhythmic agent for treatment of atrial fibrillation and atrial flutter. It blocks the delayed rectifier (IKr) current and augments the slow inward Na^+ current. Ibutilide (Corvert®) increases the refractory period without effect on conduction velocity or contractility, and is useful in rapidly terminating atrial fibrillation and flutter.[1] Under a multicenter study, the efficacy was higher for atrial flutter than fibrillation (63 vs. 31%), especially in patients with a shorter duration of arrhythmia and a normal left atrial size. The major side effect is polymorphic ventricular tachycardia (VT) (Torsade de pointes), which has been reported in up to 8.3% of patients receiving ibutilide. It may be considered as an alternative to electrical cardioversion under monitored condition.

Dofetilide

Dofetilide (Tikosyn®) is a "pure" class III agent that inhibits the rapid (IKr) delayed rectifier K^+ current. It prolongs atrial and ventricular refractory periods, elevates ventricular fibrillation (VF) threshold, and exhibits "reversed use-dependence" with minimal negative inotropic effect. Dofetilide was evaluated in the treatment of both atrial and ventricular arrhythmias, and can be considered as an alternative antiarrhythmic drug to amiodarone. Dofetilide is metabolized via the hepatic CYP3A4 cytochrome system, but is mostly (80%) excreted in its active form. Therefore, its use must be carefully monitored and adjusted according to patients' renal function.

Dofetilide therapy has been shown to be effective in treating atrial fibrillation or flutter, even in patients with significant ventricular dysfunction.[2-4] Currently, dofetilide is restricted to prescribers and hospitals that have participated in a designated Tikosyn® Education Program. Serial ECG assessments of QT (QTc) interval and measurement of creatinine clearance are essential during mandatory in-hospital initiation of this drug. Concurrent use with other drugs known to prolong QTc interval is not recommended. Other class I or class III antiarrhythmics should be stopped prior to dofetilide initiation. Concurrent use of potassium-depleting diuretics is contraindicated because of the risk of hypokalemia and/or hypomagnesemia resulting in malignant arrhythmias such as Torsade de Pointes. Other adverse drug interactions involving certain antibiotics, antifungal, tricyclic antidepressants, phenothiazines, and verapamil must be excluded. Patients' complete medication list should be carefully reviewed prior to dofetilide initiation. Similar cautions and guidelines are also applicable to patients on sotalol.

Adenosine

Adenosine antagonizes adenylate cyclase and decreases intracellular cyclic AMP and calcium conductance. It is a physiologic calcium antagonist and causes potent SA node and AV node

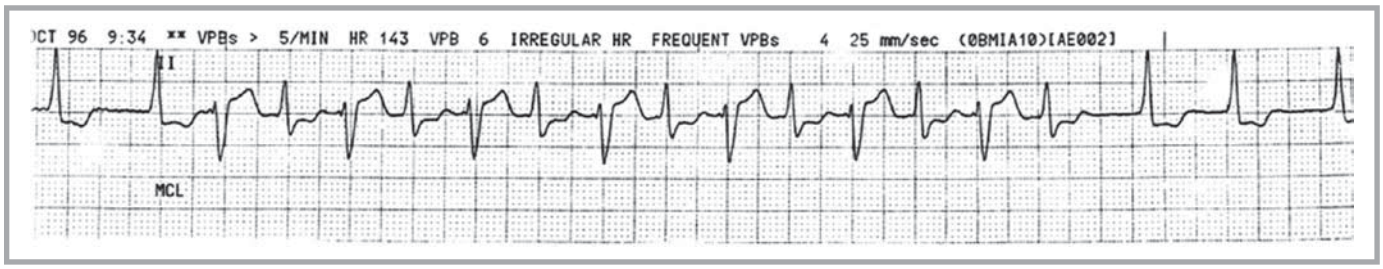

FIGURE 51-6

Digitalis induced bi-directional ventricular tachycardia (VT) with alternating bundle branch block QRS morphologies.

depression. The clinical indications for adenosine (Adenocard®) are acute management of narrow QRS supraventricular tachycardia (SVT) and for diagnosis of unknown wide QRS tachycardia. The advantage of its utility resides in its ultrashort half-life of less than 10 s. The adverse reactions include nausea, flushing, hypotension, bradycardia, heart block, and bronchospasm. Adenosine effects can be blocked by methylxanthines, caffeine, and theophylline.

Digitalis

In therapeutic concentration, digitalis has both direct and indirect cardiac effects. It directly blocks the Na-K-ATPase and causes an elevation in intracellular Na^+ concentration that subsequently induces intracellular Ca^{++} loading (via the Na^+-Ca^{++} exchanger). These effects lead to enhanced myocardial contractility and reduced AV nodal conduction. The predominant indirect effects of digitalis are mediated through the parasympathetic autonomic nervous system. Digitalis enhances vagal tone on the heart and causes a reduction in sinus rate, a shortening of atrial refractory periods (increases atrial rate in atrial fibrillation or flutter), and suppression of AV nodal conduction. It slows ventricular rate response during atrial fibrillation and flutter by "indirect" vagal AV nodal block.

Digitalis toxicity:
- Paroxysmal atrial tachycardia with AV block
- "Regularized" atrial fibrillation
- VT with alternating QRS morphologies

Most of the drug is excreted unchanged in urine, and thus, dose adjustment is necessary in patients with renal impairment. Any arrhythmia can develop in patients with digitalis toxicity. The key to diagnosis is a high index of suspicion. The hallmark of digitalis toxicity is ectopic arrhythmias (due to triggered activity based on delayed afterdepolarization (DAD)) with concomitant conduction blocks. The classic digitalis toxic arrhythmia is atrial tachycardia with AV block. The most common digitalis toxic arrhythmia is ventricular arrhythmias such as bigeminy, junctional rhythm with various degrees of sinus, and AV nodal suppression.

In patients with atrial fibrillation, digitalis toxicity may present as high grade AV block with an enhanced junctional escape rhythm, and thus, gives the appearance of a "regularized" ventricular rate response during atrial fibrillation. Occasionally, "bi-directional," alternating bundle branch block VT, or narrow QRS fascicular VT may occur (Fig. 51-6). Serum digoxin levels are often elevated, but may be within therapeutic range in elderly patients, patients with hypokalemia, or in patients with hypothyroidism. Conservative therapy by withholding digitalis with potassium/magnesium supplementation is the treatment of choice for digitalis-related arrhythmias. Phenytoin may be indicated for symptomatic digitalis toxic arrhythmias. Life-threatening arrhythmia should be treated with antidigoxin monoclonal-antibodies (Digibind®). Temporary pacing may be necessary in patients with symptomatic bradycardia.

MECHANISMS OF ARRHYTHMIA

Because of the shortcomings of Vaughan Williams classification, a new approach of antiarrhythmic drug management was proposed in 1991. The new system focuses on the mechanisms of arrhythmia, including identification of vulnerable parameters that can be specifically

targeted by antiarrhythmic drugs.[5] As described in Chap. 19 on cardiac arrhythmias, the mechanisms of arrhythmias can be divided into (A) abnormal automaticity, (B) triggered activity, and (C) reentry. The abnormal automatic depolarizations are due to either abnormal slopes of phase 4 spontaneous depolarizations or abnormal membrane "threshold" potentials (Fig. 51-7). The treatment of abnormal automaticity should, thus, be focused on reducing the slopes of phase 4 depolarizations by Ca^{++} channel blockers (in the case of Ca^{++}-dependent depolarizations), β-blockers, or correcting the abnormally depressed membrane threshold potential. Arrhythmias based on triggered activity are initiated by afterdepolarizations, either EADs or DADs (Fig. 51-8). Polymorphic VTs associated with long QT intervals (either congenital or drug-induced Torsade de Pointes) are thought to be due to EADs, whereas DADs are classically related to digitalis intoxication (with cellular calcium overload). Shortening the APD (QT interval) at fast heart rate by administration of catecholamines or pacing is the treatment of choice for Torsade de Pointes.

The predominant mechanism for most clinical arrhythmias is reentry. The pre-requisites of reentry include (1) an initiating event, most commonly a premature beat, (2) heterogeneous tissue properties that predispose unidirectional block with refractoriness in some part of the circuit, (3) alternative pathways for impulse propagation, and (4) "critically" slow conduction that allows impulse reenters the previously refractory part of the circuit (Fig. 51-9). In general, reentry may be targeted by drugs that either suppress the initiating premature beats or alter the properties of the reentrant circuit. Na^{+} channel blockers (class IA, IC) may slow impulse conduction or cause conduction block. Along with β-blockers or Ca^{++} channel blockers (class II and IV), they may prevent reentry by eliminating premature beats, or by creating bi-directional block within the circuit. Some Na^{+} channel blockers (class IA) and K^{+} channel blockers (class III) increase tissue refractoriness to such an extent that conduction wave fronts in the circuit are *insufficiently* slow for the recovery of excitability in regions where unidirectional block occurred (thus, never getting reentry started) (Fig. 51-10). These are the mechanistic basis for the selection of antiarrhythmic drugs in a clinical scenario.

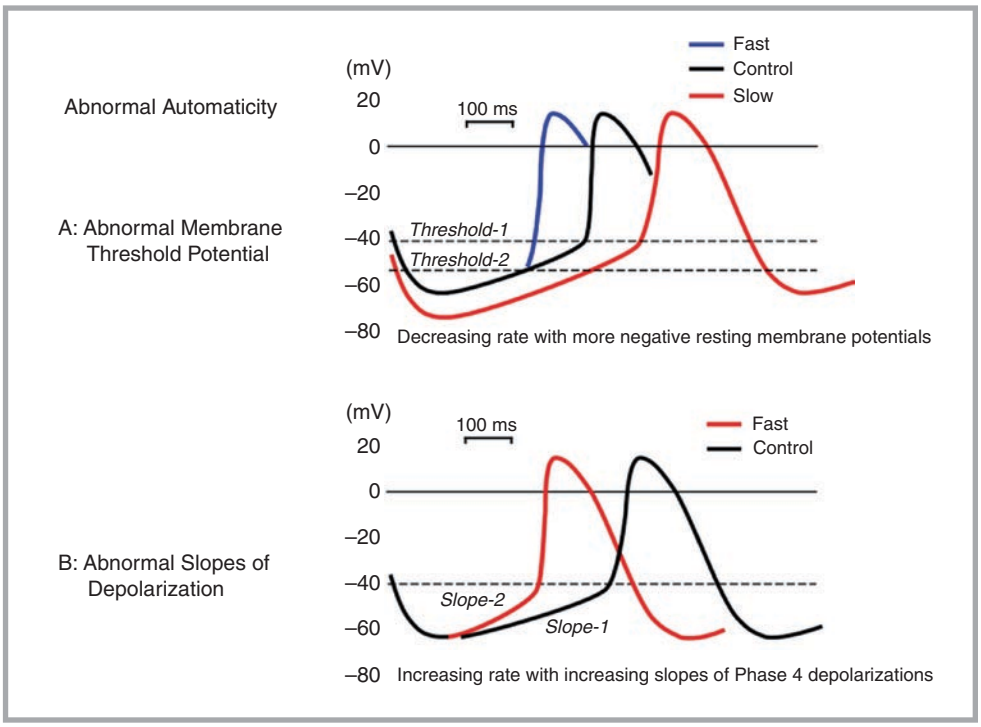

FIGURE 51-7

Abnormal automaticity is due to either (**a**) abnormal membrane threshold potentials, or (**b**) abnormal slopes of phase 4 spontaneous depolarizations. (**a**) An abnormally depressed threshold potential (threshold-2) results in earlier action potential formation (faster rate) compared to controls (threshold-1). A more negative resting membrane potential takes longer to reach threshold and results in a slower rate. (**b**) An increased slope (slope-2) of phase 4 depolarization results in earlier activation and faster rate compared to controls (slope-1).

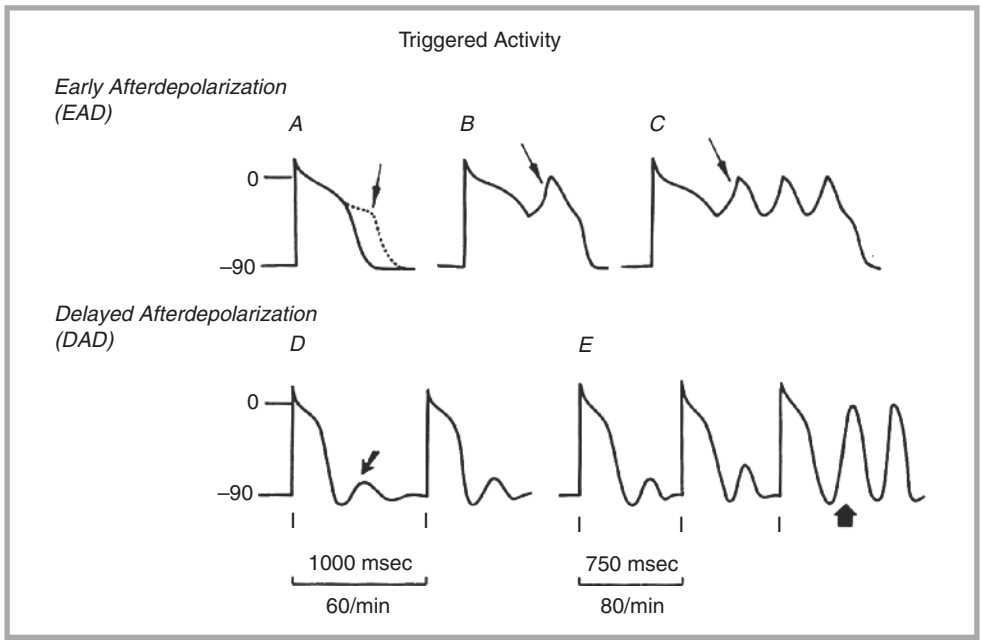

FIGURE 51-8

Triggered activities are caused by abnormal cell membrane voltage oscillations, induced by preceding action potentials. Early afterdepolarizations (EADs) occur in late phase 2 or phase 3 of the action potential, before complete cellular repolarization (**a**). When such membrane voltage oscillation reaches the threshold, a second membrane depolarization was induced (**b**). Repetitive EADs may occur with bradycardia or reperfusion injury (**c**). Delayed afterdepolarizations (DADs) occur in late phase 3 or early phase 4 when the membrane potential is fully repolarized (**d**). DADs are thought to be responsible for certain digitalis toxic arrhythmias, as well as catecholamine-dependent atrial and VTs (**e**).

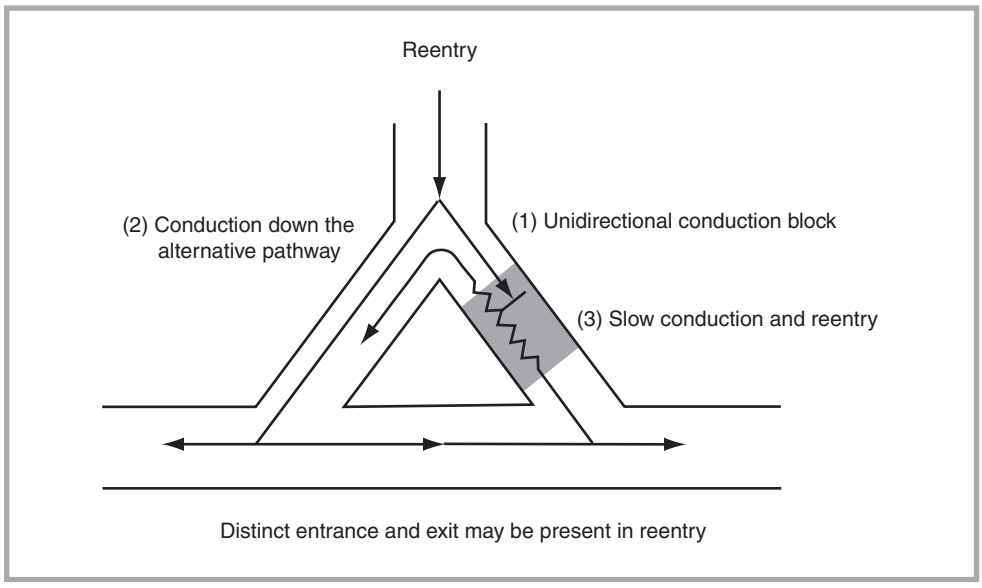

FIGURE 51-9

Critical components of a reentrant circuit: (1) unidirectional block, (2) alternative impulse pathways, and (3) "critically" slow conduction that reenters the previously refractory part of the circuit.

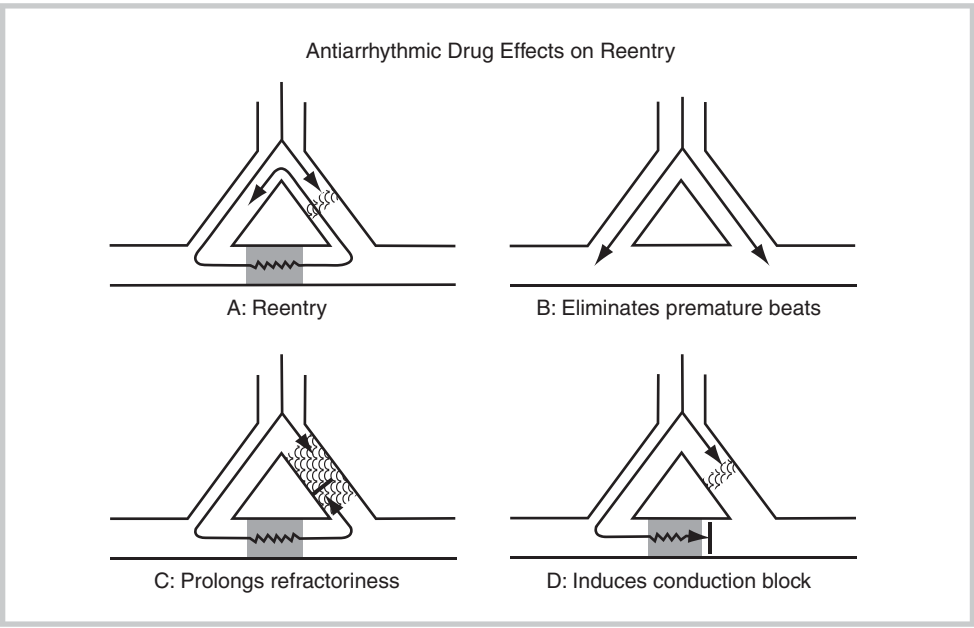

FIGURE 51-10

The antiarrhythmic drug effects on reentry (**a**) include: (**b**) eliminating premature triggering beats, (**c**) increasing refractoriness with insufficient recovery of excitability, (**d**) inducing conduction block within the circuit.

GENERAL PRINCIPLES OF ANTIARRHYTHMIC THERAPY

It is essential to be familiar with patient's underlying diagnoses, anatomical substrate, and arrhythmia history. Multiple medical conditions may exist that either cause new rhythm disturbances or result in exacerbation of preexisting arrhythmias. The management approach needs to be holistic and various factors such as hypoxia, electrolyte imbalance, ischemia, sepsis, heart failure, renal insufficiency, or drug toxicity must be considered. The prognosis is mostly determined by the underlying cardiac or medical status.

An accurate diagnosis is imperative for proper antiarrhythmic therapy. Supraventricular arrhythmias must be distinguished from ventricular tachyarrhythmias or preexcited tachycardias. Indications, goals, and treatment end points must be clearly defined for the individual patient prior to initiation of antiarrhythmic therapy. The primary indication for antiarrhythmic therapy is prevention of sudden death due to VT or VF and rarely supraventricular preexcited arrhythmias. The secondary indication is to alleviate symptoms attributable to arrhythmia. In addition, the acute therapeutic objectives of arrhythmia termination should be differentiated from the chronic treatment goals of preventing arrhythmia recurrence. Occasionally, achieving the therapeutic end point of arrhythmia termination or prevention may not be possible or feasible. Alternatively, palliative goals such as rate control during chronic atrial fibrillation or slowing of VT to improve hemodynamic tolerance may be acceptable.

Indications of antiarrhythmic therapy:
- Primary: sudden death prevention.
- Secondary: symptomatic alleviation

Therapeutic goals:
- Acute: arrhythmia termination
- Chronic: arrhythmia prevention.
- Therapeutic vs. palliative

Several factors must be considered for optimal antiarrhythmic therapy. These include (1) antiarrhythmic efficacy, (2) side effect profiles, and (3) long-term drug safety and tolerance. The selection of an antiarrhythmic drug must be individualized. First and foremost, a "class" of drug is examined based on their actions on the "targeted" arrhythmia (Table 51-4). A specific drug within the class can then be selected after careful considerations of potential cardiovascular and noncardiovascular adverse effects. The side effect profiles consist of several categories that include (1) subjective symptoms, (2) end-organ toxicity, (3) negative inotropic effect, and (4) proarrhythmia. In addition, drug interactions with other agents cannot be ignored, especially in critically ill patients with multiorgan dysfunction on multiple medications (Table 51-5). Last, the long-term safety and tolerance should also be evaluated. A once- or twice-a-day dosing regimen is far more acceptable to patients. Multiple dosing (t.i.d. or q.i.d.) results in poor compliance and potential complications due to fluctuating plasma drug levels.

Selection of optimal antiarrhythmic agents depends on:
1. Antiarrhythmic drug efficacy
2. Side effect profiles (cardiovascular vs. noncardiovascular)
   - Negative inotropic effect
   - End-organ toxicity
   - Symptomatic toxicity
   - Proarrhythmia
3. Drug interactions
4. Long-term drug safety and tolerance

TABLE 51-4

CLASSIFICATIONS OF DRUG ACTIONS BASED ON ARRHYTHMIA MECHANISMS

ARRHYTHMIAS	MECHANISMS	TARGETED PARAMETERS	REPRESENTATIVE DRUGS
	Reentry (Na^+ dependent)		
Typical atrial flutter	Long excitable gap	↓ Conduction and excitability	Na blockers (*IA*, *IC*)
Orthodromic AVRT			Na blockers (*IA*, *IC*)
Sust. monomorphic VT			Na blockers
Atypical atrial flutter	Short excitable gap	↑ Refractory period	K blockers (amiodarone, sotalol)
Reentrant atrial tach			
AF			
Mono-, polymorphic VT			Quinidine, procanamide, disopyramide
VF			Bretylium
	Reentry (Ca^{++} dependent)		
AVNRT		↓ Conduction and excitability	Ca-channel blocker
Orthodromic AVRT			Adenosine
Verapamil-sensitive-VT			
	Automaticity		
Inappropriate sinus tach	Enhanced	↓ Phase 4 depolarization	β-adrenergic blockers
Idiopathic VT			Na-channel blocker
Ectopic atrial tachy	Abnormal	Hyperpolarize diastolic pot	Ca or Na-channel blocker
Accel idioventricular rhythm		↓ Phase 4 depolarization	M2 agonist
	Triggered Activity		
Torsade de Pointes	EADs	↓ AP duration	β-agonist, vagolytic drugs to increase rate
		↓ EADs	β-blockers, Mg^{2+}
Digitalis toxicity	DADs	↓ Ca overload	Ca-channel blockers
Idiopathic VT			Na-channel blockers
		↓ EADs	β-adrenergic blockers
			Adenosine

TABLE 51-5

INFLUENCES OF DISEASE STATES ON ANTIARRHYTHMIC DRUG PHARMACOKINETICS

DISEASE OR CONDITION	EFFECTS
Congestive heart failure	Reduced clearance of Lidocaine Procainamide Flecainide Reduced volume of distribution of Lidocaine
Liver disease	Reduced clearance of Lidocaine Disopyramide Phenytoin β-blockers
Renal disease	Reduced clearance of Disopyramide Procainamide Bretylium Flecainide Tocainide
Myocardial infarction/ischemia	Reduced clearance of Procainamide Altered protein binding of Lidocaine Quinidine

PRACTICAL PHARMACOLOGIC MANAGEMENT OF ARRHYTHMIAS

Supraventricular Arrhythmias

In general, supraventricular tachyarrhythmias (SVT) can be categorized to "AV node-dependent" vs. "AV node-independent" types based on their mechanisms (Fig. 51-11). The "AV node-dependent" SVTs utilize the AV node as an integral part of the circuit, such as AV nodal reentrant tachycardia (AVNRT) or AV reciprocating tachycardia (AVRT).

AVNRT is the most common form of reentrant narrow complex SVT. It is caused by reentry within the AV nodal region along two functionally distinct pathways. Such "dual AV nodal pathway" physiology consists of a fast-conducting pathway that generally has a longer refractory period and a slower-conducting pathway that has a shorter refractory period. During this common/typical (slow–fast) form of AVNRT, anterograde conduction down the slow-pathway with retrograde conduction over the fast-pathway activates the atria nearly simultaneously as the impulse reaches and depolarizes the ventricles, resulting in an extremely short VA time. Occasionally, the anterograde conduction proceeds down a "slow" AV nodal pathway with the retrograde conduction up the "fast" AV nodal pathway, and the so called uncommon/atypical form of "fast–slow" AVNRT (Fig. 51-12). Orthodromic AVRT is a reentry involving both atria and ventricles. The circuit consists of anterograde conduction down the AV node (Ca^{++}-dependent) and retrograde VA conduction up the accessory pathways/bypass tracts (Na^{+}-dependent). In both AVNRT and orthodromic AVRT, drugs that block impulse conduction at the AV node level (class II, IV) terminate the arrhythmias by interrupting the anterograde limb of the reentry circuit (AV node-dependent).

Patients with SVT often present with symptoms of palpitations, anxiety, lightheadedness, chest pain, dyspnea, and rarely syncope. However, patients may become hemodynamically unstable due to concomitant valvular disease, ischemia, or ventricular dysfunction. For acute

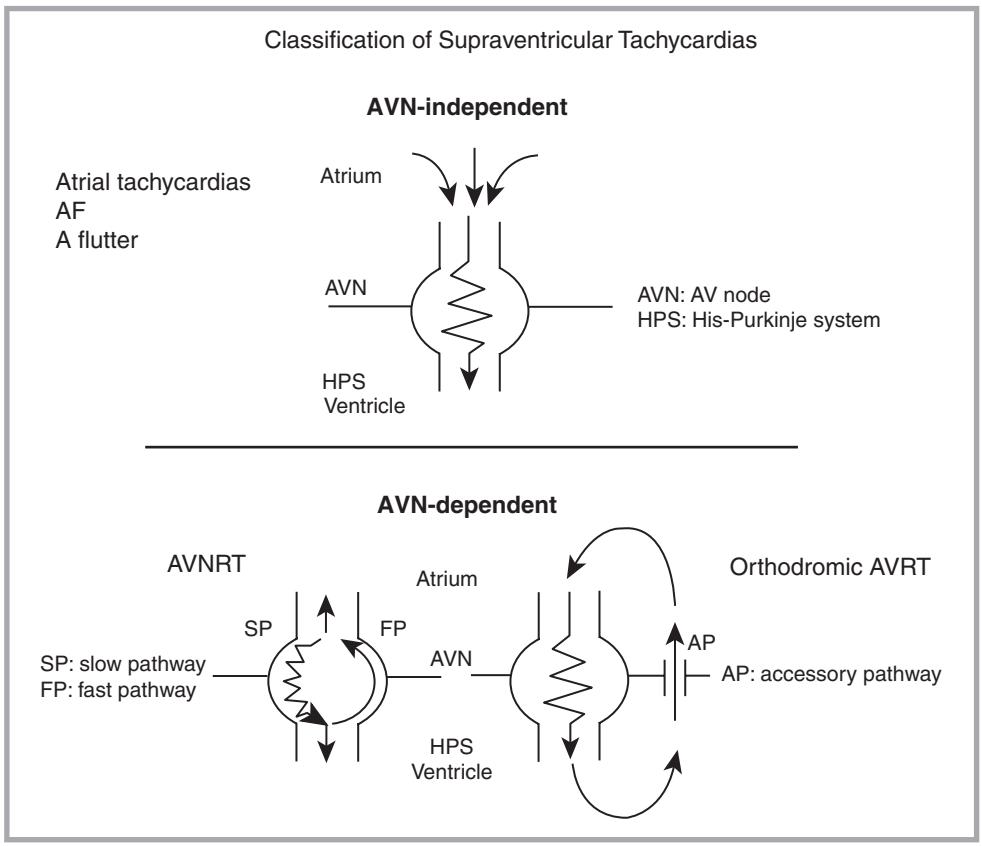

FIGURE 51-11

Classification of supraventricular tachycardia (SVT) mechanisms. SVTs can be classified into "AV node-dependent" or "AV node-independent" arrhythmias. The AV node is not required for maintenance of arrhythmias that originate above the AV node in "AV node-independent" SVTs. These include all forms of atrial tachyarrhythmias. The "AV node-dependent" SVT utilize the AV node as a critical part of the circuit, and interruption of impulse propagation at the AV node terminates such arrhythmias. These include AV nodal reentrant tachycardia (AVNRT) and AV reciprocating tachycardia (AVRT) utilizing a bypass tract.

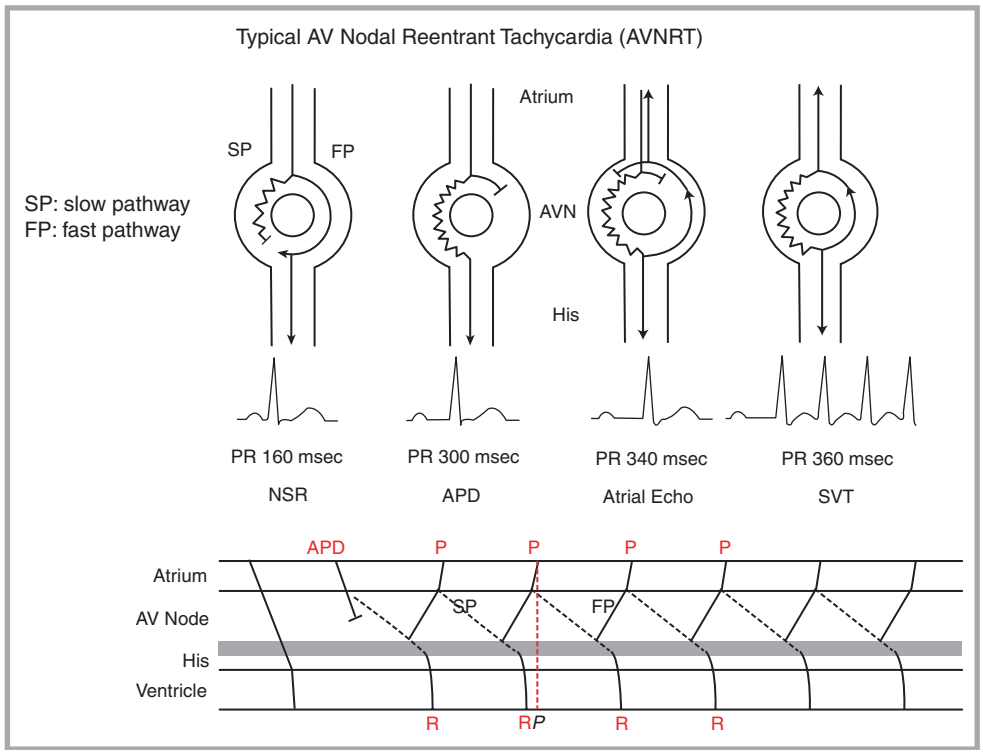

FIGURE 51-12

An illustrative example of the "typical" AVNRT. The AV node is schematically divided into dual AV nodal pathways that consist of a slowly conducting α-pathway and a rapidly conducting β-pathway. During normal sinus rhythm, the impulse preferentially conducts over the fast-pathway. A premature atrial depolarization (APD) blocks at the fast-pathway and travels down the slowly-pathway resulting in a prolonged PR interval. When a critical degree of slow conduction within the circuit is present (PR interval reaches 340 ms), a single atrial echo results (single reentrant beat). Further slowing in the circuit may result in sustained reentry. The lower ladder diagram illustrates the RP relationship during AVNRT. During "typical" AVNRT, the impulse propagates down the slow AV nodal pathway and conducts retrogradely up the fast AV nodal pathway. The atria and ventricles are activated nearly simultaneously in a "parallel" activation pattern, resulting in an extremely short VA time.

pharmacologic management of SVT, practice guidelines promote the use of adenosine as the first drug of choice for its diagnostic and therapeutic values. ECG monitoring is required during the administration of adenosine. Complications of bronchospasm and VF are rare, although resuscitation equipments should be available. Adenosine is contraindicated in cardiac transplantation or patients with severe obstructive lung disease. Patients who are hemodynamically stable, verapamil (class IV) or β-blockers (class II) can be given (Table 51-6). For chemical cardioversion of SVTs, second-line drugs such as procainamide (class IA) or ibutilide (class III) may be considered.

The arrhythmogenic mechanisms reside above the AV node level for "AV node-independent" SVTs and the AV node is not required for maintenance of arrhythmia. Atrial fibrillation, atrial flutter, or atrial tachycardias are examples of "AV node-independent" SVTs. AV nodal blockers (class II, IV) do not affect the arrhythmias and only slow the ventricular rate response for hemodynamics and symptomatic improvement. Direct membrane acting drugs, such as a Na^+ channel blockers or a K^+ channel blockers (class I, III), will act on the atrial myocardium, as well as AV bypass tracts (consist of myocardial fibers: Na^+-dependent). These agents are effective in both acute and chronic treatments of atrial tachyarrhythmias and SVTs involving bypass tracts. Amiodarone and Sotalol have both class III action and AV nodal blocking properties. They can be used effectively in all forms of SVTs.

TABLE 51-6

ACUTE PHARMACOLOGIC MANAGEMENT OF PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIAS

DRUG	DOSING	SIDE EFFECTS	COMMENTS
Regular tachycardia with narrow QRS complex			
First-line agents			
Adenosine	6 mg rapid IV bolus, may repeat in 1–2 min with 12 mg Ultrashort half-life ~10 s	Flushing, chest pain, hypotension, AV block and transient asystole, bronchospasm, atrial fibrillation Nonsustained ventricular tachycardia (uncommon)	Caution in heart transplant patients because of prolonged asystole, use with caution in patients with reactive airway disease
Verapamil	IV 5 mg every 3–5 min to maximum of 15 mg	Hypotension, heart block, negative inotropic effect	If hypotension develops, use calcium 1 g IV as antidote
Alternative agents			
Diltiazem	0.25 mg/kg IV bolus over 2 min, may repeat 0.35 mg/kg IV bolus then start continuous infusion of 5–15 mg/h	Hypotension, heart block, negative inotropic effects	If hypotension develops use calcium 1 g IV as antidote.
Metoprolol	IV 5 mg over 2 min, may repeat up to three doses (15 mg)	Hypotension, heart block, bradycardia, negative inotrope, bronchospasm- use with caution in patients with asthma	If patient becomes bradycardic, use beta agonists (dopamine, dobutamine, isoproterenol) and glucagon to reverse bradycardia/hypotension.
Esmolol	200–500 μg/kg over 1 min then 50–200 μg/kg/min over 4 min		
Propranolol	IV 0.15 mg/kg over 2 min		
SVT and atrial fibrillation with preexcitation or SVT refractory to drugs above			
Procainamide	15–17 mg/kg IV at 50 mg/min rate, then 1–4 mg/min infusion	Hypotension, widening of QRS complex, torsades de pointes	
Ibutilide	>60 kg use 1 mg over 10 min, if <60 kg use 0.01 mg/kg over 10 min	Prolonging QT interval, torsades de pointes	Caution in hypokalemia, ECG monitor required for 4–6 h after administration

SVT supraventricular tachycardia

Ventricular Arrhythmias

Unfortunately, antiarrhythmic treatment of ventricular arrhythmias is much less explicit. Most ventricular tachyarrhythmias (VT/VF) associated with structural heart diseases are thought to involve reentry (either single or multiple reentrant circuits) in ventricular myocardium. Since myocardial reentry involves Na^+-dependent tissue, class II and IV drugs are ineffective and only direct membrane acting agents (class I, III) should be considered. However, the empiric use of class IC antiarrhythmic drugs for suppression of ventricular ectopy after myocardial infarctions was associated with an excess of mortality as demonstrated by the pivotal cardiac arrhythmia suppression (CAST) trial.[6] In contrast, amiodarone did not increase mortality in patients with ventricular dysfunction after myocardial infarctions as shown in the European Myocardial Infarction Amiodarone Trial (EMIAT) and the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT) trials.[7,8]

Idiopathic VTs in the setting of minimal heart disease represent exceptions. These VTs include the right or left ventricular outflow tract (RVOT/LVOT) VTs, fascicular, or verapamil-sensitive VTs that originate from the left posterior fascicle near the apical ventricular septum (see Chap. 19 on "cardiac arrhythmias"). Class II and IV drugs can be used as first-line drugs for these arrhythmias.

Atrial Fibrillation/Flutter

Patients with new onset of atrial fibrillation/flutter may develop severe decompensation and heart failure. This is due to the loss of "atrial kick," abbreviated and irregular diastolic filling, and rapid ventricular rate response. The primary goal of treatment is rate control for symptoms relief. Beta-blockers for acute rate control during rapid atrial tachyarrhythmias include intravenous esmolol, metoprolol, and propranolol. Cautions must be exercised in patients with chronic obstructive airway disease, acute heart failure, and bradycardia/conduction disease. Digoxin is often ineffective in decreasing the ventricular response acutely during atrial fibrillation or flutter.

After rate control, antiarrhythmic therapy may be initiated to restore sinus rhythm and to prevent arrhythmia recurrence (Fig. 51-13). For patients without structural heart disease, agents such as flecainide, propafenone, or sotalol are recommended as the initial drugs of choice.[9,10] Secondary agents such as amiodarone or dofetilide may be considered if the first-line drugs are ineffective or not tolerated.[11-14]

Based on the efficacy and side effect profile, the use of class IA agents is limited.[15] Disopyramide and flecainide may be appropriate in vagally-mediated atrial fibrillation, whereas β-blockers and sotalol might be useful with adrenergically induced arrhythmias. Safety data support the use of dofetilide and amiodarone in patients with heart failure. In patients with coronary heart disease, sotalol with its β-blocking properties should be considered. In patient with hypertension without left ventricular dysfunction, flecainide or propafenone are first-line drugs because they do not prolong repolarization or QT interval. Amiodarone is recommended in patients with substantial ventricular hypertrophy since hypertrophied myocardium may be prone to ventricular proarrhythmia.[16]

For many patients with atrial fibrillation, a realistic goal may be rate control, but not necessarily to restore/maintain sinus rhythm. The AFFIRM trial (atrial fibrillation follow-up investigation of rhythm management) evaluated the long-term outcomes of such approach, either "rhythm control" (maintaining sinus rhythm) or "rate control" (controlling the ventricular rate response to less than 80 beats/min at rest during atrial fibrillation). The rate control treatment involved AV nodal blocking drugs such as digoxin, β-blockers, and/or calcium channel blockers, whereas amiodarone, propafenone, and sotalol were the most commonly used antiarrhythmic agents to maintain sinus rhythm. There was no difference in mortality between the two strategies.[17]

In general, the risk of thromboembolic complication in patients with atrial fibrillation increases about five-fold compared to those without atrial fibrillation.[18] This risk is increased drastically (15-fold) in patients with rheumatic valvular atrial fibrillation. Adequate anticoagulation status must be verified before attempted cardioversion (either electrical or

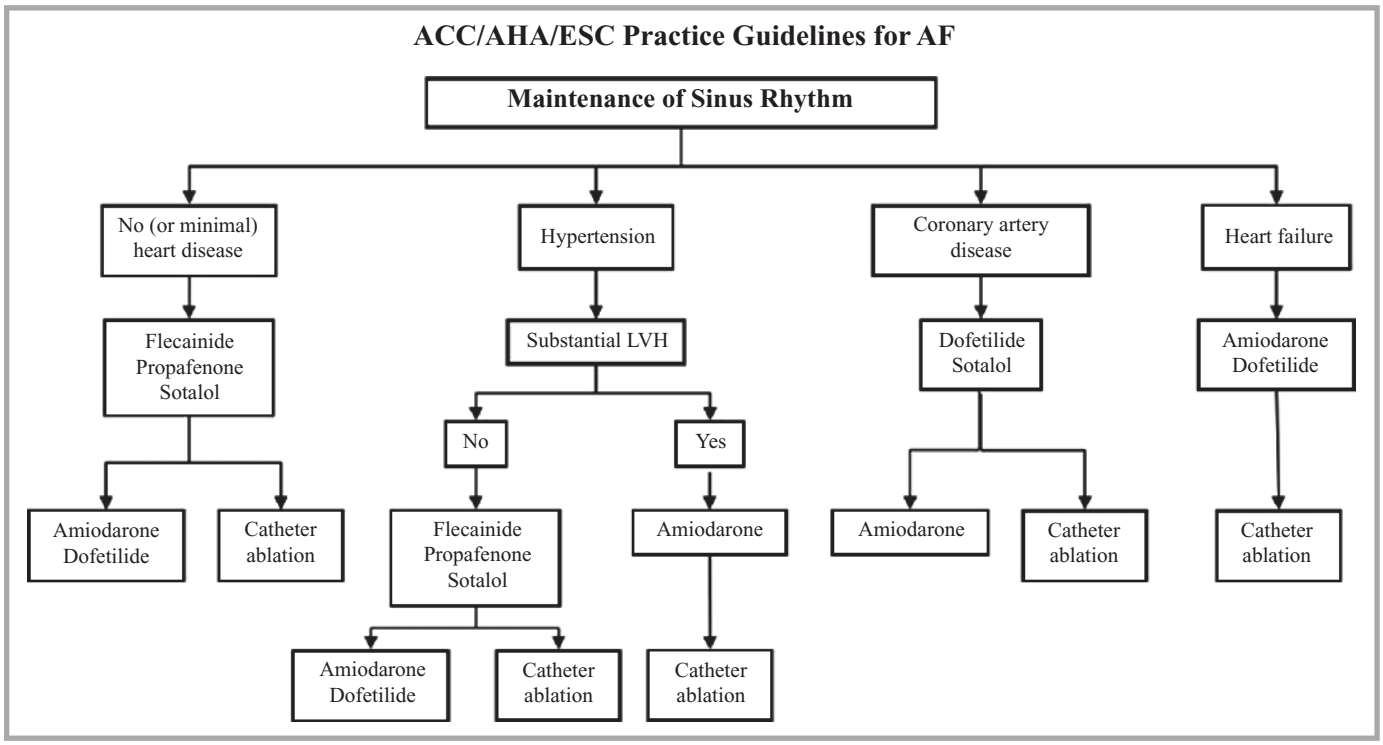

FIGURE 51-13

ACC/AHA/ESC 2006 Guidelines for the management of patients with atrial fibrillation. A report from the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for practice guidelines.

chemical). Therapeutic warfarin level must be maintained at an international normalized ratio (INR) of 2–3 for a minimum of 3 weeks prior to cardioversion and continued for at least 4 weeks after restoration of sinus rhythm. Chronic anticoagulation is recommended in those patients with risk for stroke and a high CHADS score (*c*ardiac failure, *h*ypertension, *a*ge >75 years, diabetes, prior *s*trokes or transient ischemic attacks).

METHODS TO GUIDE THERAPY

Methods are needed to evaluate patients' clinical responses to antiarrhythmic drugs and to guide therapy. For nonlethal arrhythmias, therapy guided by symptomatic assessment and plasma drug concentration is acceptable. However, empirical use of antiarrhythmic drugs with subjective evaluation for treatment of ventricular arrhythmias is potentially hazardous, especially in critically ill patients with structural heart disease (see proarrhythmia). Cardiology/electrophysiology consultation should be considered in these patients.

The use of plasma drug concentrations to adjust drug dosage is an acceptable method with limitations. Only a small number of antiarrhythmic drugs can be measured by routine clinical laboratories. The plasma drug level does not necessarily reflect the physiologic effects on individual patients. A "sub-therapeutic" quinidine level may represent a physiologically effective dosage in some patient. Furthermore, plasma drug level does not take into account the effects of active metabolites. For example, procainamide is a class IA agent, whereas its major metabolite from hepatic acetylation, NAPA exhibits class III drug action. Using the combined "procainamide+NAPA" level to assess the efficacy of procainamide therapy can be misleading as the "combined" value reflects both class IA and class III activities. In patients with renal insufficiency or with fast hepatic metabolism (produce a disproportionally high NAPA level), the "procainamide+NAPA" level overestimates the class IA effects. However, the "combined" level is useful in estimating the risk of adverse reactions with procainamide therapy.

Electrocardiographic manifestation of drug actions:
PR: AV nodal conduction: class II, IV
QRS: His-Purkinje, ventricular conduction: class I
QT: APD/repolarization: class III
IA: QRS and QT interval prolongation
IB: minimal effect on QRS and QT intervals
IC: significant QRS prolongation, bundle branch block
II/IV: PR interval prolongation
III: QT interval prolongation

In addition to plasma drug levels, the overall pharmacologic effects of antiarrhythmic drugs in patients can be assessed by the analysis of a routine 12-lead electrocardiogram. The electrocardiographic manifestations of drug actions are intuitive. The PR interval is determined predominantly by the AV nodal conduction time, and thus, indicates the effects of β-blockers and Ca^{++} channel blockers (class II and IV). The QRS duration reflects the impulse conduction through the His-Purkinje system and the ventricular myocardium. The myocyte action potentials and that of the specialized conduction system are "Na^+-dependent." The QRS width is, thus, dominated by the effects of Na^+ channel blockade (class I). The QT interval represents the APD and repolarization governed by the K^+ channels (class III).

The class I-A drugs exhibit K^+ channel inhibition, in addition to Na^+ channel blockade activity. The combined effects produce a moderate widening of QRS duration with QT interval prolongation. The I-C drugs are the most potent Na^+ channel blockers with significant depression of phase 0 upstroke and conduction velocity in Na^+ dependent tissues (ventricular myocardium and His-Purkinje system). This is manifested by prolongation of QRS duration and/or development of bundle branch block without alteration of ventricular repolarization. The K^+ channel blockers (class III) cause predominately QT prolongations, whereas class II and IV drugs affect AV nodal conduction with PR interval prolongation.

The criteria for determination of antiarrhythmic drug efficacy using either Holter monitor or exercise testing is somewhat variable. To be considered effective, it generally requires a total elimination of nonsustained arrhythmia events, up to a 90% reduction of couplets and approximately a 50% reduction in premature atrial or ventricular complexes. The role of invasive electrophysiologic study (EPS) in assessing antiarrhythmic drug responses and proarrhythmia is beyond the scope of this chapter and is less useful for daily management of patients.

PROARRHYTHMIA

The definition of proarrhythmia is a significant aggravation of arrhythmia occurring in temporal relation to the initiation of drug therapy or changes in dose. Since antiarrhythmic drugs alter the electrophysiologic properties of cardiac tissues, some of these changes can actually promote arrhythmia recurrences. The mechanisms of proarrhythmia are complex and a number of types of proarrhythmia have been recognized and are listed in Table 51-7. The development of new arrhythmias is clearly a manifestation of proarrhythmia. This may include conversion of nonsustained arrhythmia episodes to sustained tachycardias, induction of Torsades de Pointes (Tdp) with QT prolongation, or development of heart block and bradycardia. Proarrhythmia may also present as a worsening of preexisting arrhythmias. Changes in arrhythmia characteristics with more frequent recurrences, faster rate, and longer duration

TABLE 51-7

DEFINITIONS OF PROARRHYTHMIA

- Worsening of preexisting arrhythmias
  - Increasing frequency and complexity of arrhythmias
  - Conversion of nonsustained to sustained episodes
  - Altering the arrhythmia characteristics
    - Faster rate, longer duration
    - Incessant recurrences
    - More difficult to terminate
- Uncovering "hidden" arrhythmogenic substrate
  - Development of a new arrhythmia
  - Conversion of nonsustained to sustained arrhythmias
  - Torsade de pointes, polymorphic VT
  - Supraventricular tachycardias
- Induction of conduction block / suppression of escape foci
  - Bradycardias
  - Sinus nodal dysfunction
  - Atrioventricular block
  - His-Purkinje block
- All of the above

TABLE 51-8

DRUGS REPORTED TO CAUSE QT INTERVAL PROLONGATION AND TORSADE DE POINTES

DRUGS	EXAMPLES
Antiarrhythmics	Class IA and III
Antifungal	Fluconazole, itraconazole, ketoconazole
Antihistamine	Astemazole, diphenhydramine, terfenadine
Antibiotics	Erythromycin, TMP-Sulfa
Antimalarial/antiprotozoal	Chloroquine, mefloquine, pentamidine, quinine
Gastrointestinal	Cisapride
Psychiatric	Haloperidol, lithium phenothiazine, tricyclic antidepressants
Other	Amantidine, chloral hydrate, indapamide, probucol, tacrolimus, vasopressin papaverine, cocaine, bepridil

with less hemodynamic stability can be problematic. Occasionally, incessant arrhythmia can develop that may be refractory to attempts of termination, either by pacing or high energy shocks. A classic example of proarrhythmia is Torsades de Pointes associated with the use of class I-A or class III drugs. The development of polymorphic VT in the setting of prolonged QT interval is related to triggered activity based on EAD from delayed ventricular repolarizations. This is further exacerbated by hypokalemia, hypomagnesemia, and bradycardia (Table 51-8) (Fig. 51-14).

A common manifestation of proarrhythmia is the acceleration of ventricular rate during antiarrhythmic drug treatment of atrial fibrillation or flutter (Fig. 51-15). With the use of a class IA or IC antiarrhythmic agent, adequate AV nodal blockade is essential. As the Na^+-channel blocker slows the atrial impulse and input to the AV node, less encroachment of the nodal refractoriness occurs and the anterograde conduction may actually be facilitated. In addition, the vagolytic properties of the IA drugs also tend to accelerate conduction through the AV node.

Proarrhythmia events usually occur within several days of initiation of a new drug or dosage changes. However, it may present as an acute idiosyncratic reaction occurring within the first few doses, especially for class IA and class III drugs. Occurrences of proarrhythmia are often influenced by the pharmacokinetics and drug metabolism, changes in substrate (new myocardial infarction, ischemia), adverse interaction with other medications, electrolyte imbalance, autonomic tone, and heart rate changes (use-dependency and reverse use-dependency). The incidence of proarrhythmia has been reportedly as high as 30–40% in some patients, and is influenced by the presenting arrhythmia, individual agents, and patient-specific risk profiles. Meta-analysis of trials of antiarrhythmic therapy in postinfarction patients has demonstrated an unfavorable odds ratio with increased mortality, especially with the class I agents (Fig. 51-16). The overall odds ratio favors class II (β-blockers) and class III drugs (such as amiodarone) for mortality reduction.[19]

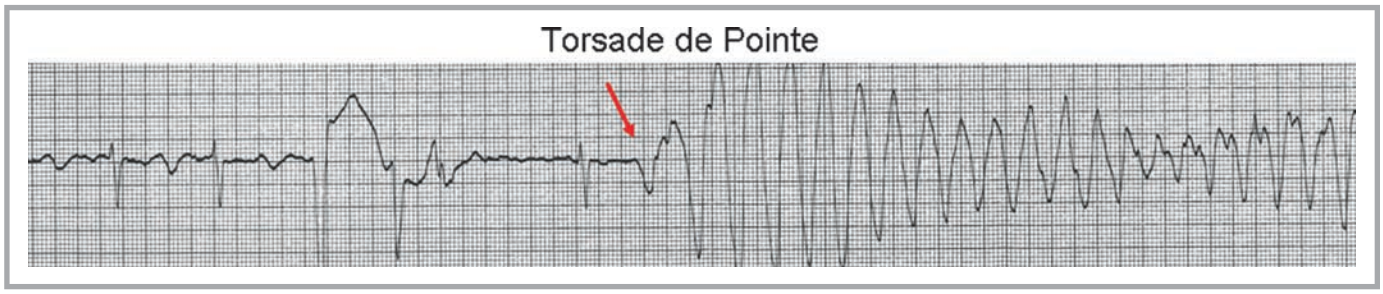

FIGURE 51-14

Torsades de Pointes (Tdp), the "twisting of the points," typically describes a polymorphic VT associated with prolonged QT intervals. The underlying rhythm is atrial fibrillation with QT prolongation. A PVC (*arrow*) after a "long-short" sequence induced Torsades de pointes.

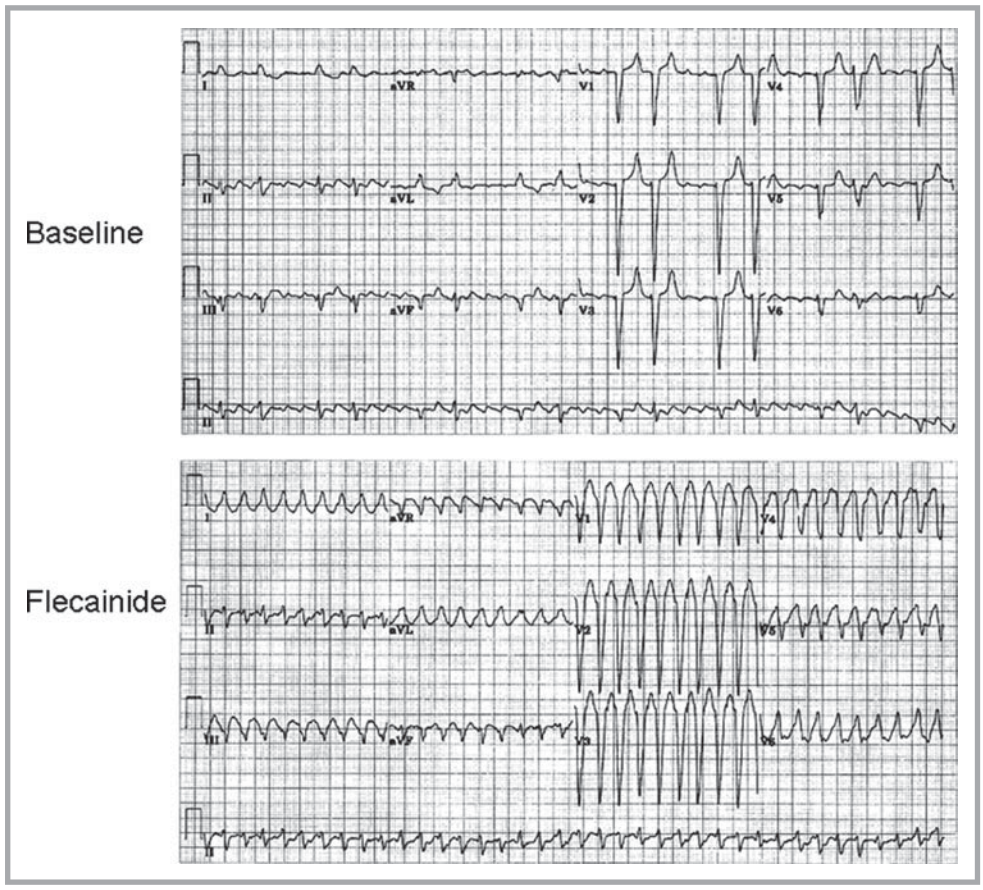

FIGURE 51-15

Acceleration of ventricular rate during antiarrhythmic treatment of atrial flutter. The baseline rhythm is atrial flutter with alternating 2:1 and 4:1 AV conduction. The atrial flutter cycle length is at 200 ms (~300 bpm) with an averaged ventricular rate of ~91 bpm. Flecainide is a potent Na^+-channel blocker that slows the conduction velocity during atrial reentry. The atrial flutter cycle length on drug is at ~270 ms (~222 bpm). The ventricular rate response is paradoxically accelerated to 1:1 AV conduction at 222 bpm.

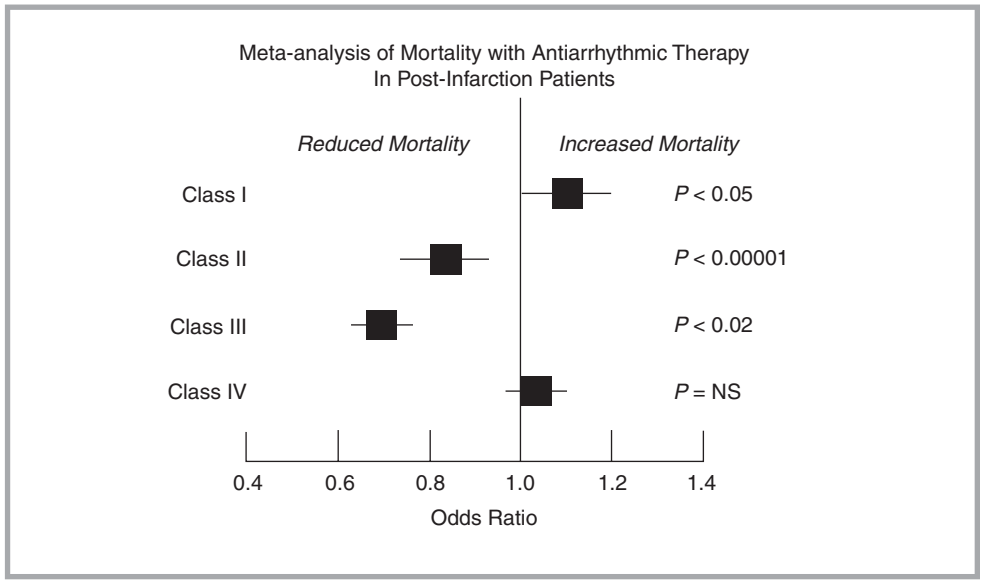

FIGURE 51-16

Meta-analysis of mortality with antiarrhythmic therapy in postinfarction patients. The overall odds ratio favors class II (β-blockers) and class III drugs (such as amiodarone) for mortality reduction. The use of class I and class IV antiarrhythmic drugs is associated with an increased mortality (adapted from Teo et al.[19] Copyright 1993 American Medical Association. All rights reserved).

The risk of proarrhythmia can be estimated by careful assessment of patient's clinical risk profile (Table 51-9). Proarrhythmia risk is low in patients with minimal structural heart disease who presents with nonlife-threatening arrhythmias. Proarrhythmia risk is significantly elevated in patients with structural heart disease and ventricular dysfunction who present with high grade sustained ventricular tachyarrhythmias (Fig. 51-17).[20] In hospitalized patients with multiorgan disease on many medications, the physicians must be keenly

CASE STUDY: PART 2

The case study ECG showed a polymorphic VT, consistent with the diagnosis of Torsade de Pointes (Tdp). The estimated QT interval is markedly prolonged. The patient had structural heart disease, ventricular dysfunction, and atrial fibrillation. She is on Dofetilide (a class III antiarrhythmic drug), which caused a delayed ventricular repolarization. Drug interactions between Erythromycin and Dofetilide resulted in further QT prolongation and the development of polymorphic VT related to triggered activity. This was further exacerbated by hypokalemia and other electrolyte abnormalities.

The immediate intervention for Torsade de Pointes is defibrillation with discontinuation of the offending agents. Administration of intravenous magnesium may be considered. Shortening ventricular repolarization with isoproterenol infusion or overdrive pacing at faster heart rates are also appropriate therapies for drug-induced Torsade de Pointes.

TABLE 51-9

Multiple medication interactions

aware of the "risk-benefit ratio" before initiating antiarrhythmic drugs. Electrocardiographic monitoring is essential in high-risk patients starting antiarrhythmic drugs. Exercise stress test may provoke proarrhythmia by sympathetic stimulation, or "use-dependency" at fast heart rates. Table 51-10 lists commonly used antiarrhythmic drugs, their major metabolic pathways (mostly involves the hepatic cytochrome systems) and route of elimination, dosing regimen, and common adverse effects (Table 51-10).

NEW INVESTIGATIONAL DRUG DEVELOPMENTS

Azimilide is a new class III agent that inhibits both rapid (IKr) and slow (IKs) delayed rectifier K^+ currents. It induces a rate-independent prolongation of refractory periods and QT intervals without "reverse use-dependent" response. It also blocks α- and β-adrenergic

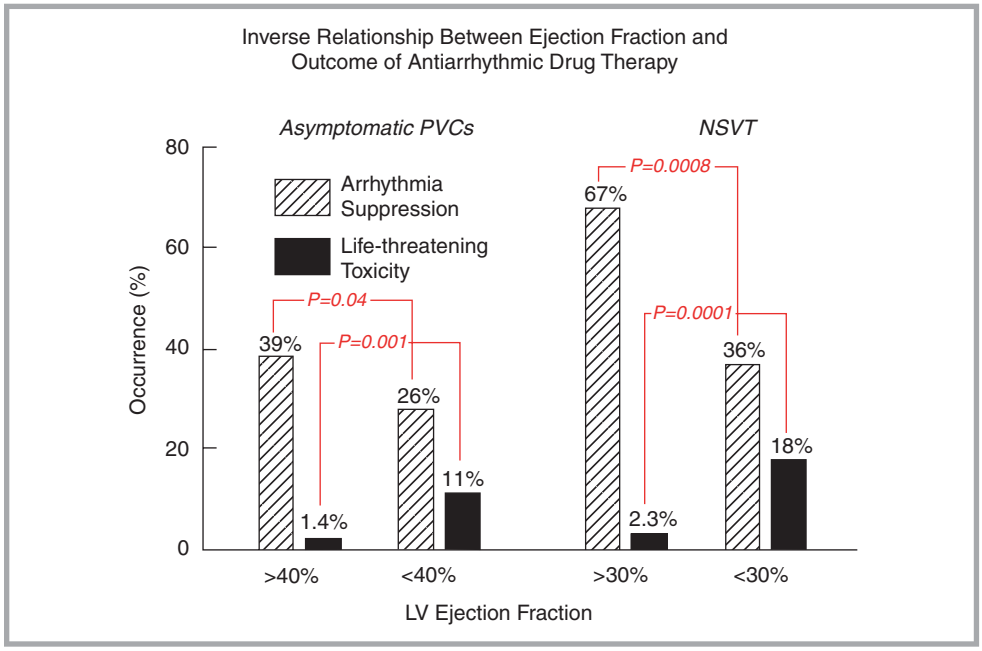

FIGURE 51-17

The inverse relationship of proarrhythmia risk vs. ventricular ejection fraction and the presenting arrhythmias. In patients with minimal structural heart disease who presents with low grade arrhythmias (asymptomatic PVCs), higher LV ejection fraction (EF) is associated with greater efficacy of arrhythmia suppression and lower life-threatening toxicity. The proarrhythmia risk is significantly elevated (18%) in patients with depressed LV ejection fraction (EF<30%) who present with potentially life-threatening arrhythmias (nonsustained VT), compared to those with less ventricular dysfunction (from Pratt et al[20] reprinted with permission from Elsevier).

TABLE 51-10

COMMONLY USED ANTIARRHYTHMIC DRUGS

DRUG	ROUTE	PHARMACOKINETICS	DOSING	ADVERSE EFFECTS
Quinidine	PO IV	Bioavailability: 70–80% CYP3A4 $T_{1/2}$=6–8 h Therapeutic: 2–6 mg/L	Quinidine sulfate: 300–400 mg q 4–6 h, PO Quinidine gluconate: 324–648 mg q 8 h, PO, or IV 0.25 mg/kg/min to max 10 mg/kg	GI upset, hypotension, liver dysfunction, QT prolongation, polymorphic VT
Procainamide	PO IV	Bioavailability: 75–90% *N*-acetyl-transferase/CYP2D6 Renal eliminated $T_{1/2}$=2–8 h Therapeutic: 4–15 mg/L	Oral: 50 mg/kg/day IV 15–17 mg/kg loading dose then 1–4 mg/min	GI upset, hypotension, lupus, QT prolongation, Torsades de pointe
Disopyramide	PO	Bioavailability: 70–95% CYP3A4 Renal elimination $T_{1/2}$=4–10 h Therapeutic: 2–6 mg/L	Oral: 400–800 mg day in divided doses	Dry eyes, dry mouth, urinary retention, hypotension, QT prolongation, torsades de pointes
Lidocaine	IV	Bioavailability: 20–40% CYP3A4/CYP2D6 $T_{1/2}$=1–3 h Therapeutic: 2–5 mg/L	IV 1–1.5 mg/kg IV load then 1–4 mg/min	CNS toxicities
Mexiletine	PO	Bioavailability: 80–90% CYP2D6/CYP1A2 $T_{1/2}$=6–17 h Therapeutic: 4–10 mg/L	Oral: 200–400 mg q 8 h	CNS toxicities, peripheral neuropathy
Flecainide	PO	Bioavailability: 70–90% CYP2D6 Renal elimination $T_{1/2}$=7–22 h Therapeutic: 0.3–2.5 mg/L	Oral: 40–200 mg q 12 h	Use-dependency, myocardial suppression, AV block, ventricular arrhythmias

Propafenone	PO	Bioavailability: 12–23% CYP2D6/CYP3A4/CYP1A2 *T*½=5–8 h	Oral: 150–300 mg q 8 h	Use-dependency, myocardial suppression, AV block, bronchospasm
Amiodarone	PO/IV	Bioavailability: 30–70% CYP3A4/CYP2C8 *T*½=20–100 days Therapeutic: 1–2.5 mg/L	Oral: 800–1,200 mg/day in divided doses up to 10 g, then 200–400 mg/day IV (atrial): 150 mg IV load over 20 min, then 1 mg/min for 6 h, then 0.5 mg/min IV (ventricular): 300 mg IV push, then 150 mg IV, then 1 mg/min for 6 h, then 0.5 mg/min	CNS toxicities, corneal microdeposits, hyper or hypothyroidism, pulmonary fibrosis, heart block, QT prolongation, hepatitis, GI upset, photosensitivity
Sotalol	PO	Bioavailability: 90–95% Renal elimination	Oral: 40–160 mg every 12 h	QT prolongation, torsades de pointes
Dofetilide	PO	Bioavailability: 85–90% CYP3A4 Renal	Oral: 125–500 mg every 12 h	QT prolongation, torsades de pointes
Ibutilide	IV	Bioavailability: 100% Beta oxidation	IV: 0.01 mg/kg over 10 min, repeat in 10 min if arrhythmia does not terminate	QT prolongation, torsades de pointes

Pharmacokinetic outlines the major system involved in the drug metabolism and route of elimination

*T*½: (drug's elimination half-life)

receptors in addition to K^+ channel blockade. Azimilide has been studied for prevention of recurrent atrial fibrillation, supraventricular, and ventricular arrhythmia.[21-24] In addition to amiodarone, sotalol, and dofetilide, it represents an alternative class III antiarrhythmic drug.

Dronedarone, approved by the FDA in July 2009, is structurally and mechanistically similar to amiodarone, but is without iodination and less lipophilic than amiodarone. It is also a potassium, calcium, and sodium channel blocker, as well as possesses alpha and beta adrenergic blocking effects in addition to coronary vasodilation. Dronedarone has been studied for the maintenance of atrial fibrillation and atrial flutter.[25] Similar to amiodarone, the electrocardiographic changes in humans with dronedarone include dose-dependent prolongations of the PR and QTc intervals. The DAFNE (dronedarone atrial fibrillation study after electrical cardioversion) study included patients with paroxysmal, lone atrial fibrillation, as well as atrial fibrillation secondary to various structural heart diseases. The primary end-point showed a significant increase in the median time to the first episode of atrial fibrillation recurrence with dronedarone 800 mg/day compared to placebo.[26] The most common side effects with dronedarone are diarrhea, vomiting, nausea, and gastroenteritis. The EURIDIS (European Trial in Atrial Fibrillation or Flutter Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm) and ADONIS (American–Australian Trial with Dronedarone in Atrial Fibrillation or Flutter for the Maintenance of Sinus Rhythm) trials enrolled similar patient populations. The results of both trials demonstrated that dronedarone increases the median time to the first recurrence of atrial fibrillation and flutter compared to placebo.[27] However, neither trial shows a mortality benefit. Dronedarone reduces the incidence of cardiovascular events in patients with atrial fibrillation,[28] but may increase mortality in patients with severe heart failure.[29] The current role of dronedarone remains to be defined depending on further efficacy and safety studies compared to other agents, such as flecainide, propafenone, and sotalol.

Another agent under investigation for atrial fibrillation is Vernakalant. Vernakalant is considered a class III agent that works by blocking the inward sodium channel, which is responsible for the rapid upstroke of the action potential, and therefore, reduces impulse conduction velocity and tissue excitability.[30] Furthermore, Vernakalant blocks the ultrarapidly activating (I kur) delayed rectifier potassium current specifically in the atria, thereby increasing atrial APDs and enhancing refractoriness, without affecting ventricular repolarizatons and potentially increasing the risk of ventricular proarrhythmia. Vernakalant has a short half-life (about a 2-h) and is metabolized via the hepatic CYP2D6.

Atrial Conversion Trial I and II (ACT I and II) are two phase 3 studies evaluating the efficacy of intravenous Vernakalant for cardioversion of patients with recent onset of atrial fibrillation. The most common side effect occurring during the intravenous and oral dosing were dysgeusia, paresthesia, sneezing, nausea, cough, pruritis, and hypotension. Further studies are needed to determine the long-term use in patients with chronic atrial fibrillations, heart failure, acute coronary syndromes, prolonged QTc, and bradycardia.

SUMMARY

The principles of antiarrhythmic drug management are based on the physiologic actions of antiarrhythmic drugs and mechanisms of arrhythmias. This chapter provides a framework for clinical approaches to antiarrhythmic drug. An accurate arrhythmia diagnosis may imply, with variable certainty, the arrhythmia mechanism based on collation of clinical information and electrocardiographic data. Effective pharmacologic therapy requires identifying a class of drugs with the most appropriate pharmacologic actions for targeting the most vulnerable parameter(s) of the arrhythmia based on its mechanism. Secondary assessments of both cardiovascular and noncardiovascular side effect profiles screen for inappropriate drug interactions and minimize adverse responses. Finally, considerations of long-term safety and tolerance identify the optimal agent for the individual patient.

REVIEW QUESTIONS

1. **A 71-year-old woman with prior myocardial infarctions who was admitted with congestive heart failure and paroxysmal rapid atrial fibrillation. She has had four episodes of atrial fibrillation in the last 6 months requiring hospital admissions. She has been treated with quinidine (324 mg, q 8 h), but continues to experience recurrent episodes with occasional heart failure exacerbation. Which would be the best antiarrhythmic drug for this patient?**
   - **A.** Procainamide
   - **B.** Amiodarone
   - **C.** Beta-blocker
   - **D.** Flecainide

2. **A 68-year-old Asian man with a nonischemic cardiomyopathy, who presented with recurrent dizziness and syncope. He was recently started on low dose diuretic and procainamide (500 mg, q 6 h), which was initiated 1 week ago for paroxysmal atrial fibrillation. The ECG showed a widened QRS duration with corrected QT interval of 530 ms. The procainamide/NAPA levels were 7.2/18.8 mg/dL. What should be the first step of treatment?**
   - **A.** Discontinuation of procainamide
   - **B.** Implantation of a defibrillator
   - **C.** Increase the procainamide
   - **D.** Holter monitor

3. **What is the best electrocardiographic parameter for the assessment of physiologic effects of class I-C antiarrhythmic drugs?**
   - **A.** The PR interval
   - **B.** The height amplitude of the QRS
   - **C.** The sinus rate
   - **D.** The width of QRS
   - **E.** The QT interval

4. **Which of the following arrhythmias is commonly associated with digitalis toxicity?**
   - **A.** Ventricular ectopies
   - **B.** Sinus bradycardia with junctional rhythm
   - **C.** Atrial tachyarrhythmias with various AV block
   - **D.** Alternating BBB tachycardias
   - **E.** All of the above

5. **A 65-year-old man with coronary artery disease underwent a coronary artery bypass grafting procedure. Two days after the surgery, the patient developed new onset of atrial fibrillation with a rapid ventricular rate. Which of the following responses would be most appropriate?**
   - **A.** Start procainamide for conversion of atrial fibrillation
   - **B.** Administer digitalis
   - **C.** Administer beta-blocker or calcium channel blocker for rate control in atrial fibrillation
   - **D.** Start amiodarone for conversion of atrial fibrillation
   - **E.** Both C and D

ANSWERS

1. The answer is B. This elderly patient has structural heart disease and ventricular dysfunction. Her atrial fibrillation is poorly tolerated and is refractory to a class I-A drug. An alternative antiarrhythmic drug is a class III agent for chronic therapy to prevent arrhythmia recurrence. The best tolerated drug with the least proarrhythmia side effect profile is amiodarone in this particular patient. Given her age and underlying heart disease, low dose amiodarone (200 mg daily) is associated with the best compliance with an acceptable risk of end-organ toxicity.
2. The answer is A. This etiology of the patient's syncope and dizziness is most likely due to nonsustained ventricular tachyarrhythmia, especially in an elderly man with structural heart disease. His QT interval is significantly prolonged with a disproportionally elevated NAPA level (class III effect) compared to that of procainamide. This may be related to patient's hepatic acetylation metabolism of procainamide. In addition, the initiation of diuretic may predispose the patient to electrolyte imbalance and proarrhythmia aggravation. The first-line of therapy is to discontinue procainamide and correct any electrolyte abnormalities.
3. The answer is D. The class I-C antiarrhythmic drugs are the most potent sodium channel blockers with significant suppression of impulse conduction velocity over the ventricular myocardium. This translates to a prolonged ventricular activation time and QRS widening. The class I-C drugs have no effects on cellular repolarization (QT interval) or the AV nodal conduction (PR interval).
4. The answer is E. Digitalis toxicity can be associated with many arrhythmias. The classic "digitalis toxic" rhythms are atrial tachyarrhythmias with AV block and ventricular arrhythmias with alternating bundle branch block morphologies. Other forms of arrhythmias can also be observed. The key to correct diagnosis is a high degree of suspicion of digitalis toxicity.
5. The answer is E. For new onset atrial fibrillation, an AV node-independent arrhythmia, direct membrane-active class III agents, such as amiodarone, may be used for arrhythmia conversion. However, for acute management, an AV nodal blocker should be administered first for heart rate control, especially considering the postoperative high catecholamine state and the slow onset of action of amiodarone. The efficacy of digitalis is low for acute rate control in the postoperative period with a high adrenergic tone.

CHAPTER 52

BENJAMIN SANCHEZ, JR.

Acute Coronary Syndromes

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Define acute coronary syndromes.
- Understand the basic pathophysiology of acute coronary syndromes.
- Recognize the signs and symptoms of acute coronary syndromes.
- Identify and evaluate different biomarkers.
- Risk stratify patients.
- Know the major treatment strategies for acute coronary syndromes.

INTRODUCTION

Acute coronary syndromes are one of the most common diagnoses for patients admitted to a medical intensive care unit. During the past decade, substantial strides have been made in our understanding of acute coronary syndromes and in the development of a variety of management strategies. Despite these advances, acute coronary syndromes continue to be a significant cause of morbidity and mortality. Acute coronary syndromes may present as unstable angina, and both non-ST segment elevation and ST segment elevation myocardial infarctions. However, many patients may have signs of cardiac injury such as an elevated troponin

CASE STUDY: PART 1

A 59-year-old man became increasingly concerned about progressive chest pain over 3 days and he saw his primary care physician as an outpatient at 1:00 pm. He was known to have diabetes mellitus and hyperlipidemia, and he was trying hard to stop smoking. He was chest pain free upon presentation; however, he describes the chest pain as retrosternal "tightness" with radiation to his jaw. This chest discomfort is associated with nausea, shortness of breath, and occasionally, diaphoresis. Initially, the discomfort occurred only with exertion; however, this current episode caused him to awake abruptly from his sleep at approximately 5:00 am. He had taken his wife's sublingual nitroglycerin, which provided him immediate relief. He also admits to having worsening dyspnea on exertion over the past 6 months. He had an exercise stress test last year in which he achieved his target heart rate without evidence of perfusion defects and with a normal left ventricular ejection fraction. He has not had any prior cardiovascular procedures including cardiac catheterization, pacemaker implantation, or coronary artery bypass graft surgery (CABG). His last episode of chest discomfort was at 9:00 am.

Physical exam revealed a heart rate of 95 beats/min, a blood pressure of 130/85 mmHg in both arms, and a respiratory rate of 12 breaths per minute. He was not in acute distress; however, he appeared slightly unsettled. His physical exam is otherwise normal without evidence of abnormal cardiac findings. The electrocardiogram was normal. Despite the patient's initial reluctance, his primary doctor transferred him by ambulance to the emergency department for further evaluation.

level without the typical presentation of an acute coronary syndrome. Although the final mechanism of cardiac injury or cell death may be similar, treatment strategies often differ from those patients with typical acute coronary syndromes.

This chapter will provide an overview of acute coronary syndromes beginning with its definition. Pathophysiology of acute coronary syndromes as well as evaluation, diagnosis, and treatment will be discussed.

DEFINITION OF ACUTE CORONARY SYNDROMES

The World Health Organization (WHO) defines myocardial infarction as a combination of at least two of the following three characteristics: (1) typical features such as chest discomfort, (2) a rise in cardiac enzymes, and (3) typical electrocardiogram (ECG) pattern involving the development of Q waves.[1,2] However, the recent introduction of new tests to define myocardial infarction will require a revision in this definition. New sensitive cardiac biomarkers and imaging technologies have led to an improved ability to detect myocardial injury and necrosis in patients who would otherwise not be labeled as having a myocardial infarction by the WHO criteria.

The Joint European Society of Cardiology/American College of Cardiology Committee published a statement in September 2000 to refine the definition of an acute myocardial infarction. Criteria for an acute, evolving, or recent myocardial infarction include a rise and gradual fall of biomarkers for myocardial necrosis with at least one of the following: (1) ischemic symptoms, (2) development of pathologic Q waves on ECG, (3) ECG changes indicative of ischemia (i.e., ST segment elevation or depression), and (4) percutaneous coronary intervention.[3] A summary of the elements that comprise this new definition are provided in (Table 52-1).

Acute coronary syndromes refer to those patients with STEMI, NSTEMI, and unstable angina.

Acute coronary syndromes refer to patients who suffer from an ST-segment myocardial infarction (STEMI), non-ST-segment myocardial infarction (NSTEMI), and unstable angina (Fig. 52-1). STEMI patients are those patients who fulfill the European Society of Cardiology/American College of Cardiology (ESC/ACC) criteria with clear ST-segment elevation in two or more contiguous leads. In general, patients who have elevations in biomarkers for myocardial necrosis with other ESC/ACC criteria for myocardial infarction without ST segment elevation are NSTEMI patients. Finally, patients with ischemic symptoms without elevations of cardiac biomarkers are considered as unstable angina patients.

TABLE 52-1

A SUMMARY OF THE JOINT EUROPEAN SOCIETY OF CARDIOLOGY/AMERICAN COLLEGE OF CARDIOLOGY COMMITTEE STATEMENT ON THE DEFINITION OF MYOCARDIAL INFARCTION

Definition of M1.
Criteria for acute, evolving or recent MI.
Either one of the following criteria satisfies the diagnosis for an acute, evolving or recent MI:
1) Typical rise and gradual fall (troponin) or more rapid rise and fall (CK-MB) of biochemical markers of myocardial necrosis with at least one of the following:
   a) Ischemic symptoms
   b) Development of pathologic Q waves on the ECG
   c) ECG changes indicative of ischemia (ST segment elevation or depression) or
   d) Coronary artery intervention (e.g., coronary angioplasty)
2) Pathologic findings of an acute MI
Criteria for established MI
Any one of the following criteria satisfies the diagnosis for established MI:
1) Development of new pathologic Q waves on serial ECGs. The patient may or may not remember previous symptoms. Biochemical markers of myocardial necrosis may have normalized, depending on the length of time that has passed since the infarct developed
2) Pathologic findings of a healed or healing MI

SOURCE: Alpert et al.[3] Reprinted with permission from Elsevier

Patients with acute coronary syndromes may present with ST segment elevation, ST segment depression, and left bundle branch blocks or with a normal electrocardiogram.

However, there are limitations to these criteria. For example, significant ST-depression in the anterior leads may actually demonstrate a posterior "ST-segment elevation" myocardial infarction. In patients who present with a left bundle branch block, whether old or new, myocardial infarction may be identified with biomarker elevations; however, there may be confusion concerning the type of acute coronary syndrome that is present. Confounding variables on the electrocardiogram such as preexcitation syndromes, left ventricular hypertrophy, and bundle branch blocks may also complicate the interpretation. In addition, new criteria for myocardial infarction are needed for post-cardiac surgery patients. As a result of the process of cardioplegia, post-cardiac surgery patients often have clinically insignificant elevated troponin levels. There is a clinically acceptable degree of myocardial necrosis in those patients who undergo cardiac surgery. Post-operatively, these patients do not have signs of ongoing ischemia or hemodynamic or electrical instability. Unfortunately, no cardiac biomarker can distinguish between actual myocardial infarction vs. "expected" myocardial necrosis from the procedure. Postoperative myocardial infarctions typically result in significantly elevated biomarkers, along with ST segment deviation, and regional wall motion abnormalities.

CASE STUDY: PART 2

The 59-year-old man presents to the emergency department. In transit, he once again developed retrosternal chest pain that was very similar to the discomfort that he experienced over the past few days. He was quickly triaged to a monitored bed and 2 L of nasal cannula oxygen was started, an intravenous catheter was inserted, and he was placed on a monitor. His initial blood pressure was 120/80 mmHg with a heart rate of 90 bpm. His respirations were unlabored at 22 breaths per minute. Pulse oximetry was 95%. He appears uncomfortable and diaphoretic. His physical exam showed no evidence of jugular venous distention, his lungs were clear to auscultation, and there was no bipedal edema. The chest X-ray was normal. The electrocardiogram showed 2 mm ST segment depressions in the anterolateral leads. The initial myoglobin level and CK-MB were normal and a troponin I level was 0.4 ng/mL. Both the basic metabolic profile and complete blood count were normal.

Initial management began almost immediately upon arrival with 325 mg p.o. of aspirin. He was then given a sublingual 0.4 mg nitroglycerin tablet as well as 5 mg IV metoprolol followed by an oral dose of 25 mg metoprolol. He was given SQ low-molecular weight heparin, enoxaparin, based on his weight. Finally, given the positive troponin level and his overall clinical presentation, he was loaded with 300 mg of clopidogrel p.o. Within 5 min, his chest pain resolved and the ST-segment depressions returned to baseline. The patient seemed medically stable at that point.

PATHOPHYSIOLOGY OF ACUTE CORONARY SYNDROMES

Atherosclerosis

A discussion concerning how atherosclerosis develops is crucial for understanding the pathophysiology of acute coronary syndromes. Although there are various hypotheses for the development of atherosclerosis, the most widely acceptable one concerns the response-to-injury of the vascular endothelium.[4] Although the precise mechanism is not completely understood, it is the exposure of the vascular endothelium to mechanical or toxic injury that may trigger a cascade of events that leads to the development of atherosclerosis. The role of other factors such as genetic predisposition, infections, or possibly an elevated homocysteine level, as triggers or cofactors for atherosclerosis are less well understood. Endothelial dysfunction is presumed to develop from recurrent injury that may begin early in life. Suspected agents that may induce vascular injury and lead to the development of atherosclerosis include elevated and oxidized low-density-lipoprotein (LDL), the presence of diabetes mellitus, and continued cigarette smoking.

In general terms, the process of atherosclerosis begins with oxidized LDL. Oxidized LDL is consumed by macrophages in the subendothelial layer of blood vessels. In turn, these activated macrophages stimulate the release of cytokines and or chemoattractants. Vascular smooth muscle cells migrate from the media to the intima where they become activated and proliferate. These activated smooth muscle cells produce collagen and other matrix molecules. These extracellular molecules are important in the development of the fibrous cap seen in plaques. Over time, there is an accumulation of both cellular and extracellular material. "Mature" plaques tend to have a better developed fibrous cap with or without significant calcifications. Other plaques that do not have such a fibrous cap may be more vulnerable to plaque rupture.[6]

The endothelium plays a vital role in the pathogenesis of atherosclerosis.

Endothelial dysfunction plays a central role in the development of atherosclerosis as demonstrated with the introduction of acetylcholine into coronary arteries. Under normal circumstances, acetylcholine would lead to arterial dilatation. However, when endothelial dysfunction is present in the setting of atherosclerosis, the coronary vessels may not only fail to dilate, but paradoxically vasoconstrict. Endothelial dysfunction, which may result from injury as described above, also leads to the development of chemoattractants. Endothelial dysfunction may also lead to the formation of receptors such as vascular cell adhesion molecule-1, (VCAM-1). Endothelial cells develop these receptors which bind to monocytes as well as T-cells in early plaque formation. The endothelium also secretes monocyte chemoattractant protein-1. These conditions lead to increased permeability of the endothelium to cells and LDL. Finally, smooth muscle cells and endothelial cells produce growth factors and cytokines that further accelerate the process of atherosclerosis (Fig. 52-2).[7]

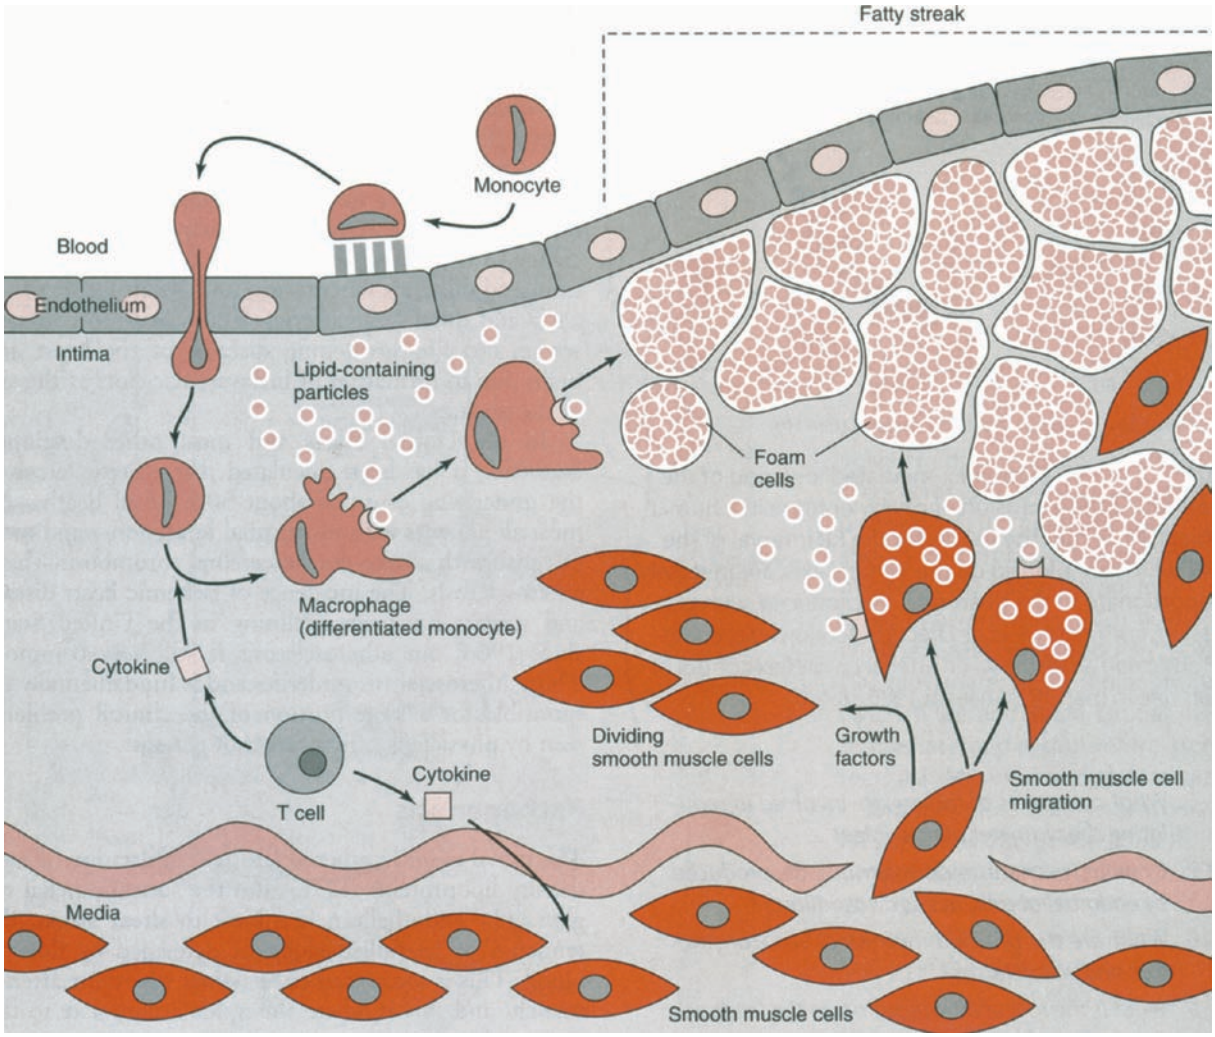

FIGURE 52-2

Summary of formation of atherosclerosis. Formation of a fatty streak in an artery. Following vascular injury, monocytes bind to the endothelium, then cross it to the subendothelial space and become activated tissue microphages. The macrophages take up oxidized LDl, becoming foam cells. T cells release cytokines, which also active macrophages. In addition, the cytokines cause smooth muscle cells to proliferate. Under the influence of growth factors, the smooth muscle cells then move to the subendothelial space where they produce collagen and take up LDL, adding to the population of foam cells. (Reprinted with permission from Hajjar and Nicholson[61]).

The Vulnerable Plaque

Plaque rupture and plaque erosion are the two proposed mechanisms of plaque disruption.

Plaques can be classified into two broad categories, those with soft lipid-rich layers and those with a hard collagen-rich sclerotic tissue (fibrous cap). The most vulnerable plaques are thought to be the lipid-rich with a "thin" fibrous plaque. These types of plaques tend to have a necrotic core. The precise mechanism of the rupture is not completely clear, however, there are two proposed mechanism of plaque disruption. One, which probably occurs in the vast majority of cases, is plaque rupture. Plaque rupture often occurs at the "shoulder" of the

plaque. This "shoulder" area of the plaque is the interface area of the lipid-rich core and the intraluminal area of the blood vessel. Shear stress at the edge of the plaque may play a role in the rupture.[8] In addition, an inflammatory response occurs involving activated T-cells which secret extracellular matrix degrading enzymes (plasminogen activators and matrix metalloproteinases). These enzymes may weaken the cap leading to its vulnerability. The second rupture mechanism is slow plaque surface erosion until the rich lipid core is exposed.[9] Regardless of the mechanism of plaque disruption, exposure of the thrombogenic material of the plaque leads to the initiation of the acute coronary syndromes.

The result of plaque disruption and thrombus formation may lead to distinct clinical presentations. If the thrombus is transient or if there is incomplete occlusion, myocardial necrosis may be avoided. With incomplete vessel occlusion, there may be sufficient coronary flow to avoid myocardial necrosis; however, the occlusion may still result in anginal symptoms and dysfunctional myocardium. Moreover, the location of the thrombosis is important. If an occlusion occurs proximally in a larger coronary vessel, a considerable amount of myocardium is at risk for infarction. A thrombus forming distally in a smaller vessel may not have the same clinical significance.

Role of Platelets

In acute coronary syndromes, platelet adhesion, activation, and aggregation are central to the development of acute thrombosis. Von Willebrand factor, fibronectin, laminin, and collagens are factors that are found within the subendothelial layers of blood vessels. After plaque rupture or erosion, these factors are now exposed to the platelets resulting in adhesion and activation of the platelets. The platelets undergo a conformational change and release granules that contain a number of factors. These factors include platelet-activating factors such as adenosine diphosphate, thromboxane A2, and serotonin, as well as many other compounds. In addition, adenosine diphosphate, epinephrine, collagen, thrombin, and serotonin are platelet agonists that further activate platelets.[10]

Activated glycoprotein IIb–IIIa receptors are involved in the cross-linking of platelets resulting in platelet aggregation.

Glycoprotein (GP) receptors are important receptors on the surface of the platelets. GP Ia–IIa bind to exposed collagen, and GP Ib binds to von Willebrand factor. With well over 80,000 receptors on the surface of platelets, the most common GP receptors are GP IIb–IIIa. In the inactivated state, these receptors have very limited affinity to fibrinogen. Once activated however, there is a high affinity to fibrinogen resulting in bridging of the platelets or platelet aggregation. In addition, CD40 ligands are expressed once the platelets have become activated. These ligands mediate the binding of the platelets to leukocytes. These platelet-leukocyte complexes result in further release of cytokines.[11]

Coagulation Cascade

Tissue factor is a glycoprotein found on the surfaces of cells within the subendothelial layer of blood vessels. Exposure of tissue factor results in the coagulation cascade initiation via the activation factor VIIa. This process in turn results in a small production of thrombin that activates platelets. It is this activation of the platelets that leads to large-scale formation of thrombin via the factor IXa-factor VIIIa complex.[12]

Thrombin plays a vital central role in the development of thrombosis after plaque rupture or erosion. The main function of thrombin is to convert fibrinogen to fibrin in the formation of thrombus. In addition to activating platelets, thrombin activates factors V, VIII, XI & XIII. Factor XIII is crucial in the formation of cross-links of fibrin in order to stabilize clot formation. Thrombin also induces the proliferation and migration of smooth muscle cells and fibroblasts. Thrombin also causes an upregulation of tissue factor and promotes monocyte adhesion to the endothelium and secretion of various cytokines and growth factors.

There are a number of factors that influence the degree of thrombus formation. A specific tissue factor antigen has been identified in the core of plaques. Higher levels of tissue factor antigen have been seen in patients with acute coronary syndromes. Plaques that tend to have higher or richer lipid content in the core of the plaque tend to be more procoagulant. Increased levels of fibrinogen, plasminogen activator inhibitor-1, and factor VII have been seen in

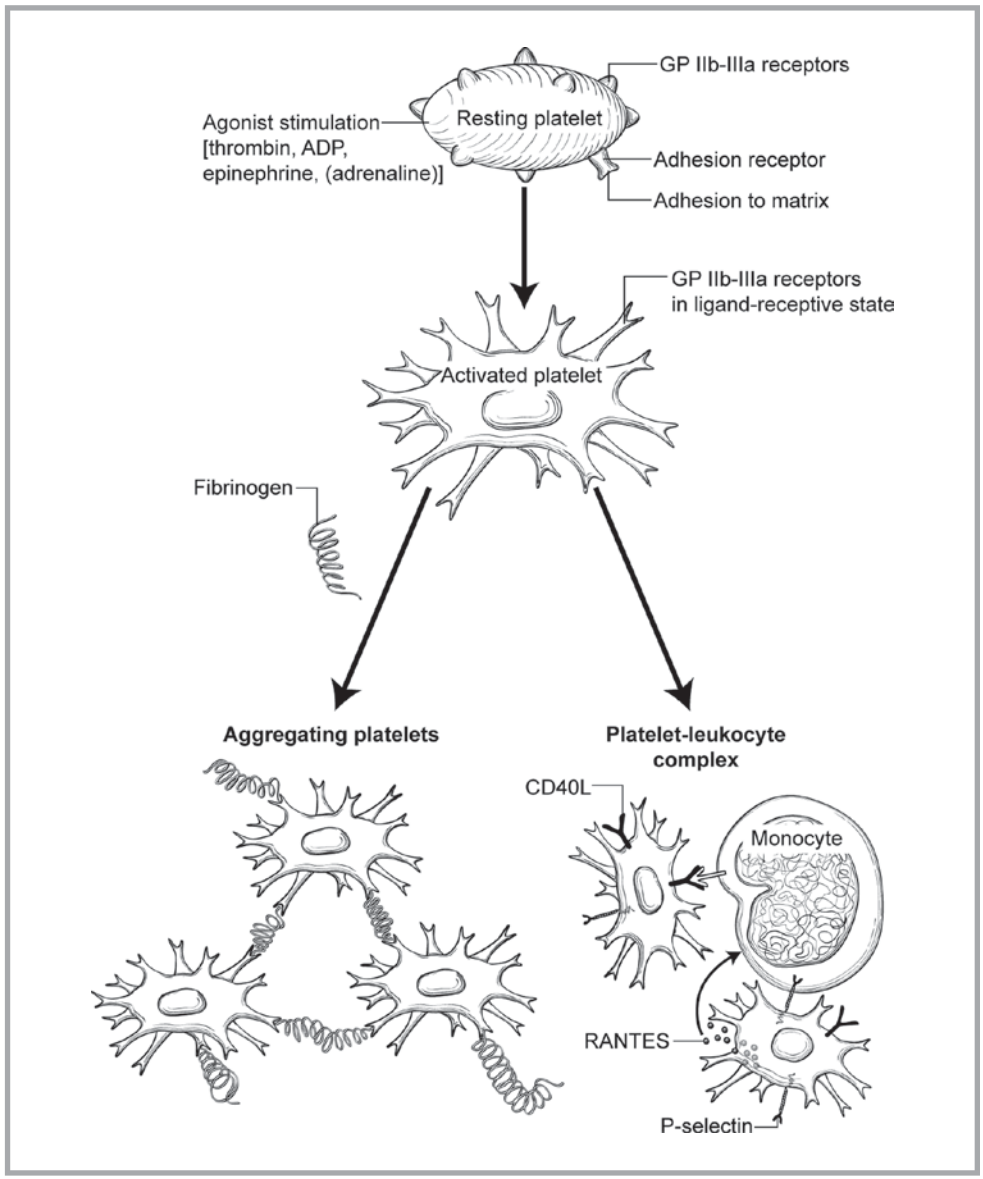

FIGURE 52-3

Activation and aggregation of platelets and the formation of platelet-leukocyte complexes. Stimulation of platelets by adhesion or agonist receptors induces transition of Glycoprotein (GP) IIb–IIIa receptors to active ligand-binding receptors. Glycoprotein IIb–IIIa occupied by fibrinogen support aggregation through the formation of bridges between adjacent platelets. Activated platelets express P-selectin and CD40 Ligand (CD40L) on their surface. These receptors mediate the binding of leukocytes, thus forming complexes between the cells. ADP, adenosine diphosphate. (Illustration by Alice Y. Chen. Modified with permission from Crawford MH, DiMarco JP, Paulus WJ. Acute coronary syndromes. In: *Cardiology*. 2nd ed. Mosby; 2004. pp. 311-462. Copyright Elsevier, 2004).

patients with acute coronary syndromes. Markers of inflammation such as interleukin-6 and C-reactive protein are also elevated[13] (Fig. 52-3).

DIAGNOSIS OF ACUTE CORONARY SYNDROMES

Clinical Presentation

History

Traditional risk factors for coronary artery disease (CAD) include male gender, advanced age, diabetes mellitus, hypertension, hyperlipidemia, family history of premature heart disease, and cigarette smoking.[5]

The diagnosis of acute coronary syndromes should begin with a high index of suspicion especially in those patients who have traditional risks factors, such as being of male gender, over the age of 50 years, smoking, diabetes mellitus, hypertension, family history of coronary disease, and hyperlipidemia. If these risk factors are not present, the index of suspicion should remain since patients can present without these diagnoses. Typical features of chest discomfort that are consistent with angina include chest pressure often with radiation to the left arm, precipitated by exercise or emotions, and relieved with rest or the use of sublingual

nitroglycerin. However, there are atypical presentations, especially in certain subsets of patients such as women, the elderly and patients with diabetes. Particular attention should be made to those patients who may not be able to communicate their symptoms such as critically ill and postoperative patients. A disproportionate number of patients with acute coronary syndrome present in the early morning hours as compared to other times of the day and night. There are circadian rhythms involving the rise and fall of plasma cortisol and epinephrine, as well as cyclic variations in systemic blood pressure that influence the underlying pathology of coronary disease. The onset of symptoms is also a clinically important information. In addition, any prior information from cardiovascular procedures such as cardiac catheterization and stress tests and CABG are important to consider when evaluating patients.

Typical angina is chest pressure that lasts for about 15 min that is precipitated by activity or high emotional stress. In addition, this chest pressure is usually relieved with sublingual nitroglycerin or rest.

The characteristics of the chest discomfort may be atypical. Chest pain may be sharp in intensity, and at first misdiagnosed as indigestion or heartburn. The chest pain may be relapsing in nature. Associated symptoms may or may not be present such as nausea, vomiting, shortness of breath, and diaphoresis. Indeed, some patients may actually present with these symptoms only. Atypical presentations include variation in the radiation of discomfort. It may shoot to the left arm; however, the pain may radiate to the jaw, neck, back, shoulders, or even to the right arm. Other atypical symptoms may include weakness, dizziness, or syncope. Some patients may exhibit symptoms of congestive heart failure such as orthopnea, paroxysmal nocturnal dyspnea, bipedal edema, or dyspnea on exertion.

Patients who present with atypical presentations of cardiac ischemia are women, patients with diabetes, elderly patients, and critically ill patients.

Physical Examination

The physical examination of a patient with an acute coronary syndrome may be rather unremarkable; however, the lack of physical findings does not exclude the possibility that an acute coronary syndrome is evolving. Physical examination in the setting of acute coronary syndromes begins with an overall general assessment. Patients with ischemic symptoms may appear anxious, pale, or diaphoretic due to sympathetic release. They may have cool clammy skin if they are in cardiogenic shock. Patients may present with arterial hypertension from their discomfort, or be normotensive, or hypotensive if they are experiencing cardiogenic shock. Patients may also present with low-grade fevers due to autonomic release, however high-grade fevers are unlikely. A patient's respiratory status may be stable or unstable with imminent respiratory failure, depending upon the presence and degree of pulmonary edema.

A normal physical examination does not exclude the possibility that a patient is experiencing an acute coronary syndrome.

Patients may present with specific signs of cardiogenic shock or congestive heart failure.

Whether patients themselves postpone care, or whether they experience unrecognized atypical symptoms, patients who present late to treatment may be at risk for cardiogenic shock. In addition, ischemia of large territories of myocardium, such as the anterior myocardial wall, or unsuccessful revascularization increases the risk of congestive heart failure or shock. Signs of congestive heart failure include: jugular venous distension, lung inspiratory crackles, third heart sound or gallop, hepatomegaly, and lower extremity edema.

Mechanical complications may also be present on physical examination. A mitral regurgitation murmur may be present as demonstrated by a holosystolic murmur heard best at the apex. A ventricular septal defect may occur with evidence of a pansystolic harsh murmur heard throughout the precordium. A pericardial friction rub may be present. A right-sided S3 (cardiac gallop that waxes and wanes with inspiration and expiration) may be present with right ventricular infarction along with evidence of right ventricular failure (i.e., hepatomegaly, hepatojugular reflex, or lower extremity edema). A patient may experience refractory hypoxemia in the setting of a right ventricular failure due to a right-to-left shunt resulting from a patent foramen ovale.

Mechanical complications include congestive heart failure, cardiogenic shock, mitral regurgitation, ventricular septal defect, and cardiac rupture.

Electrocardiogram (ECG)

Many patients with acute coronary syndromes will have some abnormalities noted on the electrocardiogram; however, some patients may present with a normal electrocardiogram. These patients may no longer present with ischemia due to transient occlusion of a coronary vessel. The electrocardiogram may be "electrically silent" or normal in patients with acute coronary syndromes.[14]

Most patients with acute coronary syndrome will present with abnormalities on the electrocardiogram; however, a normal electrocardiogram does not exclude the presence of an acute coronary syndrome.

Patients may present with nonspecific T-wave abnormalities or T-wave inversions. Unlike ST segment elevation, T-wave inversion may persist for a period of time even after the ischemia has resolved. ST-segment depression may be present during episodes of ischemia.

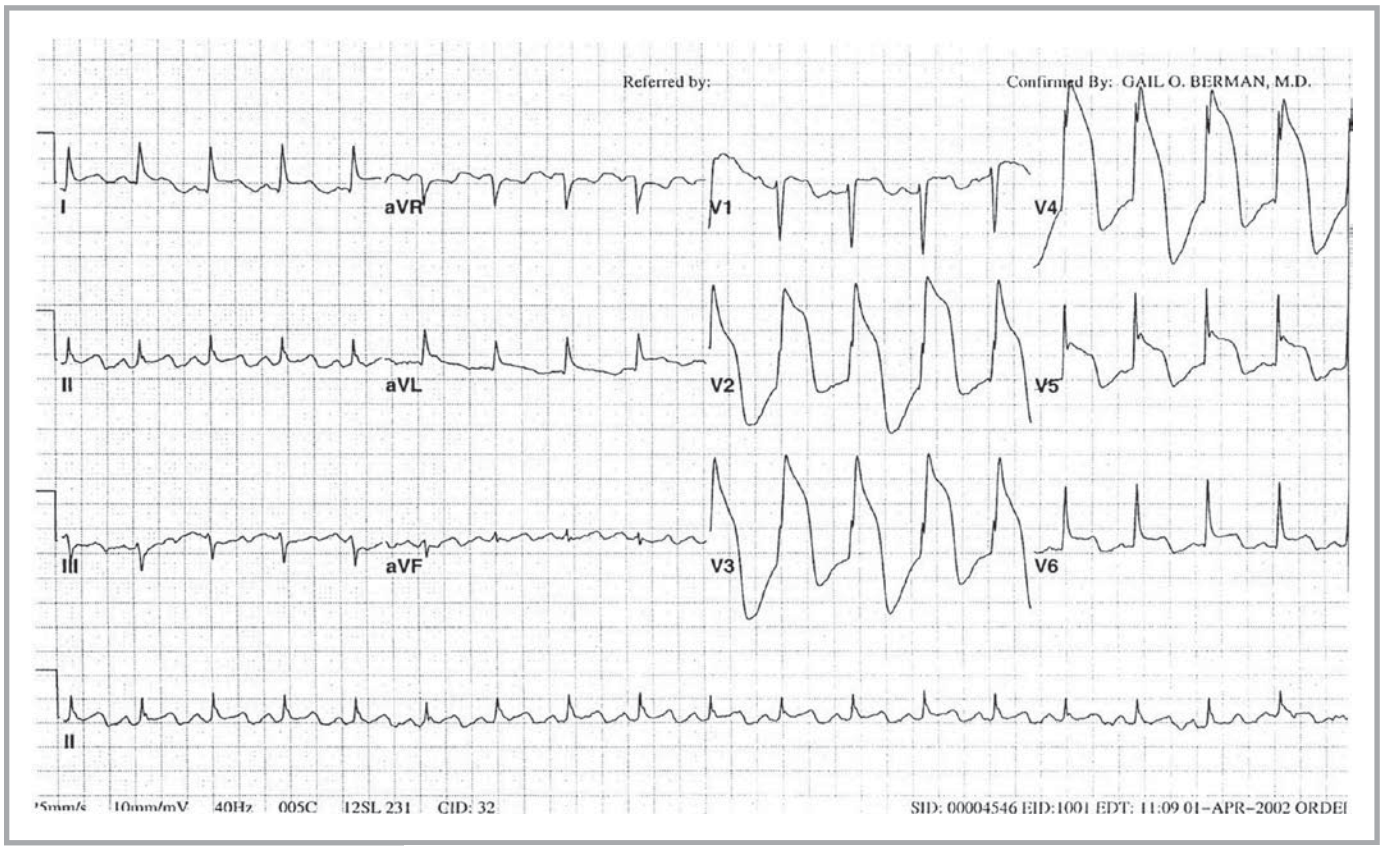

FIGURE 52-4

Dramatic ST-elevation in Leads V2 to V6 typical of an anterolateral ST segment elevation myocardial infarction.

There are many conditions that may mimic ST-segment depression or T-wave abnormalities. Pre-excitation syndromes, left ventricular hypertrophy, paced rhythms, or bundle branch blocks may confound the diagnosis of an acute coronary syndrome.

By definition, an ST-segment elevation myocardial infarction will present with new elevated ST-segments measuring at least 0.1 mV (0.1 mm) in at least two contiguous leads.[15] A typical anterolateral ST-segment elevation myocardial infarction is seen in Fig. 52-4. A typical inferior ST-segment elevation is seen in Fig. 52-5. An established myocardial infarction is characterized by the presence of pathologic Q waves. A presumed new left bundle branch block may not have the typical ST-elevation. Characterization of the ST-segment changes in a patient with a prior myocardial infarction needs to be further defined. In addition, the approximate timing and electrocardiographic progression of an ST-segment elevation myocardial infarction is important. As long as the ST-segments remain elevated, the infarction remains defined as acute or subacute. The exception to this rule is persistent ST-elevation after several days would be consistent with a left ventricular aneurysm. Right ventricular leads should be obtained in the setting of an inferior wall myocardial infarction as demonstrated in Fig. 52-6 with ST-elevation in lead V4.

An ST-segment elevation myocardial infarction can be diagnosed on the 12 lead electrocardiograms in the presence of a complete right bundle branch block.

Many conditions may mask a myocardial infarction on a standard twelve lead ECG. These include prior myocardial infarction or left bundle branch blocks, the presence of electrolyte abnormalities, and the effects of many different medications. There are many conditions that can mimic a myocardial infarction. These include left ventricular hypertrophy, infiltrative cardiomyopathy, preexcitation syndrome, pulmonary embolism, pericarditis, conduction disturbances, and early repolarization. The presence of a left bundle branch block often makes it difficult to determine the presence of an ST-segment elevation; however, the presence of a right bundle branch block does not. An example of an anteroseptal myocardial infarction is seen in Fig. 52-7. An example of acute pericarditis is seen in Fig. 52-8.

IMAGING MODALITIES

Chest X-Ray

The initial chest X-ray is often a portable film obtained in the emergency or in the intensive care unit. The most common abnormalities found include pulmonary edema, pleural effusions and cardiomegaly. Pulmonary edema on chest X-ray reflects elevated left ventricular end-diastolic pressure. However, there may be a lag time until pulmonary edema is eventually seen on the chest X-ray. In addition, there may be a delay after left ventricular end-diastolic pressure has returned to normal for resolution of pulmonary edema on chest X-ray. Pleural effusions are more often seen on the right side of the thorax. This is thought to be due to more efficient lymphatic draining through the thoracic duct in the left hemithorax where as the lymphatic drainage of the right hemithorax via the azygous vein may be congested from right ventricular failure. Rarely, a widened mediastinum may be present in the setting of an aortic dissection. Aortic dissections have been known to cause ST-segment elevation myocardial infarctions. Finally, it has been shown that the degree of pulmonary edema and the presence of cardiomegaly on chest X-ray correlate with an increased risk of death in the setting of an acute myocardial infarction.[16]

Echocardiography

Echocardiography plays a vital role in the diagnosis and management of acute coronary syndromes. Echocardiography can identify regions of ischemia. Ischemic myocardial segments, especially those with transmural ischemia, will typically lose their ability to contract. These conditions produce segmental wall motion abnormalities on an echocardiogram; however, normal contractility does not exclude the presence of ischemia. Echocardiography can provide an estimate of left ventricular ejection fraction that correlates strongly with angiography. Therefore, it can identify patients at risk for congestive heart failure and provide information concerning long-term prognosis. Cardiac Doppler and color flow Doppler will identify valvular abnormalities such as mitral regurgitation. Echocardiography can also identify other mechanical complications such as ventricular septal defect, aneurysm, and pseudoaneurysm. Finally, it may determine the presence of an aortic dissection, pericardial effusion, or left ventricular thrombus.

On occasion, echocardiography may not provide adequate information due to limited endomyocardial definition. This may occur in patients with chronic obstructive pulmonary disease or obese patients. This situation may make detection of segmental wall abnormalities difficult. A transesophageal echocardiogram may improve definition, especially when mechanical complications of an acute coronary syndrome are suspected.

Nuclear Imaging

Nuclear imaging consistently detects areas of ischemia and provides information concerning left ventricular ejection fraction, the size of the infarct, and the extent of ischemic myocardium at risk. However, nuclear imaging is not routinely used for all patients for diagnosing acute coronary syndromes. Stress nuclear imaging also provides valuable information about the extent of ischemia and left ventricular ejection fraction in medically stable patients. Nuclear stress tests also provide valuable information on risk stratification in medically stable patients.

Cardiac Computed Tomography/Magnetic Resonance Imaging

Cardiac CT scans can provide information regarding the presence of coronary atherosclerosis; however, these scans are not routinely used in patients who have unstable CAD. CT scans can be helpful in identifying left ventricular aneurysms, coronary artery bypass anatomy and aortic dissections.

Cardiac MRI can also provide valuable information regarding infarct size and identify viable vs. nonviable myocardium and the early phases of myocardial ischemia. It can also identify myocardial edema, fibrosis, ventricular wall thinning and both cardiac chamber sizes and left ventricular function. Evaluating mechanical complications, such as differentiating an aneurysm from a psuedoaneurysm, is important. However, Cardiac MRI at times has limited practicality in unstable patients who are difficult to transport and cannot undergo a relatively long study and in patients with acute coronary syndromes who often have ferromagnetic devices.

USE OF LABORATORY TESTS IN THE DIAGNOSIS

Biomarkers

Biomarkers that are used for the assessment of cardiac injury in the setting of acute coronary syndromes should have certain characteristics. Biomarkers should be specific and sensitive for cardiac injury. Increased levels should be quickly detectable after the onset of cardiac injury and they should be sustainable for those patients who present later in the course of their infarction. However, these levels should also return to baseline in a reasonable period of time in order to exclude reinfarction. Biomarkers should also be able to estimate infarction size and prognosis. The most commonly used cardiac biomarkers are creatine kinase, myoglobin, and troponin. The properties of the most common biomarkers are seen in Table 52-2. The typical timing of the rising and falling of biomarker levels related to the temporal onset of cardiac ischemia is seen in Fig. 52-9.

Creatine Kinase

Determination of creatine kinase (CK) levels remains an important tool in the diagnosis of acute coronary syndromes. There are three CK isoenzymes that result from combinations of M and B chains. CK-MM is found in most tissues, and CK-BB is found in the brain and in the gastrointestinal tract. Although it is found in other tissues besides cardiac muscle, CK-MB is somewhat more specific to the heart. B chains are produced during neonatal development as well as during skeletal muscle injury. Thus, skeletal muscle injury may result in increases in B chain production leading to false positive CK-MB elevation. Until the development of troponin assays, this would often lead to confusion in the diagnosis of acute coronary syndromes. In addition, patients with renal failure as well as those with hypothyroidism also have elevated CK-MB.[17]

Falsely elevated CK-MB may be seen in rhabdomyolysis, renal failure, and hypothyroidism.

The percentage of CK-MB to total CK may assist in differentiating cardiac muscle injury from skeletal muscle injury. Any cardiac injury, from acute coronary syndromes to myocarditis, can result in CK-MB release. The greater the percentage of CK-MB to the total CK, the more likely the release is due to cardiac muscle injury. However, acute skeletal muscle injury may continue to confound the diagnosis. An increased percentage of CK-MB may increase the test's specificity; however, the overall sensitivity may decrease due to a proportional increase in total CK. During chronic skeletal injury, the increased production of B chains may result in a false positive test results.

As a result of the "washout" effect, CK-MB levels may rise quickly after recanalization of the occluded coronary artery.

There is a well-defined "washout" effect of CK-MB after recanalization. Reperfusion may result in a higher proportion of CK-MB in the plasma compared to chronically occluded blood vessels. This results in CK-MB reaching peak levels within 16 h. CK-MB may return to baseline within 24 h. This phenomenon may partially explain why the CK-MB levels peak earlier in NSTEMI patients. This may also reflect transient occlusion and recanalization of coronary blood flow.[18]

CK-MB levels are useful in determining infarct size and the development of reinfarction.

CK-MB remains useful despite the revolution of troponin in that it provides information regarding the timing of the myocardial infarction and estimation of infarct size.[18] CK-MB level increases can be seen within 4–6 h after acute infarction. Nearly all patients will have a rise within 12 h. Peak levels usually occur at 24 h and return to normal levels in 36–72 h. CK and CK-MB levels can be used to estimate myocardial infarct size that can be useful in

TABLE 52-2

PROPERTIES OF CARDIAC MARKER PROTEINS

PROTEIN	MOLECULAR MASS (KD)	FIRST DETECTION[A] (H)	DURATION OF DETECTION	SENSITIVITY	SPECIFICITY
Fatty acid binding protein	12	1.5–2	8–12 h	+++	++
Myoglobin	16	1.5–2	8–12 h	+++	+
CK-MB	83	2–3	1–2 days	+++	+++
Troponin I	33	3–4	7–10 days	++++	++++
Troponin T	38	3–4	7–14 days	++++	++++
CK	96	4–6	2–3 days	++	++
Aspartate transaminase	103	6–10	3–5 days	++	+
LDH	135	6–10	5–7 days	++	+

establishing prognosis. However, caution should be used in comparing patients with levels following recanalization. Patients with reestablished flow may have greater total amounts of CK-MB compared to those without established flow. CK-MB levels have also been useful in predicting prognosis after a percutaneous coronary intervention.[19]

Myoglobin

The staccato phenomenon seen with myoglobin levels occurs with rapid occlusion and reperfusion of the infarct related artery. Therefore, a myocardial infarction may not be detected if myoglobin levels are used alone without other biomarkers.

Myoglobin remains a very sensitive marker for cardiac injury. Increased levels of myoglobin are detected early within 1–4 h of the event. However, myoglobin levels are not specific to cardiac muscle and may be elevated in patients with renal insufficiency. However, the negative predictive value is highly accurate in that a lack of a rise in myoglobin levels over 4–6 h may exclude myocardial infarction. However, troponin levels are more often used in this situation. In addition, there is a "staccato phenomenon" which occurs with rapid occlusion and reperfusion of coronary vessels. Occlusion and early rapid reperfusion of the coronary vessel may lead to a very rapid fall in the myoglobin levels. Therefore, the myoglobin level may return to within normal limits. This would imply that no infarction occurred. Therefore, myoglobin levels may rise and fall quickly without detection.[20]

Troponin

Troponin T and Troponin I are very specific and sensitive for myocardial cell necrosis.

Prior to the routine use of troponin levels to assess myocardial ischemia, approximately 30% of non-ST-segment elevation myocardial infarction patients would have been classified as having unstable angina.[15] The introduction of troponins has revolutionized the diagnosis and management of acute coronary syndromes. There are three distinct troponins. Troponin C (cTnC) is present throughout the smooth muscle and therefore lacks specificity. Troponin I (cTnI) and troponin T (cTnI) are highly specific for cardiac tissue and reside only in the heart. During severe skeletal injury, skeletal muscle may express more neonatal myocytes. Fortunately, there is no evidence of any cTnI release in patients with skeletal muscle injury even in the case of severe rhabdomyolysis. There are several fetal isoforms of cTnT that are expressed in response to severe skeletal injury. Fortunately, most assays are not affected by these fetal isoforms. Therefore, the specificity to cTnT and cTnI are very similar and are very helpful in distinguishing between acute coronary syndromes and rhabdomyolysis.

Troponins are sensitive compared to creatine kinase and other biomarkers. Therefore, it has the ability to diagnose a myocardial infarction that would otherwise not have been detected. Increased levels of troponins remain typically elevated for 1–2 weeks. This allows

detection of myocardial infarction even days after the event. Troponin levels may have sustained elevation due to the fact that troponins are closely coupled to the myocardial contractile apparatus that causes it to be released more slowly. Unfortunately, there is no relationship between the persistence of increases in troponin and infarct size, the type of infarction, or the intervention used. Troponin levels may be seen within 2–4 h following infarction with most patients having elevated levels within 8–12 h. Peak values occur at approximately 24 h.[15]

Any elevation in the troponin levels increases the risk of death in patients with acute coronary syndromes.

Troponin levels have prognostic value in acute coronary syndromes (Fig. 52-10). STEMI patients who present with elevated troponin levels have a poor prognosis generally occurring in patients who have a late presentation or those who have poor flow postpercutaneous intervention. Elevated troponin levels in NSTEMI patients also correlate with a poor prognosis.[21]

Occasionally, there will be an increase in troponin levels without elevation of other cardiac biomarkers. This is due to the improved sensitivity of the troponin assay. Patients, who present with ST-segment changes, whether these changes are ST-segment elevation or depression, will more than likely, have an elevation in troponin. In addition, most patients who receive benefit from glycoprotein IIb/IIIa inhibitors have elevated troponin levels compared to those who do not.

There are many clinical scenarios other than coronary syndromes that cause elevated troponin levels.

Thus, most authorities advocate more aggressive medical care when troponins are elevated in the acute coronary syndromes. However, there are many conditions that can cause an elevated troponin level without the presence of atherosclerosis.[22] These situations are listed in Table 52-3. Aggressive standard treatment with anticoagulation has not been demonstrated to be beneficial. It is difficult to determine the correct course of treatment for these patients other than treating the underlying disease process in most cases such as those patients who present with sepsis. Congestive heart failure, whether acute or chronic, may present with an elevated troponin level. Elevated troponin levels with congestive heart failure have been shown to have prognostic value when used in combination with B-type natriuretic peptide BNP levels reflect overall intravascular volume.[23] Patients who present with congestive heart failure and acute coronary syndromes have an overall worse prognosis. Conditions that cause hypotension or hypertension have been associated with elevated troponin levels. Any trauma to the heart including cardiopulmonary resuscitation or defibrillator discharges can cause an increase in troponin. Finally, it was initially thought that an elevated troponin in the setting of renal failure was due to issues related to the assay

determination and renal clearance. However, it has become clear that a significant portion of these elevations represent a degree of cardiac injury. These increases have short and long-term significance. Patients with renal failure often have hypertension, diabetes, or hyperlipidemia. These patients are at risk for the development of coronary atherosclerosis and should be aggressively managed.

Other Laboratory Tests

Serum Lipids

All patients who present with an acute coronary syndrome should have their lipid profile determined within 24–48 h. After 48 h, HDL levels begin to fall and may not reflect a patient's true baseline. In addition, triglyceride levels can be inaccurate. For those patients who present later in the phase of an acute coronary syndrome, it is recommended to wait at least 6–8 weeks after the acute event before rechecking lipid levels.

Inflammation Markers

C-reactive protein, an indicator of an inflammatory response, has been used to predict mortality risk. However, C-reactive protein levels cannot accurately predict a myocardial infarction. Chronic inflammation or acute infection can result in elevated C-reactive protein levels and limit the use of C-reactive protein to predict the cardiovascular risk in patients with these conditions.[24] Other markers, such as IL-6 levels, have been investigated; however, determination of IL-6 levels is not routinely measured.

Brain Natriuretic Peptide

ProBrain natriuretic peptide (proBNP) is released from ventricular myocytes in response to increased ventricular pressure and is subsequently degraded to N-terminal proBNP (NT-proBNP). NT-proBNP is also transformed to BNP. Both NT-proBNP and BNP levels can be routinely measured. BNP levels have been shown to predict death in patients with acute coronary syndromes. In a study involving 1,756 patients with acute coronary

CASE STUDY: PART 3

As the emergency department physician is requesting a cardiology consultation, the patient once again has an episode of chest discomfort. Within seconds of the onset of chest pain, the patient has a cardiac arrest and ventricular fibrillation is immediately recognized. The patient is cardioverted with 200 J to a normal sinus rhythm, then intravenously administered 150 mg of amiodarone and started on a maintenance dose of 1 mg/min for the first 6 h. The patient recovered quickly and was unaware of the recent events. He continued to have chest discomfort. A repeat ECG demonstrated 3 mm ST segment elevations in the anterolateral leads. His blood pressure decreased to a systolic pressure of 85 mmHg. His heart rate is now 97 bpm and he has mild inspiratory crackles on lung auscultation. He appears uncomfortable, diaphoretic, and pale. His skin is cool and clammy. His peripheral pulses are diminished. The patient was immediately taken to the cardiac catheterization laboratory.

In the cardiac catheterization laboratory, the coronary angiogram demonstrated a 100% proximal occlusion with thrombus of the left descending coronary artery. The left circumflex artery and the right coronary artery were relatively free of any significant disease. A percutaneous intervention was performed with the placement of a drug-eluting stent without complications. A right heart catheterization was performed because of the possibility of cardiogenic shock in the setting of an acute coronary syndrome. The capillary wedge pressure was 25 mmHg while the cardiac output was 3.8 L/min. and the cardiac index was 1.9 L/min/m^2. A decision was made to support the patient's circulation with an intra-aortic balloon pump (IABP). Subsequently, the capillary wedge pressure decreased to 20 mmHg and the cardiac output increased to 5.2 L/min. The patient was stable at the time of transfer to the Cardiac Intensive Care Unit.

syndromes, serum NT-proBNP levels were measured at a median time of 3 h after the onset of symptoms. Increasing levels of NT-proBNP were associated with higher short-term (30 days) and long-term mortality rates. NT-proBNP levels were independent of clinical variables, ECG, and troponin T in patients with or without ST-segment elevation. These levels were also an independent predictor of severe heart failure despite previous history of heart failure or signs of left ventricular dysfunction.[25]

RISK STRATIFICATION FOR ACUTE CORONARY SYNDROMES

Aggressive early revascularization should be considered in patients who present with ST-segment elevation myocardial infarction, persistent chest pain with a left bundle branch block, or ST-segment depression in the setting of an acute posterior wall (ST-segment elevation) myocardial infarction. Risk stratification is important in the initial evaluation of patients with unstable angina and NSTEMI. In general, higher risk patients benefit from more aggressive treatments such as the use of glycoprotein IIb/IIIa and invasive strategies.

Identification of high-risk features in patients presenting with unstable angina or non-ST-segment myocardial infarct is important in risk stratification.

Risk assessment begins with a review of the patient's clinical presentation, past medical history, and physical examination. The quality of the chest discomfort, a prior history of CAD, male gender, older age (greater than 70 years), and increasing number of traditional risk factors are all risk factors for poor patient outcome. Diabetes is associated with an overall poorer outcome. Patients may present with typical or atypical features of chest discomfort that may confound the risk assessment. Chest discomfort that is not relieved with nitroglycerin or is relieved with a "GI cocktail" does not eliminate the possibility of angina. Patients who present with a history of CABG and percutaneous coronary intervention are also at higher risk. On physical examination, evidence of cardiogenic pulmonary edema, a third heart sound or new or worsening mitral regurgitation increase the risk for poor outcome. Hypotension, bradycardia, and tachycardia predict increased risk of death and morbidity.

Transient ST-segment depression of at least 0.05 mV (0.5 mm) with chest discomfort at rest strongly suggests acute ischemia due to severe CAD. Of note, care must be taken to exclude a posterior ST-segment elevation myocardial infarction in the setting of significant ST-depression in the anterior precordial leads. The addition of posterior chest leads may help to differentiate the two situations. A posterior ST-segment elevation myocardial infarction should be treated aggressively. Deep inverted T waves, at least 2 mm, are nonspecific but may suggest ischemia.

TABLE 52-4

TIMI RISK SCORE FOR UNSTABLE ANGINA/NON-ST ELEVATION MYOCARDIAL INFARCTION

TIMI RISK SCORE	ALL-CAUSE MORTALITY, NEW OR RECURRENT MI, OR SEVERE RECURRENT ISCHEMIA REQUIRING URGENT REVASCULARIZATION THROUGH 14 DAYS AFTER RANDOMIZATION (%)
0–1	4.7
2	8.3
3	13.2
4	19.9
5	26.2
6–7	40.9

The TIMI risk score is determined by the sum of the presence of seven variables at admission; one point is given for each of the following variables: age 65 year or older: at least three risk factors for CAD; prior coronary stenosis of 50% or more: ST-segment deviation on ECG presentation: at least two anginal events in prior 24 h: use of aspirin in prior 7 days: elevated serum cardiac biomarkers. Prior coronary stenosis of 50% or more remained relatively insensitive to missing information and remained a significant predictor of events. Reprinted with permission from Antman et al.[27]
CAD coronary artery disease; *ECG* electrocardiogram; *MI* myocardial infarction

Approximately 1–6% of patients with a NSTEMI have a normal electrocardiogram. Thus, a normal ECG does not exclude the possibility of an acute coronary syndrome.

Pathologic Q waves do suggest prior CAD. Serial electrocardiograms improve the sensitivity of detecting acute coronary syndromes. However, a normal electrocardiogram does not exclude an acute coronary syndrome. Approximately 1–6% of patients with a normal ECG presenting with chest discomfort consistent with angina will have a NSTEMI.[26]

Elevation in cardiac biomarker levels is also important in the initial risk assessment. Slightly elevated cardiac cTnT (greater than 0.01 but less than 0.1 ng/mL), cTnI or CK-MB assures at least intermediate risk. Elevated troponins correlate with worsening prognosis. However, as noted above, it is important to rule out any other noncardiac causes of an elevated troponin.

The ACC/AHA guidelines, TIMI risk score, and the GRACE registry are all tools in the assessing risk in patients who present with unstable angina/non-ST segment elevation myocardial infarction.

Specific tools from trials and registries have been developed in an effort to assign risk. The TIMI (thrombolysis in myocardial infarction trial) risk score for unstable angina/non-ST-segment elevation myocardial infarctions has been developed (Table 52-4). The seven predictor variables are (1) age 65 years or older, (2) at least three risk factors for CAD, (3) prior coronary stenosis of 50% or more, (4) ST-segment deviation on electrocardiogram at presentation, (5) at least two anginal events in prior 24 h, (6) use of aspirin in prior 7 days, and (7) elevated serum cardiac markers.[27] In addition, there is the GRACE (Global Registry of Acute Coronary Events) model that predicts 30-day and 1-year mortality.[28] In addition, the American College of Cardiology/ American Heart Association UA/NSTEMI guidelines on short-term risk assessment of death and nonfatal myocardial infarction are seen in Table 52-5.[15]

INITIAL CONSERVATIVE vs. INVASIVE STRATEGIES

Routine use of coronary angiography in all patients with unstable angina/non ST-segment elevation myocardial infarction is not recommended.

Patients who present with ST segment elevation or persistent left bundle branch block with ongoing chest pain should be considered for immediate reperfusion therapies such as cardiac catheterization or thrombolytic therapies. Some patients who present with unstable angina or non-ST segment myocardial infarctions may be initially managed more conservatively under certain clinical scenarios. Therefore, treatment strategies, with consideration of initial conservative vs. early aggressive strategies, have been developed for unstable angina/non-ST segment myocardial infarctions

The potential benefit of an early invasive approach is that it defines coronary anatomy. Approximately 15% of cardiac catheterizations are "normal" without evidence of CAD.[29] Left main stenosis and severe triple vessel disease can be quickly determined. There is also the potential for reduction of subsequent hospitalizations and in the number of anti-anginal medications. The potential benefit of a conservative approach is the possibility of lowering the risk of serious complications associated with revascularization.

High-risk patients, as determined by risk assessment models should be considered for an early invasive strategy.

Patients who are clearly at high risk should be considered for early invasive strategy. An algorithm for the early aggressive approach is shown in Fig. 52-11. In those patients who are

TABLE 52-5

SHORT-TERM RISK OF DEATH OR NONFATAL MYOCARDIAL INFARCTION IN PATIENTS WITH UNSTABLE ANGINA/NSTEMI[A]

FEATURE	HIGH RISK AT LEAST ONE OF THE FOLLOWING FEATURES MUST BE PRESENT	INTERMEDIATE RISK NO HIGH-RISK FEATURE, BUT MUST HAVE ONE OF THE FOLLOWING	LOW RISK NO HIGH- OR INTERMEDIATE-RISK FEATURE BUT MAY HAVE ANY OF THE FOLLOWING FEATURES
History	Accelerating tempo or Ischemic symptoms in preceding 48 h	Prior MI. peripheral or cerebrovascular disease, or CABG; prior aspirin use	
Character or pain	Prolonged ongoing (greater than 20 min) rest pain	Prolonged (greater than 20 min) rest angina, now resolved, with moderate or high likelihood of CAD	Increased angina frequency, severity, or duration
		Rest angina (greater than 20 min) or relieved with rest or sublingual NTG	Angina provoked at a lower threshold
		Nocturnal angina	New onset angina with an onset of 2 weeks to 2 months prior to presentation
		New-onset or progressive CCS class III or IV angina in the past 2 weeks without prolonged (greater than 20 min) rest pain but with intermediate or high likelihood or CAD	
Clinical findings	Pulmonary edema, most likely due to ischemia New or worsening MR murmur S_3 or new/worsening rales Hypotension, bradycardia, tachycardia Age greater than 75 years	Age greater than 70 years	
ECG	Angina at rest with transient ST-segment changes greater than 0.5 mm	T-wave changes	Normal or unchanged ECG
	Bundle branch block, new or presumed new	Pathological Q waves or resting ST-depression less than 1 mm in multiple lead groups (anterior, interior, lateral)	
	Sustained ventricular tachycardia		
Cardiac markers	Elevated cardiac TnT, TnI, or CK-MB (e.g., TnT or TnI greater than 0.1 ng/mL)	Slightly elevated cardiac TnT, TnI, or CK-MB (e.g., TnT greater than 0.01 but less than 0.1 ng/mL)	Normal

CABG coronary artery bypass graft surgery; *CAD* coronary artery disease; *CCS* Canadian Cardiovascular Society; *CK-MB* creatine kinase-MB fraction; *ECG* electrocardiogram; *MI* myocardial infarction; *MR* mitral regurgitation; *NTG* nitroglycerin; *TnI* troponin I; *TnT* troponin T; *UA/NSTEMI* unstable angina/non-ST-elevation myocardial infarction

[a]Estimation of the short-term risks of death and nonfatal cardiac ischemic in UA (or NSTEMI) is a complex multivariable problem that cannot be fully specified in a table such as this: therefore, this table is meant to offer general guidance and illustration rather than rigid algorithms. Adapted from AHCPR Clinical Practice Guidelines No. 10[63]

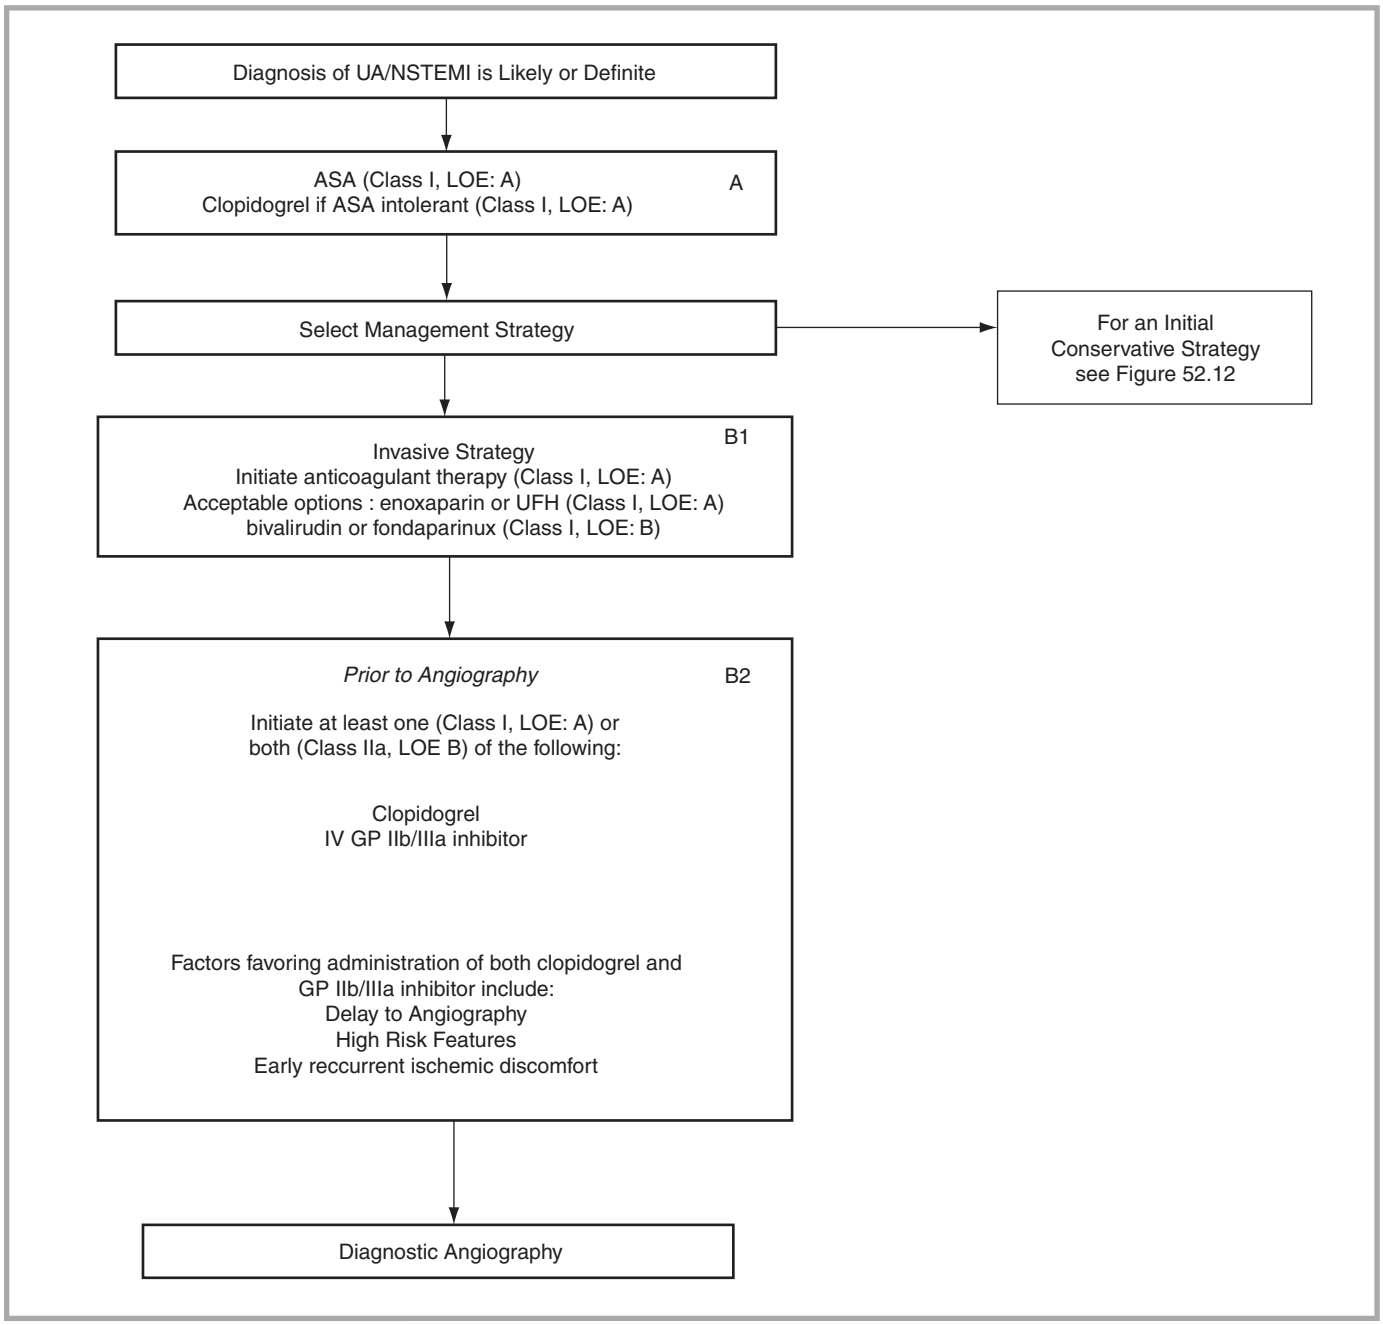

FIGURE 52-11

Early aggressive approach in patients with unstable angina or non-ST segment myocardial infarction. (From Anderson et al.[15] Reprinted with permission from Elsevier).

considered "urgent," the use of a GP IIb/IIIa or clopidogrel may be delayed at the physician's discretion until the time of coronary angiography. For those patients who are "early" but not "urgent," GP IIb/IIIa and/or clopidogrel is recommended if there are no contraindications. Patients with low risk features may be considered for a conservative approach as found in Fig. 52-12. Conservative vs. early invasive approaches in intermediate-risk UA/NSTEMI patients remains controversial. Lack of the use of "upstream" Glycoprotein IIb/IIIa inhibitors and trials using angioplasty have only confounded the situation. More randomized trials are needed to further clarify this issue.

TREATMENT OF ACUTE CORONARY SYNDROMES

Initial Care/Supportive Therapy

Patients suspected of having an acute coronary syndrome should be placed on a continuous ECG monitor.

The initial management of patients with acute coronary syndromes is crucial for they are at risk for sudden cardiac death. Patients should be placed on a continuous ECG heart rhythm monitor. A portable defibrillator and antiarrhythmic medications should be readily available. Patients should have stable venous access to administer medications for treatment and resuscitation, if needed. Supplemental oxygen for those patients without evidence of hypoxemia remains controversial but is generally employed. Supplemental oxygen should be administered to those patients who develop congestive heart failure or for other causes of hypoxemia. Finally, patients should be rapidly and safely transported to an emergency department or coronary intensive care unit.

Medications

Aspirin

All the patients who are suspected of having an acute coronary syndrome should receive aspirin unless there is a specific contraindication or allergy.

Trials have shown conclusively that aspirin (ASA) consistently reduces rates of reinfarction and death, with or without ST-segment elevation.[30] Unless there is a specific contraindication, ASA should be administered to all patients who present with acute coronary syndromes as soon as it is suspected. ASA acts by inhibiting COX-1 within the platelets; therefore, reducing the formation of thromboxane A_2 which inhibits platelet aggregation. The initial oral dose of ASA should be between 182 and 325 mg. There is more rapid absorption with the nonenteric coated aspirin. Bleeding risk increases with increasing dose of ASA. Due to the interaction of ASA with ibuprofen, an alternative analgesic should be considered.[31] The reported interaction of ASA and ACE inhibitors does not appear to be clinically relevant.[32]

The long-term use of ASA at the time of discharge from the hospital is recommended. In patients who receive medical therapy without coronary stent placement, ASA 75–162 mg/day should be given indefinitely. In those patients who receive bare-metal stents, 162–325 mg of ASA should be given for at least 1 month, followed by 75–162 mg/day indefinitely. Patients with drug-eluting stents should receive 162–325 mg/day for at least 3–6 months, then 75–162 mg/day indefinitely. For those patients who are allergic to aspirin, aspirin desensitization should be considered especially in those patients undergoing percutaneous coronary intervention or CABG.[15]

Adenosine Diphosphate Receptor Antagonists

There are currently two approved adenosine diphosphate receptor antagonists, ticlopidine and clopidogrel. Due to potential adverse effects of ticlopidine, including neutropenia and rarely thrombotic thrombocytopenic purpura, clopidogrel has now been used more widely.

As demonstrated in the CURE trial, clopidogrel has been shown to be beneficial, especially in the setting of elevated troponin levels and the adjuvant use of a glycoprotein IIb–IIIa inhibitor during percutaneous coronary intervention.

Clopidogrel's effect on platelet aggregation is irreversible; however, without a loading dose, this action would take days to occur. Clinical trials have shown that loading with a 300 mg dose is safe followed by 75 mg/day. However, larger trials are needed to establish whether an initial dose of 300 or 600 mg of clopidogrel is optimal.

In those patients who are allergic to ASA, clopidogrel is at least as effective as ASA in the secondary prevention of acute coronary syndromes. In those patients who presented with UA/NSTEMI, clopidogrel has been shown to reduce the combined endpoint of cardiovascular death, myocardial infarction or stroke (11.5% of placebo and 9.3% with the clopidogrel group, risk ratio [RR] = 0.80, p less than 0.001)[33] (Fig. 52-13). There is a slight increase in the risk of bleeding, especially in patients undergoing CABG within 5 days of stopping clopidogrel.[15] In the CURE trial, in patients who had a percutaneous coronary intervention (2,658 of 12,562 patients), clopidogrel reduced the overall composite endpoint of cardiovascular death, myocardial infarction, or urgent target-vessel revascularization within 30 days by 30% ($p = 0.03$). Given the results of the PCI-CURE study, clopidogrel is recommended in patients who undergo percutaneous coronary intervention.[34] There is additional benefit when

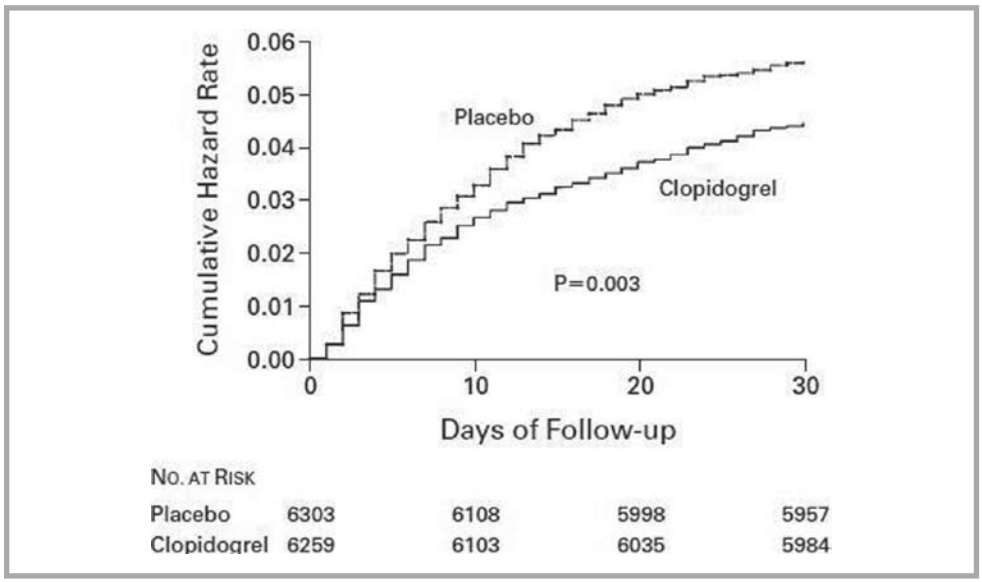

FIGURE 52-13

Results from the CURE Trial: effects of clopidogrel on combined endpoints of death, myocardial infarction and stroke. (From Yusuf et al[33]. Copyright 2001 Massachusetts Medical Society. All right reserved).

a glycoprotein IIb/IIIA is added during PCI; however, the main benefit occurs when there is an elevation in troponin level. Due to the fact that clopidogrel increases the risk of bleeding during major cardiac surgery, clopidogrel should be held for at least 5 days prior to surgery.

The durations of aspirin and clopidogrel therapies, as recommended by the ACC/AHA, are shown in Fig. 52-14. However, the duration of therapy for drug-eluting stents remains unclear due to the fact that there have been case reports of late thromboses in drug-eluting stents.

Nitrates

Nitrates provide symptomatic relief by reducing preload, reducing afterload, and vasodilating coronary arteries.

Due to its endothelium-independent effects on coronary and peripheral blood vessels, nitrates reduce myocardial oxygen demand, which in turn provides symptomatic relief. Nitrates decrease myocardial oxygen demand and oxygen delivery by reducing preload through venous dilatation, decreasing systolic blood pressure and left ventricular afterload, and vasodilatating coronary arteries and improving myocardial collateral blood flow.

Intravenous nitroglycerin can be used to provide relief if chest discomfort remains refractory to sublingual nitroglycerin or beta-blocker therapy. Intravenous nitroglycerin can be titrated by increments of 10 mcg/min every 3–5 min to a maximum of 200 μg/min until symptoms are relieved. With the exception of perhaps one study, intravenous nitroglycerin has not been shown to affect the overall mortality. Tolerance may develop after continuous nitroglycerin use over 24 h. After the patient is stabilized, topical or oral nitrates may be used.

Nitrates are contraindicated in patients who are hypotensive and should be used with caution in acute coronary syndromes with possible right ventricular involvement.

The adverse effects of nitrates include headache and hypotension. Nitrates should be used with caution in patients with right ventricular involvement, especially in the setting of an inferior ST-segment elevation myocardial infarction. Changes in right ventricular preload may lead to a precipitous drop in blood pressure. Nitrates should be avoided if the systolic blood pressure is less than 90 mmHg. In normotensive patients, systolic blood pressure should not be reduced to less than 110 mmHg. Patients who present hypertensive should not have the presenting mean arterial blood pressure reduced by more than 25%.

Morphine

Morphine remains a reasonable alternative to relieve symptoms despite adequate antiischemic and antianginal therapy.

Morphine is a reasonable treatment to consider in patients with continued chest pain despite adequate antiischemic and antianginal therapy. Morphine sulfate should be administered intravenously in doses ranging from 1 to 5 mg. Morphine provides relief by causing venodilatation and reducing ventricular preload. In addition, morphine can improve pain and anxiety, which may reduce the circulating catecholamines. Potential side effects of morphine

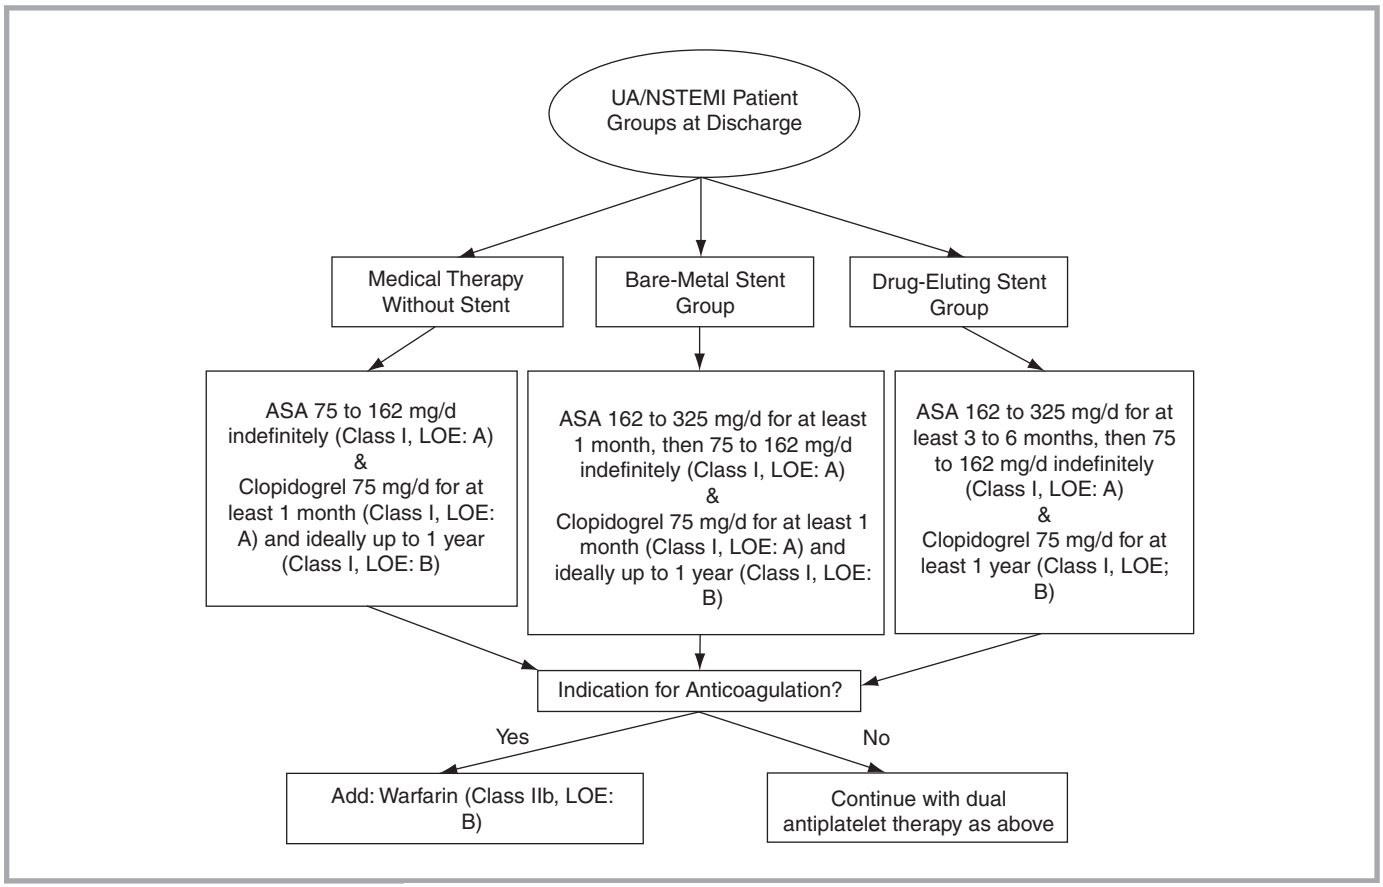

FIGURE 52-14

ACC/AHA recommendations on the use of aspirin and clopidogrel in unstable angina (UA) and non ST-segment elevation myocardial infarction (NSTEMI). (From Anderson et al.[15] Reprinted with permission from Elsevier).

include nausea, vomiting, bronchospasm, and significant respiratory depression. A recent large observational registry suggests a higher likelihood of death with the use of morphine sulfate; however, large randomized trials are needed to validate this observation.[35]

Beta-Blocker Therapy

In patients without specific contraindications to beta-blocker therapy, this therapy has been shown to improve the mortality rate and patient's symptoms likely by decreasing myocardial oxygen demand through both its negative chronotropic and ionotropic effects. To a lesser degree, it can reduce afterload by dreceasing systolic blood pressure. Beta-blockers also reduce the incidence of ventricular arrhythmias and reinfarction after a myocardial infarction.[36-38]

In a hemodynamically stable patient, intravenous beta-blocker therapy should be immediately administered in the setting of a ST-segment elevation myocardial infarction. This intervention should be followed by an oral beta-blocker indefinitely which has been shown to improve the long-term survival. In unstable angina (UA)/NSTEMI patients, beta-blocker therapy may be initiated orally; however, greater caution should be used with the use of intravenous beta-blockers within the first 24 h. In the hemodynamically *unstable* patient, aggressive early beta-blocker therapy may be less beneficial and perhaps harmful due to the increased risk of cardiogenic shock and uncompensated heart failure. The absolute contraindications for beta-blocker use include hypotension, cardiogenic shock, bradycardia, decompensated congestive heart failure, severe bronchospasm, and heart block.

Once the patient stabilizes, and there are no contraindications, oral beta-blockers may be instituted prior to discharge from the hospital. In this situation, the long-term benefits of beta-blockers are obtained, even if beta-blockers are initiated days after the initial contraindication resolves.[39] In addition, benefits from beta-blocker therapy occur with or without left ventricular dysfunction. The indication for secondary prevention has been derived from relative limited data and extrapolation from the data obtained in patients suffering from heart failure, chronic stable angina, and STEMI.

Calcium Channel Blocker Therapy

Calcium channel blockers have been shown to improve morbidity in patients experiencing an acute coronary syndrome. However, calcium channel blockers are considered as second line agents after beta-blockers for alleviating symptoms or for the control of blood pressure. Therefore, calcium channel blockers can be utilized for patients who remain symptomatic with chest pain that are unresponsive or not tolerating nitrates. Patients with significant bronchospasm, who are unable to use beta-blockers, may also be considered as candidates for calcium channel blocker therapy. Reduction in myocardial oxygen demand results in symptomatic relief. The negative chronotropic effects of calcium channel blockers on the sinoatrial node result in a modest reduction in sinus rhythm rates. However, verapamil may actually cause a reflex tachycardia due to profound vasodilatation, which in turn may worsen myocardial ischemia.

The negative ionotropic effects of calcium channel blockers reduce myocardial oxygen demand by decreasing myocardial contractility. In the setting of unstable angina/ NSTEMI, verapamil and diltiazem may have shown some benefit in terms of a modest reduction in mortality rate and are therefore recommended as second or third line agents after beta-blockers.[40] However, rapid-release nifedipine (dihydropyridines) has shown to be detrimental due to significant hypotension and is therefore not recommended.[41] Adverse effects of calcium channel blockers are hypotension, bradycardia, atrioventricular block, and congestive heart failure. Calcium channel blockers are considered as third line agents for antianginal relief after consideration of the use of nitrates and beta-blockers. The combination of calcium channel blockers and beta-blockers should be used with caution due to the possibility of worsening hypotension, bradycardia, heart block, and congestive heart failure.

Short acting rapid-release nifedipine has been shown to be detrimental in the setting of acute coronary syndrome due to significant hypotension.

Calcium channel blockers are considered as third line agents for antianginal relief after consideration of the use of nitrates and beta-blockers.

Renin-Angiotensin-Aldosterone System Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors are widely used in acute coronary syndromes. They have been shown to improve the mortality rate in patients with left ventricular dysfunction after a myocardial infarction as well as those without left ventricular dysfunction.[42] Adverse effects include hypotension, renal failure, hyperkalemia, and cough. Caution should be given to avoid hypotension in patients with myocardial infarction. Angiotensin receptor blockers have also been shown to be beneficial in patients who are otherwise intolerant of ACE inhibitors.[43] Aldosterone receptor blockers, epelerone and spironolactone, can also be used in patients following a myocardial infarction complicated by left ventricular dysfunction.[44]

Statins

Lipid-lowering agents, statins in particular, have been demonstrated to reduce mortality and cardiac event rates following a myocardial infarction.[45] Recent trials, as noted in the Adult Treatment Panel III 2004 guidelines, confirm the goal of reaching a minimal LDL of less than 100 mg/dL for those patients with CAD. However, in the guidelines, patients with acute coronary syndromes are considered to be at high risk. These patients may benefit with lowering the LDL goal even lower, to below 70 mg/dL. Statin therapy should be initiated as an inpatient procedure. Some patients may present to the hospital with low LDL levels, however, LDL levels may drop shortly after a myocardial infarction; therefore, these levels may be unreliable. Therefore, these patients should be started on statin therapy. The initial dose of statin remains controversial. However, more importantly, it has been determined that

patients are started on statin therapy in the intensive care unit and prior to discharge often continue therapy as an outpatient.[46] Assessment of liver function tests is recommended given that many patients may present with liver dysfunction in the setting of cardiogenic shock.

Anticoagulants

There are now multiple anticoagulants that can be used to manage acute coronary syndromes. Multiple trials have demonstrated various levels of efficacy and safety; however, care must be taken with trials that demonstrate noninferiority among the anticoagulants. Chronic anticoagulation with coumadin with a specific indication such as atrial fibrillation can be safely administered with careful assessment of the potential risk and benefits. There is limited information, however, concerning the chronic use of aspirin, clopidogrel, and coumadin therapy.

Heparin

Unfractionated intravenous heparin should be closely monitored with activated partial thromboplastin times.

Unfractionated heparin has been shown in limited trials to be beneficial in reducing recurrent ischemic events in acute coronary syndrome patients.[47] Unfractionated heparin is composed of a mixture of polysaccharide chains of varying sizes from 5,000 to 30,000 Da. Unfractionated heparin activates antithrombin, which in turn inactivates thrombin, factor IXa, and factor Xa. Unfractionated heparin requires careful monitoring, using the activated partial thromboplastin time. Weight adjusted doses of unfractionated heparin can provide more consistent and safe anticoagulation. Some patients do not reach therapeutic levels within 24 h of administration of unfractionated heparin. There is also a vague clinical possibility of a "rebound" effect in which discontinuation of unfractionated heparin causes a reactivation of thrombus formation. Furthermore, heparin does not inhibit clot bound thrombin. Patients should be watched closely for potential bleeding complications, and the platelet count should be monitored to detect the possibility of heparin-induced thrombocytopenia. The recommended duration of unfractionated heparin therapy during an acute coronary syndrome is unclear. Treatment typically occurs over 2–8 days or until an angiogram, percutaneous coronary intervention, or CABG is performed.

Various LMWHs have differing anti-Xa factor and anti-Ia factor inhibitions.

Low-molecular-weight heparin (LMWH) consists of smaller molecular chains with weights of about 5,000 Da. Variations among the LMWH's result in varying anti-Xa factor and anti-Ia factor inhibition. LMWH acts through its inhibition of factor Xa activity not thrombin. LMWHs have more predictable dosing due to improved bioavailability and longer half-lives. LMWH does not require laboratory monitoring, as does unfractionated heparin. LMWH may also cause heparin-induced thrombocytopenia; however, this seems to occur less frequently. Major bleeding rates are similar. Minor bleeding may be more frequent. In general, LMWH have comparable results to unfractionated heparin.

Randomized trials have compared LMWH to unfractionated heparin in terms of outcomes of death, myocardial infarctions or revascularization. Dalteparin and nadroparin had similar rates of death or nonfatal myocardial infarction compared to unfractionated heparin.[48,49] However, trials involving enoxaparin show benefits favoring enoxaparin in terms of a death and nonfatal myocardial infarction combined endpoint compared to unfractionated heparin. The main difference with enoxaparin appears to be a reduction of nonfatal myocardial infarction.[50] There are differences between various LMWH's in terms of death, myocardial infarction, and recurrent angina. However, the reason for these differences remains unclear but may be explained by study design, differences in patient populations, different molecular weights, or anti-factor Xa/antifactor IIa ratios.

DIRECT THROMBIN INHIBITORS

Initially, there was enthusiasm for direct thrombin inhibitors since there are potential advantages of these agents over heparin. Direct thrombin inhibitors do not bind to plasma proteins; therefore, they have more predictable anticoagulation compared to heparin. Direct thrombin

inhibitors can inhibit even fibrin-bound thrombin. In addition, platelet factor 4, released by activated platelets, can inhibit heparin activity; however, platelet factor 4 does not interfere with the procoagulant effects of direct thrombin inhibitors.

Hirudin is the first direct thrombin inhibitor. There have been extensive trials conducted with hirudin and its analog bivalirudin. In the setting of unstable angina, comparing hirudin with heparin, hirudin showed a reduction in the combined composite endpoint of cardiovascular death, myocardial infarction, and refractory angina.[51] However, bleeding complications may have occurred more frequently with hirudin. Bivalirudin may be more effective than heparin in reducing postinfarction angina in those patients with acute coronary syndrome who have undergone percutaneous coronary intervention. Bleeding complications may also be lower with bivalirudin as compared to heparin.[52] Clopidogrel or a glycoprotein IIb/IIIA inhibitor should be given prior to cardiac catheterization if bivalirudin is to be given during an acute coronary syndrome. Direct thrombin inhibitors are most often used in the setting of heparin-induced thrombocytopenia. These agents, however, are less frequently used due to cost and issues concerning safety, specifically bleeding rates.

DIRECT FACTOR Xa INHIBITORS

Fondaparinux is a recently developed factor Xa inhibitor. Fondaparinux offers the advantage of inhibiting the coagulation cascade upstream. Fondaparinux also appears to have predictable anticoagulation effects. Due to the compound's prolonged half-life, fondaparinux has the advantage of daily dosing. When directly compared to enoxaparin in patients with acute coronary syndrome, fondaparinux has been shown to be noninferior in terms of the composite endpoint of death, myocardial infarction and refractory ischemia. However, there was significant catheter associated thrombus during the cardiac catheterization.[53] There were less major bleeding events with fondaparinux. Given the issues concerning fondaparinux catheter associated thrombus, unfractionated heparin is preferred during the cardiac catheterization. In addition, this has led to the lack of widespread use of fondaparinux. However, there may be a role for fondaparinux in patients who are at increased risk for bleeding or in the setting of low risk patients.

Glycoprotein IIb–IIIa Inhibitors

In general, glycoprotein IIb–IIIa inhibitors block approximately 80% of the platelet receptors leading to a very potent antiplatelet effect.

As described in the previous section on platelet activity, glycoprotein IIb/IIIa receptors are involved in the cross-linking of platelets with fibrinogen leading to platelet aggregation. Glycoprotein IIb–IIIa inhibitors block approximately 80% of IIb/IIIa platelet receptors. This results in a very potent antiplatelet effect. There are three widely used inhibitors, abciximab, eptifibatide, and tirofiban.

Abciximab is a murine antibody that has a very high affinity with irreversible binding. The half-life of this medication is short; however, given its strong affinity, the effects on platelet aggregation lasts for 24–49 h. Eptifibatide is a cyclic heptapeptide containing the distinguishing KGD (Lys–Gly–Asp) chain. Tirofiban differs in that the nonpeptide includes the chain of RGD (Arg–Gly–Asp). These particular sequences represent the sequence associated with fibrinogen. Fibrinogen is vital in the cross-linking of platelets via the IIb–IIIa inhibitors during platelet aggregation. Both eptifibatide and tirofiban are reversible agents and have relatively short half-lives with antiplatelet effects lasting 4–8 h.

There have been many trials involving all three glycoprotein IIb–IIIa inhibitors. Abciximab has been well studied in percutaneous intervention trials demonstrating reduced rates of myocardial infarction or the need for urgent revascularization.[54] In acute coronary syndromes, abciximab has reduced the rate of death, myocardial infarction, or urgent revascularization within 30 days. However, in the CAPTURE trial, the main benefit was seen in those patients with an elevated troponin level. The evidence for benefit was less for those patients without an elevation in troponin levels.[55] One major trial demonstrated that abciximab resulted in no benefit if percutaneous intervention was not anticipated.[56] Therefore,

Glycoprotein IIb–IIIa inhibitors have been shown to have the most benefit in patients with elevated troponin levels in unstable angina/ NSTEMI.

abciximab is indicated when percutaneous coronary intervention is anticipated. Eptifibatide and tirofiban, in combination with heparin, have been shown to reduce the primary combined endpoint of death, myocardial infarction, or refractory ischemia.[57,58] These benefits have been shown to last as long as 6 months. Once again, as with abciximab, the main benefit occurred in patients with elevated troponin levels. Eptifibatide and tirofiban have been approved for patients with unstable angina and NSTEMI who are treated medically or with percutaneous intervention.

There has been clear benefit in those patients who are to undergo a percutaneous coronary intervention with glycoprotein IIb–IIIa inhibitors. However, the evidence of benefit is less clear when the patients are treated medically without the use of percutaneous coronary intervention. There may be an increase in potential bleeding risks without achieving any substantial benefit.

The combination of aspirin and glycoprotein IIb–IIIa inhibitors is clearly safe. However, there have been increased rates of serious bleeding complications with the use of glycoprotein IIb–IIIa inhibitors and unfractionated heparin. The recommendation is to initially reduce the dosage of unfractionated heparin when used in conjunction with a glycoprotein IIb–IIIa inhibitor. In addition, there may be an increased risk of bleeding with LMWH.

The combination of aspirin, clopidogrel, heparin, and glycoprotein IIb–IIIa inhibitors are reserved for those patients who demonstrate high-risk features. Patients who have recurrent ischemia despite adequate therapy may also be considered. Consideration must be taken into account concerning the risk of serious bleeding vs. the potential benefits in this situation.

Thrombolytics

Thrombolytic therapy should be considered in patients who present within 6 h of the onset of ST-segment elevation or persistent chest pain with a left bundle branch block. After 6 h, the potential benefit of thrombolytic therapy is unclear. Thrombolytic therapy has been shown to be more beneficial in patients with large territories of myocardium at risk. There is no benefit to the use of thrombolytics in patients with unstable angina or NSTEMI.[59] In addition, there are a number of contraindications to thrombolytic therapy, which include but are not limited to severe hypertension, bleeding diathesis, or hemorrhagic stroke.

Risks of thrombolytic therapy obviously refer to bleeding complications, the most serious being intracerebral bleeding. Other areas of bleeding can occur, especially bleeding from the gastrointestinal tract and arterial puncture sites. In addition, there is the risk of an allergic response with streptokinase. Reocclusion is a serious potential complication, which is seen in a significant number of patients.

There are many potential benefits of emergent percutaneous coronary intervention over thrombolytic therapy. PCI offers low rates of intracerebral hemorrhages. Rapid evaluation of the coronary anatomy with identification of high-risk CAD such as left main disease or severe multivessel disease is possible. PCI offers higher reperfusion rates of the infarct related artery over thrombolytics. The main drawback to PCI remains to be its limited availability on quick notice especially if the patient needs to be transferred to a tertiary care cardiac center.

Intra-aortic Balloon Pump Therapy

IABP therapy has been widely used in the setting of acute coronary syndromes. IABP is indicated in patients with refractory angina despite adequate therapy, congestive heart failure, and cardiogenic shock. It is also indicated in patients with hemodynamically unstable mitral regurgitation or ventricular septal defects. IABP has been used to support the safe performance of high-risk percutaneous coronary interventions.

The deflation phase of the IABP cycle performance results in after load reduction resulting in relief of chest pain and improved hemodynamics. In addition, it improves coronary blood flow by augmenting diastolic blood pressures. Adverse effects of IABP therapy include thrombocytopenia, infection, vascular injury including aortic dissections, and

CASE STUDY: PART 4

Within 24 h after arrival to the Cardiac Intensive Care Unit, the patient developed worsening dyspnea without chest pain. His total CK was 2,500 U/L. His estimated left ventricular ejection fraction was 25–30% with severe hypokinesis of the entire anteroseptal wall and apex of the heart. He subsequently required a 100% nonrebreather mask. Swan-Ganz catheter cardiac index was 1.8 L/min/m^2 with a pulmonary capillary wedge pressure of 30 mmHg. Arterial blood pressure was 90/70 mmHg with adequate diastolic augmentation of the IABP. He had a cardiac S3 gallop with inspiratory crackles on physical examination and his chest X-ray showed significant bilateral lung edema. He was started on intravenous dobutamine and administered 40 mg of intravenous furosemide. Subsequently, his cardiac index improved and his capillary wedge pressure decreased and all symptoms dramatically improved. Once he became hemodynamically stable, an oral ACE-inhibitor was started without any complications. Within days of treatment of the myocardial infarction, the IABP was removed, antiarrhythmics were discontinued and the patient was able to tolerate all of his prescribed medications. He was transferred eventually to the step-down telemetry unit.

The patient recovered well without further evidence of congestive heart failure, arrhythmias, or recurrent chest pain. He was ambulating without symptoms and tolerating his doses of aspirin, clopidogrel, ACE-inhibitor, and statin. He was started on a low dose of an oral beta-blocker without complications. Aggressive risk factor modification education was begun and included strict glycemic control measures, reduction of his LDL, and tobacco cessation. He and his family were educated on potential recurrent cardiac symptoms. Outpatient cardiac rehabilitation was planned and a cardiologist for additional risk factor modification and further consideration for an intracardiac defibrillator discharged him from the hospital in stable condition with close follow up.

embolization. Contraindications include significant aortic regurgitation, aortic aneurysms, or aortic dissections.

PATIENT EDUCATION

Clearly, in addition to medical therapy, patients certainly achieve benefit with patient education. Smoking cessation has been clearly demonstrated to significantly reduce mortality and the incidence of recurrent myocardial infarctions. Strict glycemic control in diabetic patients is very important, both in the early medical phase of inpatient treatment and in the outpatient setting. Lipid management, with attempts to achieve the desirable LDL goal, is also crucial. Strict blood pressure control both in the critical care unit and as an outpatient is important. Along with a balanced diet and exercise, patients should attempt to achieve their ideal body weight. Finally, cardiac rehabilitation is under-utilized despite its proven benefit in patients who have suffered an acute coronary syndrome and should be strongly considered.

SUMMARY

Extensive research over the last three decades has led to a more thorough understanding of the pathophysiology of acute coronary syndromes. This in turn has enhanced management strategies to a higher level than ever before and improved mortality and morbidity in the majority of patients who suffer a variety of acute coronary syndromes. Prompt recognition and early risk stratification remain crucial in this management process. Measurements of troponin levels have revolutionized the clinician's approach to acute coronary syndromes. Guidelines for the assessment, treatment and risk assessment of patients with acute coronary syndromes have been developed to assist the clinician. Controversy exists concerning early invasive vs. conservative management strategies, especially in intermediate-risk patients. However, patient education and risk factor modification remain paramount in the prevention and treatment of acute coronary syndromes.

REVIEW QUESTIONS

1. **True or False. Persistent elevations of troponin I levels indicate infarct size.**

2. **Which of the following has been demonstrated in patients with acute coronary syndromes?**
   - **A.** Reduced fibrinolytic activity due to decreased plasma levels of plasminogen activator inhibitor-1
   - **B.** Decreased activity of fibrinogen
   - **C.** Increased interleukin – 6 levels
   - **D.** Decreased coagulation factor VII
   - **E.** Decreased levels of homocysteine

3. **A 55-year-old male presents to the emergency department with an episode of chest pain that was relieved with three sublingual nitroglycerin and 2 mg of intravenous morphine. During the episode of chest pain, the electrocardiogram showed T-wave inversions in the anterolateral leads. His physical examination did not demonstrate any evidence of congestive heart failure. His chest pain totally resolved. He has no prior cardiac history of cardiac workup. His initial measurements of biomarkers, including troponins were negative. There were no contraindications to the use of anticoagulants. He was not diabetic and his left ventricular ejection fraction was normal. Which of the following is appropriate initial therapy for this patient?**
   - **A.** Aspirin
   - **B.** Aspirin, Clopidogrel
   - **C.** Aspirin, Clopidogrel, Enoxaparin
   - **D.** Aspirin, Clopidogrel, Enoxaparin, Tirofiban
   - **E.** Aspirin, Clopidogrel, Tirofiban

4. **True or False: Glycoprotein IIb/IIIa inhibitors have consistently been proven to be very beneficial is patients who have elevated troponin levels in acute coronary syndromes or in patients who do not receive percutaneous intervention.**

5. **A patient with typical angina presents to the emergency room. He continues to have chest pain despite the use of sublingual nitroglycerin, beta-blockers, and morphine. A standard 12 lead electrocardiogram is performed which shows sinus rhythm at 60 bpm with 2–3 mm ST segment depression in leads V2 to V4. His current blood pressure is 85 mmHg systolic. He appears somewhat diaphoretic. His skin is cool and clammy. His cardiac exam is otherwise unremarkable. His initial laboratory data and cardiac biomarkers have not been completed. Which of the following would be performed next?**
   - **A.** An echocardiogram to evaluate for mitral regurgitation
   - **B.** Posterior leads placement
   - **C.** CT scan of the thorax
   - **D.** Right ventricular lead placements
   - **E.** Chest X-ray

6. **A patient presents with an anterior ST segment elevation myocardial infarction to the emergency department after 12 h of the onset of his symptoms. He appears to be hemodynamically stable but continues to have chest pain. This hospital does not have the capabilities to perform cardiac catheterization. The delay of transferring the patient to a center that can perform cardiac catheterization is approximately 90 min. The most appropriate next step is to:**
   - **A.** Administering thrombolytics
   - **B.** Transfering the patient as soon as possible to a tertiary care hospital with a cardiac catheterization laboratory
   - **C.** Administering half-dose thrombolytics
   - **D.** Administering half-dose thrombolytics with full dose enoxaparin
   - **E.** None of the above

ANSWERS

1. False. Troponin levels have not correlated well with the size of the myocardial infarction. Persistent elevated levels reflect slow release from the contractile apparatus of the myocytes and not decreased clearance or infarct size. Troponins are very sensitive to cardiac injury. However, they do not reflect whether or not the injury occurred in the setting of a ST segment or Non-ST segment myocardial infarction. Troponins provide retrospective diagnosis of myocardial infarction. Total CK and CK-MB may provide a better estimation of infarct size.
2. The answer is C. Increased interleukin – 6 levels. Certain factors have been associated in patients with acute coronary syndromes. Increased levels of fibrinogen and coagulation factor VII have been determined in patients with coronary artery disease. Reduced fibrinolytic activity has also been seen; however, this is a result of increased levels of plasminogen activator inhibitor-1. Increased levels of homocysteine and lipoprotein (a) are identified with coronary artery disease. Markers of inflammation such as C-reactive protein, increased levels of IL-6, platelet-monocyte complex, and ligand CD40 have been identified in patients with acute coronary syndromes.
3. The answer is C. This patient appears to be experiencing an acute coronary syndrome, specifically unstable angina. He appears to be at intermediate risk given that he has typical angina with T-wave inversions in the anterolateral leads. He is not at high risk due to the lack of ST segment deviation, the lack of congestive heart failure, and the lack of a significant increase in troponin levels. However, the patient is certainly not at low risk given his abnormal ECG and typical unstable angina. All patients should, if not contraindicated, be given an aspirin. Given the intermediate risk, the patient should receive a Clopidogrel load of 300 mg followed by 75 mg. The patient should receive an anticoagulant, specifically heparin, whether unfractionated or LMWH. Glycoprotein IIb/IIIa inhibitors are more appropriate if the patient has higher risk features or if the patient has elevated troponin levels.

4. False. Glycoprotein IIb/IIIa inhibitors have been shown to provide mortality benefit and reduction in nonfatal myocardial infarction in patients with acute coronary syndromes. However, the strongest benefit occurred in patients with an elevated troponin level and percutaneous coronary intervention. There is little evidence that prolonged use of these inhibitors without percutaneous intervention confers any significant benefit.
5. The answer is B. Patients who present with ST segment depression in anterior leads should be considered for posterior ST segment elevation myocardial infarction. Posterior leads may be placed in order to confirm the diagnosis. An echocardiogram may also be performed to evaluate the posterior as opposed to anterior wall segment hypokinesis that may suggest the diagnosis of a posterior myocardial infarction. However, an echocardiogram to evaluate the presence of mitral regurgitation may not help to differentiate between anterior or posterior wall ischemia. Confirmation of a posterior wall with persistent chest pain is an indication for rapid cardiac catheterization or thrombolytic therapy.
6. The answer is B The most appropriate answer is transferring the patient to a tertiary cardiac care hospital with a cardiac catheterization. Despite the late presentation, if the patient continues to have chest pain with persistent ST segment elevation, cardiac catheterization may still be beneficial. Thrombolytics beyond 12 h of onset of symptoms have shown little benefit whether at full or half dose.

Hypertensive Crisis

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the difference between malignant hypertension, hypertensive emergency, and hypertensive urgency.
- Understand the pathophysiology of a hypertensive crisis.
- Evaluate and diagnose hypertensive crisis using history, physical examination, and laboratory studies.
- Know the various classes of drugs to treat hypertensive crisis, their mechanisms of action, and their use in treating hypertensive emergencies.
- Recognize the secondary causes of hypertensive emergencies and the drugs used in their treatment.

INTRODUCTION AND DEFINITIONS

Hypertension is a common disease, affecting approximately 30% of adults or about 60 million people in the United States.[1,2] Normal blood pressure is defined as a systolic pressure of less than 120 mmHg and a diastolic pressure of less than 80 mmHg.[3] Hypertension is defined as a systolic pressure of 140 mmHg or higher, or a diastolic pressure of 90 mmHg or higher.[3] Pre-hypertension is defined by pressures between the values of normality and defined hypertension.[3] The group of patients with pre-hypertension is at increased risk for developing hypertension. The severity and duration of hypertension determine the cardiovascular risk

CASE STUDY: PART 1

A 60-year-old man is brought to the emergency department confused and complaining of a headache. His son states that his father's left side is weak and he had to help him walk to the car. Last night when he first complained of headache he was unable to read the newspaper because of difficulty focusing his vision. The son quickly remembers that his father's only medical problem is hypertension and he points out that medication noncompliance has been a recurrent problem. Vital signs were immediately taken and the patient's blood pressure taken from the right arm is 240/144 mmHg and heart rate is 112 bpm. There is not a significant difference in blood pressure between both arms. Oxygen saturation by pulse oximetry is 96%.

over time.[3] Poorly treated hypertension places the patient at increased risk for acute severe rises in blood pressure.[4] Such terms as hypertensive emergency, urgency, and crises have been used to describe sudden severe rises in blood pressure which places the patient at extreme risk for or involves critical end-organ damage. Hypertensive crises include patients with hypertensive emergencies and urgencies.[5] Hypertensive crisis, defined as a severe elevation in systemic blood pressure (>179/109 mmHg), has an incidence of <1% in the American hypertensive population,[6] and accounts for 25% of all urgent/emergent patient visits to a medical section of an emergency department,[7] one third of which had a hypertensive emergency.

Hypertensive crisis can be divided into hypertensive emergency and hypertensive urgency.[5,8] Hypertensive emergency is defined as a severe elevation in blood pressure accompanied by end-organ damage (brain, heart, aorta, eye, or kidneys). Hypertensive emergencies require rapid control of blood pressure, usually with intravenous quick onset, short-acting medications, and eventually intensive care monitoring. Hypertensive urgencies are elevations in blood pressure, without acute end-organ damage, which can usually be treated with oral medications over a period of days usually without an intensive monitoring setting. The main distinction between hypertensive emergency and urgency is the presence of end-organ damage, not the magnitude of elevation in blood pressure. The term malignant hypertension has been used in the past to describe an elevated blood pressure condition with associated encephalopathy or nephropathy.

A hypertensive emergency, which requires immediate therapy, is defined as an elevated blood pressure with signs of end-organ damage.

Hypertensive urgency is defined by severe hypertension without signs of end-organ damage. It can be treated with oral antihypertensive medications.

Hypertensive emergencies are more common in the elderly and African Americans, with men being affected 2 times greater than females.[4,9] The most common presentation of a hypertensive emergency is a patient with a preexisting history of hypertension, already prescribed antihypertensive medication, who is poorly controlled or noncompliant on current therapy.[4,10] However, there are other causes of hypertensive emergencies (Table 53-1). If untreated, hypertensive crisis is ultimately fatal. The development of effective antihypertensive pharmacologic therapy has resulted in successful treatment even in patients with severe end-organ damage.[11]

The difference between hypertensive emergency and urgency is the presence of end-organ damage and not the degree of blood pressure elevation.

TABLE 53-1

CAUSES OF HYPERTENSIVE EMERGENCIES

Essential or accelerated hypertension
Acute aortic dissection
Preeclampsia and eclampsia
Acute myocardial infarction or ischemia
Endocrine disorders
Pheochromocytoma (excess catecholamines)
Aldosteronism
Renin-secreting tumors
Glucocorticoid excess
Renal diseases
Chronic pylonephritis
Renal parenchymal disease (glomerulonephritis)
Renovascular disease
Drugs
Cocaine
Amphetamines
Clonidine and methyldopa withdrawal
Monoamine oxidase inhibitor interactions
Central nervous system injury/trauma

CASE STUDY: PART 2

Our hypertensive patient has several abnormalities on physical examination. He is clearly confused, unable to follow simple commands, and incapable of lifting his left arm. Papilledema is seen on fundoscopic exam. Lungs are clear, but his heart is tachycardic and a faint S_4 gallop is heard along the left sternal border. He does not have lower extremity edema. Laboratory studies were ordered stat. Intravenous access is obtained and normal saline solution is infused.

PATHOPHYSIOLOGY

The development of hypertensive crisis is a combination of increased humeral vasoconstrictors, loss of vascular autoregulation, and volume depletion.

While the complete pathophysiology leading to a hypertensive emergency remains poorly understood, the initial step involves a severe and often sudden increase in systemic vascular resistance. This almost always occurs in an individual with more than mild hypertension. The trigger for this event generally goes unidentified. The increase in resistance can be related to a vasoconstrictor such as angiotensin II or norepinephrine in response to hypovolemia, overproduction of renin and other vasoconstrictors, and disruption of blood flow autoregulation in renal and cerebral vascular beds. The overproduction of renin leads to an increase in blood pressure via angiotensin II. Studies have found malignant hypertensive patients to have high plasma renin activity, and other studies suggest that angiotensin II may have cytotoxic effects on blood vessel walls. Overproduction of renin also leads to intravascular volume depletion. Loss of autoregulation in vascular beds, coupled with continued release of vasoconstricting substances and volume loss, results in progressive increases in systemic vascular resistance and eventual organ ischemia and necrosis (end-organ damage). Other effects that play a role in this process include endothelial damage, platelet and fibrin deposition, and intravascular hemolysis leading to vascular fibrinoid necrosis and intimal proliferation. This entire process results in tissue ischemia and the further release of vasoactive substances, which drives forward a vicious cycle of repetitive injury.[8,12]

Hypertensive crisis can be mistaken for thrombotic thrombocytopenic purpura due to the presence of hemolysis, acute renal failure, and changes in mental status.

DIAGNOSIS

The history, physical examination, and initial laboratory studies are important in determining the severity of the hypertensive crisis presentation. Management decisions are substantially different between hypertension emergency and urgency presentations, with the former having evidence of critical end-organ damage and the later without. The clinical presentation of hypertension emergency is directly related to the specific end-organs that are involved.

History

Important risk factors in the development of hypertensive emergencies include use of birth control pills, tobacco use, and untreated or poorly controlled hypertension.

A complete drug history should include prescribed and over-the-counter medications and illicit drug use (oral, inhaled, and intravenous).

Evaluation of patients with hypertensive emergency should include a complete medical history including previous renal problems, coronary artery disease, hypertension, and peripheral vascular disease.

Certain symptoms reflect various forms of end-organ damage (Tables 53-2 and 53-2a). Frequent complaints on presentation include headache, visual symptoms, focal neurological deficits, chest pain, back pain, weight loss, and shortness of breath. In the evaluation of hypertensive emergency, a careful history should be taken with emphasis on prior medical conditions such as hypertension, renal problems, coronary artery disease, unstable angina, prior myocardial infarction, aortic aneurysm, peripheral vascular disease, eclampsia, and prior episodes of hypertensive crisis. A detailed history of current medications (prescribed and over-the-counter, including herbal products and nutritional supplements, should be obtained, as well as information concerning the use of illicit drugs such as amphetamines, cocaine, and PCP (pentachlorophenol)). Patients should be asked if there was an abrupt discontinuation of their beta-blocker or central sympatholytic medication since stopping these agents could lead to severe rebound hypertension. The patient should also be asked about usual blood pressure values.

TABLE 53-2

INITIAL EVALUATION OF HYPERTENSIVE EMERGENCY

History
History: chest pain (myocardial ischemia/injury, aortic dissection), dyspnea (pulmonary edema), back pain (aortic dissection), headache (encephalopathy, subarachnoid hemorrhage), visual disturbances (retinopathy)
Medical: hypertension, coronary artery disease, renal disease, peripheral vascular disease, cerebral vascular disease
Medications: prescribed (assess compliance)
Over-the-counter medications (antihistamines and herbal products)
Illicit drugs: amphetamines, cocaine
Physical examination
Blood pressure: in both upper extremities while patient supine and standing (volume depletion)
HEENT: assess for papilledema (increased intracranial pressure), retinal hemorrhages, and exudates (retinopathy)
Lungs: bilateral inspiratory crackles (pulmonary edema)
Cardiac: extra heart sounds such as an S_3(heart failure), mitral regurgitation (papillary muscle rupture)
Abdomen: bruit (partial occlusion of a renal artery)
Extremities: peripheral edema (left ventricular failure), absent arterial pulse (aortic dissection)
Neurologic: weakness; altered mental status (hypertensive encephalopathy and cerebrovascular accident)
Laboratory studies
Serum electrolytes (pressure naturesis, hypokalemia due to secondary hyperaldosteronism)
Blood urea nitrogen and creatinine (renal insufficiency)
Complete blood count and peripheral blood smear (hemolysis due to microangiopathic hemolytic anemia)
Urinalysis (interstitial nephritis and glomerulonephritis)
Cardiac enzymes (cardiac injury)
Electrocardiogram (cardiac ischemia and injury)
Chest X-ray (pulmonary edema, aortic dissection)
CT scan or MRI of head (cerebral ischemia or bleeding)
CT scan or MRI of the chest (aortic dissection)
Echocardiogram (left ventricular dysfunction, mitral regurgitation)

TABLE 53-2A

GRADES OF RETINOPATHY

GRADE OF RETINOPATHY	RETINAL SIGNS
None	No signs
Mild	Arteriolar narrowing, arteriovenous (AV) nicking, opacity copper wiring of arteriolar wall
Moderate	Hemorrhage, microaneurysm, cotton-wool spot, hard exudate
Malignant	Signs of moderate plus swelling of the optic disk

Physical Examination

Blood pressure should be taken in both upper extremities. A fundoscopic examination should be done to rule out papilledema.

The physical examination should attempt to identify evidence of end-organ damage (Tables 53-2 and 53-2a). Blood pressure should be measured in both arms using the appropriate size blood pressure cuff while the patient is supine and standing. There could be a large positional difference in patients who have intravascular depletion due to pressure-induced natriuresis. Using an appropriate size blood pressure cuff is very important, since the use of a small cuff in an obese patient has been shown to artificially elevate blood pressure.[13] A pressure discrepancy between arms is suggestive of aortic dissection or occlusive vascular disease.

While the pupils are fully dilated, a complete fundoscopic exam should be done, looking for papilledema, retinal exudates, hemorrhages, or retinopathy (see Table 53-3). A careful examination of the lungs and heart should focus on signs of pulmonary edema (inspiratory crackles) and heart failure (murmur, left ventricular gallop). Neck vein distention is often found when heart failure occurs. If an abdominal bruit is appreciated on auscultation of the abdomen, renovascular hypertension should be suspected; a pulsatile mass may be an

TABLE 53-3

CLASSES OF ANTIHYPERTENSIVE MEDICATIONS USED IN HYPERTENSIVE EMERGENCY

DRUGS	USUAL DOSE	RECOMMENDED USES
Direct vasodilators		
Nitroprusside	IV 0.25–10 μg/kg/min and titrate up in increments of 0.5–1.0 μg/kg/min	Hypertensive crisis, intracranial hemorrhage, cerebral infarction, myocardial infarction
Nitroglycerine	IV 5–100 μg/min	Acute myocardial infarction, left ventricular failure
Hydralazine	10 mg IV then 5–20 mg every 20–30 min (maximum 50 mg)	Eclampsia
Beta-blockers		
Esmolol	250–500 μg/kg loading dose over 1 min then infuse 50–100 mg/kg/min	Aortic dissection
Labetolol (alpha and beta-blocker)	IV bolus 20 mg then 20–80 mg every 10 min IV infusion 0.5–2 mg/min	Hypertensive encephalopathy, intracranial Hemorrhage, cerebral infarction, myocardial Infarction, aortic dissection, acute renal failure
Alpha-blocker		
Phentolamine	IV bolus 5–20 mg every 10–30 min as required	Eclampsia Pheochromocytoma, cocaine toxicity
Calcium antagonists		
Nicardipine	IV 5–15 mg/h	Myocardial infarction, acute renal failure, eclampsia
Verapamil		Aortic dissection when beta-blockers contraindicated
Diltiazem	5–20 μg bolus (repeat every 5–30 min)	
Clevidipine	IV 5–10 μg/h (increase by 5 μg every 30 min) IV 1–2 mg/h (double the dose every 90 s)	Postoperative hypertension
Angiotension-converting enzyme Inhibitors		
Enalapril	0.625–1.25 mg IV initial dose, then 1–25.0 mg IV every 6 h	Acute left ventricular failure
Central agents		
Clonidine	0.2 mg initially PO (a patch form is available)	Hypertensive urgency
Miscellaneous		
Fenoldopam	0.1 μg/kg/min and increase by 0.05 μg/kg/min	Renal failure

abdominal aortic aneurysm. A careful neurologic evaluation assessing level of consciousness, reflexes, and muscle strength is also required. Focal neurological deficits, especially lateralizing signs, may indicate ischemic or hemorrhagic stroke. Delirium suggests encephalopathy. Extremity pulses should be checked carefully for pulse deficits, which may indicate aortic dissection or occlusive vascular disease.

Laboratory Studies

Laboratory testing should include a complete blood count, white cell differential, and peripheral smear to identify schistocytes and target cells (microangiopathic hemolytic anemia), serum electrolytes, blood urea nitrogen, creatinine (intravascular volume status and renal impairment), cardiac enzymes (cardiac injury), and urinalysis (renal disease). An electrocardiogram (myocardial ischemia, left ventricular hypertrophy) and chest X-ray (pulmonary

CASE STUDY: PART 3

Laboratory studies showed hemoglobin of 17 g/dL, Serum potassium of 3.4 mg/dL, blood urea nitrogen of 42 mg/dL and a creatinine of 2.7 mg/dL. Old studies were not available for comparison, but his son was not aware of a history of renal disease. Left ventricular hypertrophy and sinus tachycardia were easily seen on electrocardiogram. A non-contrast head computed tomography study suggested bilateral diffuse white matter abnormality without structural asymmetry.

CASE STUDY: PART 4

The patient was transferred urgently to an intensive care bed, an arterial line was inserted, and intravenous nitroprusside was started. Nitroprusside was titrated using arterial line measured blood pressures and intravenous fluid resuscitation was accessed by urine output. Blood pressure decreased to 184/100 mmHg within 2 h and neurological abnormalities abated. He was restarted on his outpatient antihypertensive therapies and nitroprusside was weaned and then discontinued. Transfer to floor care allowed for patient and family education to be done. A subsequent hemoglobin was 13.8 g/dL and serum creatinine decreased to 1.4 mg/dL. The patient was discharged home after 4 days of hospitalization with an appointment to see his primary care physician within a week.

vascular congestion, widened mediastinum due to aortic dissection) should be done in all patients. Tables 53-2 and 53-2a outlines the various laboratory findings in the workup of a patient who is in hypertensive crisis.

Computerized tomography (CT scan) without contrast or magnetic resonance image (MRI) of the head should be included in the initial hypertensive evaluation if a neurologic process is suspected. Further evaluation of left heart function can be assessed by performing an echocardiogram if left ventricular dysfunction is suspected or if the patient has signs consistent with myocardial ischemia. An echocardiogram helps to distinguish systolic from diastolic left ventricular dysfunction and will identify mitral regurgitation, which is often found during a hypertensive crisis. There are differences in hypertension treatment based on what type of cardiac dysfunction is present. Renal ultrasound by doppler technique is recommended if renal artery stenosis is suspected. In cases of suspected aortic dissection or aneurysmal dilatation, a CT scan with contrast or a MRI of the chest and abdomen should be done to identify the location and extent of the process.

If a neurologic process is suspected, a CT or MRI of the head should be included in the initial evaluation.

Hypertensive patients with suspected left ventricular dysfunction or ischemia can be assessed with an echocardiogram.

In cases of suspected aortic dissection or aneurysmal dilation, initial studies should include a contrast CT or MRI of the chest and abdomen to determine location.

MANAGEMENT

When hypertension crisis presents, the majority of patients have no evidence of end-organ damage and can be diagnosed as having hypertensive urgency. The severely elevated blood pressure is identified during the evaluation of a complaint or health problem that is not related to end-organ damage. These patients can be treated with oral antihypertensive therapy to lower blood pressure gradually over 24–48 h. Treatment should be started with low doses and progress to incrementally higher doses as needed. Excessive and rapid blood pressure reduction should be avoided in order to minimize disturbances in pressure/flow autoregulatory relationships in critical organ arterial beds and associated morbidity.[14] This is particularly important in elderly patients with preexisting peripheral vascular, cerebrovascular, and cardiovascular diseases. Mean arterial pressure should be reduced by no more than 25% during the first 24 h of treatment.

The ultimate treatment goal during a hypertensive emergency is to control systemic blood pressure to prevent further end-organ damage.[15] Patients should receive their care in an intensive care unit where continuous (beat-to-beat) blood pressure monitoring can occur via an intra-arterial line. Treatment should be tailored to each patient, based on the extent of

end-organ damage and comorbid conditions. Initially, rapid-acting intravenous antihypertensive medications should be used since precise and rapid blood pressure control is mandatory. Just how quickly, and to what extent, blood pressure needs to be reduced remains unclear. Abnormal pressure/flow organ bed autoregulation occurs in patients with hypertensive emergency who have ongoing end-organ damage; therefore, excessive correction of blood pressure could dangerously reduce perfusion and accelerate organ injury further. This is why it is crucial to use a continuous intravenous infusion of a rapidly titratable antihypertensive agent to reduce diastolic blood pressure by 10–15% or to approximately 110 mmHg over a period of 30–60 min. If necessary, an additional 15% reduction over the next 2–3 h can be pursued.

During a hypertensive emergency, diastolic blood pressure should be reduced by 15% over a period of 30 min, except in the case of aortic dissection or aneurysmal dilatation where this reduction should be achieved in at least 15 min.

However, in aortic dissection or aneurysm, a 20% reduction in diastolic blood pressure or decreasing systolic blood pressure to <120 mmHg and mean arterial blood pressure to <80 mmHg should be accomplished within 5–10 min.[16,17] In this setting it is important to first reduce heart rate using beta-blocker therapy to prevent the vasodilator-induced increase in heart rate and cardiac output that increases vascular wall sheer stress. Once blood pressure has been stabilized and end-organ damage halted using intravenous medications, oral antihypertensive medication can be instituted and intravenous therapy can be tapered and discontinued.

Patients with hypertensive emergency require frequent blood pressure monitoring either with an automatic blood pressure cuff or an indwelling arterial line. Other support, such as mechanical ventilation, Swan–Ganz catheter, or hemodialysis, may also be required.

Patients presenting in hypertensive crisis usually have ongoing pressure natriuresis and intravascular hypovolemia and require rehydration with intravenous normal saline.[18] This helps restore organ perfusion and prevent a precipitous fall in blood pressure as antihypertensive therapy is initiated. Patients presenting with alterations in mental status or pulmonary edema may require intubation and assisted mechanical ventilation. Placement of a Swan–Ganz catheter may be considered to assess volume status and aid in fluid management. Patients who present with hypertension due to renal parenchymal disease or who present in renal failure may require hemodialysis.

PHARMACOLOGIC AGENTS FOR HYPERTENSIVE CRISIS

Selection of a pharmacologic agent in hypertensive crisis depends on the rapidity with which blood pressure needs to be controlled. This involves discerning a hypertensive emergency from a hypertensive urgency presentation. Oral therapies are generally used when control of blood pressure is urgent while intravenous medications are preferred when rapid blood pressure control is necessary to minimize end-organ damage.[8,18,19] For patients with hypertensive urgency, it is likely best to use an oral agent with a rapid onset of action. The short-term goal is to reduce blood pressure within 24–72 h and appropriate follow-up is essential. Often a poorly compliant patient may just need to resume their antihypertensive therapy. For previously untreated patients, transition to long-acting therapy will eventually be necessary. Antihypertensives often considered for the initial treatment of hypertension urgency include captopril, clonidine, labetalol, extended-release nifedipine, and amlodipine.

Hypertensive urgency can be treated with oral antihypertensive therapy, and control should be achieved over several hours.

A number and variety of medications are available for the treatment of hypertension emergency (Table 53-3). The patient's particular presentation mandates the choice of therapy selected.[8,15,18,19] A parental therapy that can be administered in a precise controlled fashion is a key consideration in the selection of agent used. These patients should receive their care in an intensive care unit, where vital signs can be continuously monitored.

Direct Vasodilators

Sodium Nitroprusside

Nitroprusside is a direct arterial and venous vasodilator with an immediate onset of action and short half-life. It is the agent of choice in the treatment of most hypertensive emergencies.

Intravenous sodium nitroprusside has long been considered the agent of choice in the treatment of hypertensive crises.[8] It has an immediate onset of action and a very short plasma half-life.[20] Sodium nitroprusside is an arterial and venous vasodilator that reduces both cardiac afterload and preload. Cardiac output and coronary blood flow remain unchanged unless

the patient has coronary artery disease, in which case there may be a reduction in regional coronary blood flow (vascular steal phenomenon) placing the patient at risk for myocardial ischemia[21] This phenomenon is most important during a myocardial infarction.[22] Since nitroprusside decreases systemic blood pressure and could affect cerebral blood flow (CBF) and intracranial pressure, there may be a concern in using this agent in hypertensive patients with neurological symptoms.[23] Renal blood flow remains unchanged, and plasma renin activity can increase.

Nitroprusside can inhibit hypoxia-induced pulmonary vasoconstriction and lead to arterial hypoxemia.

Nitroprusside degrades nonenzymatically to cyanide and with liver metabolism to thiocyanate. Thiocyanate is less toxic than cyanide and is renally excreted. These two toxic metabolites can accumulate with the use of high doses or continued use of nitroprusside for extended periods. The risk of toxicity is especially pronounced in patients with hepatic or renal disease.[15] Cyanide/thiocyanate toxicity is usually seen when the total dose of nitroprusside exceeds 300 mg or when the infusion rate is ≥20 μg/kg/min. Cyanide toxicity includes coma, seizure, and cardiac instability resulting in death.[24] Metabolic acidosis is a heralding event. Therefore, nitroprusside should not be administered for a prolonged period of time.

Nitroprusside is metabolized in the liver to cyanide and thiocyanate. These toxic metabolites rapidly accumulate in patients on high doses or those with renal or hepatic disease.

Nitroprusside is usually started at a dose of 0.5 μg/kg/min and titrated in increments of 0.5–10 μg/kg/min until blood pressure is effectively controlled. Nitroprusside has the advantage of a rapid onset of action and is easily titrated. The medication is degraded upon exposure to light and so must be wrapped in a special fashion. Nitroprusside can alter pulmonary blood flow, which can result in higher perfusion to poorly oxygenated alveolar areas of the lung, thereby increasing intrapulmonary ventilation-perfusion mismatching and shunting causing arterial hypoxemia. Patients should be converted to oral blood pressure medications as soon as their blood pressure has been controlled.

Nitroglycerin

Nitroglycerin has long been used as a therapy for the treatment of hypertensive crisis in patients with cardiac ischemia. Nitroglycerin dilates coronary arterioles, arteries, and venules. It is a very potent venodilator that lowers blood pressure by reducing preload and cardiac output. It may cause reflex tachycardia, especially in patients with intravascular volume depletion, which includes many patients who present with hypertensive emergency.[18] Nitroglycerin reduces cerebral and renal blood flow and should be avoided in patients with increased intracranial pressure, renal insufficiency and aortic/subaortic stenosis. Nitroglycerin is absorbed by plastic tubing and containers. Its adverse effects include headache, tachycardia, flushing, nausea, and vomiting. Tolerance to nitroglycerin may develop with prolonged use.

Nitroglycerin dilates coronary arterioles, large and small arteries, and venules, and reduces cardiac preload. It is the drug of choice in myocardial infarction. Tolerance may develop with prolonged use.

Nitroglycerin has a rapid onset of action with a peak effect achieved in 2–5 min. The effects of nitroglycerin persist 5–10 min after the drug is abruptly discontinued. The initial intravenous dose of nitroglycerin is 5–10 μg/min. Nitroglycerin is considered the drug of choice in hypertension associated with acute coronary syndromes.

Nitroglycerin is absorbed by plastic tubing. Its side effects include headache, tachycardia, flushing, nausea, and vomiting.

Hydralazine

Hydralazine is a direct arteriolar vasodilator with a short onset of action and a relatively long plasma half-life.[25,26] The peak effect of intravenous hydralazine occurs in 5–20 min and has a duration-of-action of 2–6 h. Hydralazine is metabolized in the liver, but approximately 8% is excreted unchanged in the urine. In patients with renal insufficiency, hydralazine doses may be reduced due to a longer elimination time. Hydralazine can induce reflex tachycardia and sudden drops in blood pressure, which can be prolonged. It is not recommended in patients with ischemic heart disease and aortic dissection. Hydralazine has also been associated with the development of systemic lupus erythematosis-like reaction, rheumatoid arthritis, drug fever, rash, gastrointestinal complaints, and peripheral neuropathies. In most cases, removal of the drug is curative. Hydralazine causes sodium and water retention and is used in treating pregnancy-induced hypertension (preeclampsia and eclampsia).[18] It is best to avoid hydralazine in hypertensive crisis because of its unpredictable blood pressure response.

Hydralazine is a direct arteriolar vasodilator and is used in patients with eclampsia. Hydralazine is associated with development of a lupus-like reaction, arthritis, drug fever, and rash.

Diazoxide

Diazoxide is an arterial vasodilator. It is contraindicated in patients with coronary artery disease, myocardial ischemia, or aortic dissection because it can induce a reflex tachycardia.

Diazoxide, a potent arterial vasodilator, is rarely used in the treatment of hypertensive emergency. The effects of diazoxide are seen within minutes following an intravenous bolus of 50–100 mg. Boluses can be repeated every 15 min to a total dose of 600 mg or until blood pressure is lowered to the desired level. The effects of diazoxide can last for up to 12 h, and large boluses can produce rapid and extreme falls in blood pressure. Diazoxide is associated with a reflex tachycardia that can induce angina or myocardial ischemia, and it is contraindicated in patients with coronary artery disease, angina, myocardial infarction, aortic dissection, and intracerebral hemorrhage.

Beta-Blockers

Labetalol

Labetalol is both an alpha- and a beta-blocker and has both an intravenous and oral form. It produces vasodilatation without a change in cardiac output.

Labetalol is a competitive selective alpha-1 and a noncardioselective competitive beta-blocker (beta-1 and beta-2).[27] Labetalol acts on both alpha- and beta-receptors to produce vasodilation without stimulation of cardiac output. Labetalol also has an additional direct vasodilatory effect. Labetalol has both intravenous (infusion and bolus) and oral forms. Intravenous labetolol has an onset of action that begins within 5 min and a peak effect in 5–30 min; duration-of-action is 2–4 h. Labetalol is usually administered as a 20-mg bolus, which can be followed either by a repeat 20–80 mg bolus (every 10–15 min), or more commonly, by an intravenous infusion at 0.5–2 mg/min, which is titrated to effect.[18] Labetalol is metabolized in the liver, so doses should be reduced in patients with liver failure. Less than 5% of labetolol is excreted in the urine.

Labetalol is useful in the treatment of hypertensive emergency caused by aortic dissection or myocardial ischemia.

Labetalol produces a decrease in systemic arterial pressure with minimal influence on total peripheral blood flow. Cardiac output remains stable, and cerebral, renal, and coronary blood flows are maintained. There is a decrease in pulmonary artery pressure and pulmonary capillary wedge pressure. Labetalol is especially useful in cases of malignant hypertension accompanied by myocardial ischemia or aortic dissection. However, because of its effects on beta-receptors, it can decrease forced expiratory volume in one second (FEV1) in patients with chronic obstructive pulmonary disease or asthma and should not be used in cases where beta-blockers are contraindicated.[8]

Esmolol

Esmolol is an ultrashort-acting, cardioselective, beta-adrenergic blocking agent useful in treating hypertension associated with myocardial infarction.

Esmolol is an ultrashort-acting cardioselective beta-adrenergic blocking agent. It has a rapid onset of action (within 60 s) and a short half-life (10–20 min). It can be administered intravenously as a bolus or by infusion. Esmolol had been used to treat supraventricular arrhythmias. It has been shown to be effective in treating hypertension associated with myocardial infarction and postoperative hypertension.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (ACE inhibitors) decrease total peripheral vascular resistance while causing little change in heart rate, cardiac output, or pulmonary artery wedge pressure. ACE inhibitors decrease blood pressure by decreasing systemic concentrations of angiotensin II, inhibiting local vascular effects of angiotensin II, and increasing concentrations of bradykinin, a vasodilator. Unfortunately, the response to ACE inhibitors is variable because their effectiveness depends on the patient's plasma volume and renin activity. ACE inhibitors should be used with caution in cases of bilateral renal artery stenosis.

Enalaprilat is the most common ACE inhibitor used in the treatment of hypertensive emergency. Enalaprilat has an onset of action of 10–60 min and duration-of-action of 2–6 h. It is given as an IV bolus of 1–25 mg every 6 h after an initial dose of 0.625–1.25 mg.

Dopamine Agonists

Fenoldopam

Fenoldopam is a short-acting dopamine-1 receptor agonist that causes peripheral vasodilatation. It is particularly useful in the setting of renal insufficiency since it improves renal blood flow.[28] Fenoldopam acts on dopamine receptors in the proximal and distal tubules, resulting in inhibition of sodium reabsorption and increased diuresis and sodium wasting. It has a rapid onset of action (within 5 min), a maximal effect in 15 min, and duration-of-action of nearly 1 h. It is metabolized by the liver with no active metabolites. Fenoldopam has been found to be comparable in effectiveness to sodium nitroprusside in the treatment of hypertensive emergency. Unlike nitroprusside, fenoldopam improves creatinine clearance and sodium excretion in patients with renal insufficiency and hypertension. To date, there has been no associated rebound hypertension once the drug is discontinued.

Fenoldopam, a dopamine agonist, acts on dopamine receptors to produce renal vasodilatation. It also improves creatinine clearance and sodium excretion. Fenoldopam is useful in the treatment of hypertension with coexisting renal insufficiency.

Calcium Channel Blockers

Calcium channel blockers reduce cardiac contractility and produce vasodilatation in both the coronary and systemic blood vessels. Calcium channel blockers act by inhibiting calcium uptake, and interfering with excitation-contraction coupling in smooth muscle. The original calcium channel blockers – verapamil, nifedipine, and diltiazem – are not usually considered effective therapy in the treatment of hypertensive emergency.

The original calcium channel blockers – verapamil, nifedipine, and cardizem – are not usually considered as first-line therapy in hypertensive emergency.

Verapamil, while effectively reducing blood pressure, can also slow the heart rate, prolong the PR interval, and precipitate heart block in doses necessary to effectively control blood pressure. Verapamil is contraindicated in the treatment of hypertensive emergency in patients with preexisting cardiac conduction problems. Patients presenting with bradycardia or using digitalis or a beta-blocker are at particular risk for the development of heart block after receiving verapamil.

Although nifedipine is an effective treatment for chronic essential hypertension, it is associated with rapid falls in blood pressure that can lead to renal, cerebral, and cardiac infarctions. Because of the possibility of severe hypotension, nifedipine is not recommended in the treatment of hypertension emergency.

Nicardipine, an intravenous calcium channel blocker, is easily titratable and not associated with rapid blood pressure swings. Nicardipine reduces both cardiac and cerebral ischemia; its action is similar to nitroprusside in lowering blood pressure. It has also been shown to produce cerebral vasodilatation and can, therefore, increase intracranial pressure. Side effects of nicardipine are nausea, vomiting, headache, and hypotension. The initial intravenous dose is 5 mg/h, and it can be increased by 1–2.5 mg/h every 15 min to a maximum dose of 15 mg/h. Nicardipine has an onset and duration-of-action of 15 min and 5 h, respectively. Nicardipine is contraindicated in patients with cerebral edema or with an intracranial mass.

Nicardipine, a calcium channel antagonist, may decrease cerebral vasospasm in cases of subarachnoid hemorrhage. It is contraindicated in patients with cerebral edema or intracranial space-occupying lesions.

Clevidipine is an ultrashort-acting calcium channel blocker that causes selective arteriolar vasodilatation and reduces peripheral vascular resistance.[29] It is rapidly metabolized by red blood cell esterase (like esmolol) and easily controllable during intravenous infusion. It does not cause reflex tachycardia. It is most effective in postoperative hypertension. The pharmacological profile of this new medication suggests that it should be valuable for the treatment of hypertension emergency.

Alpha-Adrenergic Blockers

Clonidine

Clonidine is a centrally acting alpha-2-adrenergic agonist. It is now available in a transdermal patch and is useful in the treatment of hypertensive urgency and other situations in which urgent blood pressure control is not required. A side effect of clonidine is sedation, so its use is contraindicated if hypertensive encephalopathy is a concern.

Clonidine is an effective agent in treating hypertensive urgency, but is not used for hypertensive emergency. It is contraindicated in hypertensive encephalopathy because of its sedating effects.

SPECIAL CONSIDERATIONS

Hypertensive Encephalopathy

Hypertensive encephalopathy can occur with a sudden increase of systemic blood pressure. It is characterized by alterations in mental status and grade III or IV retinopathy on fundoscopic exam.

Hypertensive encephalopathy is a severe complication of systemic hypertension, and carries a poor prognosis. Encephalopathy occurs in patients who have a sudden increase in systemic blood pressure and the development of cerebral edema. It is characterized by severe headache, nausea, vomiting, alterations in mental status ranging from lethargy to coma, and even seizures. Focal neurologic findings may be seen, such as cranial nerve palsies, aphasia, and blindness. Fundoscopic exam reveals advanced retinopathy, retinal hemorrhages, exudates, cotton-wool spots, and papilledema.

Treatment of hypertensive encephalopathy is aimed at reducing mean blood pressure by 20%.

Treatment of hypertensive encephalopathy is aimed at a prompt reduction of blood pressure. Mean arterial blood pressure should be lowered by 20–25%. Current recommended agents to lower blood pressure include the direct vasodilators nitroprusside and nitroglycerin. Patients require intensive care monitoring. Once the blood pressure has sufficiently been reduced, clinical improvement should be seen. If improvement does not occur within 6–12 h, other causes of encephalopathy should be considered. Blood pressure can be further reduced over the next 48 h, and patients are often switched to oral medications once mental status improvement occurs.

Cerebrovascular Accidents

When systemic blood pressure is greater than 150 mmHg, CBF increases. Chronic elevations in systemic blood pressure result in alterations in the brain's ability to regulate CBF, producing a shift to the right in the autoregulatory curve.

Chronic hypertension results in arterial intimal and medial thickening, sclerotic plaques, and luminal narrowing. These changes result in increased cerebrovascular resistance and produce a functional abnormality in cerebral vessel autoregulation. This change can be reversed by antihypertensive therapy. In normal individuals, the brain maintains cerebrane blood flow (CBF) over a wide range of blood pressure. Cerebrovascular autoregulation is maintained by delicate and regular changes in vasoconstriction and vasodilatation. The usual autoregulatory range is between a mean arterial pressure of 50 and 150 mmHg. When systemic mean arterial pressure drops below 50 mmHg, CBF decreases. Alternately, when mean arterial pressure rises above 150 mmHg, there are increases in CBF and cerebral blood volume. Chronically elevated blood pressure shifts the autoregulatory curve to the right. Acute severe increases in blood pressure can result in cerebral edema due to increased microvascular pressure and vessel damage with necrosis, leading to subsequent vascular leakage.

Optimal therapy for patients presenting with thrombotic strokes or intracerebral hemorrhage is not known.

Optimal therapy for patients presenting with hypertensive emergency caused by cerebrovascular accidents is unclear. Immediately preceding a stroke, systemic arterial pressure increases, as does CBF. These increases are part of a protective physiologic response to maintain critical blood flow to the area of ischemic tissue. Additionally, watershed areas of brain parenchyma surrounding the stroke are dependent on an adequate perfusion pressure to remain viable. No studies have shown that hypertension has increased mortality during the acute phase of stroke, and normalization of blood pressure in acute stroke may actually worsen end-organ damage. The risks of severe elevations in systemic blood pressure need to be balanced against the risk of worsening cerebral ischemia caused by excessive reductions in blood pressure. In the setting of stroke, it is important to carefully observe blood pressure for 1–2 h to see if it will spontaneously decrease without medication. Current recommendations[30,31] suggest consideration of antihypertensive treatment for patients who require thrombolytic therapy, if there is ongoing noncerebral end-organ damage or if blood pressure remains excessive. Excessive blood pressure has been arbitrarily set as a diastolic pressure above 120 mmHg or a systolic pressure greater than 220 mmHg based on normal limits for vascular autoregulation. In these patients the goal is a 15–20% reduction in mean blood pressure (or a diastolic blood pressure between 100 and 110 mmHg).

Current recommendations suggest treatment if diastolic pressure is greater than 120 mmHg, with a goal of a 20% reduction in mean blood pressure.

Patients with large intracerebral hemorrhages have been shown to benefit from judicious lowering of their systolic blood pressure to less than 200 mmHg or the diastolic pressure to less than 120 mmHg. Short-acting agents that do not have CNS effects are preferred to maintain better control over blood pressure changes. Nitroprusside, while having a rapid onset of

action and a short half-life, is known to increase intracerebral pressure. A suitable alternate choice is labetolol. Nicardipine has also been used in the treatment of subarachnoid bleeding to reduce cerebral vasospasm.[32]

Acute Aortic Dissection

Acute aortic dissection and aneurysmal dilatation may present as an isolated hypertensive emergency. Rapid blood pressure control is required to reduce aortic wall stress. Reduction in the force of left ventricular contraction will reduce the rate of rise in blood pressure. In cases of aortic dissection and distension, therapy must include beta-blockade and vasodilation.[16,17] These goals can be achieved with a single drug such as labetalol, or a combination of beta-blocker and vasodilator such as esmolol and nitroprusside. Drugs such as nicardipine and fenoldopam can be substituted if there is concern over nitroprusside toxicity and metoprolol can be a suitable alternative for esmolol. It is important to initiate therapy with the beta-blocker before the use of a vasodilator. Vasodilatation and reflex tachycardia will increase vessel wall stress and potentially accelerate the vascular dissection/dilation process. These drugs are used to lower the systolic blood pressure to less than 120 mmHg and decrease heart rate as quickly as possible.

Treatment of aortic dissection requires a prompt reduction in blood pressure to reduce aortic wall stress. Treatment of choice includes labetalol or a combination of a beta-blocker and a vasodilator.

Along with blood pressure and heart rate reduction, a cardiothoracic or vascular surgery consultation should be urgently requested. Aortic dissections are categorized as either type A (dissections involving the ascending aorta) or type B (dissections of the descending aorta). All type A dissections require surgical intervention. Uncomplicated distal dissections are treated medically with antihypertensive agents. Distal dissections with signs of leakage of blood from the aorta, or compromised blood flow to a limb or organ are usually treated with surgery. Both surgical and medical treatments of distal dissections have similar survival rates.

All type A dissections (dissections of the ascending aorta) require surgical intervention. Type B dissections (distal or descending aorta), if uncomplicated, are managed medically. Blood flow compromise to a limb or organ or leakage of blood into the abdomen requires surgical intervention.

Preeclampsia and Eclampsia

Pregnancy-induced hypertension can range from mild to severe and does not resolve until delivery. Preeclampsia, which usually occurs after the twentieth gestational week, is a multisystem disease and includes volume depletion, vasoconstriction, disturbances in the coagulation system and liver function, proteinuria, renal failure and cerebral ischemia. Eventually, preeclampsia can lead to seizures (eclampsia). It occurs in 2–12% of pregnancies and is the major cause of maternal morbidity, perinatal death, and premature delivery. Despite the above, the outcome for the majority of women and their babies is good.

Delivery is the principle "treatment" for preeclampsia and eclampsia. Early administration of intravenous magnesium sulfate (seizure treatment or prophylaxis) and volume reexpansion are immediately necessary and antihypertensive therapy should be carefully selected and started.[33] The administration of magnesium sulfate starts with an intravenous loading dose of 4–6 g in 100 mL 5% dextrose in ¼ normal saline solution over 15–20 min followed by 1–2 g/h constant infusion while monitoring urine output and deep tendon reflexes. Hyperreflexia should abate as the condition improves. Antihypertensive therapy is indicated for patients with severe elevations in blood pressure (diastolic blood pressure >105 mmHg)[34] with treatment goals of keeping systolic blood pressure from 140 to 160 mmHg and diastolic pressure from 90 to 105 mmHg.[33-35]

Treatment of eclampsia includes magnesium for seizure prevention, intravascular volume expansion, and when necessary, antihypertensive therapy for blood pressure control.

There is no clear drug of choice for the treatment of severe hypertension during pregnancy. Hydralazine has long been considered the preferred parenteral drug of choice in patients with preeclampsia since it has a long history of safe use in this setting.[33] However, hydralazine is difficult to use since its adverse effects often mimic preeclampsia and it is a difficult to control intravenous medication. For treatment of mild hypertension (diastolic blood pressure <95), the National High Blood Pressure Education Program (NHBPEP) recommends methyldopa (a centrally acting alpha-agonist). In cases of hypertensive emergency where diastolic blood pressure exceeds 110 mmHg or systolic pressure is greater than 180 mmHg, intravenous antihypertensives such as intravenous labetalol and nicardipine

may be considered,[36,37] and the patient can be changed to hydralazine once blood pressure is controlled. Sodium nitroprusside is not generally recommended for treatment of preeclampsia unless delivery is expected within the next few hours because it crosses the placenta and can result in fetal cyanide toxicity.

Cardiac Causes of Hypertensive Emergency

Severe elevations in systemic blood pressure can result in left ventricular failure and pulmonary edema. Treatment is aimed at rapidly reducing preload and afterload. Nitroprusside and nitroglycerine are both effective agents that reduce blood pressure. Other therapies include diuretics, oxygen, and morphine sulfate.

Left ventricular failure and pulmonary edema are the result of severe elevations in systemic vascular pressure. Treatment is aimed at rapid reduction in preload and afterload to improve cardiac output. Nitroprusside and nitroglycerin are both effective agents, with supplemental oxygen and morphine sulfate, if needed. ACE inhibitors can be used once blood pressure is stable. Beta-blockers may worsen cardiac function, and therefore, are generally not indicated. Along with reducing blood pressure, management should include diuretics to facilitate fluid removal.

In cases of hypertension complicated by myocardial infarction or cardiac ischemia, nitroglycerin is the drug of choice. Nitroglycerin dilates coronary vessels and reduces myocardial oxygen consumption. Other agents that may be used are beta-blockers such as esmolol or labetalol.

Hyperadrenergic Conditions

Systemic catecholamine storm and severe hypertension can occur in patients who have a pheochromocytoma; who use or overdose with cocaine, amphetamine, or phencyclidine; who abruptly stop their clonidine or beta-blocker; or who ingest food containing tyramine while on monoamine oxidase inhibitors. In these situations beta-adrenergic blockers should be initially avoided so that unopposed intrinsic alpha-adrenergic stimulation does not further increase blood pressure or cause coronary vasospasm. Intravenous phentolamine (5–20 mg), an alpha-adrenergic blocker, can be a helpful agent in this setting,[12] especially when used in combination with nitroprusside. Hypertension due to the withdrawal of clonidine or beta-blocker is best treated with the reinstitution of discontinued medication, as well as other antihypertensive therapy as necessary. Benzodiazepines have become an important therapeutic addition for cocaine toxicity since they reduces heart rate, blood pressure, and anxiety.

Postoperative hypertension may be related to catecholamine surge and is potentially life-threatening. It occurs in the immediate postoperative period and requires emergent treatment. It is often associated with cardiovascular or neurologic surgery. The anesthesiologist is often the first to recognize the condition and decide on initial treatment, while taking pertinent patient variables into consideration. These variables include pain, temperature, volume status, acid–base balance, hypoxemia, hypercarbia, and urinary bladder distension. There is no general consensus on which antihypertensive therapy should be used, but intravenous esmolol, labetalol, nicardipine, and clevidipine have been used.[38]

SUMMARY

Hypertensive crisis is associated with significant morbidity and mortality. Hypertensive emergencies, defined as severe blood pressure elevation and acute end-organ damage, require rapid blood pressure control with potent, short-acting intravenous agents. The ICU is the ideal setting to treat this condition as it permits invasive arterial pressure monitoring and the close attention necessary for appropriate titration of therapeutic agents. The goal is to reduce blood pressure to the appropriate level while avoiding profound decrements in blood pressure, which are all too likely if titration is not carefully managed. Blood pressure reduction can be achieved over hours in cases of hypertensive urgency. Finally, it is extremely important that all patients who experience hypertension crises receive careful discharge instructions with emphasis on medication compliance and appropriate, timely follow-up care to optimize blood pressure management.

REVIEW QUESTIONS

1. **Hypertensive emergency is distinguished from hypertensive urgency by**
   - **A.** Greater elevations in blood pressure
   - **B.** Evidence of end-organ damage
   - **C.** A history of cocaine use
   - **D.** Diastolic blood pressure greater than 120 mmHg

2. **A 68-year-old man with a history of hypertension and diabetes mellitus presents with sudden right-sided weakness and dysphagia that had developed over the last 24 h. His current medications include an oral hypoglycemic medication and diltiazem. On physical exam, blood pressure is 220/140 mmHg in both upper extremities with a heart rate of 95 bpm and a respiratory rate of 16 breaths/min. Laboratory tests are all normal. EKG is normal. Further management of this patient would include all the following except**
   - **A.** CT of the head
   - **B.** Pulse oximetry and airway assessment
   - **C.** IV antihypertensive agent to reduce blood pressure to within normal range
   - **D.** Blood pressure monitoring

3. **Nitroprusside does all the following except**
   - **A.** Has a rapid onset of action and short half-life
   - **B.** Acts only on arterial smooth muscle to reduce blood pressure
   - **C.** Is light sensitive
   - **D.** Has toxic metabolites that can limit use

4. **The antihypertensive drug of choice in preeclampsia when diastolic blood pressure is >100 mmHg is**
   - **A.** Clonidine
   - **B.** Enalapril
   - **C.** Hydralazine
   - **D.** Nitroglycerine

5. **Which of the following is true?**
   - **A.** Hypertensive encephalopathy is characterized by changes in mental status and findings of advanced retinopathy
   - **B.** In cases of cerebral ischemia, blood pressure reduction is advised if the diastolic blood pressure exceeds 90 mmHg
   - **C.** Most patients who present with hypertensive emergency have no prior diagnosis of blood pressure problems
   - **D.** Labetalol is a beta-2-selective adrenergic blocking agent

ANSWERS

1. The answer is B. Both hypertensive urgency and emergency are characterized by extreme elevations in blood pressure. However, patients with a hypertensive emergency also have evidence of end-organ damage, unlike patients with hypertensive urgency. The organs most commonly affected are the heart, brain, and kidneys. Patients with hypertensive emergency require blood pressure be reduced over the course of 30 min to 1 h. Although cocaine use is associated with episodes of hypertensive emergency and urgency, it does not distinguish one from the other.
2. The answer is C. For a patient presenting with hypertensive emergency due to a cerebral event, the initial workup should include a CT of the head to assess for bleeding or cerebral edema, frequent blood pressure monitoring, and pulse oximetry and airway assessment. Antihypertensive agents should be used to reduce the patient's blood pressure as diastolic pressure is well above 120 mmHg. However, blood pressure should NEVER be reduced to normal levels because this may affect blood flow to the affected area and worsen symptoms.
3. The answer is B. Nitroprusside is a rapid-acting drug that produces both arterial and venule vasodilation. It has a half-life of minutes, making it easily titratable. The medication is light sensitive and is broken down into cyanide and thiocyanate. These toxic metabolites can accumulate to toxic levels, especially in patients with renal failure or in those who require high doses for an extended period of time.
4. The answer is C. Hydralazine is the parenteral drug of choice in patients with preeclampsia and diastolic blood pressure >100 mmHg. It is a direct vasodilator and has a long history of safety and efficacy in treatment of preeclampsia. Other possible agents include labetalol. Methyldopa, a centrally acting alpha-agonist, is useful in the treatment of mild hypertension (diastolic blood pressure <95 mmHg). Agents to be avoided include calcium agonists, because of possible synergistic effects with magnesium, and ACE inhibitors or angiotensin II blockers. Both ACE inhibitors and angiotensin II receptor blockers have been associated with fetal abnormalities.
5. The answer is A. The only true statement is that hypertensive encephalopathy is characterized by changes in mental status and findings of advanced retinopathy along with elevated blood pressure. In treating hypertension associated with cerebral ischemia, blood pressure reduction is advised once the diastolic blood pressure exceeds 120 mmHg. The majority of patients presenting with hypertensive emergency have a prior history of hypertension and are usually noncompliant or poorly controlled on their current medications. Labetalol is a noncardioselective beta (beta-1 and beta-2) blocker and a selective alpha-1-blocker. Labetalol produces vasodilation without stimulation of cardiac output.

CHAPTER 54

LL. ARMANDO SAMUELS, FAAHUD A. YAFAI, AVRUM GILLESPIE, AND JESSE GOLDMAN

Dialysis

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the physiologic principles of dialysis and renal replacement therapy (RRT).
- Be familiar with the nomenclature and modalities of dialysis and RRT.
- Understand the complications associated with dialysis therapy.
- Recognize the general indications for dialysis therapy and the considerations in selection of a specific renal replacement modality.

The kidneys remove metabolites and toxins from the blood, maintain body fluid balance, and regulate electrolyte and acid/base balance. Renal replacement therapies (RRT) can only approximate these functions. Artificial RRT for the treatment of acute kidney injury (AKI) was first introduced during the Korean War. Over the past several decades, technologic improvements have resulted in several treatment options that include peritoneal dialysis (PD), hemodialysis, and continuous renal replacement therapies (CRRT). Moreover, technologic improvements in vascular catheters, semipermeable membranes, and dialysis machinery have resulted in a variety of dialysis prescription options. The clinical indications for choosing these different modalities have not been precisely defined. The choice of therapy often depends on several conditions that include availability of vascular access, types of dialysis machinery, availability of skilled personnel, and patient-specific factors. This chapter reviews the different types of RRT and the indications and complications confronting the clinician in the ICU setting.

CASE STUDY

Mr. Smith is a 71-year-old male who was found unresponsive at home. He was intubated by EMS and in the Emergency department; his blood pressure was 70/42 mmHg and his heart rate was 134 bpm. His past medical history was notable for hypertension, for which he took an angiotensin-converting enzyme (ACE) inhibitor thiazide combination, and diabetes for which he took glipizide. On exam, he was an ill-appearing male with decreased skin turgor and right-sided bronchial breath sounds. His chest X-ray revealed multilobar pneumonia. The white blood cell count was 16,000 l, the serum creatinine was 1.4 mg/dL, and the blood urea nitrogen (BUN) was 34 mg/dL. He was started on broad spectrum antibiotics. Despite aggressive fluid resuscitation, he remained hypotensive, requiring two vasopressors for blood pressure support. The FiO_2 was 100%. By day 4, he remained on vasopressors and his urine output was 280 mL over 24 h, despite fluids. His chest X-ray showed pulmonary edema. The serum creatinine and BUN increased to 3.1 and 85 mg/dL, respectively. His serum potassium was 5.9 mmol/L. Multiple pigmented granular casts were seen on urine microscopy, consistent with the diagnosis of acute tubular necrosis. Nephrology was consulted for the possible need for renal replacement therapy (RRT).

The decision was made to start him on RRT. The indications were worsening hyperkalemia and uremia, as well as fluid management in an oliguric patient with volume overload. The patient's blood pressure was too low to tolerate intermittent hemodialysis (IHD). Continuous veno-venous hemodiafiltration (CVVHDF) with heparin anticoagulation was initiated. A right internal jugular dialysis catheter was placed. The patient remained stable on CVVDHF and was weaned off all but one pressor, while remaining in neutral fluid balance. His ultrafiltrate matched his fluid requirements (medications and vasopressors). Over the next 3 days, his serum potassium decreased to 3.6 mmol/L. The CVVHDF had no clotting events. However, termination of the CVVHDF treatment was required twice. Once for a CT scan of his chest and once for a bronchoscopy. On day 8, the nurse noticed bright red blood in his nasogastric tube. His partial thromboplastin time (PTT) was 64 s. (1.5× the normal range) and his hemoglobin had dropped by 2 g/dL. His heparin anticoagulation was stopped and he continued on CVVHDF, over the next 3 days. The filter, however, would clot at least once daily without anticoagulation and he required an additional transfusion for blood lost in the discarded filter and tubing.

Despite the recent GI bleed and transfusion requirements, his hemodynamics improved and the patient no longer required vasopressors. The decision was made to change the patient to thrice-weekly IHD. The patient tolerated 3 L of net fluid removal, per treatment. The patient was still unable to be weaned from the ventilator, and there was pulmonary edema present on chest X-ray. An extra treatment of dialysis was scheduled and an additional 3 L of ultrafiltrate was removed. The patient was successfully weaned and was extubated. The patient was transferred to the floor. Of note, on day 24, the patient's urine output increased to 2.5 L/day and creatinine began to decrease without dialysis. The patient was discharged to a skilled nursing facility, no longer requiring hemodialysis.

PHYSIOLOGIC PRINCIPLES OF DIALYTIC THERAPY

A review of the basic mechanisms of solute and water transport across semipermeable membranes is necessary to understand the relative efficacy of the different forms of dialysis therapy. Solute transport across a semipermeable membrane occurs via two different mechanisms, diffusion and convection. With diffusion, solute movement is driven by the solute concentration gradient between the two compartments (Fig. 54-1a) and is limited by the thickness and permeability of the membrane. Diffusive transport is more effective for molecules with a relatively lower molecular weight. In convection, solutes are dragged along with water when fluid moves from one compartment to another (Fig. 54-1b). This process is called ultrafiltration and is dependent on the hydraulic permeability of the membrane, as well as the hydrostatic pressure differential between the compartments. Solute transport is dependent on the volume of ultrafiltrate, the sieving capacity of the membrane, and the solute concentration in plasma water.

Dialysis is the technique wherein solutes are removed from a patient's blood through the use of a semipermeable membrane.

The diffusive transport of solute is dependent on both membrane permeability and solute molecular size. Convective transport is dependent on membrane hydrostatic permeability and transmembrane pressure gradient.

Dialysis Membranes

Dialysis membranes vary in composition, thickness, and their geometric design, factors that affect their ultrafiltration capacity and solute permeability. The four different types of membranes used for dialysis are (1) cellulosic, made from cotton; (2) cellulose substitute, made from cellulose acetate; (3) synthetic, made of a chemical polymer; and (4) cellulosynthetic, made from cellulose combined with a synthetic polymer (Table 54-1).

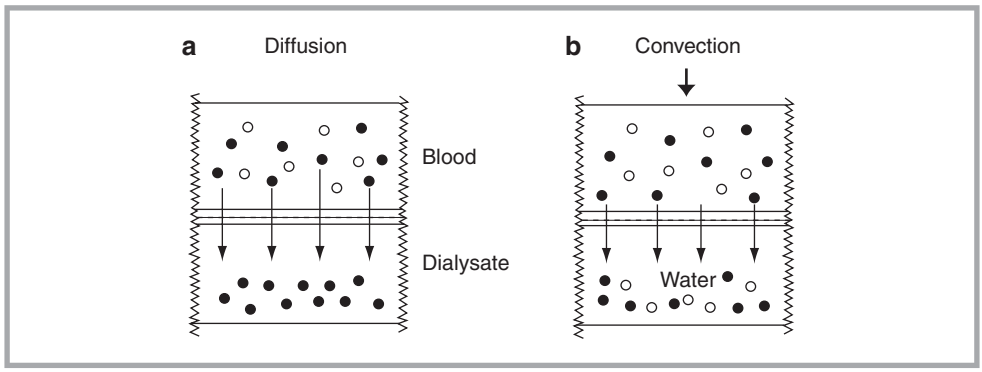

FIGURE 54-1

Basic mechanisms of solute and water transport across semipermeable membranes. (**a**) *Diffusion:* Solute movement is driven by the solute concentration gradient between the two compartments. The diffusion rate is limited by solute molecular weight and the thickness and permeability of the membrane. (**b**) *Convection:* Solutes are dragged along with water when fluid moves from one compartment to another; this is called ultrafiltration. The ultrafiltration rate is dependent on the hydraulic permeability of the membrane and the hydrostatic pressure differential between the compartments. Solute transport is dependent on the volume of ultrafiltrate and the sieving capacity of the membrane.

TABLE 54-1

COMPARISON OF DIALYTIC MEMBRANES

FILTER TYPE	SYNTHETIC	CELLULOSIC
Membrane	Polysulfone Polyamide Polyacrylonitrile (PAN) Polymethacrylate (PMMA)	Cuprophan (cellulose) Cellulose diacetate Hemophan (cellulosynthetic)
Geometry	Hollow fiber and plate	Hollow fiber and plate
Membrane thickness	Thick	Thin
Primary mechanism	Convection	Diffusion
Hydraulic permeability	High	Low
Removal of large molecules (>10^2 kDa)	Good (high sieving coefficient)	Poor (low sieving coefficient)
Biocompatibility	Good	Poor
Primary application	Continuous therapy, intermittent therapy	Intermittent therapy
Cost	High	Low

Over the last several years, synthetic membranes have replaced cellulosic membranes for IHD. Synthetic membranes are thick and have both higher hydraulic permeability and sieving capacity than the cellulosic membranes. Synthetic membranes are more dependent on convection for solute removal and are, thus, suitable for continuous therapies. The high convective component of continuous replacement therapy leads to large ultrafiltration volumes (15–20 L/day) and removal of solute over a wide range of molecular weights (10–40 kDa). Previously, the cellulose membranes were used most frequently. These membranes are thin, have a relatively low hydraulic permeability and a reduced sieving capacity, and are much more dependent on diffusion for solute removal. With synthetic membranes, small molecules (<20 kilodaltons, kDa) such as urea can be efficiently and rapidly removed without excessive fluid loss.

A replacement solution is often needed when synthetic filters are used because plasma electrolytes (bicarbonate, sodium, calcium, and phosphate) are also removed. The composition of the replacement fluid should be individualized and appropriate for each patient, often consisting of a modified saline solution with a buffer such as acetate or bicarbonate (Table 54-2). Because acetate is associated with vasodilatation and hypotension, during dialysis bicarbonate

TABLE 54-2

REPLACEMENT SOLUTION COMPOSITION

Electrolytes	Glucose
Sodium, 140–155 mmol/L	Buffers (one must be selected)
Potassium, 0–4 mmol/L	Bicarbonate
Calcium, 1.5–1.75 mm/L	Acetate
Magnesium, 0–0.75 mm/L	Lactate (converted to bicarbonate)
Chloride, 110–120 mm/L	Citrate

has largely replaced acetate as a buffer. The bicarbonate concentration can be adjusted on many machines, as indicated by individual patient needs and lab values. If calcium and magnesium replacement is necessary, they should not be mixed with bicarbonate solutions as they will precipitate.

RENAL REPLACEMENT MODALITIES

Intermittent Hemodialysis

Intermittent hemodialysis
- The most common dialysis prescription for AKI
- Requires complex machinery
- Requires a high blood and dialysate flow rate
- Achieves a rapid decrease in plasma solute concentration

IHD is the therapy most commonly used for the treatment of AKI in the intensive care unit.[1] This therapy is done in sessions lasting a few hours using a sophisticated machine and requires a specially trained nurse. Hemodialysis machines have a precise dialysate-preparing module, blood warmers, and antibubbling systems, and are primarily diffusion dependent with a higher dialysate flow rate (500 mL/min) compared to blood flow (200–300 mL/min). Blood flow runs countercurrent to the dialysate through the filter, where a rapid decrease in plasma and extracellular solute concentration occurs during a relatively short period of time (Fig. 54-2). IHD is relatively inefficient in removing intracellular solutes because of the delay in equilibration between compartments. A sudden rebound in plasma urea concentration is generally observed a few hours after dialysis has ended. Consequently, IHD fails to achieve complete purification of body fluid.

Complications Related to IHD

Acute hypotension is the most common complication of intermittent dialysis treatments (Table 54-3). When fluid is removed from the intravascular compartment, the oncotic pressure increases, and thus, promotes refilling from the interstitium. Hypotension may develop

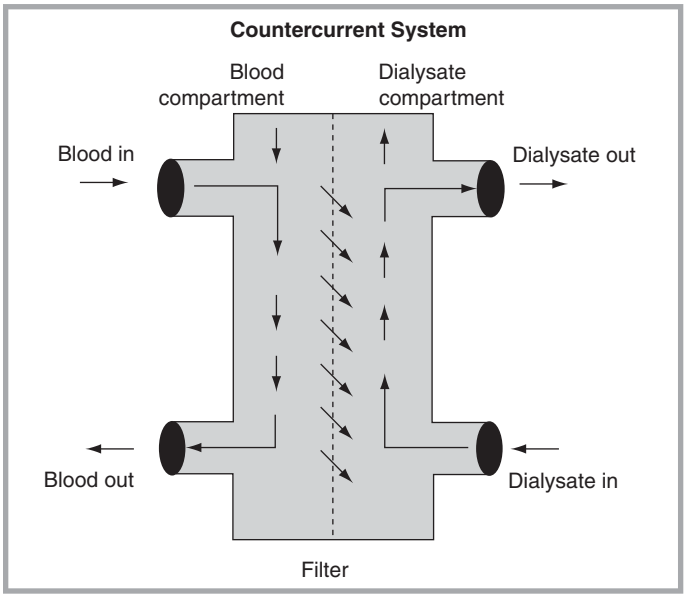

FIGURE 54-2

Blood flow runs countercurrent to the dialysate through the filter, where a rapid decrease in plasma and extracellular solute (*arrows*) concentration occurs over a relatively short period of time.

TABLE 54-3

COMPLICATIONS ASSOCIATED WITH INTERMITTENT HEMODIALYSIS

Severe hypotension	Hypoxemia and hypoventilation
Type A and B filter reactions	Bleeding
Dysequilibrium syndrome	Air embolism
Worsened brain edema	Cardiac arrythmias

if too much fluid is removed too fast or if mobilization of fluid from the interstitial compartment is impeded by the presence of heart failure, sepsis, or low oncotic pressure.[2] Moreover, the rapid removal of potassium or calcium can promote cardiac dysrhythmias, which can be further exacerbated by the rapid correction of acidemia with bicarbonate-rich dialysate.

Intermittent therapies may also cause what has become known as dysequilibrium syndrome. This syndrome is thought to occur because solute is removed from the intravascular space and serum osmolality decreases faster than that of the intracellular space. Water then shifts into the brain cells, causing cerebral edema. This syndrome can manifest by causing headaches, lethargy, disorientation, and seizures.

Dialysis Membrane Biocompatibility

No membrane material is completely biocompatible; however, some materials are less biocompatible than others. Cellulose membranes have the lowest biocompatibility and have been shown to induce cytokine release and complement activation via the alternative pathway when blood comes into contact with the polysaccharide membrane surface. Intense systemic complement activation leads to the release of the anaphylotoxins C3a and C5a and also results in both granulocyte and monocyte activation, with generation and release of proinflammatory reactive oxygen species, leukotrienes, and other cytokines. Thus, a potential adverse effect of hemodialysis membrane bioincompatibility, particularly in AKI patients, would include development or prolongation of the systemic inflammatory response syndrome (SIRS), characterized by fever, hypercatabolism, leukocytosis, and worsening of tissue injury.[3]

Adverse reactions resulting from dialysis membrane bioincompatibility have been subclassified as either immediate (type A) or delayed (type B).[2] Symptoms of a type A reaction occur immediately after the initiation of dialysis, but may be delayed for as much as 30 min. Patients may experience a sense of impending doom, dyspnea, urticaria, itching, and abdominal pain. Cardiac arrest and even death have also been reported. These reactions are thought to occur from substances in the dialyzer or contamination with bacterial peptides. The treatment is immediate cessation of the treatment without return of the patient's blood. Depending on the severity of the symptoms, the patient may require anaphylaxis therapy. Reactions occurring beyond 30 min after the initiation of dialysis therapy are more common, but less severe. These delayed reactions (type B) are most commonly manifested by subjective complaints of back or chest pain. They are most likely complement-mediated and the treatment is supportive. Complement activation lessens with the increased biocompatibility of the filter.

Synthetic membranes are increasingly used in the critically ill patient requiring hemodialysis. However, even these membranes are not without problems. Rarely, anaphylactoid reactions are observed in patients dialyzed on polyacronylnitrile (PAN; AN69) synthetic membranes who are receiving concomitant ACE inhibition. The electronegative surface charges of these membranes activate the kallikrein system and promote bradykinin generation. ACE inhibitors impair bradykinin degradation; thus, when they are used in combination with these membranes, circulating bradykinin levels can increase and cause hypotension and bronchospasm.[2] Discontinuation of ACE inhibitors or substitution of another filter, where possible, should be considered.

Continuous Renal Replacement Therapies

CRRT nomenclature can be at times confusing and include modalities known as CAVH (continuous arteriovenous hemofiltration), CAVHD (continuous arteriovenous hemodialysis), CAVHDF (continuous arteriovenous hemofiltration), CVVH (continuous veno-venous

TABLE 54-4

CONTINUOUS REPLACEMENT THERAPIES

	IHD	PD	SCUF	CVVH	CVVHD	CVVHDF
Vascular access	AV	None	AV/VV	VV	VV	VV
Pump	Yes	None	Sometimes	Yes	Yes	Yes
Blood flow (mL/min)	300	–	50	150	150	150
Dialysate flow (mL/min)	500	33[a]	None	None	16	16
Urea clearance (mL/min)	225	8.5[a]	1.7	17	30	30

IHD intermittent hemodialysis; *PD* peritoneal dialysis; *SCUF* slow continuous filtration; *CAVH* continuous arteriovenous hemofiltration; *CVVH* continuous veno-venous filtration; *CAVHD* continuous arteriovenous hemofiltration; *CVVHD* continuous veno-venous hemodialysis; *CVVHDF* continuous veno-venous hemodiafiltration
[a]Value is dependent on exchange rate. Numbers shown are based on an exchange rate of 2L every hour

hemofiltration), CVVHD (continuous veno-venous hemodialysis), CVVHDF (continuous veno-venous hemodiafiltration), and SCUF (slow continuous ultrafiltration). All these modalities employ the use of synthetic, highly permeable membranes, and differ with regard to how the circulatory system is accessed as well as their principal method of solute removal (Table 54-4).

Arteriovenous Modalities

These modalities depend on the patient's mean arterial pressure (MAP) as the driving force for blood flow across the membrane (Fig. 54-3). Vascular access requires two large-bore (8 Fr.) catheters, one arterial and the other venous, which are placed in the femoral vessels. The technique is relatively simple and driven by the arteriovenous pressure differential, which obviates the need for a blood pump and complicated machinery. The modalities are similar to the veno-venous modalities except in regard to blood flow, which is dependent on the systemic blood pressure. Blood flow may be unreliable in hypotensive patients and those with peripheral vascular disease. These modalities have been largely replaced by veno-venous modalities, which eliminate the risks of an arterial catheterization.

Continuous renal replacement therapies
- Employs synthetic, highly permeable membranes
- Employs low blood flow rate
- Achieves slow decrease in plasma solute concentration
- Better tolerated in patients who are hemodynamically unstable
- Heparin dosing should be adjusted to maintain minimal elevations in the PTT

Veno-Venous Modalities

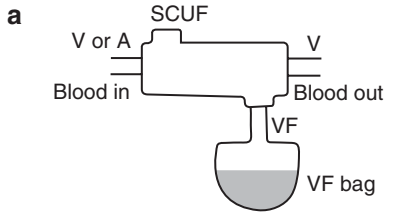
These modalities require that only a single large central vein is cannulated with a double lumen dialysis catheter. One port opening midcatheter (A) supplies blood to the filter and the other port (V) at the tip of the catheter is used to return blood to the patient (Fig. 54-3b, c). This procedure requires special dialysis equipment with a pump that permits continuous blood flow. In CVVH, solute removal is achieved by convective clearance. In addition to ultrafiltration, CVVHD also employs diffusive solute clearance with the addition of dialysis. The blood and dialysate flow through the filter in countercurrent directions so that the existing gradient across the membrane can be maintained at all times (Fig. 54-3c). The ultrafiltration rate is slower than in CVVH to protect against hypotension.[4] There is more solute clearance in CVVHD than in CVVH. In CVVHDF the blood flow rate ranges between 100 and 150 mL/min (Fig. 54-3b). Small molecules are removed by diffusion and larger molecules by convection. The dialysate flow is 1–2 L/h. Because of the large amount of ultrafiltration, replacement fluid is necessary.

SCUF

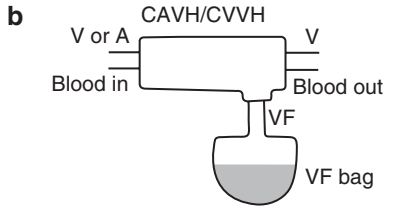
SCUF is similar to CVVH or CAVH, but the primary goal is removal of fluid and not solute (Fig. 54-3a). The usual blood flow ranges between 50 and 100 mL/min, adjusted to achieve an ultrafiltrate volume of 2–5 mL/min, and replacement fluid is generally not needed. This modality is useful for patients with heart failure.[5]

FIGURE 54-3

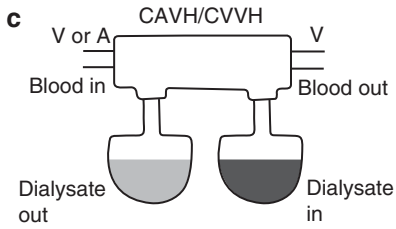
The nomenclature and circuitry of continuous renal replacement therapies. In (**b**) (continuous arteriovenous hemofiltration), (**d**) (continuous arteriovenous hemodialysis), and (**d**) (continuous arteriovenous hemofiltration), the transmembrane gradient is dependent on the difference between the venous (V) and arterial (A) pressure. In (**b, c**) (continuous veno-venous hemofiltration), (**d**) (continuous veno-venous hemodialysis), and (**d**) (continuous veno-venous hemodiafiltration), a perfusion pump on the venous (*blood in*) is required to maintain the transmembrane pressure gradient.



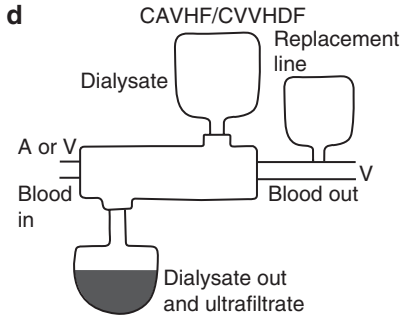
Slow Continuous Ultrafiltration
-blood flow (Qb) 50-100 ml/min
-ultrafiltration rate (Qf) 2-5 ml/min
-an artery or a vein can be used
-indicated in fluid overload (CHF)



Continuous Hemofiltration
If an artery and a vein are used-CAVHD
If two veins are used-CVVHD
(need a machine pump)
-blood flow (Qb) 50-200 ml/min
-ultrafiltration rate (Qf) 8-25 ml/min
-replacement fluid is needed
-no dialysate is used
-clearance of solute occurs by convection



Continuous Hemodialysis
If an artery and a vein are used-CAVHD
If two veins are used-CVVHD
-CAVHD blood flow (Qb) 70-100 ml/min
-CAVHD ultrafiltration rate (Qf) 10-15 ml/min
-CVVHD blood flow (Qb) 50-200 ml/min
-CVVHD dialysate flow (Qd) 15-30 ml/min
-dialysis soultion is used
-solute clearance mainly occurs by diffusion
-replacement solution is not needed



Continous Hemodiafiltration
-blood flow (Qb) 50-200 ml/min
-ultrafiltration rate (Qf) 8-12 ml/min
-dialysate flow (Qd) 10-20 ml/min
-dialysis soultion is used
-solute are removed by convection and diffusion
-replacement solution is needed

Specific Problems of Continuous Renal Replacement Therapies

Vascular Access

A vascular access is achieved at the bedside by percutaneously placing a noncuffed double lumen catheter into a central vein. These catheters can be inserted in either the femoral or internal jugular veins at the bedside. The size of the catheters most commonly used for dialysis is 11.5 Fr. These catheters provide a blood flow that varies between 250 and 350 mL/min. The subclavian vein should be avoided because venous stenosis may develop that can compromise the use of the ipsilateral arm if the patient requires permanent vascular access. Before starting dialysis, proper position of catheters should be confirmed by chest X-ray. It is recommended that all noncuffed catheters be changed at least every 3 weeks. Catheters used for femoral venous access should be at least 19 cm in length and should not be kept in place for more than 5 days because of the high risk of infection.[6]

Circuit Clotting and Anticoagulation

Patency of the extracorporeal circuit and the integrity of the dialysis membrane are important in maintaining the efficacy of RRT. Filter integrity is less problematic in IHD compared to CRRT because IHD is done over a shorter period of time with higher blood flows. The exposure of blood and plasma to the filter membrane results in the activation of the coagulation factors, clotting, and ultimately filter failure. Heparin is used commonly to achieve regional anticoagulation and prolong filter life. Other agents such as citrate and argatroban have also been used.[7] Heparin is usually infused prefilter (arterial access side) (see Fig. 54-3) as a loading dose of 5–10 U/kg and at a maintenance rate of 3–12 U/kg/h. Regulating anticoagulation to maintain the permeability of the filter can be one of the most difficult problems in CRRT. The viability of the filter needs to be monitored; it typically lasts up to 72 h. When clots are visible in the tubing or filter, the filter must be replaced as the efficiency of the filter has been compromised. Anticoagulation has been reported to cause bleeding in 5–26% of patients on CRRT. The heparin dosage should be reduced to maintain minimal elevations in the PTT. Other efforts to prolong filter life include infusing the replacement fluid prefilter to, in effect predilute the blood. Factors that may impact the longevity of the filter include a reduced blood flow in the extracorporal circuit and hypercoagulable disorders, such as disseminated intravascular coagulation (DIC), heparin-induced thrombocytopenia (HIT), and antithrombin III deficiency.

Hypothermia and Filter Reactions

A mild reduction in core temperature often occurs among patients receiving CRRT; this appears to be more prevalent with replacement of large volumes of ultrafiltrate. Simple rewarming of the replacement fluid or the returning blood in the venous circuit may prevent or reduce the degree of hypothermia. Filter reactions on CRRT have been discussed earlier.

PERITONEAL DIALYSIS

Despite the advances in hemodialysis, PD represents a viable renal replacement alternative. In this type of dialysis, the peritoneum is used as the semipermeable membrane. Here, 1–3 L of dextrose- and salt-containing solution is introduced into the peritoneal cavity and is allowed to dwell for 1–6 h. Diffusive clearance occurs because of the concentration gradient that exists between the peritoneal capillary network and the dialysate.[2] The ultrafiltration rate (convective clearance) is dependent on the concentration of the glucose (1.5, 2.5, or 4.25%) in the dialysate; the higher the glucose concentration, the better the ultrafiltration. Shortening the dwell times to 1 h, and thus, increasing the cycle frequency can increase the ultrafiltrate volume. However, because of a lower efficiency, PD may not adequately remove sufficient waste products for patients who are hypercatabolic.[8]

Peritoneal dialysis
- Employs the peritoneal cavity as a dialysis membrane
- Dialysate is instilled into the peritoneal cavity and then drained
- Requires placement of peritoneal catheter
- Efficiency is dependent on cycle length

PD has been largely abandoned in the ICU as a treatment of AKI in favor of extracorporeal dialytic modalities. PD requires surgical placement of a peritoneal catheter and may be contraindicated for patients suffering from burns or abdominal sepsis or for those with a history of abdominal surgery. Moreover, this modality is limited in the ICU because of its impact on respiration. The increased abdominal pressure caused by the PD fluid may limit diaphragmatic excursion and compromise ventilation among patients with respiratory insufficiency.[9] Despite these disadvantages, PD may be more appropriate in certain circumstances. It may be useful for patients with severe congestive heart failure (CHF) or severe hypotension because dialysis is not dependent on extracorporeal blood flow. It also does not require anticoagulation, and thus, can be used safely for patients who have a high risk of bleeding or when anticoagulation is contraindicated.

General indications for initiating dialysis therapy:
- Therapy is indicated for patients who manifest clinical evidence of uremia or biochemical evidence of solute or fluid imbalance.

GENERAL INDICATIONS FOR INITIATING DIALYSIS IN THE ICU

General indications for dialysis therapy are listed in Table 54-5. There is no consensus on the optimal timing for the initiation of dialysis therapy in the critically ill patient with AKI; RRT is usually considered for patients who manifest clinical evidence of uremia (pericarditis, encephalopathy, hemorrhage) or biochemical evidence of solute or fluid imbalance. Dialysis is usually not initiated in end-stage renal disease (ESRD) until the creatinine clearance is less than 10 mL/min. Extrapolation of this criterion to critically ill patients in the ICU is inappropriate because AKI is a nonsteady-state process with daily fluctuations in body water, catabolic rate, and urea production. Biochemical disturbances such as hyperkalemia, marked acidosis, uremia, and fluid overload are the most common renal-related indications for RRT.

Renal Indications

Hyperkalemia

The most common cause of hyperkalemia in the ICU is a decrease in renal excretion. The kidney has a large capacity to excrete potassium, and patients usually become hyperkalemic only when the GFR is less than 10 mL/min. Nonrenal causes of hyperkalemia are the result of shifts in potassium from the intracellular to the extracellular space that may occur among patients who are hyperosmolar, or have rhabdomyolysis syndromes, tumor lysis syndrome, or inorganic acidosis. Hyperkalemia resulting from increased potassium intake is unusual if renal function is normal. However, patients who receive rapid IV or oral potassium administration can develop hyperkalemia. Falsely elevated potassium levels can be seen in thrombocytosis (platelet counts >500,000/mL), leukocytosis (leukocyte counts >100,000/mL), or when blood is collected while using a tourniquet and contracting the muscle to increase blood return.

Acidosis

Patients with severe acidosis resulting from AKI may benefit from dialysis. The use of exogenous bicarbonate therapy to control acidemia has been controversial.[10] Bicarbonate therapy can worsen the condition of critically ill patients by causing volume overload and hypernatremia. Rapid correction of acidosis can be accomplished with IHD by using a bicarbonate-rich dialysate (35–38 mEq/L), which allows back diffusion across the membrane into the blood. However, the clinician should be aware that metabolic alkalosis may occur at the end of IHD, which can promote hypokalemia and symptomatic hypocalcemia.

Uremia

A BUN greater than 100 mg/dL usually indicates a severely decreased glomerular filtration rate (GFR <10 mL/min). However, many nonrenal conditions can elevate BUN to this level. In general, urea is a poor index of GFR because it is filtered and then reabsorbed by the renal tubule. Among patients with a reduction in circulating blood volume or low renal perfusion, the BUN can become markedly elevated compared with creatinine. Other conditions such as

TABLE 54-5

INDICATIONS FOR DIALYSIS IN THE INTENSIVE CARE UNIT

Renal	Nonrenal
Hyperkalemia (K^+>6.5)	Toxic ingestion
Acidemia	Volume overload secondary to:
Uremia (pericarditis, encephalopathy, GI bleeding)	Hyperalimentation
Volume overload secondary to renal failure	Heart failure with pulmonary edema
	Liver failure
	Hypertransfusion

gastrointestinal hemorrhage, corticosteroid use, and excessive protein ingestion (total parenteral nutrition [TPN], or enteric nutrition) may cause high levels of circulating urea that are often the result of catabolic mechanisms.

Hypervolemia

There is evidence that volume overload may be an independent risk factor for mortality in patients in the ICU.[11] It is not uncommon for critically ill patients to have in excess of 10 L of extravascular fluid. The rate of volume removal should be monitored closely without compromising hemodynamic stability. Once the optimal volume status has been achieved, RRT can be prescribed according to the anticipated fluid administration requirements (intravenous fluids, TPN, antibiotics) and guided by the objective measurements of intravascular volume and mean arterial blood pressure.

Nonrenal Indications

Toxins or Drug Removal

Hemodialysis can be used to treat life-threatening intoxications. The removal of a toxin or drug by hemodialysis depends on biochemical properties that include protein binding, water and lipid solubility, state of ionization, and molecular size. Moreover, hemodialysis can correct the metabolic acidosis that results from certain toxins (methanol, aspirin, and ethylene glycol). Hemoperfusion is a form of dialysis in which a resin-containing cartridge is used to bind the offending toxin (Table 54-6).

Hyperalimentation

Protein-caloric malnutrition has been implicated as one of the factors that contribute to the high mortality among critically ill patients with AKI.[12] Nutritional depletion has been associated with increased nosocomial infections, reduced or delayed wound healing, tissue repair, and muscle weakness, all of which may complicate weaning from the ventilator. Frequently, aggressive nutritional support can be provided only if dialysis is used to compensate for the large amounts of fluid associated with parenteral nutrition administration.

Congestive Heart Failure (CHF)

Among patients with severe heart failure, the low cardiac output and resulting renal hypoperfusion may lead to an increase in the levels of circulating renin, angiotensin, aldosterone, catecholamines, and antidiuretic hormone (ADH). These pathophysiologic events serve to further increase sodium and fluid retention, and the patient may become refractory to medical therapy. Isolated ultrafiltration (intermittent or SCUF) can be used effectively to reduce

TABLE 54-6

DIALYSIS FOR TOXIC INGESTIONS: INDICATIONS FOR HEMODIALYSIS AND/OR HEMOPERFUSION

DRUG	LEVEL
Amphetamine	–
Barbiturates	5 mg/dL
Glutethimide	4 mg/dL
Methaqualone	4 mg/dL
Aspirin	80 mg/dL
Theophylline[a]	30–40 mg/dL
Methanol	50 mg/dL
Ethylene glycol	50 mg/dL
Lithium	2.5 mEq/L

[a]Hemoperfusion is preferred

fluid retention in these patients.[5] Some of these patients may exhibit an improvement in their heart failure and a return of renal function. For others, this technique can buy time until a more definitive therapy such as heart transplantation is available.

Liver Failure

Patients with liver failure may have azotemia resulting from a variety of pathophysiologic abnormalities, such as prerenal azotemia, acute tubular necrosis, acute interstitial nephritis, glomerular diseases (IgA nephropathy, cryoglobulinemia, and glomerulonephritis), as well as hepatorenal syndrome. Hepatorenal syndrome is a condition characterized by reduction of renal function due to liver failure. Hepatorenal syndrome is usually a diagnosis of exclusion as these patients have no evidence of intrinsic renal disease and do not respond to volume expansion. CRRT is often the therapy of choice for these patients given the hemodynamic instability.[13] Hepatorenal syndrome carries an extremely high mortality rate without liver transplantation. RRT is usually reserved for those patients who are candidates for liver transplantation. The utilization of anticoagulation to maintain patency of the extracorporeal circuit should be done cautiously as many of these patients have bleeding disorders.

CHOICE OF RENAL REPLACEMENT THERAPY IN THE CRITICALLY ILL PATIENT

Choice of RTT in the critically ill patient:
- Recurrent hypotension has been strongly associated with a delay in functional renal recovery.

The choice of dialytic therapy is often dependent on the (1) clinical indication for dialysis, (2) the presence of other organ system dysfunction, (3) availability of vascular access, (4) the technical support and training of personnel, and (5) anticipated duration of dialysis therapy (Fig. 54-4). The advantages and disadvantages of each of these modalities are presented in Tables 54-7–54-9. There is only limited information comparing the efficacy of CRRT vs. IHD in the treatment of AKI in the critically ill patient. If the indications for dialysis were hyperkalemia or toxic ingestion, IHD would be the most effective prescription. On the other hand, the majority of patients in the ICU have some degree of hemodynamic instability that makes IHD risky. Recurrent hypotension has been strongly associated with delay in functional renal recovery by further aggravating hypoperfusion-mediated renal ischemic injury. CRRT is generally better tolerated in hemodynamically unstable patients because the removal of solutes and water is slower and achieved over a prolonged period of time, allowing increased time for mobilization of fluid from the extravascular compartment.[4] Moreover, the rapid compartmental shifts of electrolyte and solute concentration can be avoided. Typically, IHD raises intracranial pressure (ICP).[14] CRRT may also be the therapy of choice in conditions associated with increased ICP such as subarachnoid hemorrhage or hepatorenal syndrome.[15] One disadvantage to CRRT is that continuous anticoagulation is required to prevent frequent clotting of the circuit, whereas IHD can be performed more easily without the use of anticoagulation.

When to Initiate Replacement Therapy?

While many of the fluid and electrolyte disturbances can be managed in the intensive care unit setting, it is common to initiate RRT before the signs and symptoms of overt uremia. The current literature suggests that outcomes are improved for patients who are started "early" on RRT. This concept was first proposed by Teschan et al in the 1960s. They recommended starting RRT when the BUN was 90–100 mg/dL.[16] More recently, Gettings et al showed in 100 critical trauma patients that survival was improved nearly twofold greater in those started with a BUN <60 as opposed to those with a BUN >60.[17] Demirkiliç et al also showed reduction of days in the ICU on mechanical ventilation, and an overall improvement in survival for cardiac surgery patients started when the urine output was less than 100 mL/8 h despite furosemide.[18] Lastly, analysis of the data from the PICARD (The Program to Improve Care in Acute Renal Disease), a large observational study from five academic medical

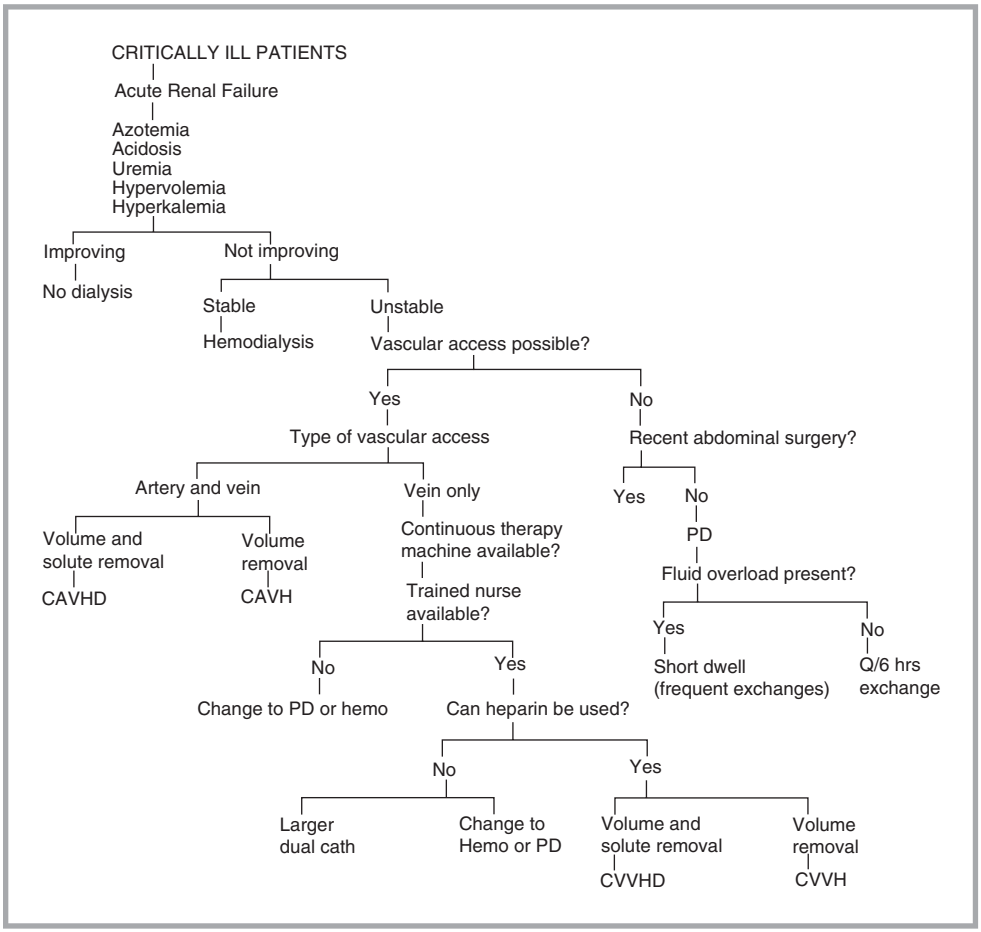


FIGURE 54-4

Algorithmic approach to renal replacement therapeutic (RTT) management of the critically ill patient with acute renal failure. *PD* peritoneal dialysis.

TABLE 54-7

INTERMITTENT HEMODIALYSIS

ADVANTAGES	DISADVANTAGES
Rapid correction of hyperkalemia	Hypotension is common
High ultrafiltration capacity	Dysequilibrium syndrome
Efficient drug/toxin removal	Complex machine
Allows time for dialysis independence	Technical personnel required
Can be used without anticoagulation	Poor solute control

TABLE 54-8

CONTINUOUS HEMODIALYSIS

ADVANTAGES	DISADVANTAGES
Technically simple	Frequent filter clotting
Hemodynamically well tolerated	Anticoagulation often necessary
High membrane sieving and adsorptive capacity	Large amounts of dialysate and replacement fluid needed
No solute concentration rebound	Requires 1:1 nursing staffing
Stability of total body solute and fluid balance	

TABLE 54-9

PERITONEAL DIALYSIS

ADVANTAGES	DISADVANTAGES
No machines needed	Low efficiency
No need for anticoagulation	Risk of peritoneal access
Hemodynamically well tolerated	Respiratory compromise
No need for vascular access	Protein losses
Easy monitoring	

centers, showed that the relative risk of death was 2 times greater in those started with a higher BUN.[19] Critics of this data, however, argue that the outcomes are artificially inflated as many of those patients started "early" would have recovered without RRT and were generally less ill. Many of these studies had a small number of patients enrolled; a recent large metaanalysis found no statistically significant difference between "early" vs."late" patient-groups.[20,21]

Dosing and Modality

A great deal of controversy exists regarding the dosing of RRT and modality in the ICU. Nonetheless, most would agree that patients get less than their prescribed dose. This is attributed to both interruptions in the schedule secondary to procedures and hemodynamic instability, as well as the catabolic state of the critically ill patient. Several studies have shown that outcomes are improved with increasing the dialysis prescribed dose. Most notably, Ronco, et al showed in critically ill patients on CVVH that a higher dialysis dose (35–45 mL/h/kg of effluent) had a twofold increase in survival, especially in patients with sepsis.[22] The study was done with CVVH, and CVVHDF is currently the preferred method and has been shown superior in small studies as well as metaanalyzes.[20,21,23] Another landmark paper by Schiffl et al compared daily vs. IHD and showed that patients on daily dialysis had decreased mortality and decreased time to renal recovery.[24] These findings had not been reproduced in large meta-analyses. A large recent study of over 1,100 patients by the VA/NIH Acute Renal Failure Trial Network did not demonstrate any differences in intensive 6 days a week IHD vs. 3 times a week or higher dose CRRT. Intensive RRT in critically ill patients did not decrease mortality, improve recovery of kidney function, or reduce the rate of nonrenal organ failure as compared with less intensive therapy.[25]

SUMMARY

RRT for the critically ill patients has evolved differently than therapy for patients with ESRD. Despite significant advances in therapy, the associated mortality from AKI among patients with multiple organ dysfunction remains high, and the clinical impact of RRT on patient outcome remains unclear. Precise indications for RRT prescription for the critically ill patient and the timing for initiation of RRT have yet to be clearly defined. Consideration as to which form of RTT is best should be given to the available resources, the clinical situation, and the needs of the individual patient.

REVIEW QUESTIONS

1. **Solutes are removed during dialysis by which of the following mechanisms?**
   - **A.** Diffusion
   - **B.** Convection
   - **C.** A and B

2. **A patient develops chest and back pain, dyspnea, and hypotension 5 min after starting dialysis therapy. What is the most likely diagnosis?**
   - **A.** Acute allergic reaction to heparin sulfate
   - **B.** Dissecting aortic aneurysm
   - **C.** First-use dialysis syndrome (type A)
   - **D.** Acute myocardial infarction

3. **Synthetic membranes interact less with plasma components than cellulose membranes.**
   - **A.** True
   - **B.** False

4. **Which of the following CRRT does not require a pump?**
   - **A.** CVVHD
   - **B.** CVVH
   - **C.** CAVHD
   - **D.** CVVHDF

5. Which of the following is the most common complication of dialytic therapy?
- **A.** Air embolism
- **B.** Hypotension
- **C.** Headache
- **D.** HIT

6. A 4-year-old diabetic is admitted to the ICU with acute on chronic renal failure and sepsis. The decision to initiate dialysis therapy is made. Which of the following vascular access sites is the least appropriate for the placement of the dialysis catheter?
- **A.** Femoral vein
- **B.** Subclavian vein
- **C.** Right internal jugular vein
- **D.** Left internal jugular vein

7. A 25-year-old patient with HIV nephropathy is admitted to the intensive care unit with a serum potassium level of 8 mEq/dL. The best dialytic modality for this patient is
- **A.** CVVHD
- **B.** IHD
- **C.** PD
- **D.** CAVHD

8. A 41-year-old man with a dilated cardiomyopathy and left ventricular ejection fraction of 5% is admitted to the ICU with oliguric renal failure that is refractory to diuretics and a serum creatinine of 7 mg/dL. His systemic blood pressure is 80/50. Which dialytic modality would be the least appropriate?
- **A.** CVVHDF
- **B.** IHD
- **C.** PD
- **D.** CAVHD

9. A 52-year-old male patient with end-stage liver disease awaiting liver transplantation is admitted to the ICU with hepatic encephalopathy, hypotension, and oliguric renal failure. On admission, temperature is 38°C, BP is 80/50 mmHg, RR is 30/min, and HR is 110/min. On physical exam he is lethargic but arousable. His abdomen is distended with a fluid wave and there is 3+ edema. His serum BUN and creatinine are 106 and 3.0 mg/dL, respectively. His prothrombin time is 29 (INR of 3.0). Which form of dialytic therapy would be the most appropriate?
- **A.** CVVHDF
- **B.** PD
- **C.** Intermittent dialysis
- **D.** CAVHD

ANSWERS

1. The answer is C. Solutes are removed through a semi-permeable membrane by two mechanisms, diffusion and convection. In diffusion, the movement of solute from one compartment to another is driven by an electrochemical gradient. Smaller molecules have more kinetic energy and are preferentially removed according to the size of the concentration gradient. Larger molecules are removed inefficiently or not at all. Solute movement continues until equilibrium is reached between the compartments. With convection, solutes are dragged from one compartment to the other along with fluid. The membrane only stops molecules larger than the membrane pore size and larger molecules are removed more efficiently. Dialysis uses a combination of both convection and diffusion.

2. The answer is C. First-use dialysis reaction (type A) is the result of the activation of leukocytes and plasma proteins with a fresh dialysis filter membrane.

3. The answer is A. Cellulose membranes (cellulose and cellulose acetate) are much less biocompatible and are more likely to result in complement and leukocyte activation. Although synthetic membranes are more biocompatible, they are more costly.

4. The answer is B. Hypotension is the most common complication of dialysis therapy. Hypotension may develop if too much fluid is removed too fast or if mobilization of fluid from the interstitial compartment is impeded by the presence of heart failure, sepsis, or low oncotic pressure.

5. The answer is C. In CVVH, CVVHD, and CVVHDF, a roller pump on the venous (blood-in) line creates hydrostatic pressure, which drives the solvent through the membrane and is required to maintain the transmembrane pressure gradient.

6. The answer is B. The subclavian vein is not a preferred catheterization site because catheter kinking and compromised blood flow may occur in this location. Subclavian catheters also have a greater risk of causing stenosis and thrombosis, which may affect the effluent branches of the superior vena cava, innominate vein, and brachiocephalic truncus. Catheterization of the internal jugular vein is far less likely to cause thromboses and stenoses, but the site is more prone to infection, particularly in patients with a tracheostomy. Femoral access is preferred because spontaneous reductions of blood flow through the catheter occur less frequently in the femoral vein compared to the jugular and subclavian sites. Improved blood flow improves filter life and hemodialysis efficacy.

7. The answer is B. Hyperkalemia frequently accompanies AKI, crush injury, or any massive tissue destruction. Rapid removal of potassium is required, which is not possible with slow continuous hemodialysis or PD.

8. The answer is C. IHD rapidly removes intravascular fluid by ultrafiltration, which is followed by delayed refilling from extravascular spaces. This intravascular hypovolemia is poorly tolerated in patients with systolic dysfunction, and the increased vasoconstriction leads to activation of the renin angiotensin system, further aggravating renal dysfunction and heart failure. Slow continuous hemofiltration avoids the roller coaster periods and beneficially affects cardiac function even in end-stage, diuretic-resistant cardiomyopathy. As preload declines and ventricular filling pressures improve, the patient achieves a more favorable point on the Starling curve. Improvement in cardiac function often results in improved renal function and diuretic sensitivity. Slow ultrafiltration techniques are most suitable as initial treatment of CHF resistant to conventional medical therapy or in emergent situations of sudden cardiac decompensation. PD is better suited as long-term maintenance therapy for those patients who are not candidates for heart transplantation.

9. The answer is A. Continuous RRT is preferred in patients suffering from acute hepatic failure with elevated ICP, which is the major cause of death in these patients with stage IV hepatic encephalopathy. CRRT can be used as a bridge for liver transplantation in acute on chronic hepatic failure or hepatorenal syndrome. Because the MAP and serum osmolality remain relatively stable during CRRT, cardiovascular stability is achieved in patients with cirrhosis renal failure.

CHAPTER 55

FIROOZEH ALVANDI, SALEH AYACHE, ELIZABETH T. DRUM, AND JAY H. HERMAN

Use of Blood Components

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Describe the composition of the different components extracted from whole blood.
- Assess the impact of anemia, particularly in critical care patients and patients with cardiovascular disease.
- Recognize clinical indications, clinical thresholds, and contraindications for the use of specific blood components.
- Recognize various aspects of platelet refractoriness.
- Recognize the risk associated with transfusion.
- Describe the modifications to blood components and recognize the indications for the use of modified blood components.
- Identify alternatives and adjuncts to allogeneic blood component transfusion.

INTRODUCTION

Physicians who work in the ICU often encounter patients with complex transfusion requirements. Optimal management of transfusion needs requires careful assessment of a given patient's clinical condition, an understanding of current state-of-the-art transfusion practices, and the associated risks and benefits. Judicious use of blood as a valuable, often life-saving, yet not entirely risk-free resource is paramount. The decision to transfuse should be

CASE STUDY: Part 1

A 69-year-old male with a history of coronary artery disease, hypertension, and stroke, was admitted to the hospital for urgent coronary artery revisualization. The patient was on a daily antiplatelet therapy which was discontinued on the day of the procedure, and two ABO compatible, leukocyte-reduced apheresis platelet concentrates were transfused in an effort to prevent bleeding during the procedure. Forty-five minutes after the transfusion but before the procedure, the patient became tachypneic, tachycardic, and dyspneic with pulse oximetry saturation of 83% on 100% rebreather, hypotensive (55/35 mmHg), and febrile (100°F). Chest auscultation revealed a new finding of bilateral rales. Respiratory support including intubation and mechanical ventilation was initiated immediately. There was no evidence of rash, angioedema or bronchospasm, cardiac arrhythmia, ischemia, or hemorrhage. The physician ordered a chest X-ray, which showed bilateral diffuse airspace infiltrates consistent with pulmonary edema, a change from the clear lung fields on the X-ray from the previous day. Diuresis was initiated but did not result in significant improvement of the pulmonary edema. Transient leukopenia was evident on a CBC obtained 2 h after the reaction began. Blood bank laboratory workup revealed no evidence of hemolysis, and no clerical or laboratory error. The patient was weaned from ventilation with almost complete recovery of respiratory function within 48 h of the onset of the acute reaction.

What is the differential diagnosis of the causes of this transfusion reaction?
What is the most appropriate next step in the workup?
What is the most likely pathophysiologic mechanism of this reaction?

The decision to transfuse should be based on careful assessment of clinical indications and with minimal reliance on preset transfusion algorithms or laboratory values.

When a decision is made to transfuse, informed consent must be obtained prior to transfusion whenever possible.

Whole blood is collected from volunteer donors who must undergo a detailed health questionnaire and meet donor eligibility criteria.

Every donation undergoes a battery of tests for the detection of infectious agents.

Blood banks have extensive policies and procedures in place to optimize the safety and efficacy of the transfusion process.

Diligent and meticulous clerical checks to positively identify the intended recipient and the unit of blood issued for transfusion begin in the laboratory and continue into the clinical setting where positive identification of the patient and confirmation of correct blood unit assignment are again required before the blood product is administered.

based on careful assessment of clinical indications with minimal reliance on preset transfusion algorithms or laboratory values ("transfusion triggers").

When the decision is made to transfuse, informed consent must be obtained prior to transfusion whenever possible. While the safety of the blood supply has improved over time, the risks associated with transfusion have not been completely eliminated.

This chapter reviews blood component therapy for critically ill patients, including basic information regarding component composition and the collection process, indications for and associated adverse sequelae of transfusion and massive transfusion, modifications to blood components, and some alternatives and/or adjuncts to allogeneic transfusion.

BLOOD DONOR SCREENING AND OTHER MEASURES TO ENHANCE TRANSFUSION SAFETY

Whole blood is collected from volunteer donors (without remuneration or other form of compensation) who must undergo a detailed health questionnaire and meet donor eligibility criteria intended to enhance the safety of the donation process for the donor and the safety of the blood supply for the transfusion recipient. Although every donation undergoes a battery of tests, strict adherence to the donor criteria (prescreening process) helps identify individuals whose behavior may place them at risk for compromising the potency, purity, and/or efficacy of blood components. Basic measures such as proper collection technique and clean, optimized storage conditions in the blood bank further enhance the overall safety of transfusion.

Blood banks have extensive policies and procedures in place to ensure the safety and efficacy of the transfusion process, from component storage to proper patient identification and specimen processing. The regulations are particularly stringent concerning correct patient sample (specimen) identification. Lack of strict adherence to such regulations (proper specimen labeling) can result in misidentification of patients and potentially erroneous transfusions, which may lead to detrimental outcomes for the recipient. Diligent and meticulous clerical checks to positively identify the intended recipient and the unit of blood issued for transfusion begin in the laboratory and continue into the clinical setting where positive identification of the patient and confirmation of correct blood unit assignment are again required before the blood product is administered.

WHOLE BLOOD AND COMPONENT PREPARATION

Whole blood is rarely available for allogeneic use. Generally, a whole blood donation of 500±50 mL is separated into red blood cells (RBCs), platelet concentrate (PC), and the plasma portion which is usually rapidly frozen to provide fresh-frozen plasma (FFP) and which may be further processed into cryoprecipitate. Whole blood can be stored for up to 35 days at refrigerated temperatures of 1–6°C. It is used mainly for autologous (donated by the recipient) transfusion and, in limited situations, where replacement of both volume and oxygen-carrying capacity are needed (loss of RBCs accompanied by acute loss of volume).

Generally, a whole blood donation is separated into RBCs, platelet concentrate, and FFP which may be further processed to make cryoprecipitate.

RBCs can be stored for up to 42 days at refrigerated temperatures of 1–6°C.

RED BLOOD CELLS

A need to increase oxygen-carrying capacity is the only indication for transfusion of RBCs. Usually, acute hemorrhage in otherwise healthy individuals can initially be managed with colloid or crystalloid infusion, followed by blood transfusion in more severe hemorrhage.[1,2] In acute anemia, the body attempts to maintain oxygen delivery to the tissues by increasing stroke volume and heart rate, which leads to an increased cardiac output.[3,4]

The indication for transfusing RBCs is to increase oxygen-carrying capacity.

If volume is the only deficit, this can be addressed with crystalloid and colloid solutions.

Response to Anemia

In chronic anemia, diminished oxygen-carrying capacity is compensated by an increased cardiac output, recruitment of additional capillaries, redistribution of blood flow (from peripheral tissue to cardiac and central nervous system), and increased production of 2,3-diphosphoglycerate (2,3-DPG) by RBCs. In addition, acidosis, if present, will result in a decreased affinity of hemoglobin for oxygen; this decreased affinity leads to an increased release of oxygen at the tissue level.[1-7]

When assessing a patient's ability to tolerate or compensate for the effects of anemia, it is important to keep in mind the acuity of the anemia (acute vs. chronic), and to be aware of the numerous factors that may affect compensatory mechanisms. In anemic patients with cardiac dysfunction, and those taking vasoactive cardiac medications, these compensatory mechanisms may be compromised. Anesthetized (general anesthesia) patients, on the other hand, may have decreased cerebral and cardiac oxygen demands and lower blood pressure, stroke volume, cardiac output, and peripheral vascular resistance.[2,8]

When determining when to transfuse, considerations include the duration of the anemia, and whether there is an increased oxygen requirement as would be expected in patients with fever, in pain, or with impaired cardiac and/or pulmonary function.

Oxygen transport can be decreased secondary to anemia or hypovolemia and thus it is important to recognize and distinguish between the effects of acute anemia and hypovolemia.[2] In patients with hypovolemic anemia, where both red cell mass and plasma volume are reduced, the hematocrit and hemoglobin may initially appear normal or artificially high. In chronic anemia, an expanded plasma volume may have the opposite effect on the measured hematocrit and hemoglobin. This should be taken into consideration before transfusion, especially in patients with expanded plasma volume who could be at risk for fluid overload.

When assessing a patient's ability to tolerate or compensate for the effects of anemia, it is important to keep in mind the acuity of the anemia.

In acute anemia, the body attempts to maintain oxygen delivery to the tissues mainly by increasing stroke volume and heart rate to increase cardiac output.

In chronic anemia, diminished oxygen-carrying capacity is compensated by increased cardiac output, recruitment of more capillaries, redistribution of blood flow (from peripheral tissue to cardiac and central nervous system), and increased RBC production of 2,3-DPG.

Clinical Thresholds for Red Blood Cell Transfusion in Critically Ill Patients

In recent years, a trend toward a more restrictive approach to transfusion therapy has emerged.[9,10] For example, as per the American Society of Anesthesiologists Task Force transfusion guidelines, RBC transfusion is rarely indicated when the hemoglobin (Hgb) concentration is above 10 g/dL and is usually indicated when the hemoglobin is less than 6 g/dL.[2]The decision to transfuse in patients with hemoglobin levels between 6 and 10 g/dL should be based primarily on the patient's symptoms and risks for complications and comorbidities.

In recent years, a trend toward more restrictive transfusion approach has emerged.

RBC transfusion is rarely indicated when the hemoglobin concentration is above 10 g/dL and is generally indicated when the hemoglobin is less than 6 g/dL.

The decision to transfuse in patients with hemoglobin levels of 6–10 g/dL should be based primarily on the specific patient's symptoms and risks for complications and comorbidities.

Patient with compromised cardiac and/or pulmonary function may require transfusion at higher hemoglobin levels.[11]

A prospective randomized study of 838 intensive care unit patients indicated that a restrictive transfusion strategy (transfusing at Hgb levels below 7 g/dL and maintaining Hgb levels of 7–9 g/dL, $n=418$) was as effective and possibly superior to a liberal one (transfusing at Hgb levels below 10 g/dL and maintaining Hgb levels of 10–12 g/dL, $n=420$) in critically ill patients. Thirty-day mortality was similar in both groups (18.7% vs. 23.3% with $p=0.11$) with the lowest mortality observed in less acutely ill patients below 55 years of age.[12] Subsequently, a subset analysis of patients with cardiovascular disease concluded that a restrictive RBC transfusion strategy appeared to be safe in most of these critically ill patients, with the possible exception of patients with acute myocardial infarcts and unstable angina.[13] A comparable pediatric study arrived at a similar conclusion.[14] Utilization of RBC transfusion in pediatric intensive care units (PICU) is similar to that in adults when using the same criteria for the initiation of transfusion.[15]

A restrictive transfusion strategy has been found to be as effective and possibly superior to a liberal one.

Other studies, including an analysis of the impact of severe anemia in patient populations who for personal and/or religious reasons refused blood transfusion, indicate that low hemoglobin levels increased morbidity and mortality significantly more in patients with cardiovascular disease, a difference that became apparent at hemoglobin concentrations of 10 g/dL and increased as the hemoglobin level fell.[5,16-18]

Low hemoglobin levels have been found to increase morbidity and mortality significantly more in patients with cardiovascular disease.

The oxygen-carrying capacity in the healthy state is higher than the body's oxygen requirement and a sizeable reserve exists.[1] It is usually unnecessary to transfuse a patient to a normal hemoglobin level. In general, it is expected that 1 U of RBCs will increase hemoglobin by approximately 1 g/dL in an average-sized recipient. It is important to keep in mind that in patients who receive significant amounts of fluids, an expected increase in hemoglobin/hematocrit may not be immediately obvious due to the readjustment of blood volume after transfusion.[1] For this reason and others, the response to RBC transfusion should be monitored.

The oxygen-carrying capacity in the healthy state is higher than the body's oxygen requirement and a sizeable reserve exists.

The response to RBC transfusion should be monitored.

One unit of RBCs is expected to increase hemoglobin by 1 g/dL in an average-sized adult.

Red Blood Cell Transfusion in Sickle Cell Anemia Patients

In sickle cell disease, an even greater number of variables affect the decision to transfuse. This condition is caused by a DNA base substitution leading to the production of abnormal hemoglobin (Hgb S). The RBCs assume a sickle shape under low oxygen tensions, leading to the occlusion of small blood vessels; multiple tissues and organs may be affected, resulting in bone pain, stroke, acute chest syndrome, hepatic failure, and priapism. Although simple transfusion does not usually ameliorate vasoocclusive episodes, transfusion of RBCs is sometimes desirable to increase the oxygen-carrying capacity and decrease the erythropoietic drive.

The major indications for RBC transfusion in sickle cell disease are anemia and vasoocclusion.[6] Patients with sickle cell disease have some degree of anemia for which they are relatively well compensated, but as a result tend to have an expanded plasma volume. In certain instances, such as bleeding, infection, splenic sequestration, or hemolysis, an acute anemia is superimposed upon the chronic anemia and a simple transfusion may be required in symptomatic patients. Because the patient adjusts to chronic anemia, transfusion is usually not indicated even at a hemoglobin level below that which would trigger transfusion in acutely bleeding patients. The abnormal red cells in sickle cell disease also exhibit hyperviscosity, which worsens at higher hematocrits. Simple red cell transfusion increases the total hematocrit while the Hgb S remains relatively constant, resulting in increased viscosity and oxygen-carrying capacity, but little to no increase in oxygen delivery. Achieving 70% hemoglobin A and 30% hemoglobin S (relative fraction) with transfusion of RBCs is considered adequate.[19] It is usually sufficient to transfuse these patients to their baseline hemoglobin level.

Patients with sickle cell disease have some degree of anemia for which they are relatively well compensated, but as a result tend to have expanded plasma volume.

When acute anemia is superimposed upon the chronic anemia, a simple transfusion may be required in symptomatic patients.

Achieving 70% hemoglobin A and 30% hemoglobin S (relative fraction) with transfusion of RBCs is considered adequate.

Erythrocytapheresis, or red cell exchange, is a superior method for the treatment of ICU patients with sickle cell complications such as acute chest syndrome, retinal infarction,

stroke, priapism, or hepatic crisis, as it results in dramatic improvement and affords removal of hemoglobin S in addition to the transfusion of normal RBCs. Moreover, red cell exchange has the advantage of avoiding the iron overload commonly seen in sickle cell and other chronically, multiply transfused patients. To perform this procedure using apheresis machinery, dual lumen, larger-bore catheters, stiff enough to withstand high flow rates, are required.

Erythrocytapheresis is a superior method for the treatment of patients with sickle cell complications.

The RBC carries many antigens, the presence or absence of which is genetically determined, yielding significantly diverse phenotypes based in part on ethnicity. When a patient is exposed to a RBC antigen that is not present on his or her own RBCs, it is likely that the patient will make antibodies toward that antigen. Once a clinically significant alloantibody is identified in the plasma of a patient, the subsequent RBCs to be transfused must be negative for the corresponding antigen in order to prevent hemolysis of the transfused cells and associated complications. Procurement of these antigen negative RBC units may be time-consuming and becomes increasingly difficult in patients who develop multiple antibodies. This in turn can result in delays in the provision of compatible blood in a crisis. Communication and coordination with the transfusion medicine service in a timely manner, is essential in order to ensure availability of blood for patients with multiple antibodies. The increased rates of alloimmunization observed in sickle cell patients can be attributed to a disparity in race and red cell phenotype existing between these recipients and the donor population.[20] Phenotyping the RBCs of sickle cell patients early in the course of transfusion management in order to provide more closely phenotypically matched blood is believed to reduce the incidence of alloimmunization in this patient group.[21]

The increased rates of alloimmunization in sickle cell patients can be attributed to a disparity in race and red cell phenotype existing between these recipients and the donor population.

PLATELETS

Platelet concentrates in the United States are available as either platelets separated from whole blood donation and then pooled, or collected by apheresis from a single donor. Each unit of apheresis-derived platelets (single donor platelets or SDP) contains a minimum of 3×10^{11} platelets with a median dose of SDP containing approximately 4.2×10^{11} platelets, and each unit of whole-blood derived platelets (random donor platelets or RDP) contains a minimum of 5×10^{6} platelets. Therefore, a pool of four to six RDP is equivalent to the average SDP. Platelets are stored for only 5 days at room temperature (20–24°C) due to the potential for bacterial overgrowth; these bacteria are introduced during the collection process via retained skin plugs.

Platelets may be separated from whole blood or collected by apheresis.

A pool of four to six RDP is equivalent to the average SDP.

The availability of two types of platelet products can result in confusion. While the indications for transfusion of either product are basically the same, some practitioners believe that SDP are superior to RDP, because a therapeutic dose will expose the recipient to just one donor vs. multiple donors; it should be noted that nonspecifically assigned SDPs are just as random as RDPs. A single RDP (not a pooled product) that is sufficient for infants and small children is still a single-donor exposure. However, SDP are more practical when matched platelets are needed, as in the case of alloimmune platelet refractoriness, since only one donor needs to be found.

The plasma in which the platelets are stored is from a donor(s), so there is the potential for allergic reaction or transfusion-related acute lung injury (ALI) as well as hemolysis when donor and recipient are ABO incompatible (see the section on "Adverse sequelae of transfusion" in this chapter). There are other nuances in choosing either SDP or RDP, which are summarized in a 1999 review by Herman and Chambers published in the journal *Transfusion Medicine Reviews*.[22]

Platelets are generally indicated as deficit replacement for bleeding associated with thrombocytopenia, qualitative platelet function defects, or if the patient has taken therapeutic agents that impair platelet function. Platelets are also indicated prophylactically in patients with low platelet counts scheduled for invasive procedures or surgery.

Platelets are indicated as deficit replacement or prophylactically in patients with low platelet counts scheduled for invasive procedures or surgery, or considered to be at risk for bleeding.

With regard to prophylactic platelet transfusion, the same dilemma regarding which transfusion trigger to use exists as with RBC transfusion. A similar trend toward a more restrictive transfusion approach is supported by studies in selected patient populations. Most stable

patients, including oncology patients and those with aplastic anemia can tolerate relatively low platelet levels of 10,000/μL or less.[23] More restrictive guidelines have been proposed based on a study of patients with acute leukemia suggesting that a threshold of 5,000/μL be used for the initiation of platelet therapy in most stable patients.[24] However, the treatment must be individualized, taking into consideration risks for bleeding and coexisting clinical factors such as fever, which may necessitate transfusion to higher platelet counts. A multicenter controlled trial of leukemia patients compared transfusion thresholds of 10,000/μL and 20,000/μL, except in cases of fever and minor bleeding, and concluded that the lower threshold was adequate.[25,26]

For patients undergoing invasive procedures platelet counts in the range of 40,000–50,000/μL are desirable. For those with CNS lesions or undergoing neurosurgical procedures, platelet counts of 75,000–100,000/μL are preferable, though there is little data to support this higher target.[27] For active bleeding in the setting of thrombocytopenia the goal should be 40,000/μL or greater.[6] The reason(s) for thrombocytopenia should be rigorously sought; critically ill patients often have multiple and complex clinical issues that lead to thrombocytopenia.

Massive blood loss and subsequent massive transfusion can result in dilutional thrombocytopenia; platelet transfusion should be based on careful clinical assessment guided by the institution's massive transfusion protocol(s).

Platelets are difficult to maintain on inventory and are often needed urgently. Emergent clinical situations often necessitate transfusion of ABO incompatible platelets. Females of child bearing potential who are Rh negative should receive Rh negative platelets whenever available. If Rh negative platelets are not available, Rh positive platelets may be administered with Rh immune globulin to prevent Rh alloimmunization.

Prophylactic platelet transfusion is generally not recommended in thrombotic thrombocytopenic purpura (TTP) where there is increased platelet activation and consumption. It is also not recommended in autoimmune idiopathic thrombocytopenic purpura (ITP) and heparin-induced thrombocytopenia (HIT) in the absence of active or life-threatening hemorrhage due to ineffectiveness and/or the risk of worsening the underlying disease process.[6]

Prophylactic platelet transfusion is generally not recommended in TTP, ITP, or HIT.

Platelet Refractoriness

Some patients become refractory to platelet transfusions due to antibodies they have made to the class I human leukocyte antigens (HLAs) that exist on platelets. Apheresis platelet donors may be typed for HLA antigens and their platelets matched to the recipient to avoid the patient's antibodies. However, because of the extreme polymorphism of the HLA system it is often impossible to find an exact match; in such circumstances, partially matched platelets may be used. It is also possible to crossmatch a sample from the unit of platelets with the patient's serum. A compatible crossmatch implies that the antibodies in the patient do not correspond to antigens present on that donor's platelets, and has been shown to be successful in achieving an increment in platelet count in the absence of DIC or other nonimmune-mediated platelet consumptive states. Ideally, the response to platelet transfusion should be monitored with a 1-h posttransfusion platelet count which can distinguish immune from nonimmune causes of platelet transfusion failure.

Some patients become refractory to platelet transfusions due to the antibodies they have made to the class I HLA that exist on platelets.

Ideally, the response to platelet transfusion should be monitored with a 1-h posttransfusion platelet count which can distinguish immune from nonimmune causes of platelet transfusion failure.

To correct for patient size and the amount of platelets transfused, the corrected platelet count (CCI) is a useful calculation. See Fig. 55-1 for CCI calculation. A therapeutic dose of platelets, approximately 5.5×10^{10} platelets/μL/10 kg body weight, should increase the platelet count in an average-sized adult by approximately 5,000/μL per meter square of the body surface area. A patient may be considered refractory to platelet transfusion therapy when the 1 h posttransfusion CCI is less than 7,500 on two occasions.[28,29]

A therapeutic dose of platelets, approximately 5.5×10^{10} platelets/μL/10 kg body weight should increase the platelet count in an average-sized adult by approximately 5,000/μL/m^2 body surface area.

A patient may be considered refractory to platelets when the 1 h posttransfusion CCI is less than 7,500 on two occasions.

As mentioned, platelet refractoriness may have an immune or a nonimmune basis. Immune-mediated refractoriness is usually due to the presence of HLA antibodies, often caused by prior transfusion or pregnancy, and results in a poor 1-h CCI.[30] The presence of alloantibodies can be determined by HLA antibody screening also known as PRA (panel reactive antibodies), lymphocytotoxic antibody tests, or the class I HLA antibody test, which if positive would be an indication for the use of matched SDP. Patients who have adequate

$$\text{CCI} = \frac{(\text{Posttransfusion platelet count} - \text{pretransfusion platelet count}) \times \text{body surface area (in } m^2)}{\text{Number of platelets transfused (in multiples of } 10^{11})}$$

FIGURE 55-1

Calculation of corrected count increment.

1-h CCI, but poor 24-h CCI, are most likely refractory due to nonimmune causes.[30] Infection, fever, disseminated intravascular coagulation (DIC), hypersplenism, and enhanced platelet destruction by some medications can cause nonimmune-mediated refractoriness and these patients may benefit from more aggressive platelet therapy/higher platelet doses in face of decreasing platelet counts.[6]

Patients who have adequate 1-h CCI, but poor 24-h CCI, are most likely refractory due to nonimmune causes.

FRESH-FROZEN PLASMA

FFP is by definition the plasma portion which is separated from the whole blood donation or collected by apheresis and frozen within 8 h to maintain the integrity of the heat-labile clotting factors V and VIII. It can be stored frozen for 1 year at −18°C or below. A unit of FFP is expected to contain approximately 1 U/mL of all coagulation factors on average, based on the definition that 1 mL of normal plasma contains 1 U of a coagulation factor. No standard volume is possible for units of FFP; in the case of FFP separated from whole blood, the volume depends on the amount of plasma present in the original unit of whole blood and also on whether or not a unit of random donor platelets was also produced (since platelets must be suspended in a small amount of plasma). There is also biologic variation among factor levels in donors; so the actual factor activity cannot be standardized. Due to this variation, as well as variation in patient size, it may be necessary to transfuse patients with 2–4 U of FFP for adequate clotting factor replacement. A dose of 10–20 mL/kg is generally considered an adequate therapeutic dose depending on patient size and severity of coagulopathy; coagulation parameters should be measured to determine and monitor the efficacy of treatment.

FFP is plasma separated from a whole blood donation or collected by apheresis and frozen within 8 h.

FFP is expected to contain approximately 1 U/mL of all coagulation factors on average, based on the definition that 1 mL of normal plasma contains 1 U of a coagulation factor.

A dose of 10–20 mL/kg is generally accepted as an adequate therapeutic dose.

FFP is indicated for patients with multiple coagulation factor deficiencies who are bleeding or undergoing invasive procedures. It may also be used to treat coagulation factor deficiencies when specific factor concentrates are not available. Multiple factor deficiencies are most likely to be seen in critically ill patients with liver disease or patients with DIC where coagulation factors are being consumed. Dilutional coagulopathy secondary to massive transfusion is also observed in the ICU setting. Patients transfused with large volumes of packed cells and crystalloids following massive blood loss and fluid resuscitation have a relative deficiency of functional platelets and plasma; it is likely that thrombocytopenia and coagulation deficiencies will result. When a patient has received excess amounts of warfarin-containing compounds, the resulting deficiency of vitamin K-dependent factors can be treated with vitamin K alone; however, this treatment may require 10 h to be fully effective, so if a patient is actively bleeding or requires emergency surgery, it will be necessary to transfuse FFP.

FFP is indicated for use in patients with multiple coagulation factor deficiencies who are bleeding or undergoing invasive procedures.

FFP is not needed to treat prolongations in the prothrombin time (PT) or activated partial thromboplastin time (APTT) until they are increased more than 1.5 times the mean normal range.[31] Mild prolongations are likely to occur before factor levels are too low for hemostasis; this is also true for patients who are about to undergo minor procedures, such as thoracentesis, paracentesis, or liver biopsy, who have mild prolongations.

FFP is not needed to treat prolongations in PT or APTT until they are increased more than 1.5 times the mean normal ranges.

Use of FFP in the Treatment of Thrombotic Thrombocytopenic Purpura

Another indication for FFP in the ICU or other settings is the treatment of TTP. TTP presents with clinical features of thrombocytopenia (often severe), microangiopathic hemolytic

anemia, neurologic symptoms, fever, and occasionally renal dysfunction. Schistocytes are seen on the blood smear as a result of widespread platelet thrombi in the circulation causing a microangiopathic process, and unusually large multimers of von Willebrand's factor (vWF) leading to thrombus formation. As a result of hemolysis, marked elevations in lactate dehydrogenase (LDH) are usually seen. A deficiency of vWF-cleaving protease leading to the accumulation of large von Willebrand's multimers and the ensuing disease process has been shown to be responsible for TTP. Two forms of the disease exist: a familial form in which there is a genetic basis to the deficiency and an acute form where some external factor elicits an autoantibody inhibitor that causes the deficiency.

TTP had a mortality greater than 90% until the early 1980s when plasmapheresis with FFP as the replacement fluid became the first line of treatment. Plasmapheresis should commence on an emergency basis and continue daily with at least one plasma volume of FFP until platelet count normalizes for 2–3 days and signs of hemolysis subside. Studies have shown a clear benefit with this type of early and aggressive treatment.[6,32]

It was previously believed that patients who failed to respond to treatment with FFP or relapsed soon after such treatment sometimes did better with cryosupernatant rather than FFP. The cryosupernatant fraction of plasma is what remains after the cryoprecipitate is produced (see discussion that follows on cryoprecipitate). Because cryoprecipitate contains vWF, the remaining plasma is thus deficient and will have fewer ultralong multimers as well, while the vWF-cleaving protease remains. However, there is no definitive evidence supporting a clear benefit to the use of cryosupernatant (or cryoprecipitate-poor plasma) over FFP in the treatment of TTP.[33] With apheresis, the same catheter concerns exist as for red cell exchange in sickle cell anemia.

CRYOPRECIPITATE

Cryoprecipitate consists of the cold-insoluble high-molecular weight glycoproteins that precipitate when FFP is thawed.

Cryoprecipitate is mainly used for the treatment of dysfibrinogenemia, hypofibrinogenemia, and rare Factor XIII deficiency.

A therapeutic dose of cryoprecipitate for an average-sized adult consists of approximately 8–10 U of cryoprecipitate pooled, a volume of approximately 80–150 mL.

Cryoprecipitate consists of the cold-insoluble high-molecular weight glycoproteins that precipitate when FFP is thawed slowly at 1–6°C. It can be stored frozen for 1 year at −18°C or below and contains Factor VIII (>80 IU), vWF, Factor XIII (30% of that found in original plasma), and fibrinogen (150–250 mg). Cryoprecipitate is mainly indicated for the treatment of dysfibrinogenemia, hypofibrinogenemia (<100 mg/dL, often associated with DIC, massive transfusion, or thrombolytic therapy), and rare Factor XIII deficiency. Cryoprecipitate is not usually used for Factor VIII and Factor VIII/vWF replacement since concentrated preparations with minimal to no risk of viral transmission are available. Uremic patients who are bleeding or scheduled to undergo invasive procedures may also benefit from cryoprecipitate administration.[34]

A unit of cryoprecipitate is expected to increase fibrinogen by 5–10 mg/dL; thus a therapeutic dose of cryoprecipitate for an average-sized adult consists of 8–10 U of pooled cryoprecipitate with a total volume of 80–150 mL. See Fig. 55-2 for the formula to calculate the number of cryoprecipitate bags (units) necessary to correct hypofibrinogenemia.

MASSIVE TRANSFUSION

Massive transfusion is defined as replacement of one or more blood volumes in a patient within 24 h and can be associated with various complications.

Acute loss of volume is usually managed initially with colloids or crystalloids.

Massive transfusion is defined as the replacement of one or more blood volumes in a patient within 24 h. Acute loss of volume is usually managed initially with colloids or crystalloids. When significant loss of red cells occurs transfusion of RBCs becomes necessary.

$$\frac{(\text{Desired fibrinogen level mg/dL} - \text{initial fibrinogen level mg/dL}) \times \text{patient's plasma volume dL}}{200\ \text{mg (average amount fibrinogen per unit of cryoprecipitate)}}$$

TABLE 55-1

EXAMPLE OF A MASSIVE TRANSFUSION PROTOCOL

Large amounts of crystalloid initially
Uncrossmatched RBCs emergently
Transfuse one unit of FFP after each unit of RBC
Transfuse one random donor platelet (RDP) unit after each unit of RBC and FFP
Or, if using single donor (apheresis) platelets (SDP): After RBC and plasma are alternated until 6–10 U (depending on institution's preference/protocol) of each have been given, give one apheresis platelet
Usual MTP blood component ratios: 1 RBC: 1 FFP: 1 RDP

SOURCE: Data from Malone et al[52]

Hypothermia, tissue ischemia, acid–base and electrolyte disturbances can occur. The combined use of fluids and RBCs, often leads to coagulation and hemostatic deficiencies in this setting. Often coagulation factors, fibrinogen, and platelets decrease to levels inadequate for hemostasis after one to two blood volumes have been transfused. Laboratory evaluation of PT, aPTT, fibrinogen, and CBC and other parameters (such as D-dimer in cases of suspected DIC), greatly aids in the assessment and monitoring of patients with massive blood loss; unfortunately in urgent clinical situations there may not be time to obtain this information. A fibrinogen level greater than 100 g/dL and platelet counts greater than 50,000/μL are usually considered acceptable; exact clotting factor activity level for hemostasis in multiple factor deficiencies is not defined.[6] Hypothermia, acidosis, citrate toxicity (due to chelation of calcium by citrate anticoagulant in blood components), particularly in patients with renal or liver dysfunction, and other biochemical and electrolyte disturbances may also occur in the massive transfusion setting and related parameters should be adequately monitored.

The combined use of fluids and RBCs, often leads to coagulation and hemostatic deficiencies in massively transfused patients.

Use of massive transfusion algorithms or protocols that call for aggressive and timely transfusion of RBCs, FFP, platelets, and possibly cryoprecipitate, have been demonstrated to improve survival in hypovolemic shock secondary to rapid and massive blood loss. The most common clinical settings include ruptured aortic aneurysms, blunt or penetrating trauma, or massive GI bleeds. Certainly, if time allows, the need for each of these components should be determined by a careful assessment of the patient's clinical status, underlying disorders, and comorbidities in conjunction with the evaluation of laboratory parameters; but often, this approach is not feasible in the setting of emergent and life-threatening massive blood loss.

Use of massive transfusion algorithms or protocols that call for aggressive and timely transfusion of RBCs, FFP, platelets, and possibly cryoprecipitate, have been demonstrated to improve survival in hypovolemic shock secondary to rapid and massive blood loss. The most common clinical settings include ruptured aortic aneurysms, blunt or penetrating trauma, or massive GI bleeds.

An example of a massive transfusion protocol is outlined in Table 55-1. Typically, FFP transfusion is considered when the PT reaches 1.5 times the mean of normal range, platelets transfusion is considered at counts below 50,000/μL, and cryoprecipitate use is considered at fibrinogen levels less than 100 mg/dL.[35] It is helpful if institutions use their own experience and blood component usage, based on their own patient populations, in establishing massive transfusion protocols.

Typically, FFP transfusion is considered when the PT reaches 1.5 times the mean of normal range, platelet transfusion at counts below 50,000/μL, and cryoprecipitate at fibrinogen levels less than 100 mg/dL.

TRANSFUSION REACTIONS: ADVERSE SEQUELAE OF TRANSFUSION

Although the U.S. blood supply is the safest in the world, transfusion can be associated with infectious and noninfectious adverse sequelae. Though incredibly infrequent, virally mediated infectious diseases still occur. (See Table 55-2 for the current estimated/calculated risks of transfusion transmitted viruses).[36,37] Immune and nonimmune-mediated reactions of acute or delayed onset with mild to marked severity can also occur and are classified as hemolytic or nonhemolytic in type.

Virally mediated infectious diseases are not the only complications of transfusion.

Collectively, these entities are called transfusion reactions and include: transfusion transmitted viral illnesses, sepsis from bacterially contaminated blood components, hemolysis due to blood group incompatibility, alloimmunization from foreign red and/or white blood cell antigens, iron overload from large quantities of RBC transfusions over time, allergic

TABLE 55-2

ESTIMATED RISK OF TRANSFUSION TRANSMITTED VIRAL DISEASE IN THE US PER TRANSFUSION

Hepatitis B	Less than 1/200,000
HIV 1 and 2	Less than 1/2,000,000
Hepatitis C	Less than 1/2,000,000
HTLV I and II	Less than 1/2,000,000 (cellular blood components)

HIV human immunodeficiency virus; *HTLV* human T-lymphotrophic virus

reactions, anaphylaxis, fever, volume-overload, and other adverse sequelae. Some of these topics will be reviewed in this chapter. A more extensive discussion of adverse sequelae of transfusion can be found in textbooks of transfusion medicine (see additional readings at the end of this chapter).

Most reactions occur within the first 15 min of initiation of transfusion, but may occur at any point during or after transfusion. When a transfusion reaction is suspected, the transfusion should immediately be stopped and intravenous access maintained with normal saline solution. The patient, if unstable, should be appropriately managed. The blood bank/transfusion medicine service should be notified as soon as possible and the appropriate documentation completed and returned to the blood bank with the implicated units (in accordance with institutional procedures and policies).

Most reactions occur within the first 15 min of initiation of transfusion, but can occur at any point during or after transfusion.

When a transfusion reaction is suspected, the transfusion should immediately be stopped and intravenous access maintained with normal saline solution. The patient, if unstable, should be appropriately managed. The blood bank/transfusion medicine service should be notified as soon as possible and the appropriate documentation completed and returned to the blood bank with the implicated units.

Signs and symptoms that suggest transfusion reaction are numerous and significant overlap exists between different types of transfusion reactions. Certain signs and symptoms such as onset of fever, respiratory difficulty, chills, back/flank pain, hemoglobinuria, and significant changes in blood pressure and pulse rate during or shortly after transfusion may be indicative of a major transfusion reaction. Timely recognition of such signs and symptoms are essential for appropriate patient management and laboratory workup, proper classification of the reaction, and initiation of the appropriate measures for management and future prevention. The basic transfusion reaction workup includes reconfirmation of the patient's and the unit's blood group and Rh type to rule out clerical error (to confirm that the intended blood component unit was administered to the intended recipient and not erroneously infused into another patient), performance of direct antiglobulin tests (DAT) to evaluate for presence of antibody–antigen interaction and assessment of the patient's plasma for evidence of hemolysis.

Onset of fever, respiratory difficulty, chills, back/flank pain, hemoglobinuria, and significant changes in blood pressure and pulse rate during or shortly after transfusion may be indicative of a major transfusion reaction.

Hemolytic Transfusion Reactions

An acute hemolytic transfusion reaction is the immune-mediated destruction of infused incompatible RBCs occurring during or within 24 h of transfusion.[38] Most cases are due to the administration of a blood unit to a patient other than for whom it was intended, often as a result of clerical error, resulting in an ABO incompatible transfusion. The implicated antibody–antigen reaction leads to complement fixation potentially resulting in severe intravascular hemolysis and associated adverse sequelae such as shock, renal failure, DIC, and/or fatality. The signs and symptoms include fever, chills, flank, abdominal or chest pain, nausea and vomiting, dyspnea, tachycardia, hypotension, a sense of distress, hemorrhage, and hemoglobinuria during or within 24 h of transfusion. Fever, chills, dyspnea, and other nonspecific findings are not unique to this type of reaction and can be observed in association with other reactions. However, the presence of one or more of these signs or symptoms requires that the transfusion be stopped and the possibility of a hemolytic transfusion reaction be investigated. Prevention centers on ensuring that the correct ABO compatible unit is administered to the intended patient. This is accomplished by means of meticulous clerical checks in the issuing blood bank and appropriate patient and unit identification prior to the initiation of transfusion.

An acute hemolytic transfusion reaction is an immune-mediated destruction of infused incompatible RBCs occurring during or within 24 h of transfusion.

Most cases are due to the administration of a blood unit to a patient other than for whom it was intended (clerical error).

The implicated antibody–antigen reaction leads to complement fixation resulting in potentially severe intravascular hemolysis.

Prevention centers on ensuring that the correct ABO compatible unit is administered to the intended patient by means of meticulous clerical checks in the issuing blood bank and appropriate patient and unit identification prior to the initiation of transfusion.

Delayed hemolytic transfusion reactions occur days to weeks after a transfusion of RBCs containing antigen(s) against which the recipient has previously formed antibodies (anamnestic immune response). The signs and symptoms, including fever, jaundice, malaise, and anemia, are usually less severe than those associated with acute hemolytic transfusion reactions

as the antibody–antigen interactions in most cases do not lead to significant complement fixation and result mainly in extravascular hemolysis. Often symptoms may be attributed to the patient's underlying condition(s). For instance, a mild elevation of bilirubin and LDH associated with a decreased haptoglobin, in a patient with previously diagnosed hemolytic anemia, may be attributed to the patient's underlying disease and not necessarily to a recent transfusion. Failure to achieve an expected increase in hemoglobin/hematocrit, associated with an elevation in bilirubin and LDH, a decreased haptoglobin, a positive DAT, and detection of a new or unexpected antibody in the antibody screen are findings compatible with a delayed hemolytic transfusion reaction. Observation and monitoring of the patient are usually sufficient management. Prevention consists of serologic identification of antibodies and avoidance of the corresponding RBC antigen(s) in subsequent transfusions.

Hemolytic transfusion reactions in sickle cell patients can lead to profound anemia and sickle crisis, due to the destruction of both transfused and autologous RBCs (bystander hemolysis) particularly in patients with concomitant suppressed erythropoiesis. This is referred to as sickle cell hemolytic transfusion reaction syndrome. In such situations, additional transfusion may exacerbate the anemia and may be associated with a fatal outcome.[39]

Delayed hemolytic transfusion reactions occur days to weeks after a transfusion of RBCs containing antigen(s) against which the recipient has previously formed antibodies (anamnestic immune response).

The signs and symptoms are usually less severe than those associated with acute hemolytic transfusion reactions as hemolysis is usually mainly extravascular.

Prevention consists of serologic identification of antibodies and avoidance of the corresponding RBC antigen(s) in subsequent transfusions.

Hemolytic transfusion reactions in sickle cell patients can lead to sickle cell hemolytic transfusion reaction syndrome.

Additional transfusion during a sickle cell hemolytic transfusion reaction may exacerbate the anemia and be associated with a fatal outcome.

Febrile Nonhemolytic Transfusion Reactions

These reactions are among the most common of transfusion reactions and typically present as an increase of 1°C or more above baseline during or shortly after transfusion, unrelated to or unexplained by the patient's clinical condition.[38] The fever is commonly accompanied by chills and/or rigors. Transfusion should be stopped when such a rise in temperature is observed, the blood bank/transfusion service notified, and the unit and transfusion set returned to the blood bank to rule-out acute hemolysis or bacterial contamination. Febrile nonhemolytic transfusion reactions (FNHTR) result from proinflammatory cytokines and pyrogens in the blood component passively infused into the patient, or from endogenous pyrogens elaborated by the patient as a result of leukocyte-antigen–antileukocyte-antibody interactions. Patients who have a history of such febrile reactions should receive leukocyte-reduced blood components and may benefit from the administration of antipyretics prior to transfusion.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) presents as noncardiogenic pulmonary edema during or within hours of transfusion. Clinically, TRALI presents as acute onset of marked respiratory distress, dyspnea, cyanosis, hypoxia, hypotension, fever, and pulmonary edema manifested as bilateral pulmonary infiltrates on chest X-ray. The pathway to injury is not fully understood; however, two mechanisms have been proposed (one immune-mediated and the other nonimmune-mediated) to explain the pulmonary capillary endothelial damage and subsequent pulmonary edema.[38]

Criteria for the diagnosis of TRALI consist of severe onset of hypoxemia (PaO_2/FiO_2 ≤300 mmHg or O_2 saturation ≤90% on room air) during or within 6 h of transfusion (although most cases occur within 2 h), in a patient with no evidence of circulatory overload, without preexisting ALI and associated with bilateral diffuse lung infiltrates on chest X-ray. In the presence of other risk factors for ALI such as sepsis, DIC, aspiration, trauma, shock, recent surgery, and in settings of massive transfusion, TRALI may still occur and would be referred to as "possible TRALI." For a summary of criteria to diagnose TRALI see Table 55-3.[40]

If TRALI is suspected, the transfusion must be stopped immediately and supportive care administered; this may include endotracheal intubation and mechanical ventilation in severe cases. The transfusion service/blood bank should be notified, the blood unit(s) in question returned to the blood bank and hemolysis ruled out. Chest X-ray should be obtained as soon as possible; this also serves to document the presence of pulmonary infiltrates which would support a diagnosis of TRALI. In most instances patients are expected to recover within 48–96 h (80% recovery rate).[38,40] The most frequent diagnosis with which TRALI is confused is transfusion-associated circulatory overload (TACO). However, in contrast to TACO,

FNHTR are among the most common of transfusion reactions and typically present as an increase of 1°C or more above baseline during or shortly after transfusion, unrelated to or unexplained by the patient's clinical condition.

Transfusion should be stopped when such a rise in temperature is observed, the blood bank/transfusion service notified, and the unit and transfusion set returned to the blood bank to rule-out acute hemolysis or bacterial contamination.

Patients who have a history of such febrile reactions should receive leukocyte-reduced blood components and may benefit from the administration of antipyretics prior to transfusion.

TABLE 55-3

SUMMARY OF THE CRITERIA FOR THE DIAGNOSIS OF TRALI

Acute onset of new lung injury during or within 6 h of transfusion
Hypoxemia
PaO_2/FiO_2 ≤300 mmHg or PO_2 ≤90% on room air bilateral infiltrates on frontal chest radiograph
No evidence of circulatory overload
Pulmonary artery occlusion pressure of ≤ 18 mmHg or no evidence of left atrial hypertension
No preexisting ALI[a]

ALI acute lung injury; *TRALI* transfusion-related acute lung injury
[a]"Possible TRALI": presence of alternate ALI risk factor(s) or massive transfusion does not exclude the possibility of TRALI

TRALI presents as noncardiogenic pulmonary edema during or within hours of transfusion.

TRALI presents as acute onset of marked respiratory distress, dyspnea, cyanosis, hypoxia, hypotension, fever, and pulmonary edema, manifested as bilateral pulmonary infiltrates on chest X-ray.

The most frequent diagnosis with which TRALI is confused is TACO.

In contrast to TACO, TRALI is not associated with an elevated B type natriuretic peptide level and does not generally respond to diuresis.

Patients are expected to recover within 48–96 h in most cases.

TACO manifests as pulmonary edema of cardiogenic origin, resulting in respiratory distress and other symptoms similar to those of TRALI, but it is associated with increased central venous pressure.

Patients with compromised cardiac pumping capacity, abnormal renal function, chronic anemia leading to a hyperkinetic and/or plasma volume expanded state, and children and the elderly are at higher risk for TACO.

Prevention includes attention to the recipient's pretransfusion volume status and slower rates of infusion.

TRALI is usually not associated with an elevated B type natriuretic peptide level and does not generally respond to diuresis.[41]

If TRALI is diagnosed, blood samples from the patient can be submitted to determine the human leukocyte (HLA)/human neutrophil (HNA) antigen and antibody status; similar studies will be performed on the donor(s) and if it is determined that the donor has anti-HLA or anti-HNA antibodies, the donor will be deferred from future donation. Absent infusion of blood from the same donor, a patient who has experienced TRALI is not necessarily at increased risk of TRALI with subsequent transfusions. Although plasma containing components including platelets are overrepresented in reported cases, TRALI can occur with any blood component and has become the number one cause of transfusion-related mortality in reports to the FDA (food and drug administration).[40]

Transfusion-Associated Circulatory Overload

Transfusion-associated circulatory overload (TACO) manifests as pulmonary edema of cardiogenic origin, resulting in respiratory distress and other symptoms similar to those of TRALI, but it is associated with increased central venous pressure. Patients with compromised cardiac or renal function, chronic anemia leading to a hyperkinetic and/or plasma volume expanded state, and children and the elderly, are at a higher risk for TACO.[38] When circulatory overload is suspected, the transfusion should be stopped, supportive care provided, and the transfusion service/blood bank notified. Prevention includes attention to the recipient's pretransfusion volume status, particularly in patients at risk noted above, who may be unable to adjust to even small changes in intravascular volume. When transfusing such patients, it is recommended that slower administration rates be used (1 mL/kg body weight per hour).[38] It may be necessary for the blood bank to divide a single unit of blood into aliquots, each of which can be administered slowly without exceeding the maximum allowed time for infusion (4 h).

It is important to recognize signs and symptoms associated with transfusion reactions and to notify the blood bank in a timely manner in order to facilitate acquisition of blood studies and diagnosis. It is recommended that transfusion of any blood product be discontinued until the presence of serious transfusion reactions has been excluded.

MODIFICATION OF BLOOD COMPONENTS

Leukoreduction

White blood cell content of cellular blood components can be significantly reduced by the use of specialized filters at the time of processing, before storage, prior to issuing for transfusion, or at the bedside during transfusion, leaving less than 5×10^6 white blood cells in the component unit. Leukoreduction prior to storage removes the white blood cells thereby reducing cytokine generation during storage. As such, prestorage leukoreduction is deemed superior in the prevention of febrile nonhemolytic transfusion reactions (FNHTRs).[38] Other benefits of leukoreduction include reduction of primary HLA alloimmunization.[42,43] and a reduced risk of cytomegalovirus (CMV) transmission

TABLE 55-4

INDICATIONS FOR THE USE OF MODIFIED CELLULAR BLOOD COMPONENTS

Leukoreduction to reduce CMV transmission and HLA alloimmunization and febrile nonhemolytic reactions
Reduction of febrile nonhemolytic transfusion reactions
Patients with a history of febrile nonhemolytic transfusion reaction
Prevention/reduction of primary HLA alloimmunization
HLA antibody-negative patients with conditions that result in transfusion dependence
HLA antibody-negative patients with malignancies where chemotherapy will result in transfusion dependence
Candidates for bone marrow/stem cell/organ transplant
Reduction of CMV transmission (same criteria for CMV-seronegative components)
Newborns <1,200 g born to mothers who are CMV seronegative or with unknown CMV status
Intrauterine transfusions in pregnant women who are CMV seronegative or with unknown CMV status
Seronegative recipients of or candidates for bone marrow/stem cell/organ transplants from donors who are also seronegative
AIDS patients who are CMV seronegative
Irradiation for prevention of TA-GVHD
Fetuses receiving intrauterine transfusions and neonates who have received intrauterine transfusion
Low birth weight premature neonates (<1,200 g) transfusions
Patients with congenital immunodeficiency syndromes
Bone marrow/stem cell transplant patients
Patients with certain hematologic malignancies
Recipients of cellular components from directed donors who are biological relatives

TA-GVHD transfusion-associated graft vs. host disease; *CMV* cytomegalovirus; *AIDS* acquired immunodeficiency syndrome; *HLA* human leukocyte antigen

(white cells are a site of CMV latency).[44] For indications for modified blood components see Table 55-4.

Leukoreduction leaves less than 5×10^6 white blood cells in the component unit.

Leukoreduction prior to storage removes the white blood cells thereby reducing cytokine generation during storage.

Other benefits of leukoreduction include reduction of primary HLA alloimmunization and reduced risk of CMV transmission.

Irradiation

Cellular blood components may be irradiated to inactivate lymphocyte proliferation in the blood component unit in order to prevent transfusion-associated-graft-versus-host disease (TA-GVHD), a rare adverse outcome of transfusion which may occur in some immunosuppressed blood recipients, or immunocompetent recipients of blood from biological relatives or HLA matched donors. In TA-GVHD, foreign T cells engraft and lead to the initiation of a cellular immune response against the host. This is clinically similar to graft-versus-host disease in hematopoietic transplant recipients in whom high fevers, rash, and gastrointestinal and liver involvement are seen. The important difference, however, is that the bone marrow, which is spared in transplant patients because it is the graft, is part of the host in a transfusion recipient. Therefore, in TA-GVHD, pancytopenia is prominent and the mortality rate is in excess of 90%.

Immunocompromised patients are at risk for TA-GVHD because they may be unable to destroy the foreign T lymphocytes which are infused with the transfusion of cellular components. Immunocompetent recipients of blood components from donors who are homozygous for an HLA haplotype for which the recipient is heterozygous, are also at risk for TA-GVHD. A haplotype is composed of the genes for the HLA-related antigens A, B, C, and D which are inherited in a group as if they were a single gene. The recipient thus does not recognize the transfused cells as foreign because both haplotypes in the donor match one of the recipient's haplotypes. Since the foreign (donor) cells are not eliminated, these cells, once engrafted may recognize the nonshared haplotype of the recipient as foreign, and mount an immune response against the recipient's nonshared haplotype, leading to the same sequelae as in an immunocompromised patient. The threshold number of T lymphocytes needed to initiate this disease is not known, and leukoreduction by filtration is not appropriate for its prevention. Irradiation of cellular blood products is the only method recognized to prevent TA-GVHD.[6] For indications for modified blood components see Table 55-4.

Irradiation of cellular blood components inactivates lymphocyte proliferation in the blood component unit and is the only method recognized to prevent TA-GVHD.

In TA-GVHD, foreign T cells engraft and lead to the initiation of an immune response against the host, which includes cellular elements in the bone marrow.

The threshold number of T lymphocytes needed to initiate TA-GVHD is not known, and leukoreduction by filtration is not appropriate for its prevention.

Irradiation of cellular blood products is the only method recognized to prevent TA-GVHD.

ALTERNATIVES AND ADJUNCTS TO ALLOGENEIC BLOOD COMPONENTS

Autologous transfusion is most applicable in settings of elective surgery where blood loss is anticipated and transfusion likely.

Autologous blood donation does little to prevent or significantly reduce the risk of bacterial contamination and clerical errors resulting in erroneous transfusion, and can result in preoperative anemia and lead to wastage.

The complications associated with the transfusion of blood products have been the impetus for the development of alternatives to allogeneic transfusion. These blood conservation alternatives include donation of blood by the patient in cases of anticipated need for transfusion (perioperative autologous blood donation), acute normovolemic hemodilution, use of cell-saver technology during surgery, and pharmacologic hemostatic agents.

Autologous Blood Donation

Donation of blood for one's own use, autologous transfusion, is most applicable in settings of elective surgery where blood loss is anticipated and transfusion likely. Patients who are at risk for or have evidence of bacterial infection, significant cardiac or pulmonary disease, epilepsy, uncontrolled hypertension, or unstable angina should be excluded from autologous donation. Perceived advantages of autologous donation include potential prevention of transfusion transmitted disease and alloimmunization, and reduction of some of the other adverse transfusion sequelae. However, this practice does little to prevent or significantly reduce the risk of bacterial contamination and clerical errors resulting in erroneous transfusion, and can result in preoperative anemia and lead to wastage.[1,6]

Blood Conservation

ANVH is a technique by which whole blood is removed from the patient and the volume restored with crystalloids and colloids before surgical blood loss occurs.

The blood lost after ANVH has a dilute hematocrit. It is reinfused as needed or after cessation of surgical blood loss, infusing the last unit collected first and the first unit last.

Cell-saver technology can be used to collect the blood shed during a procedure from a sterile surgical field; after centrifugation, washing, concentration, and filtration it may be administered to the patient. Bacterial contamination and red cell hemolysis of the recovered blood may occur and the blood infused after processing is largely devoid of coagulation factors and platelets.

Acute normovolemic hemodilution (ANVH) is a technique by which the whole blood is removed from the patient and the volume restored with crystalloids and colloids before surgical blood loss occurs. The blood is reinfused as needed or after cessation of surgical blood loss, infusing the last unit collected first, and the first unit (of higher hematocrit, platelet and coagulation factor concentration) last. ANVH decreases the hematocrit resulting in reduced RBC loss during perioperative bleeding. It is considered to be more cost-effective than the practice of preoperative autologous blood donation and results in significantly less wastage.[6] It should be noted that there are risks associated with this technique and ongoing debate regarding its efficacy.Cell-saver technology can be used to collect the shed blood from a sterile surgical field. The RBCs collected in this manner are reinfused into the patient after centrifugation, washing, concentration, and filtration. This practice is relatively contraindicated and controversial in procedures where there is gross contamination of the surgical field with malignant cells, and in the presence of infection. It is also contraindicated in cases where the surgical field contains materials with procoagulant activity such as topical collagen. Bacterial contamination and red cell hemolysis of recovered blood may occur and the blood infused after processing is largely devoid of coagulation factors and platelets.[6]

Pharmacologic/Hemostatic Agents

Other means of reducing allogeneic blood requirement involve the use of pharmacologic products such as erythropoietin and iron therapy when possible. This has been deemed particularly useful in patients with renal insufficiency, anemia of chronic disease, and those for whom allogeneic transfusion is not an option.[35] These agents have the potential to optimize hematocrit prior to elective surgical procedures and in anemic patients.[6,45]

Recombinant factor VIIa is indicated for the treatment of bleeding in hemophilia patients who have developed inhibitors. Given its ability to boost thrombin generation, it has also been used in a variety of settings as a hemostatic agent to treat bleeding unresponsive to

conventional management; these settings include bleeding associated with factor VII deficiency, anticoagulation, surgery, trauma, and in patients with liver disease and extensive visceral bleeding, central nervous system bleeding, and with thrombocytopenia or functional platelet defects.[1] Anecdotes, case reports, and one prospective, randomized study in patients undergoing prostate surgery, report successful management of bleeding with recombinant factor VIIa using doses half or even less than half of what is recommended in hemophiliac patients with inhibitors.[46] Limited studies in surgical and trauma patients suggest a role for recombinant factor VIIa as a hemostatic agent[47-50] The use of this agent in trauma and surgery settings suggests a role in the reversal of coagulopathy associated with a shortening in PT with no significant improvement in mortality.[51] The major risk associated with the use of VIIa is formation of arterial and venous thrombosis.

Pharmacological agents can be used to enhance hemoglobin levels and include erythropoietin and iron therapy. Other pharmacologic agents include vitamin K, protamine sulfate used for the reversal of anticoagulation due to warfarin and heparin, respectively.

Other hemostatic agents which may be used as adjuncts to allogeneic transfusion include, but are not limited to, DDAVP (desmopressin acetate or 1-deamino-8-D-arginine vasopressin), conjugated estrogens, and antifibrinolytic agents. DDAVP increases plasma levels of Factor VIII and vWF transiently and enhances platelet adhesiveness; it can be used in situations where there is a primary platelet dysfunction such as those associated with uremia, liver disease, or medications. DDAVP provides temporary hemostasis and as such would be adequate for use in minor and moderately invasive procedures, but not in procedures where there is a need for prolonged hemostasis. It does little to decrease transfusion needs during major surgery in patients who do not have hemostatic defects.[1] Fluid retention and possible hyponatremia, blood pressure changes, tachyphylaxis, and thrombosis (rare) are among the risks associated with the use of DDAVP. DDAVP is not indicated for use in patients with type 2B von Willebrand disease where there is increased affinity of vWF for platelets resulting in the worsening of thrombocytopenia. A trial dose, days prior to anticipated use, is usually recommended to determine a patient's response to DDAVP.[1,6]

Hemostatic agents include rVIIa, DDAVP, conjugated estrogens, AMCA, EACA, fibrin sealants, and in some cases may reduce the need for allogeneic transfusion.

Conjugated estrogens can be used in treating coagulopathy in settings of GI bleed associated with angiodysplasia, uremia, von Willebrand disease, and end-stage renal disease, but are not generally useful in settings where immediate hemostasis is desired. GI upset with dyspepsia, weight gain, and gynecomastia are associated side effects. The mechanism of action of these agents is not fully understood.[1,6]

The antifibrinolytic agents include EACA (epsilon aminocaproic acid) and AMCA (tranexamic acid) and can be used for the treatment of GI and uterine bleeding, and in bleeding associated with amegakaryocytic or peripheral thrombocytopenia. Topical AMCA has been used in conjunction with DDAVP and fibrin sealant in managing hemophilia A and B patients undergoing dental procedures. These agents have been used in cardiopulmonary bypass surgery, orthopedic surgery, and liver transplantation where excessive fibrinolysis and bleeding are of particular concern. AMCA and EACA should be avoided in patients with history of thrombotic disorders associated with fibrinolysis. Prolonged use of EACA has been associated with myonecrosis. Gastrointestinal upset and headaches are common side effects of EACA and AMCA (more so with EACA than AMCA). Their use has also been associated with bladder outlet obstruction in patients with kidney or bladder bleeding. There is insufficient data to recommend the use of antifibrinolytic agents in trauma settings.[1,6]

The protease inhibitor, aprotinin, was another hemostatic agent that had antifibrinolytic properties, and had been used effectively in cardiopulmonary bypass situations where its use was associated with decreased transfusion requirement. However, this agent was removed from the US market voluntarily in May, 2008 over safety concerns related to a relationship with excess postsurgery fatality. In addition, since it is derived from bovine lung, there is theoretically a risk of transmitting variant Creutzfeldt-Jakob (mad cow) disease.

Phamacological and hemostatic agents may have associated side effects and their use should be based on a careful assessment of a given patient's clinical condition.

Other pharmacologic agents include vitamin K and protamine sulfate, used to reverse anticoagulation with warfarin and heparin, respectively, and fibrin sealants. More extensive discussion of hemostatic agents is beyond the scope of this chapter and may be found in the suggested readings at the end of this chapter.

CASE STUDY: Part 2

DISCUSSION

This patient experienced acute pulmonary edema very quickly after transfusion. The chief types of reactions in the differential diagnosis are TRALI, TACO, bacterial contamination and anaphylaxis. Cardiogenic pulmonary edema in TACO is associated with hypertension, is likely to respond to diuresis, and does not usually present with fever. Sudden onset of hypotension and hypoxia can occur in anaphylaxis, but fever is not a feature of anaphylactic or allergic reactions and is often associated with angioedema, wheezing, and stridor. Bacterial contamination usually presents with high fever, abdominal cramping, skin flushing, and shock. Pulmonary edema in TRALI is noncardiogenic, often presents with sudden onset dyspnea, hypotension and fever, and does not usually respond to diuresis. Severe febrile reactions may have respiratory symptoms associated with them, but are not commonly associated with the development of pulmonary edema.

When TRALI is suspected clinically, further workup recommended is human leukocyte antigen (HLA) type and antibody screen of the patient's blood sample and HLA and human neutrophil antigen (HNA) antibody screen of each of the donors of the units transfused. Most cases of TRALI are immune-mediated (mostly associated with passively infused donor antibody against recipient HLA or HNA and less frequently associated with recipient antibody against passively infused donor HLA or HNA). Donors who have been exposed to foreign HLA/HNA, for instance through transfusion, transplant, or through pregnancy, are more likely to be implicated in cases of TRALI. In some cases, no donor or recipient HLA or HNA antibody is detected, which suggests that there are nonimmune-mediated causes for TRALI. TRALI reactions are essentially a property of the product due to donor-derived factors rather than the recipient, and hence have low likelihood of recurrence.

In the case study presented, after evaluation of the clinical symptoms and laboratory results, the blood bank physician strongly suspected TRALI and recommended appropriate workup, requesting a sample from the patient to be sent for HLA type and screen which revealed a negative HLA antibody screen and the following HLA type: A(3,24) B(18,61) Cw (5,10) DQ2,8 DR52,53. As part of the TRALI workup, the donor center was able to obtain a sample from the each of the donors of the platelets received by the patient, and tested these for the presence of HLA and HNA antibody screen, with the following results:

Donor 1(female):
Anti-HLA antibodies to DR 1,4,10,103 DQ5 DR53
Antineutrophil antibody negative

Donor 2 (female):
Anti-HLA antibodies to B18 DR8,15,16 DR52
Antineutrophil antibody negative

The HLA antibody from donor 1 against the patient's HLA DR53 and the antibodies from donor 2 against the patient's HLA B18 and DR 52 may each or all have contributed to the TRALI in this patient.

SUMMARY

Blood components are a valuable resource that, although life-saving, may be associated with adverse sequelae and should be used judiciously for optimal patient care.

It is important for the clinicians who practice in critical care settings, where blood is commonly transfused, to be aware of the varied blood component choices and characteristics, associated risks and benefits, and potential alternatives and/or adjuncts to allogeneic blood use. Such awareness is not only useful for the management of patients, but can facilitate effective communication of relevant issues pertaining to transfusion when obtaining informed consent. When transfusion is an option, overreliance on algorithms and "triggers" should be avoided, except in the setting of carefully constructed massive transfusion protocols which have been found to be useful in avoiding both over- and undertransfusion. The decision to transfuse must be guided by careful consideration of the patient's clinical status, symptoms, and supporting laboratory and clinical parameters, thus optimizing patient care and the use of valuable and limited resources.

REVIEW QUESTIONS

1. **All the following statements regarding leukoreduction are correct, except:**
   - **A.** It significantly reduces primary alloimmunization to HLA antigens in patients who have not yet made antibodies from previous transfusions
   - **B.** It markedly decreases the risk of CMV transmission
   - **C.** It prevents transfusion-associated graft-versus-host disease
   - **D.** It decreases the incidence of febrile nonhemolytic transfusion reactions

2. **A 62-year-old patient on chronic deep venous thrombosis prophylaxis with warfarin and with a known history of hepatitis C and cirrhosis is admitted for a history of hematemesis of 2–3 days duration. The patient is scheduled to undergo upper GI endoscopy. Vital signs are stable and the hemoglobin is unchanged over 24 h. Hemoglobin level is 8.6 g/dL and platelet count is 59,000/µL. The INR for PT is 6.5 (therapeutic range, 2–3) and the aPTT is 48 s (1.6 times normal). Based on this, which of the following should your initial approach to improve the patient hemostasis in preparation for procedure include :**
   - **A.** Vitamin K 10 mg IM; transfusion of 6 U of platelets; transfusion of 2 U of RBCs to maintain a hemoglobin of 10 mg/dL
   - **B.** Vitamin K 10 mg IM; transfusion of 2 U of RBCs
   - **C.** Fresh-frozen plasma 4–6 U; transfusion of 6 U of platelets
   - **D.** Fresh-frozen plasma 4–6 U; vitamin K

3. **When obtaining informed consent for transfusion from a comatose ICU patient's next of kin, you encounter questions about blood safety and transfusion transmitted diseases. Which of the following viruses have the highest risk of transmission by transfusion?**
   - **A.** Human immunodeficiency virus (HIV)
   - **B.** Hepatitis C virus (HCV)
   - **C.** Hepatitis B Virus (HBV)
   - **D.** Human T-Lymphotropic virus (HTLV)

4. **A 35-year-old male loses approximately 1.5 L (15%) of his blood volume as a result of an accidental arterial laceration during knee surgery. The most appropriate immediate therapy is:**
   - **A.** Crystalloids and RBCs
   - **B.** FFP and RBCs
   - **C.** Whole blood
   - **D.** Crystalloids
   - **E.** FFP and platelets

5. **A 55-year-old female with pancytopenia from MDS (myelodysplastic syndrome) was admitted with fever, and nonpalpable spleen. The patient was 172 cm tall with a weight of 70 kg. The patient was found to have a platelets count of 9,000/µL. She received a unit of single donor platelets (SDP) and her count the next morning was 10,000/µL. She was transfused with another SDP and the 1 h posttransfusion count was 7,000/µL, then she received two SDP platelets and her 1 h posttransfusion count was 8,000/µL. What is the most likely explanation for this response to platelet transfusions?**
   - **A.** Hypersplenism
   - **B.** Fever
   - **C.** DIC
   - **D.** HLA alloimmunization
   - **E.** Sepsis

6. **69-year-old female with hepatitis B and hepatic failure was evaluated for liver transplant. She received 4 U of FFP. Two hours after transfusion was completed she complained of acute dyspnea associated with hypotension and fever. Her pulse oximetry decreased to 89% on room air. Posttransfusion (4 h) X-ray showed new multifocal bilateral airspace opacifications consistent with pulmonary edema.**

   What is the most likely diagnosis?
   - **A.** Transfusion-related acute lung injury (TRALI)
   - **B.** Transfusion Associate volume overload (TACO)
   - **C.** Bacterial contamination
   - **D.** Anaphylactic reaction
   - **E.** Acute hemolytic transfusion reaction

7. **Fresh-frozen plasma transfusion is indicated in all of the following, except:**
   - **A.** Replacement of clotting factors when no specific concentrates are available
   - **B.** vonWillebrand disease
   - **C.** Replacement fluid in therapeutic apheresis for treatment of TTP
   - **D.** In massive transfusion settings
   - **E.** Rapid reversal of warfarin effect

8. **A 92-year-old male with anemia without overt blood loss and decreased renal function of unknown etiology had a hemoglobin of 6.2 g/dL and a hematocrit of 18.3%. Three units of RBCs were ordered. The 3 U were transfused within 5 h. After transfusion of the last unit was completed, the patient became tachypnic, cyanotic, and experienced coughing. His blood pressure increased from 100/60 to 170/90 mmHg. The patient remained afebrile. What is the most likely diagnosis?**
   - **A.** Transfusion associate cardiac overload (TACO)
   - **B.** Transfusion-related acute lung injury (TRALI)
   - **C.** Allergic reaction to transfusion
   - **D.** Anaphylactic transfusion reaction
   - **E.** Bacterial contamination

9. **A 72-year-old male was admitted to the ICU with chest pain and diagnosed with acute myocardial infarction. Hemoglobin at the time of admission was 12.2 g/dL. Platelet count was 135,000/μL. During hospitalization, he developed pneumonia, his oxygen saturation decreased to 86% on room air, hemoglobin decreased to 8.4 g/dL, and platelet count was 110,000/μL. What is the most appropriate course of action?**
   - **A.** Transfusion of RBCs
   - **B.** Transfusion of whole blood
   - **C.** Transfusion of platelet concentrates
   - **D.** Transfusion of RBCs and platelet concentrates
   - **E.** No transfusion at this time

10. **A 35-year-old male aplastic anemia patient with shortness of breath and dizziness was found to have hemoglobin of 5 g/dL and hematocrit of 15%. He received 3 U of blood. What is the expected rise in the patient's hematocrit after the transfusion of 3 U of RBCs?**
    - **A.** 20%
    - **B.** 22%
    - **C.** 24%
    - **D.** 27%
    - **E.** 30%

ANSWERS

1. The answer is C. Leukoreduction is a process that, by means of a filter, removes 99.9% of the blood cells from a unit of blood. This process has been shown to reduce the transmission of CMV (white cells are a site for CMV latency), decrease the incidence of febrile nonhemolytic transfusion reactions, and prevent HLA alloimmunization in patients without previous exposure to blood products. Transfusion-associated graft-versus host disease (TA-GVHD) is a serious adverse sequela of transfusion seen in immunosuppressed patients who are not able to destroy foreign T lymphocytes infused along with cellular blood components; these foreign T lymphocytes will attack the immunosuppressed patient's bone marrow and cause pancytopenia and possibly death. TA-GVHD can also occur in immunocompetent recipients of blood components from donors who are homozygous for an HLA haplotype for which the recipient is heterozygous. Leukoreduction is not sufficient to eliminate the T lymphocytes that cause TA-GVHD; irradiation is the only approved and effective method for the prevention of TA-GVHD.
2. The answer is D. The patient has an upper gastrointestinal bleed. Vital signs are stable. The INR is elevated; the aPTT shows a moderate elevation; and the platelet count is decreased. The low platelet counts and coagulopathy may be in part associated with a consumptive process such as DIC while the elevated INR and PT reflect warfarin effect. Warfarin should be withheld. The patient should be treated with fresh-frozen plasma to rapidly reverse the warfarin effect and correct the INR. Although vitamin K should be given in conjunction, vitamin K alone takes about 6–10 h to be effective even if liver disease were not present. There is no indication to transfuse platelets as the platelet count is above 50,000/μL. RBCs would also not be indicated in this patient without a history of cardiac disease and in the absence of symptoms of anemia.
3. The answer is C. Current highly sensitive laboratory testing of blood donors for viral infectious agents has significantly reduced but not completely eliminated the risk of transfusion transmitted viral disease. Nucleic acid testing (NAT) has significantly reduced the window period for the detection of HIV and hepatitis C viruses. NAT is not presently deemed advantageous over the currently used sensitive hepatitis surface antigen (HBsAg) due to the slow doubling time of virus. Current estimates of the transmission of HIV, HTLV, and HCV in the US are less than 1 in 2,000,000, while the risk of transmission of HBV is estimated to be less than 1 in 200,000.
4. The answer is D. Usually in acute anemia, the body attempts to maintain oxygen delivery mainly by increasing stroke volume and heart rate to increase cardiac output and maintain tissue oxygenation. When volume is the only deficit in an otherwise healthy individual with acute blood loss, the patient can be initially managed with crystalloids and colloids.
5. The answer is D. All the answers listed are associated with platelet refractoriness. Platelet refractoriness may have an immune or a nonimmune basis. An adequate CCI may be reached in cases of nonimmune-mediated platelet refractoriness, but will usually not be sustained as platelets are sequestered, consumed, or otherwise destroyed or removed from the circulation. A failure to achieve adequate CCI on 1 h posttransfusion assessment is suggestive of immune-mediated platelet refractoriness due to the destruction of platelets by antibodies shortly after infusion. Since the patient failed to show an adequate response to each of the several platelet transfusions, the most likely cause is immune-mediated destruction of platelets by HLA antibodies. This patient has most likely become alloimmunized from prior transfusion(s) and/or pregnancies. In such a situation, use of HLA-matched SDP would be indicated. Failure to achieve adequate CCI after a double dose of platelets usually rules out hypersplenism, unless massive.
6. The answer is A. TRALI presents as noncardiogenic pulmonary edema with acute onset respiratory distress with decreased O_2 saturation, hypoxia, fever, and possible hypotension within 6 h of transfusion. The patient may require supportive care including O_2 supplementation or intubation. Criteria for the diagnosis of TRALI consist of severe onset of hypoxemia ($PaO_2/FiO_2 \leq 300$ or

PO_2 ≤90% on room air) within 6 h of transfusion (although most cases occur within 2 h), in a patient with no evidence of circulatory overload (no left atrial hypertension), without preexisting acute lung injury (ALI), occurring without a temporal relationship to alternative risk factor for ALI, and associated with bilateral diffuse lung infiltrates on chest X-ray.

7. The answer is B. vonWillebrand disease is a common hereditary bleeding disorder resulting from qualitative or quantitative abnormalities of vonWillebrand factor (vWF) which is necessary for platelet adhesion. In the absence of pharmacologic (such as DDAVP) and factor concentrates which are preferentially used to treat vonWillebrand disease, cryoprecipitate can be used as it contains factor VIII/vWF in a concentrated form compared to FFP.
8. The answer is A. Patients who are volume expanded or have compromised ability to adjust to volume changes, including those with chronic anemia, renal insufficiency/failure, cardiac disease, the elderly, and the young are particularly at risk for transfusion-associated circulatory (volume) overload. TACO presents similarly to TRALI; the main differential for TRALI is TACO. Although the distinction may be clinically difficult, certain clinical laboratory parameters may be helpful. The presence of hypertension and a high BNP level are consistent with TACO while fever, normal or low BNP level and normal or low blood pressure would suggest TRALI. In TRALI, diuresis is usually ineffective and not indicated. Most patients recover within 48–96 h. Mortality rate in TRALI is approximately 8%. See also answer to questions 6.
9. The answer is A. Transfusion of RBCs is warranted in this patient with acute myocardial infarction and increased oxygen demand. Blood component transfusion should not be dictated solely by laboratory values (hemoglobin levels, platelet counts, etc…) and should be guided by careful consideration of a given patient's clinical condition. Studies indicate that although most stable patients can be adequately managed with restrictive RBC transfusion strategies (with typical transfusion triggers of 7 g/dL or less), elderly patients with cardiac disease, including myocardial infarction, benefit from higher hemoglobin levels and may be transfused at levels greater than 7 g/dL. This patient does not require platelet transfusion as his platelet counts are adequate for hemostasis in the absence of an increased risk for bleeding. Whole blood is rarely available for allogeneic use and would be indicated mainly to increase both oxygen-carrying capacity and replace volume deficit. It is not indicated in this case where the only deficit is in oxygen-carrying capacity (RBCs) and may result in volume overload in this patient with compromised cardiac function.
10. The answer is C. A typical unit of RBCs has a hematocrit of 60% and should raise the hemoglobin by about 1 g/dL and the hematocrit by approximately 3% in an average-sized adult in the absence of ongoing bleeding. A transfusion of 3 U of RBCs should therefore increase the hematocrit by approximately 8–10%.

CHAPTER 56

EDWARD J. BLANCHARD, RAFIK SAMUEL, AND WISSAM CHATILA

Antimicrobials

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Recognize the different classes of antimicrobials used in the critical care setting.
- Understand the mechanisms of action and pharmacology of the various classes of antimicrobials.
- Identify the spectrum of coverage for specific antimicrobials.
- Describe possible adverse effects and drug interactions caused by antimicrobials.
- Select appropriate antimicrobials for various pathogens.

Patients in the intensive care unit (ICU) are often infected with multidrug-resistant organisms.

Judicious use of empiric antimicrobial therapy is needed to minimize the emergence of resistant organisms.

The ICU is a special environment that often harbors a considerable number of highly resistant organisms. Critically ill patients are frequently exposed to broad-spectrum antibiotics and invasive procedures that make them susceptible to colonization by exogenous organisms or to have overgrowth of resistant endogenous strains. As newer antimicrobials have been introduced, many organisms have demonstrated the capability to develop resistance to these newer agents; therefore, it is common to find intensivists facing the challenge of treating highly selected organisms while trying to minimize the emergence of other antibiotic-resistant organisms.

Empiric antibiotic therapy is frequently used in the ICU, but can be a double-edged sword. Early institution of adequate antimicrobial coverage in critically ill patients with documented infections improves their outcomes. On the other hand, overuse of antibiotics in noninfectious situations or the incorrect choice of empiric coverage may be associated with the development of resistant organisms and poor outcomes. In general, clinicians start with broad-spectrum antibiotics for empiric coverage. However, broad-spectrum antibiotics are not all equivalent, and they still must be tailored according to several factors. Once an infection is suspected and after obtaining appropriate diagnostic testing, three factors should help guide the choice of the antibiotic: suspected source of infection, severity of the illness, and local (hospital or ICU) microbiologic flora. The ideal empiric coverage should be an antimicrobial, or combination of antimicrobials, with good tissue penetration and tolerability. Furthermore, knowing the source of the infection, such as the lower respiratory tract, the abdomen, or the central nervous system, can help to streamline the coverage.

A review of selected characteristics of antibiotics commonly used in the ICU follows, and they are grouped according to their class. Because almost all antibiotics used in the ICU are given via the parenteral route, antimicrobials described in this chapter are primarily those given intravenously.

ANTIBACTERIAL DRUGS

There has been a significant increase in the number of antibacterials during the last two decades. The armamentarium of antibacterials has expanded, giving clinicians a wide variety of broad-spectrum agents from which to choose: newer carbapenems, new gram-positive agents like linezolid and daptomycin have been introduced, and older agents like colistin are being used again because of increasing resistance in gram-negative bacilli.

Mechanisms of Action and Resistance

The underlying mechanisms for bacterial killing and growth inhibition differ among the various classes of antimicrobials. Antibacterials are divided into bactericidal and bacteriostatic agents. Some antimicrobials are bactericidal for some strains, while bacteriostatic for others. Moreover, agents are divided according to their pharmacodynamics: some have a concentration-dependent killing effect, while others have a time-dependent killing effect. In the first group, there is a clear relationship between serum drug concentrations and the killing effect, and thus, delivering an adequate dose to reach expected levels at the site of infection is crucial for good response. On the other hand, the latter group of antimicrobials relies on the time of exposure of the bacteria to that antibiotic; the longer the exposure to the antibiotic, the greater the killing effect. Thus, for time-dependent killing drugs, their effectiveness is not related to their concentration above the minimal inhibitory concentration (MIC), but rather to the time span above the MIC; accordingly, adjusting the dosing interval is as important as giving the adequate dose.

Some antibiotics may be bactericidal for some strains, while bacteriostatic for others.

In addition, some antimicrobials exhibit another important property: postantibiotic effect (PAE). The PAE is a period of suppression of bacterial growth after exposure to the antimicrobial concentrations above the MIC. Lastly, the delivery of the antibiotic to the site of infection must be taken into account. For example, when treating meningitis, an antimicrobial that achieves good levels in the cerebrospinal fluid (CSF) should be used. All of these factors should be considered when choosing an antibacterial agent.

Although newer antimicrobials continue to be added to our armamentarium, various bacteria have developed or acquired resistance to commonly used agents. The mechanism to develop or transmit resistance varies among organisms: antimicrobial inactivation, modification of the antimicrobial target, alteration in permeability to the antimicrobial agent, and/or modification of biosynthetic pathways targeted by the antibiotic.

Knowing the pharmacologic properties and mechanisms of action of antimicrobials permits their optimal use and dosing. When giving combination antibiotic therapy, choose agents that have synergistic effects and minimal drug interactions.

Penicillins

Penicillins belong to a larger class of bactericidal antibiotics called the β-lactams, which also includes the cephalosporins, carbapenems, and monobactams. All β-lactam antibiotics work by binding to a variety of penicillin-binding proteins (PBPs) found on the inner cell membranes of certain bacteria, activate endogenous bacterial autolysins, and cause cell lysis. The activity of a β-lactam corresponds to the type of PBP and the degree of affinity to a particular PBP. Formation of β-lactamase enzymes, which hydrolyze β-lactam antibiotics, is the most common mechanism of bacterial resistance to the β-lactams. Gram-positive and gram-negative β-lactamases are different. Gram-positive β-lactamases are either inducible or constitutive, and are often plasmid-mediated. In contrast, gram-negative β-lactamases are more diverse: they are either encoded on bacterial chromosomes, plasmid-mediated, or carried on transposons. Other bacteria escape autolysis by changing the permeability of their outer membranes to antibacterials or altering their PBPs. β-lactam/β-lactamase inhibitor combinations (ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam) have an extended spectrum

β-lactam antibiotics activate bacterial autolysins by binding to specific PBPs on the cell membranes of bacteria. A variety of bacterial β-lactamases target and inactivate these β-lactam antibiotics, accounting for their resistance.

of activity, but β-lactamase inhibitors are not all equipotent. For example, tazobactam has the greatest β-lactamase-inhibiting potency. Also important is the fact that some ESBL (extended-spectrum β-lactamase) producing gram-negative organisms are resistant to all penicillins (including the extended-spectrum penicillins), cephalosporins, and aztreonam.

Cephalosporins

The cephalosporins are usually more resistant to β-lactamases than are the penicillins. Some cephalosporins (e.g., ceftriaxone) can induce production of β-lactamases in *Pseudomonas aeroginosa, Enterobacter* spp., and *Citrobacter* spp., which will affect all other β-lactam antibiotics. Pharmaceutical companies have been able to produce newer generations of cephalosporins by modifying their side chains, thus increasing their affinity to PBPs and their permeability through the outer bacterial cell membrane. It is the side chain that affects the coverage spectrum of these agents and confers some of their properties, including their pharmacokinetics and side effects.

Carbapenems

Another class of β-lactams is the carbapenems (imipenem, meropenem, ertapenem, and doripenem), but they are structurally distinct from the penicillins and cephalosporins. They share the same mechanism of action of the other β-lactams. Although the carbapenems contain the β-lactam ring, they have stereochemical characteristics that make them resistant to hydrolysis by most β-lactamases; consequently, carbapenems have the widest spectrum of activity of all the β-lactam antibiotics. However, some organisms such as *Pseudomonas* spp. are able to produce carbapenamases, conferring resistance to the carbapenems.[1]

Monobactams (Aztreonam)

Aztreonam is the only antibacterial currently available in the monobactam class. Aztreonam contains only the four-membered ring of the basic β-lactam structure. Aztreonam binds exclusively to the PBPs of gram-negative organisms; hence, it is ineffective against all gram-positive bacteria. Aztreonam is not hydrolyzed by many β-lactamases, but bacteria have developed resistance against it by blocking its uptake into the inner cell membrane or by altering their PBPs.

Aminoglycosides

Aminoglycosides exert their bactericidal activity by interfering with bacterial protein synthesis during aerobic metabolism; therefore, the presence of oxygen is required for activity. These agents are potent antibacterials because of both their concentration-dependent killing effect and time-dependent PAE on bacteria. Various mechanisms exist for organisms to develop resistance to aminoglycosides, including ribosomal alterations, changes in the porins in the bacterial cell walls, and pumping of the drug out of the bacteria. Not all agents in this group are equivalent in potency because they differ in their susceptibility to aminoglycoside-inactivating enzymes and their ability to permeate bacterial cell walls.

Fluoroquinolones

Fluoroquinolones inhibit the DNA gyrase of most gram-negative, gram-positive, and some intracellular bacteria. The observed resistance to quinolones has been explained by mutations in the DNA gyrase gene that leads to alteration in the target of the fluoroquinolones, active pumping of the drug out of the bacteria, and decreased permeability through the porins in bacterial cell walls.

Polymyxins (Colistin)

Colistin (polymyxin E) belongs to the polymyxin class of antimicrobials. It is available in primarily two forms: an oral form (colistin sulfate) and a parenteral form (colistimethate

sodium). Originally available for clinical use in the 1950s, the use of colistin decreased over the past two decades because of its side effect profile and the development of newer more tolerable agents for the treatment of gram-negative infections. However, recently, colistin has been reintroduced for the treatment of multidrug-resistant gram-negative bacilli infections. Colistin is a bactericidal agent that acts as a cationic detergent and damages the bacterial cytoplasmic membrane causing leakage of intracellular substances and cell death.[2] Acquired resistance to colistin is uncommon, but has been described in the literature.

Macrolides

Macrolides inhibit bacterial growth by interfering with protein synthesis and are bacteriostatic. Unlike erythromycin, the newer macrolides (clarithromycin and azithromycin) can penetrate the cell membrane of a few gram-negative bacilli (such as *Haemophilus influenzae* and *Moraxella catarrhalis*), and thus, have a broader spectrum of coverage compared to erythromycin. Resistance to macrolides is carried on a plasmid, resulting in alteration of their ribosomal binding site. Resistance to macrolides can also result from active pumping of the drug out of the bacteria.

Lincosamides (Clindamycin)

Clindamycin shares the same mechanism of action as the macrolides, but has a different spectrum of coverage. Clindamycin also inhibits bacterial growth by interfering with protein synthesis. As with the macrolides, resistance to clindamycin is carried on a plasmid resulting in alteration of the ribosomal binding site. Resistance to clindamycin may be inducible and not readily apparent on routine lab sensitivity testing. A clue to possible inducible clindamycin resistance *in vivo* would be a reported resistance to erythromycin on in vitro testing. The lab can perform further testing on the isolate (referred to as a D-test) to determine if the isolate has the propensity for inducible clindamycin resistance. This test is often done on *S. aureus* isolates that are reported as clindamycin sensitive and erythromycin resistant, and a positive D-test means there is potential inducible clindamycin resistance and possible in vivo failure of clindamycin.

Nitroimidazoles (Metronidazole)

Metronidazole is the only nitroimidazole available in the United States. It is bactericidal and acts by inhibiting DNA synthesis. Resistance to metronidazole results from its reduced intracellular uptake; fortunately, this is rare.

Sulfonamides

Sulfonamides exert a bacteriostatic effect by interfering with the substrate metabolism of bacteria. They inhibit enzymes involved in the formation of folic acid and act synergistically with trimethoprim to block purine synthesis. The combination of these two agents, trimethoprim-sulfamethoxazole (SMX), has a net bactericidal effect when bacteria are sensitive to both. Various mechanisms account for trimethoprim-sulfamethoxazole resistance. The two most important mechanisms are an alteration or overproduction of the dihydrofolate reductase enzyme, which is plasmid-mediated, leaving the tetrahydrofolate pathway to synthesize thymidine, and also resistance secondary to decreased cell permeability to the drug.

Glycylcyclines (Tigecycline)

Tigecycline is bacteriostatic and works by binding to the 30S ribosomal subunit of bacteria and inhibiting protein synthesis. The glycylcyclines are a family of antibiotics related to the tetracyclines, but they have been able to avoid a lot of the tetracycline resistance mechanisms that have made the tetracyclines less effective in the ICU. Tigecycline overcomes two major bacterial tetracycline resistance mechanisms: efflux pumping of the

drug out of the bacteria and ribosomal alterations that protect the bacteria from the effects of the antimicrobial.[3] Resistance or decreased efficacy of tigecycline has been noted in the clinical setting, primarily with multidrug-resistant gram-negative rods, especially *Acinetobacter* spp.[4]

Glycopeptides (Vancomycin)

Of the two glycopeptides that have been used clinically, vancomycin and teicoplanin, only vancomycin is currently available in the United States. Vancomycin exerts its activity by inhibiting cell wall synthesis of gram-positive organisms. Unfortunately, the incidence of vancomycin resistance is on the rise. Among the gram-positive bacteria that are resistant to vancomycin, *Enterococcus* spp. are by far the most common, and although they are not as intrinsically virulent as other gram-positive cocci, they are strikingly resistant to many antibiotics. *Enterococcus* spp. carries vancomycin-resistant genes on self-transferable plasmids and transposons that encode for altered vancomycin targets, thereby inhibiting vancomycin binding to the cell wall. However, more concerning is the shift in *S. aureus* MICs to vancomycin. In the 1990s, MICs to *S. aureus* of 8 μg/mL of vancomycin were reported. These organisms were termed glycopeptide intermediate *S. aureus* (GISA). More recently, there has been vancomycin resistance noted in *S. aureus*, using similar mechanisms as the enterococci. In addition, there has been an MIC creep noted in *S. aureus* where MIC's are more frequently approaching one and two.[5] When *S. aureus* MICs to vancomycin reach two, it has been shown that vancomycin is less effective and the use of an alternative antimicrobial should be considered.

Streptogramins (Quinupristin–Dalfopristin)

Quinupristin–dalfopristin is an antibiotic in the streptogramin class that has found utility in the treatment of some vancomycin-resistant gram-positive bacteria, in particular vancomycin-resistant *E. faecium*. It inhibits bacterial protein synthesis by binding to the 50S ribosomal subunit. Quinupristin and dalfopristin are bacteriostatic individually, but they have a synergistic effect and are combined into one bactericidal end product. *Enterococcus faecalis* is intrinsically resistant to quinupristin–dalfopristin secondary to an efflux pump intrinsic to this species.[6] Acquired resistance of *Enterococcus faecium* to quinupristin–dalfopristin is rare.

Oxazolidinones (Linezolid)

Linezolid is currently the only member of the oxazolidinone class of antibacterials. Like quinupristin–dalfopristin, it is useful in the treatment of vancomycin-resistant gram-positive infections. It is also an alternative treatment for MRSA infections. Linezolid is bacteriostatic and works by blocking the 50S ribosomal subunit of gram-positive organisms. An efflux mechanism accounts for intrinsic resistance of gram-negative bacteria to linezolid. Although rare, an acquired resistance of some gram-positive organisms to linezolid has been noted, in particular in some enterococcal isolates.

Cyclic Lipopeptides (Daptomycin)

Daptomycin is a bactericidal agent in the cyclic lipopeptide class of antimicrobials. Along with quinupristin–dalfopristin and linezolid, daptomycin is effective against resistant gram-positive organisms, including VRE and MRSA. Daptomycin works by binding to the cell membrane of gram-positive bacteria, weakening the cell membrane, and allowing ions to leak out of the bacteria. This leads to a depolarization of the membrane and cessation of multiple necessary bacterial cell processes, leading to the death of the bacteria. Gram-negative bacteria are inherently resistant to daptomycin because the drug is unable to penetrate their outer cell membrane.[7] Acquired resistance to daptomycin against gram-positive organisms is rare, but has been reported.

Spectrum of Coverage

Penicillins

Older-generation β-lactam antibiotics are active against primarily gram-positive aerobic organisms. β-lactam/β-lactamase inhibitor combinations and carbapenems have a wider range of coverage and are often used for empiric therapy, especially when resistant organisms are suspected.

In most ICUs, penicillin G, ampicillin, and even the penicillinase-resistant penicillins (nafcillin, oxacillin) have fallen out of favor as first-line empiric therapy because of the high incidence of resistance to these agents. Certain exceptions may exist. For example, ampicillin is recommended for the empiric treatment of acute meningitis, together with a third-generation cephalosporin ± vancomycin, in patients with defective cell-mediated immunity, due to the high risk of *Listeria monocytogenes* infection in this population. Oxacillin may be considered as initial therapy for suspected staphylococcal infections only if the local ICU flora has a very low incidence of methicillin-resistant coagulase-negative or coagulase-positive staphylococci. Once the organism and its sensitivity have been identified, the penicillins are the drugs of choice for infections caused by susceptible streptococci, staphylococci, and enterococci.

In contrast, the newer β-lactam/β-lactamase inhibitor combinations (ticarcillin-clavulanate, piperacillin-tazobactam) are often used for empiric coverage because of their broad gram-positive (excluding MRSA and some enterococcal isolates), gram-negative (including *Pseudomonas aeruginosa)*, and anaerobic spectrum. Among the β-lactam/β-lactamase inhibitor class, piperacillin-tazobactam stands out because of a greater bactericidal effect of piperacillin and the greater β-lactamase-inhibiting potency of tazobactam. Nonetheless, certain gram-negative organisms such as ESBL-producing *Klebsiella, Acinetobacter,* and *Pseudomonas* are resistant against all penicillins and usually against the extended-spectrum penicillins. Therefore, the antibacterial of choice for these organisms is usually a carbapenem if susceptible. Local ICU bacterial resistance rates should always be used to dictate the choice of empiric antibiotics.

Cephalosporins

First-generation cephalosporins (cefazolin, cephalexin) have good activity against beta-hemolytic streptococci and methicillin-sensitive *S. aureus* (MSSA). Second-generation cephalosporins (cefuroxime, cefoxitin, cefotetan) gain some gram-negative coverage while maintaining adequate gram-positive coverage. Cefuroxime is very active against MSSA and streptococcal spp. (including alpha-hemolytic streptococci) and is stable in the presence of most β-lactamases. The third generation is characterized by two types of agents: antipseudomonal cephalosporins (ceftazidime) and broad-spectrum cephalosporins (cefotaxime, ceftriaxone). Although the activity of ceftazidime is broad against gram-negative organisms, it induces resistance to many β-lactams, especially in the *Enterobacter* spp. Both cefotaxime and ceftriaxone have excellent activity against *Streptococcus* spp. and have some gram-negative activity, but their activity against MSSA is less than that of the earlier cephalosporin generations. Because of their broad coverage, cefotaxime and ceftriaxone are widely used as first-line empiric therapy for community-acquired infections, and in particular, for bacterial meningitis due to their excellent CSF levels. A fourth generation cephalosporin, cefepime, has activity of both the antipseudomonal and the broad-spectrum third-generation cephalosporins. Cefepime is stable against β-lactamases and has activity superior to ceftazidime against *Pseudomonas aeruginosa.* Cefepime also has excellent activity against streptococcal spp. and moderate activity against MSSA. Therefore, cefepime is the cephalosporin of choice in the empiric treatment of nosocomial infections and for the febrile neutropenic patient.

Carbapenems

Carbapenems have the most broad-spectrum coverage available. Except for methicillin-resistant *Staphylococcus aureus* (MRSA), *Enterococcus faecium*, *Stenotrophomonas maltophilia,* and *Burkholderia cepacia*, carbapenems inhibit almost all anaerobic, gram-positive, and gram-negative organisms. Ertapenem has a narrower spectrum of activity than the other carbapenems, and is not a good choice for *Pseudomonas* or *Acinetobacter*. In some ICUs, carbapenems are not used as first-choice empiric therapy except if resistant or polymicrobial infections are suspected. Meropenem is not significantly more active than imipenem or doripenem, but may be preferred in some ICUs because of its relatively lower incidence

of seizures than the other carbapenems. If susceptible, carbapenems are the first choice for the treatment of ESBL-producing gram-negative bacilli. It should be noted that carbapenemases may be present in broadly resistant gram-negative bacilli such as *Pseudomonas aeruginosa* and *Acinetobacter baumanii,* and to a lesser extent, *Klebsiella* spp.

Monobactams (Aztreonam)

Aztreonam has good activity against gram-negative aerobic pathogens including *P. aeruginosa,* but is usually not used as monotherapy unless susceptibility is documented. It is sometimes used as a substitute for the aminoglycosides or fluoroquinolones, or for those who are allergic to the other β-lactams. Aztreonam is ineffective against ESBL-producing gram-negative bacilli.

Aminoglycosides

Aminoglycosides are used in gram-negative infections and to enhance the activity of β-lactams and glycopeptides against some gram-positive organisms.

Aminoglycosides are well known for their excellent activity against gram-negative aerobic bacteria. They have a synergistic inhibitory effect against *S. aureus*, viridans streptococci, and enterococci when combined with an effective β-lactam or glycopeptide. Limitation to the use of aminoglycosides is related to their toxicity rather than to their activity. Nonetheless, in view of the high prevalence of resistant gram-negative bacteria in some ICUs, aminoglycosides continue to be indispensable because of their strong activity against some of these organisms. For suspected pseudomonal infections, tobramycin is preferred because it is more potent than gentamicin, and for suspected multiresistant infections, amikacin is the aminoglycoside of choice because it is less susceptible to inactivating enzymes.

Fluoroquinolones

Fluoroquinolones are remarkable for their broad coverage, including atypical intracellular organisms, and are usually preferred over aminoglycosides for gram-negative infections because of their safety profile.

Moxifloxacin does not achieve an adequate level in the urine and should not be used to treat infections of the urinary tract.

This group of antimicrobials has expanded dramatically. Intensivists have numerous potent intravenous broad-spectrum fluoroquinolones to choose from (ciprofloxacin, levofloxacin, moxifloxacin). Ciprofloxacin has excellent activity against many gram-negative bacteria. Levofloxacin and moxifloxacin have excellent activity against intracellular atypical organisms *(Chlamydia, Legionella,* and *Mycoplasma*). Compared to the newer fluoroquinolones, ciprofloxacin remains the most potent against *P. aeruginosa*. The newer fluoroquinolones, levofloxacin and moxifloxacin, have good activity against gram-positive bacteria, including some penicillin-resistant streptococcal species. Moxifloxacin is unique among the fluoroquinolones because of its activity against anaerobes. Fluoroquinolones are used to treat urinary tract infections and are still excellent drugs for this purpose because of their elevated urine concentrations, but moxifloxacin is an exception. Moxifloxacin is not eliminated by the kidneys, so it should not be used for the treatment of urinary tract infections.

Polymyxins (Colistin)

Colistin should be reserved to settings where organisms are resistant to other currently approved agents.

Colistin has a relatively narrow spectrum of activity, but is active against most gram-negative aerobic bacilli. In particular, it is usually active against multidrug-resistant *Pseudomonas aeruginosa*, *Acinetobacter* spp., *Stenotrophomonas maltophilia*, and ESBL-producing gram-negative bacilli such as *Klebsiella* spp. and *E. coli*. It is inherently inactive against the following gram-negatives: *Burkholderia cepacia*, *Serratia* spp., *Proteus* spp., *Providencia* spp., and *Pseudomonas mallei*. Other bacteria inherently resistant to colistin include all gram-positive bacteria, as well as all gram-negative cocci. Colistin is used as a last resort for the treatment of multidrug-resistant gram-negative infections, but the published literature is unclear about its efficacy in treating such infections.

Macrolides

Azithromycin and clarithromycin have surpassed the spectrum of erythromycin, but only azithromycin is available in the intravenous formulation. All three agents have some activity against respiratory gram-positive bacteria and some atypical intracellular organisms

(*Legionella, Mycoplasma,* and *Chlamydia*). The newer macrolides have the advantage over erythromycin of fewer side effects, more favorable pharmacokinetics, and enhanced potency against atypical organisms as well as *Mycobacterium avium intracellulare complex* (MAC), *Helicobacter pylori, Moraxella catarrhalis,* and *Haemophilus influenzae*. Even with the added properties of azithromycin, it is usually not preferred as first-line empiric therapy in the ICU because of its unpredictable coverage against resistant gram-positive bacteria. However, azithromycin is often used in combination with ceftriaxone for the empiric treatment of community-acquired pneumonia.

Lincosamides (Clindamycin)

Clindamycin is well known for its potent activity against gram-positive anaerobes, in particular those anaerobes that reside in the mouth, accounting for its use in the treatment of serious anaerobic infections above the diaphragm. Clindamycin also inhibits *S. aureus* (including MRSA) and some streptococcal species as well as *Toxoplasma gondii* and actinomycetes. *Clostridium difficile* and a small percentage of *Bacteroides* spp., which are found most frequently below the diaphragm, are resistant to clindamycin but not to metronidazole. Clindamycin is also used in combination with β-lactams or glycopeptides in the treatment of toxin-mediated diseases, such as necrotizing fasciitis. Clindamycin helps to decrease toxin production by inhibiting protein synthesis due to these organisms.[8]

Nitroimidazoles (Metronidazole)

Metronidazole is the preferable agent for the treatment of anaerobic abdominal and genital infections. It has activity against gram-negative and some gram-positive anaerobes, including *Bacteroides*, *Fusobacterium,* and *Clostridium* spp., as well as some protozoa including Entameoba and Giardia. Metronidazole has poor activity against anaerobes that reside in the mouth, such as *Peptostreptococcus*. Metronidazole is a good choice for the treatment of *Clostridium difficile* infection.

Sulfonamides

Sulfonamides are less effective compared to the available broad-spectrum antibiotics, and except under certain circumstances, they are not first-line therapy in the ICU. SMX is combined with trimethoprim (TMP) because of its *in vitro* synergistic activity. Sulfonamides inhibit a variety of aerobic gram-positive and negative bacteria, as well as *Nocardia* and *Pneumocystis jirovecii (carinii)*. TMP-SMX used in the ICU is often limited to patients known to have susceptible organisms, or to immunocompromised patients suspected to have *P. jirovecii* infections. TMP-SMX is also a first-line treatment for infections caused by the gram-negative bacilli *Stenotrophomonas maltophilia* and *Burkholderia cepacia*.

Glycylcyclines (Tigecycline)

Tigecycline has a broad spectrum of activity. It is active against atypicals, enterococci (including VRE), staphylococci (including MRSA), and *Streptococcus* spp. It also has some activity against most gram-negative bacilli and anaerobes, but is inherently inactive against *Pseudomonas* spp. and is less effective against *Proteus* and *Providencia* spp. Because of its broad spectrum of activity, tigecycline may be most effective in polymicrobial infections, in particular skin and soft tissue infections and intrabdominal infections. In general, tigecycline is effective against ESBL-producing gram-negative bacilli, such as *Klebsiella* spp. and *E. coli*. While tigecycline is effective in vitro against *Acinetobacter* isolates, there is increasing concern with clinical treatment failures with multidrug-resistant strains of *Acinetobacter* spp.

Tigecycline is inactive against *Pseudomonas* spp. and is less effective against *Proteus* and *Providencia* spp.

Tigecycline does not achieve adequate levels in the urine or the blood and should not be relied on for the treatment of infections of the urinary tract or for bacteremia.

Glycopeptides (Vancomycin)

Vancomycin, introduced around 40 years ago, had been the only drug available in the United States for effective treatment of resistant gram-positive organisms including MRSA and

certain enterococcus species. Newer agents, including linezolid and daptomycin, are now available for these resistant gram-positive organisms. Nonetheless, whenever *S. aureus* infections are suspected in an ICU endemic with MRSA, vancomycin must be included in the empiric therapy. Lastly, oral vancomycin has an important role in the treatment of resistant or severe *Clostridium difficile* colitis.

Streptogramins (Quinupristin–Dalfopristin)

Quinupristin–dalfopristin is not active against *Enterococcus faecalis*.

Quinupristin–dalfopristin is effective against MSSA, MRSA, streptococci, and *Enterococcus faecium*, including vancomycin-resistant strains. Quinupristin–dalfopristin is not active against other strains of Enterococcus. Therefore, it is generally not used for empiric enterococci therapy in the ICU, since *E. faecalis* is more common in hospitals than is *E. faecium*.

Oxazolidinones (Linezolid)

Linezolid is only active against gram-positive aerobes. Linezolid has a similar spectrum of activity to quinupristin–dalfopristin, including MRSA, MSSA, and streptococci. However, linezolid, unlike quinupristin–dalfopristin, is active against all species of Enterococci, including vancomycin-resistant strains. While vancomycin is generally first-line therapy for infections caused by MRSA, linezolid is an alternative therapy. Linezolid has good lung penetration and is considered the first alternative to vancomycin in patients with MRSA pneumonia. However, since linezolid is bacteriostatic, it is generally not recommended for use in infections where a bactericidal agent would be preferred, such as bacteremia and other endovascular infections.

Cyclic Lipopeptides (Daptomycin)

Daptomycin should not be used for pulmonary infections because it is inactivated by surfactant.

Daptomycin is only active against gram-positive organisms. It has a similar spectrum of activity to linezolid, which includes VRE and MRSA. Of note, daptomycin should not be used for gram-positive pulmonary infections due to inactivation of the drug by surfactant. Daptomycin, quinupristin–dalfopristin, and linezolid are important alternative therapeutic options when an MRSA isolate has an intermediate or resistant MIC to vancomycin (MIC > 2), or when MRSA infections fail to respond to vancomycin.

Pharmacology and Adverse Effects

Although it is easy enough to find antibiotic doses in various references, care should be taken to individualize the therapy in the ICU because of critical illness-altered physiology and drug interactions. Most references give the dosing according to the severity of infection and renal function, and as discussed earlier, one should also guide therapy by the susceptibility of the suspected organisms. Successful treatment is determined not only by the availability of potent antibacterials, but also the tolerability to these drugs. Maximizing therapeutic effects of a certain regimen while minimizing toxicity can be executed by tailoring drug dosing according to principles of pharmacokinetics (bioavailability, volume of distribution, and clearance) and pharmacodynamics (relationship between drug movement and pharmacologic response).

The rational approach to dosing that relies on pharmacology can be summarized as follows: (1) the volume of distribution determines the loading dose; (2) the elimination rate, i.e., clearance (excretion and metabolism), at steady-state determines the maintenance dose; (3) three to five half-lives are needed to attain steady-state plasma levels; and (4) adverse drug events are often preventable by optimizing the levels and considering drug interactions. Almost all critically ill patients are inflicted with one or more system dysfunctions that may affect protein binding, volume of distribution, and clearance. Drug interactions can increase or decrease drug effects, thereby possibly increasing the risk for toxicity or therapeutic failure. Careful consideration of these factors should eliminate most adverse reactions, but not those caused by hypersensitivity reactions, alteration in the normal bacterial flora, or idiosyncratic events, which are reactions not often related to dose or concentration. In the ICU

setting, except for specific infections and antimicrobials, the parenteral route is usually used to deliver antibiotics to maximize their bioavailability.

Penicillins

Penicillins are nonuniform regarding their protein binding, and the volume of distribution is inversely related to the degree of protein binding. Their half-life is relatively short (<2 h), requiring frequent doses per day, and most are renally excreted, requiring dose adjustment in renal failure. Nafcillin and oxacillin are an exception in this class because they are cleared by the liver. Shortening the dosing interval, as well as increasing the dose, should be considered when the volume of distribution is significantly increased. Many types of penicillin are poorly absorbed, so this can lead to diarrhea when oral therapy is needed, and usually a conversion from intravenous to oral therapy results in a significant decrease in the amount of active drug in the body.

Be aware of factors that may alter the pharmacokinetics of your antibiotic of choice, such as renal insufficiency, severe malnutrition, and drug interactions.

Side Effects

Penicillins are relatively safe agents, and their dose-related toxicity is of less concern than their hypersensitivity reactions; allergic reactions to penicillins have been reported to occur in approximately 0.7–10.0% of patients, but severe life-threatening reactions are rare. The real inconvenience of allergic reactions, after they have been documented and treated, derives from the cross-reactivity with other β-lactams, which often precludes the use of these other antibacterials. Allergic reactions may be manifested as a simple rash, urticaria, serum sickness, exfoliative dermatitis, or anaphylaxis. Interstitial nephritis, which has been seen after prolonged and large doses of β-lactams, may be immunologically mediated and is considered a form of delayed hypersensitivity. If penicillins are the only effective therapy available for patients with documented penicillin allergies, desensitization should be performed before the administration of these agents. Dose-related side effects observed with some penicillins include salt and volume overload (ticarcillin), neurotoxicity (any penicillin), and bleeding secondary to impaired platelet aggregation (ticarcillin). Reversible neutropenia (methicillin), thrombocytopenia, hypokalemia, and *Clostridium difficile* colitis are other nondose-related adverse reactions that may be seen with these antibiotics.

Nafcillin and oxacillin are the only penicillins cleared by hepatic metabolism, so they do not require dosage adjustment in renal insufficiency.

Hypersensitivity reactions are the most common side effects of cephalosporins and penicillins. There is a certain degree of cross-reactivity between these two classes and carbapenems; in the event of serious allergic reaction to one of these three classes, antibiotics from the other two classes should be avoided.

Drug Interactions

Probenecid competes with the renal tubular secretion of penicillins and has been used historically to potentiate therapy. Nafcillin inhibits the efficacy of warfarin and reduces cyclosporine levels.

Cephalosporins

Like penicillins, there is significant variation within the cephalosporins in their degree of protein binding and volume of distribution. Although most are renally excreted, hepatic metabolism and biliary elimination are important clearance mechanisms for some agents in this group (i.e., ceftriaxone). Doses of most cephalosporins should be adjusted in the presence of renal insufficiency; however, ceftriaxone does not require dosage adjustment in renal dysfunction. Moreover, ceftriaxone and cefotaxime cross the blood–brain barrier effectively and are useful for the treatment of CNS infections.

Ceftriaxone is the only cephalosporin that is metabolized by the liver, so it does not require dosage adjustment in renal insufficiency.

Side Effects

Cephalosporins are also similar to penicillins in regard to their adverse reactions. Hypersensitivity reactions are the most common side effects. Associated coagulation abnormalities, gastrointestinal symptoms, phlebitis, and *Clostridium difficile* colitis can also occur. Studies have reported 1–20% allergy cross-reactivity between penicillins and cephalosporins. Patients who had a severe allergic reaction to penicillins should not be given cephalosporins

because they are at risk to develop a similar reaction, and penicillin skin testing does not predict cephalosporin anaphylactic reactions. In general, there tends to be less cross-reactivity in penicillin allergic reactions with the higher generation cephalosporins.

Drug Interactions

Probenecid decreases the renal clearance of many cephalosporins (cefazolin, cefotaxime, cefuroxime). A group of cephalosporins containing the 1-*N*-methyl-5-tetrathiozolethiol (NMTT) side chain (cefamandole, cefotetan) have an additive anticoagulant effect to warfarin causing excessive bleeding.

Carbapenems

Imipenem is metabolized in the renal tubules and is combined with cilastin, an inhibitor of dehydropeptidase I, causing a reduction in its renal toxicity and a reduction in its metabolic clearance by the renal tubules. Meropenem is not degraded by the renal peptidase and does not require cilastatin. Both of these carbapenems have a half-life of about 1 h and are renally excreted. Imipenem is 20% protein bound and penetrates into the neurons, which may explain its greater epileptogenic potential compared to meropenem. Of note is that ertapenem has a significantly longer half-life compared to the other carbapenems. Therefore, despite its narrower spectrum compared to the other carbapenems, ertapenem may be useful when a once-daily drug is preferred and the bacterial isolate is ertapenem-susceptible.

Side Effects

As with the other β-lactams, hypersensitivity reactions are the most common adverse reactions, and cross-reactivity with the penicillins has been reported. In fact, there is probably a higher cross-reactivity between penicillin allergies and carbapenems, than with penicillin allergies and cephalosporins. Seizures can result from high doses of any β-lactam. However, among the β-lactams, carbapenems have the greatest potential to induce seizures; seizures are likely related to carbapenem overdosing in patients with risk factors including old age, preexisting central nervous system disease, and renal failure. Meropenem is known to have a less epileptogenic potential than the other carbapenems.

Drug Interactions

Concurrent therapy of carbapenems (especially imipenem) with any other drug that lowers the seizure threshold may further increase the risk for seizures.

Monobactams (Aztreonam)

The pharmacokinetic properties of aztreonam are similar to other β-lactams. It has a relatively short half-life, and is excreted mostly in the urine. Its elimination decreases in renal failure, so it requires dosage adjustment in renal dysfunction. Interestingly, aztreonam produces fewer hypersensitivity reactions and has minimal allergy cross-reactivity with penicillins or other β-lactams, except for ceftazidime. Aztreonam and ceftazidime are similar structurally, so caution should be taken in using aztreonam in patients who have had a definite allergic reaction to ceftazidime. Nausea, vomiting, rash, and an isolated rise in transaminases have been reported with aztreonam.

Aminoglycosides

Aminoglycosides are hydrophilic and polycationic compounds. Protein binding of aminoglycosides is low; they diffuse mainly into extracellular fluids and have a large volume of distribution, increasing with protein depletion. Aminoglycosides are not metabolized and are cleared almost exclusively by glomerular filtration. Therefore, dosing should be adjusted

according to renal function because of their narrow therapeutic window. Because of their toxicity profile, monitoring of aminoglycoside levels is important. The concentration-dependent killing and PAE of aminoglycosides, together with the fact that their uptake across the brush border of proximal renal tubular cells is saturable, has shifted aminoglycoside dosing frequency from intermittent dosing to once daily. Although there is enough data to suggest that once-daily administration of aminoglycosides is as effective as intermittent administration and possibly less nephrotoxic,[9] there is limited information on such practice in patients with renal insufficiency, women who are pregnant, and subgroups of critically ill patients. Nevertheless, once-daily dosing of aminoglycosides is becoming the standard dosing regimen. The one exception to this is the use of aminoglycosides with β-lactams or glycopeptides for synergy, where the standard regimen is still multidosing per day of a low dose of aminoglycoside.

Aminoglycosides have a narrow therapeutic window and are well known for their nephrotoxicity and ototoxicity. Once-daily dosing may be the preferable dosing interval to maximize killing and decrease adverse effects.

Side Effects

Aminoglycosides are known for their dose-related nephrotoxicity, ototoxicity, and neuromuscular paralysis. With the exception of the ototoxicity, these adverse reactions are reversible. Nephrotoxicity ranges from being asymptomatic with elevated creatinine to acute renal failure. The nephrotoxicity has been associated with elevated trough serum aminoglycoside levels and potentiated by hypotension, exposure to other nephrotoxic drugs, female sex, and liver disease. Ototoxicity of aminoglycosides includes vestibular damage, causing vertigo, and cochlear damage, causing hearing loss. Neuromuscular paralysis is more likely to appear with concurrent administration of neuromuscular blocking agents or with coexisting neuromuscular pathology.

Drug Interactions

Aminoglycosides have an additive renal toxicity when given with other nephrotoxic drugs, an additive ototoxicity with ethacrynic acid and possibly with furosemide, and a cumulative effect with nondepolarizing muscle relaxants. Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the renal clearance of aminoglycosides, raising their trough levels.

Fluoroquinolones

Except for moxifloxacin, fluoroquinolones are eliminated mostly by urinary excretion, and to a lesser extent, by biliary secretion. Most fluoroquinolones require dose reduction in renal dysfunction. Moxifloxacin is an exception; it does not require dosage adjustment in renal dysfunction. However, since it is not eliminated by urinary excretion, it should not be used in the treatment of urinary tract infections. Fluoroquinolones have a relatively long half-life (>4 h), and their plasma protein binding ranges from 20 to 40%. Their bioavailability is 80–100%, so the oral dose is roughly equivalent to the intravenous dose.

Side Effects

Side effects include gastrointestinal symptoms (nausea, anorexia, vomiting, diarrhea), photosensitivity (skin reactions), and neurologic symptoms (dizziness, headaches, agitation, seizures, hallucinations). Arthralgias are an uncommon side effect, and Achilles' tendon rupture is a very rare adverse effect of fluoroquinolones. They are pregnancy category C (they may interfere with skeletal formation), and their safety has not been established in the pediatric age group. Also, fluoroquinolones, especially moxifloxacin, have the potential to cause QT prolongation.

Drug Interactions

Fluoroquinolones inhibit hepatic metabolism of many drugs (theophylline, cyclosporine, midazolam, NSAIDs, warfarin) by inhibiting cytochrome P450-1A2, thereby interfering with their clearance and increasing their effect. Although minerals, antacids, sucralfate, and

morphine sulfate reduce the absorption of oral fluoroquinolones, they do not interfere with the bioavailability of intravenously administered fluoroquinolones.

Polymfyxins (Colistin)

Nephrotoxicity and neurotoxicity are the most notable adverse effects of colistin.

Colistin requires dosage adjustment in renal insufficiency. Because colistin was introduced over 50 years ago, it was not subjected to the same regulations that modern drugs are subjected to, and it, therefore, does not have standardized dosing, and there are no detailed trials on pharmacology or pharmacokinetics. In terms of side effects, the most notable side effect of colistin is nephrotoxicity, usually in the form of an acute tubular necrosis. It is a dose-dependent nephrotoxicity that is generally reversible upon discontinuation of the drug. Impaired baseline renal function or concurrent use of other nephrotoxic drugs increases the risk of colistin-induced renal failure. Another side effect of colistin is neurologic toxicity, which can manifest as dizziness, facial and peripheral paresthesias, vertigo, confusion, ataxia, and neuromuscular blockade, which can lead to respiratory failure.

Macrolides

Clarithromycin is not available for parenteral administration. Azithromycin has replaced erythromycin in many ICUs because of its favorable pharmacokinetics, minimal adverse effects, less significant drug interactions, and lower infusion volume. Macrolides are lipid soluble. They distribute extensively into the tissues and have a slow release from the tissues.

Side Effects

Gastrointestinal reactions and thrombophlebitis are common side effects during erythromycin therapy; however, incidence is lower with the newer macrolides. Hypersensitivity reactions, cholestatic hepatitis, and reversible deafness are rare, but are the more serious adverse reactions of erythromycin. Hepatitis is related to the estolate salt preparation of erythromycin and not to intravenous therapy with erythromycin lactobionate or gluceptate; therefore, a history of hepatitis after oral erythromycin is not a contraindication for the use of intravenous erythromycin or azithromycin.

Drug Interactions

Erythromycin induces liver microsomal enzymes and decreases the oxidative metabolism of many drugs. These effects are observed to a lesser degree with clarithromycin and not at all with azithromycin. Erythromycin and clarithromycin are potent inhibitors of the cytochrome P450 enzymes. Therefore, there can be increased levels and possibly toxicity when these drugs are used concurrently with the following drugs: carbamazepine, valproic acid, phenytoin, theophylline, warfarin, cyclosporine, digoxin, lovastatin, methylprednisolone, midazolam, zidovudine, bromocriptine, and ergotamine.

Lincosamides (Clindamycin)

Diarrhea is a common adverse effect associated with clindamycin. Clindamycin can cause a benign self-limited diarrhea, or may result in the more severe *Clostridium difficile* colitis. Although traditionally clindamycin has a strong association with causing *C. difficile* colitis, the cephalosporins and fluoroquinolones are probably a more common cause of *C. difficile* colitis now, given how much more often they are used in clinical practice than is clindamycin. Clindamycin can also cause nausea and rash.

Nitroimidazoles (Metronidazole)

Metronidazole has nearly 100% bioavailability, so the oral route is equivalent to the intravenous route. Metronidazole has been associated with a disulfiram-like reaction, so patients should abstain from alcohol while taking this medication. Metronidazole's side effects also

include nausea, vomiting, and diarrhea, as well as a metallic taste. There can also be a dose-related peripheral neuropathy caused by metronidazole. Metronidazole interacts with warfarin, potentiating its anticoagulant effects.

Sulfonamides

Trimethoprim has good tissue penetration and a large volume of distribution that exceeds that of SMX. TMP-SMX and their metabolites from hepatic metabolism are excreted by the kidneys. They are combined in a dose ratio of 1:5 (TMP:SMX), but because the volume of distribution of SMX is much lower than that of TMP, their plasma ratio becomes 1:20 at peak levels, the optimal ratio for synergistic activity. Dosing for TMP-SMX is based on the TMP component, and the dose is 15–20 mg/kg/day of TMP for *Pneumocystis jirovecii (carinii)* and it is 10 mg/kg/day for the treatment of other systemic infections.

Side Effects

Skin rashes due to hypersensitivity reactions are common. The rash is most commonly due to the SMX component. Through its action on the folic acid pathway, TMP interferes with vitamin replacement in patients with megaloblastic anemia and may induce severe but reversible bone marrow suppression; hence, its relative contraindication in patients who are predisposed to have megaloblastic anemia (pregnancy, patients on phenytoin, etc.). The SMX component can cause acute interstitial nephritis leading to acute renal failure. In addition, the TMP component can cause an increase in measured serum creatinine by blockade of creatinine secretion into the renal tubules, without affecting the true glomerular filtration rate. TMP can also cause hyperkalemia. Lastly, TMP-SMX is associated with aseptic meningitis that resolves with discontinuation of the drug.

Drug Interactions

TMP can increase the effects of digoxin, phenytoin, procainamide, sulfonylureas, warfarin, and zidovudine by either decreasing their renal elimination or decreasing their metabolism. In addition, TMP-SMX may reduce cyclosporine serum levels.

Glycylcyclines (Tigecycline)

Tigecycline is only available in the intravenous form. It requires no dosage adjustment in renal insufficiency or after dialysis. It is given as a loading dose of 100 mg, then 50 mg every 12 h. Dosage adjustment is required for severe hepatic impairment. Tigecycline has minimal excretion into the urine, so in general, it should not be used for infections of the urinary tract. The most common side effects are nausea, vomiting, diarrhea, and headache. Tigecycline has minimal drug interactions.

Glycopeptides (Vancomycin)

Vancomycin is not absorbed after oral ingestion, but is given orally to treat *C. difficile* colitis. Vancomycin pharmacology and reactions in this section are those of systemic intravenous therapy. Vancomycin is principally eliminated by glomerular filtration and has a variable half-life (3–13 h), and about 55% is bound to serum proteins. Obtaining vancomycin plasma levels in patients with normal or mildly-reduced renal function is somewhat controversial because there is no evidence that this practice reduces vancomycin toxicity or improves outcomes. Dosage nomograms for vancomycin based on renal function are available and may obviate the need for frequent vancomycin levels. Vancomycin is partially removed by conventional hemodialysis, and infusions at dialysis in end-stage renal disease usually assure adequate trough levels; nonetheless, slow continuous removal of vancomycin may occur during continuous veno-venous hemodialysis (CVVHD). When there is any doubt about

serum vancomycin concentrations, such as for patients with unstable renal disease or on CVVHD, levels should be obtained to maintain adequate therapeutic levels.

Side Effects

Measuring vancomycin levels is not necessary in patients with normal renal function and close to ideal body weight.

"Red-man syndrome" is a reaction to vancomycin related to the rapidity of its infusion and is not considered to be a hypersensitivity reaction. Flushing of the upper body, pruritis, and in rare cases, hypotension may result from histamine release. These reactions can be prevented by slower administration of vancomycin or by the use of antihistamines. True allergic reactions can also occur and should be differentiated from the red-man syndrome because management of the two conditions is dissimilar. Ototoxicity and blood dyscrasias have also been reported. Tinnitus and dizziness have preceded hearing loss, despite discontinuation of vancomycin. Risk factors to develop ototoxicity include renal failure, old age, and elevated peak vancomycin levels.

Drug Interactions

Increased risk of ototoxicity can occur when vancomycin is coadministered with aminoglycosides.

Streptogramins (Quinupristin–Dalfopristin)

Quinupristin–dalfopristin is only available in the intravenous form. It can cause thrombophlebitis and significant pain at the infusion site and should be administered through a central venous catheter. It inhibits the cytochrome P450 3A4 system and can result in potential drug interactions with other medications that are metabolized by this hepatic system. Quinupristin–dalfopristin has been found to cause an increase in conjugated bilirubin levels in some patients. Probably the most important factor limiting the use of quinupristin–dalfopristin is its propensity to cause significant myalgias and arthralgias.

Oxazolidinones (Linezolid)

Linezolid does not require dosage adjustment for renal or hepatic insufficiency, and has excellent oral bioavailability.

Linezolid has a bioavailability of almost 100%, so the oral form is an equivalent dosing to the intravenous form. The dose of linezolid does not need to be adjusted for renal or hepatic dysfunction. Linezolid can cause GI side effects and bone marrow suppression. The bone marrow suppression results predominantly in thrombocytopenia, which is more common when the drug is administered for longer than 2 weeks. Peripheral neuropathy is also a notable but uncommon adverse effect. Linezolid is a weak inhibitor of monoamine oxidase (MAO). It can cause a serotonin syndrome when it is used concurrently with other serotonergic agents, primarily selective serotonin reuptake inhibitors (SSRIs). This adverse effect is uncommon, but patients should be closely monitored for signs of serotonin syndrome if they are continued on linezolid and their SSRI.

Cyclic Lipopeptides (Daptomycin)

Daptomycin is only available in the intravenous form. It is rapidly bactericidal in a concentration-dependent manner and requires dosage adjustment in renal impairment. For patients with a creatinine clearance of <30 mL/min (including patients on dialysis), daptomycin should be dosed every other day. Otherwise, daptomycin is dosed at 4 mg/kg/day for skin and soft tissue infections, and it is dosed at 6 mg/kg/day for staphylococcal bacteremia and right-sided endocarditis. Daptomycin is not recommended for the treatment of pulmonary infections.

Side Effects

The most notable adverse effect of daptomycin is skeletal muscle toxicity. This can manifest as muscle pain, weakness, or even rhabdomyolysis. In general, creatine kinase levels should be checked weekly for patients on daptomycin.

Drug Interactions

There is an increased risk of skeletal muscle toxicity when daptomycin is given with other drugs that can also cause muscle toxicity, such as HMG-CoA reductase inhibitors.

ANTIFUNGAL DRUGS

Fungal infections are commonly seen in the ICU because of a sicker patient population and the frequent use of broad-spectrum antibiotics that change the host flora. The number of fungal infections in general has increased because of the rise in the number of patients who are immunocompromised (e.g., HIV, organ transplant recipients), those who have indwelling intravenous catheters, and the increased use of antibacterial agents. Although amphotericin B is a potent and broad-spectrum antifungal, it has significant adverse effects and is, therefore, not frequently used. Other classes of antifungals, including the triazoles and the echinocandins, have become more commonly used and are considered first-line agents for many fungal infections.

Mechanisms of Action and Resistance

Polyenes (Amphotericin B)

Amphotericin B and its lipid formulations belong to the polyene class of antifungals. The polyenes bind to ergosterol in the cell membrane of fungi, leading to increasing cell membrane permeability, and resulting in fungal cell lysis. Acquired resistance to amphotericin B is uncommon and is usually not considered the primary reason for failure of therapy.

Triazoles

Fluconazole, itraconazole, voriconazole, and posaconazole belong to the triazole class of antifungals. The triazoles inhibit the cytochrome P-450 dependent fungal enzyme lanosterol 14-alpha-demethylase. This enzyme converts lanosterol to ergosterol, which causes a depletion of ergosterol available for fungal cell membrane synthesis. This leads to significant damage to the cell membrane by increasing its permeability, resulting in cell lysis and death. Acquired resistance to the triazoles has been reported, in particular in some *Candida* spp.

Echinocandins

The echinocandins are caspofungin, micafungin, and anidulafungin. They disrupt fungal cell wall synthesis through inhibition of the enzyme β-1, 3 glucan synthase. Disruption of the fungal cell wall results in osmotic stress, cell lysis, and death of the organism. Acquired resistance of *Candida* spp to echinocandins has been described, but is currently still rare. Resistance is more likely to develop in *C. parapsilosis* isolates.

Spectrum of Coverage

Polyenes (Amphotericin B)

Amphotericin B has broad antifungal activity covering *Cryptococcus neoformans, Blastomyces dermatitidis, Histoplasma capsulatum, Coccidioides immitis, Sporothrix schenkii,* the various *Candida* spp., *Aspergillus* spp., and the zygomycetes (*Mucor, Absidia, Cunninghamella, Rhizopus*). Amphotericin B is inherently inactive against *Candida lucitanae* and *Aspergillus terreus*, but is active against most other fungi that cause human disease. The additive effect of amphotericin B and flucytosine has been observed for certain fungal infections, in particular Cryptococcus. This has led to the recommendation of combined therapy for cryptococcal meningitis. The newer lipid formulations of amphotericin B may substitute for the combination of amphotericin B and flucytosine for refractory fungal infections. The lipid formulations

of amphotericin B, which allow for higher tissue delivery of amphotericin B, are indicated for the treatment of patients who are unresponsive or intolerant to therapy with the traditional amphotericin B. The lipid formulations have been shown to have a lower incidence of nephrotoxicity, allowing for higher levels of amphotericin B to be administered.

Fluconazole

Fluconazole has no activity against all *C. krusei* isolates and up to 30% of *C. glabrata* isolates.

Fluconazole has activity against most *Candida* spp. (excluding all *C. krusei* and up to 30% of *C. glabrata* isolates), *Cryptococcus neoformans,* and *Coccidioides immitis*. Fluconazole is ineffective against the molds and is not reliably active against *Histoplasma* or *Blastomyces* spp. Fluconazole has become the drug of choice for all candida infections other than *C. krusei* and *C. glabrata*.[10,11] Fluconazole is a good empiric antifungal in the ICU setting if candidemia is suspected as long as the patient is stable. If unstable, an echinocandin should be used as empiric therapy for candidemia. Fluconazole is also used as chronic maintenance therapy for cryptococcal meningitis in immunocompromised patients.

Itraconazole

Itraconazole has a similar although broader spectrum of activity than fluconazole. However, because of itraconazole's variable oral absorption, fluconazole is generally the initial triazole of choice for susceptible candida infections. Itraconazole is most useful in the treatment of histoplasmosis and blastomycosis, against which fluconazole has variable activity. Itraconazole also has some activity against *Aspergillus fumigatus*, although voriconazole is the preferred antifungal for such infections.

Voriconazole

Voriconazole has no activity against the zygomycetes, and is currently the preferred treatment for *Aspergillus fumigatus* infections.

Voriconazole has a broader spectrum of activity than fluconazole and itraconazole. Voriconazole is now the first-line agent against *Aspergillus fumigatus* and has been found to be superior to traditional amphotericin B against such infections.[12] Voriconazole also has activity against *Aspergillus terreus*, which is usually resistant to amphotericin B. Voriconazole is active against other hyalohyphomycoses, including *Scedosporium apiospermum* and *Fusarium* spp. The MICs for voriconazole to *C. glabrata* and *C. krusei* are higher than those for other *Candida* spp., but they are still usually in the susceptible range. Voriconazole has no activity against the zygomycetes.[13]

Posaconazole

Posaconazole has expanded the spectrum of the triazole agents to include the zygomycetes while maintaining activity against yeasts and molds covered by voriconazole. The spectrum of activity of posaconazole includes *Candida* and *Cryptococcus* spp., most molds including the zygomycetes, and the dimorphic endemic fungi. It may also have some efficacy as salvage therapy in patients with invasive aspergillosis and coccidioidomycosis.[14]

Echinocandins

Echinocandins are only active against *Candida* and *Aspergillus* spp.

The echinocandins are active against all *Candida* spp., but they may be less effective against *C. parapsilosis* and *C. guilliermondii. C. lusitaniae*, which is commonly resistant to amphotericin B, is susceptible to the echinocandins. The echinocandins are active against *Aspergillus* spp. The addition of caspofungin to amphotericin B or voriconazole for the treatment of *Aspergillus* spp. appears to be synergistic.[15] Therefore, the echinocandins may have utility in treating such infections in combination with amphotericin B or voriconazole, or as salvage therapy as a lone agent for patients intolerant to the other antifungals. The echinocandins have no activity against other fungi.

Pharmacology and Adverse Effects

Polyenes (Amphotericin B)

Amphotericin B has poor oral absorption, but it has been delivered intrathecally, intraperitoneally, as bladder irrigation, as a nebulized aerosol, and intravenously. The discussion in this section is limited to the intravenous administration. There are several preparations of amphotericin B. The traditional formulation is given at 0.5–1.0 mg/kg/day. Candida infections should be treated with 0.5 mg/kg/day, cryptococcal infections should be treated with 0.7 mg/kg/day, and all molds and dimorphic fungi should be treated with 1.0 mg/kg/day. Other formulations are lipophilic preparations made by incorporating the parent compound into lipid complexes (liposomal amphotericin B and amphotericin B lipid complex) at a usual dosage of 3–5 mg/kg/day resulting in increased delivery of amphotericin B to fungal cells. In addition, lipid formulations affect the kidneys less dramatically and allow for higher hepatocyte and erythrocyte penetration, thereby allowing for a larger dose of amphotericin B to be administered while minimizing the toxic effects. The metabolism of both traditional and lipid complex amphotericin B is not influenced by renal or hepatic dysfunction.

Side Effects

Because of possible severe febrile reactions, malaise, generalized aches, and vomiting, premedication with acetaminophen, anti-emetics, and antihistamines is often used. Some patients require meperidine or hydrocortisone for severe infusion-related toxicity. Amphotericin B can cause phlebitis at the infusion site, which can be decreased by the administration through a central venous catheter. Other adverse reactions to amphotericin B include hypertension, hypotension, hypothermia, anemia, neurotoxicity, cardiotoxicity, flash pulmonary edema, and renal failure with severe hypokalemia and hypomagnesemia. Nephrotoxicity, which is usually reversible with stopping of the drug, is potentiated by sodium depletion, and sodium loading with intravenous fluids has been found to attenuate renal injury caused by amphotericin B. Lipid formulations cause less nephrotoxicity,[16] but unfortunately their costs are prohibitive of indiscriminate use.

Drug Interactions

An additive renal toxic effect may occur with other nephrotoxic drugs, such as cyclosporine and aminoglycosides. Ticarcillin can potentiate the hypokalemia caused by amphotericin B. The combination of amphotericin B and the antineoplastic agent cytosine arabinoside has been associated with Parkinsonism complaints.

Triazoles

Fluconazole and voriconazole are both available in intravenous and oral formulations. Both of them also have excellent oral bioavailability. The intravenous form of voriconazole is combined with a cyclodextrin vehicle, which can accumulate in the kidneys of patients with renal insufficiency. Therefore, patients with a creatinine clearance of <50 mL/min should not be given the intravenous form of voriconazole. Intravenous fluconazole does not have this restriction. Posaconazole is currently only available in the oral form, but has bioavailability exceeding 90% that can be optimized by administration of a high fat meal. Itraconazole is also only available in the oral form. It has a relatively poor and variable oral absorption. Itraconazole requires a low pH in the stomach to be absorbed, so the concomitant use of acid suppressing agents should be avoided. The oral suspension is better absorbed than the capsule formulation, so the oral suspension of itraconazole is generally preferred. Fluconazole and voriconazole require dosage adjustment in renal insufficiency, whereas no dosage adjustment is required for itraconazole and posaconazole.

Voriconazole should not be given intravenously to patients with significant renal insufficiency due to accumulation of the cyclodextrin vehicle.

Itraconazole should not be used with H2 blockers or proton pump inhibitors because it requires a low pH to be absorbed in the stomach.

Posaconazole must be given with food in order to achieve adequate levels.

Side Effects

The most common side effect of all the triazoles is GI upset, but this is most commonly seen with the itraconazole oral solution. The triazoles can cause a reversible transaminitis, which rarely leads to hepatic necrosis. Itraconazole and voriconazole carry stronger warnings regarding hepatotoxicity than do the other triazoles. High doses of itraconazole have been associated with an aldosterone-like effect, with manifestations including hypertension, hypokalemia, and less often, peripheral edema and an exacerbation of congestive heart failure. Voriconazole can cause transient and reversible visual changes, which are seen in about 30% of patients. The visual changes can include photophobia, color changes, or blurred vision. This side effect is temporally associated with drug dosing, occurring within 30 min of administration. Symptoms usually last for approximately 30–60 min. Visual hallucinations have also been reported. Another side effect associated with voriconazole is a rash.

Drug Interactions

There are multiple drug interactions with the triazoles; therefore, a patient's medication list should be carefully reviewed before initiating any triazole. In general, medications that induce hepatic cytochrome P450 enzymes (e.g., rifampin, rifabutin, phenytoin, carbamazepine, phenobarbital) can accelerate the metabolism of the triazoles, lowering their serum levels. The triazoles also have an inhibitory effect on cytochrome P-450 enzymes, leading to increased levels of cyclosporine and phenytoin and an exaggerated effect of warfarin.

Echinocandins

The echinocandins are only available in the intravenous form. None of the echinocandins require dosage adjustment in renal insufficiency. Caspofungin requires a dosage adjustment in moderate-severe hepatic impairment. It is unclear from published studies whether or not micafungin requires dosage adjustment in hepatic dysfunction, but it likely requires no dosage adjustment in mild-moderate hepatic dysfunction.[17] Anidulafungin requires no dosage adjustment for hepatic insufficiency.[18]

Side Effects

Relative to the other systemic antifungals, the echinocandins are generally well-tolerated and have few side effects. The most common side effects reported are headache, fever/chills, hypokalemia, elevated liver enzymes, and infusion-related phlebitis. The echinocandins may cause a histamine-release reaction that can result in rash, facial swelling, and vasodilation, but anaphylaxis is rare.

Drug Interactions

Caspofungin requires dosage adjustment when combined with cytochrome inducers (e.g., rifampin, phenytoin, carbamezepine). Unlike caspofungin, the other echinocandins do not appear to be affected by cytochrome inducers.

ANTIVIRAL DRUGS

The ongoing fight against human immunodeficiency virus (HIV) has spawned a large number of effective antiviral agents. In addition, and with the better understanding of viral immunology, newer agents that augment the host response, such as interferons and exogenous antibodies, have also been introduced to control several viral infections. Both immunomodulators and HIV antiretroviral agents are usually introduced in an outpatient setting rather

than for critically ill patients. The section that follows reviews antiviral agents more relevant to the ICU patient and excludes HIV therapy.

Mechanisms of Action and Resistance

Antivirals are limited in their activity and are virustatic rather than virucidal. They exhibit their antiviral activity by inhibiting viral attachment to the cell, viral macromolecular synthesis, progeny virion assembly, or by uncoating the viral genome. The majority of the available antiviral agents used in the ICU are nucleotide analogues (such as acyclovir and ganciclovir), targeting either DNA or RNA polymerases and blocking the viral genomic synthesis. Polymerases of different viruses differ in their susceptibility to the inhibition of antivirals; however, resistance results from either reduced phosphorylation of the antiviral agent and mutations in DNA polymerases (acyclovir, ganciclovir) or reduced intracellular uptake of the agent (ganciclovir). Acquired resistance of herpes simplex virus (HSV) to acyclovir and cytomegalovirus (CMV) to ganciclovir has been reported, with the frequency of resistance increasing after prolonged exposure to both agents.[19,20] For the treatment of influenza virus, the neuraminidase inhibitor oseltamivir may be used in the ICU. Increasing resistance to the neuraminidase inhibitors is being reported.

Spectrum of Coverage

Acyclovir and Valacyclovir

Acyclovir and valacyclovir (which is completely converted to acyclovir after oral administration) are indicated for herpes simplex and varicella zoster virus (VZV) infections. They are more potent against HSV-1 and HSV-2 than against VZV, and are least active against CMV. Acyclovir is the drug of choice for the treatment of HSV encephalitis, varicella (chickenpox), and herpes zoster (shingles) infections. It is effective in reducing the incidence of HSV and VZV infections in seropositive transplantation patients and possibly in treating viscerally disseminated HSV infections.

Ganciclovir and Valganciclovir

Ganciclovir, and its oral equivalent valganciclovir, are used for the treatment and prophylaxis of CMV infections, primarily in immunocompromised patients. They are less potent against HSV and VZV, but are 10–100-fold more potent against CMV than is acyclovir. However, the use of ganciclovir is usually limited to serious infections because of its toxicity. Ganciclovir is effective in the treatment of CMV pneumonia, retinitis, and gastrointestinal infections in AIDS and transplant recipients.

Oseltamivir

Oseltamivir, one of the available neuraminidase inhibitors, has been introduced to the United States market for the treatment of influenza A and B. It is effective for the treatment and prophylaxis of influenza, and may potentially be used in ICU patients who present with acute influenza. With increasing resistance to amantadine and ramantadine, these agents are no longer recommended for the treatment of influenza.

Pharmacology and Adverse Effects

Acyclovir and Valacyclovir

The bioavailability of acyclovir is only 15–30% after oral administration, but is three to five times greater with valacyclovir. Acyclovir is also available in an intravenous form. It distributes widely into body tissues and is less than 20% bound to protein. Acyclovir and valacyclovir are mostly cleared by the kidneys, so they require dosage adjustment in renal insufficiency.

Side Effects

Toxicity from acyclovir is often related to high levels of the drug in the presence of renal insufficiency.

Intravenous acyclovir and oral valacyclovir have been associated with reversible neurotoxicity (confusion, delirium, seizures, extrapyramidal signs, autonomic instability) and nephrotoxicity from either crystalline obstructive nephropathy or interstitial nephritis. Patients with renal insufficiency are at higher risk to develop neurotoxicity due to higher acyclovir serum levels.

Drug Interactions

Neurotoxicity and nephrotoxicity may be potentiated by the administration of other neurotoxic and nephrotoxic agents while on acyclovir.

Ganciclovir and Valganciclovir

Ganciclovir has adequate tissue and CSF penetration and negligible protein binding after intravenous administration. Oral valganciclovir has very good bioavailability relative to intravenous ganciclovir. Ganciclovir and valganciclovir are exclusively excreted by the kidneys, so they require dosage adjustment in renal insufficiency.

Side Effects

Ganciclovir has a small therapeutic window. It can cause a reversible myelosuppression (neutropenia, thrombocytopenia), which occurs more commonly in AIDS patients as compared to transplant recipients. Neurotoxicity (headaches, confusion, psychosis, seizures, and coma), nephrotoxicity, fever, hepatic abnormalities, and gastrointestinal symptoms are also known side effects.

Drug Interactions

Ganciclovir raises the concentration of other antiviral drugs and possibly cyclosporine. Nephrotoxic agents may alter ganciclovir clearance and increase its toxicity.

Oseltamivir

Oseltamivir is only available in the oral form, which may limit its utility in critically ill patients.

Oseltamivir is only available in an oral form, which may limit its use in critically ill patients. It needs to be initiated within 48 h of the onset of influenza symptoms to be beneficial. It may decrease the duration of influenza symptoms by several days if it is started soon after symptom onset. It is usually a well-tolerated medication, with the most common side effects being headache, dizziness, and vertigo.

SUMMARY

Antimicrobials are indispensable in the ICU, but are not a panacea for all infections. Preventive measures against nosocomial infections and judicious use of antimicrobials are pivotal in order to minimize complications that often overwhelm vulnerable critically ill patients. When faced with refractory febrile illnesses and suspected malignant infectious diseases, and before inundating patients with multiple broad-spectrum antimicrobials, common sense and clinical judgment should be used in order to avoid causing iatrogenic injuries and breeding resistant organisms. Failing antimicrobial therapy is not always indicative of ineffective antimicrobials and should prompt investigation to ensure optimal drug dosing, absence of superinfections, and exclusion of drainable abscesses before changing the antibiotics.

REVIEW QUESTIONS

1. A 60-year-old man with a history of diabetes presents with high-grade temperature, productive cough, and left lower lobe patchy opacities on chest radiograph. You decide to start empiric antibiotics for the treatment of community-acquired pneumonia. An appropriate initial antibiotic regimen for this patient would be:
- **A.** Clindamycin or metronidazole
- **B.** Ceftriaxone and azithromycin
- **C.** Imipenem and vancomycin
- **D.** Trimethoprim-sulfamethoxazole

2. Dosage adjustment in renal insufficiency is required for all of the following antibiotics except:
- **A.** Imipenem
- **B.** Ceftriaxone
- **C.** Ampicillin
- **D.** Vancomycin

3. For a patient diagnosed with staphylococcal bacteremia:
- **A.** Vancomycin is the antimicrobial of choice regardless of drug susceptibility
- **B.** Vancomycin should only be used if the patient is known to have a penicillin allergy or if the organism is MRSA
- **C.** Oxacillin with gentamicin is the treatment of choice, even if the organism is MRSA
- **D.** Vancomycin is as effective as oxacillin for MSSA

4. All of the following antifungals have activity against *Aspergillus fumigatus* except:
- **A.** Fluconazole
- **B.** Voriconazole
- **C.** Amphotericin B
- **D.** Caspofungin

5. Ganciclovir is indicated for the treatment of:
- **A.** CMV esophagitis
- **B.** Herpes zoster (shingles)
- **C.** HSV encephalitis
- **D.** Influenza A pneumonia

6. The various lipid formulations of amphotericin B:
- **A.** Are always preferred over the traditional amphotericin B
- **B.** Should be dosed the same as the traditional amphotericin B
- **C.** Allow for the administration of higher levels of amphotericin B with less nephrotoxicity
- **D.** Require dosage adjustment in the presence of renal insufficiency

7. A 40-year-old woman with HIV presents with community-acquired pneumonia and has sputum cultures that grow MRSA. Which of the following antibiotics would NOT be an appropriate choice for the treatment of her MRSA pneumonia?
- **A.** Vancomycin
- **B.** Linezolid
- **C.** Daptomycin
- **D.** Quinupristin–dalfopristin

8. The concentration-dependent killing effect of antibiotics:
- **A.** Is only seen in antibiotics that have synergy with other agents
- **B.** Does not occur in any antibiotics that would be used in the ICU
- **C.** Relies on the time of exposure of the bacteria to the antibiotic
- **D.** Indicates that the higher the serum antibiotic concentration above the MIC, the greater the killing effect

ANSWERS

1. The answer is B. For community-acquired pneumonia in adults, the most common cause is *Streptococcus pneumoniae*. The most appropriate initial antibiotic regimen would be ceftriaxone and azithromycin, which would also give coverage against atypical organisms as well. The other answer choices are either too broad (answer C) or too narrow (answer A and D) for the treatment of community-acquired pneumonia.

2. The answer is B. Ceftriaxone is the only cephalosporin that does not require dosage adjustment in renal insufficiency. All of the other answer choices require dosage adjustment in renal insufficiency.

3. The answer is B. Oxacillin (or nafcillin) is the treatment of choice for staphylococcal infections unless the organism is resistant to oxacillin, i.e., MRSA, or the patient is allergic to penicillins. Vancomycin is less effective than oxacillin for the treatment of MSSA.

4. The answer is A. Fluconazole is a triazole with no activity against *Aspergillus fumigatus*. All the other answer choices have at least some activity against this organism.

5. The answer is A. Ganciclovir is the drug of choice for CMV infections. Acyclovir is indicated for the treatment of HSV encephalitis and herpes zoster. Also, ganciclovir is not used to treat influenza pneumonia.

6. The answer is C. The lipid forms of amphotericin allow for higher levels of amphotericin to be given and reach the tissues with a decreased incidence of nephrotoxicity. The lipid forms of amphotericin are given at a higher dose than traditional amphotericin. Cost prohibits the indiscriminate use of the lipid forms of amphotericin, so they are not always the preferred form of the drug. Also, all forms of amphotericin can cause nephrotoxicity to some degree, but none of them require dosage adjustment in renal insufficiency.

7. The answer is C. All of the antimicrobials listed have activity against MRSA. However, daptomycin is inactivated by pulmonary surfactant and would not be an appropriate choice for the treatment of MRSA pneumonia.

8. The answer is D. Antibiotics that have a concentration-dependent killing effect, such as aminoglycosides, are commonly used in the ICU and rely on a high concentration above the MIC to exert their greatest bacterial killing effect.

Use of Analgesics and Sedatives in Critical Care

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the pharmacokinetics and pharmacodynamics of various sedative/hypnotics and analgesics.
- Be aware of the action of sedative/hypnotics and analgesics on central γ-aminobutyric acid (GABA) and opioid receptor systems.
- Understand the need for routine and effective sedation and analgesia in the critically ill patient.
- Make recommendations regarding the choice and appropriate dose of sedative/hypnotics and analgesics in the critically ill.
- Recognize that agitation has multiple etiologies and should be investigated as fully as possible prior to treatment.
- Recognize that agitated patients could pose danger to themselves and/or healthcare personnel, and pharmacologic intervention may be necessary to facilitate safe patient care.

Most patients admitted to an intensive care unit (ICU) struggle with anxiety, fear, apprehension, and loss of control. In addition, critically ill patients often undergo a variety of diagnostic and therapeutic interventions, most of which are associated with physical discomfort or pain. In a subset of patients, there will be an indication for the use of neuromuscular blocking agents; patients receiving these agents will be completely unable to communicate, so the need for adequate and consistent sedation, anxiolysis, and analgesia will be even more important. Fortunately, a variety of agents and techniques are available to alleviate both pain and anxiety. To safely utilize these methods of pain control and anxiolysis, however, the clinician must possess current knowledge regarding the advantages, disadvantages, and potential side effects of each of these agents.

A number of pharmaceutical agents, originally used exclusively in the operating room by anesthetists, are now used in the ICU. This transfer of new agents is appropriate given that indications for these pharmaceuticals in the ICU are often identical to their indications in the

operating room. Prolonged periods of unpleasant and often painful diagnostic or therapeutic modalities should be appropriately treated with analgesics, sedatives, anesthetics, and occasionally paralytics, regardless of the patient's location.

Alterations in the administration and pharmacokinetics of drugs used in critically ill patients may lead to a propensity for prolonged action and, in some instances, an increased incidence and severity of side effects.

However, several significant differences set apart the use of potent pharmaceutical agents in the ICU from their use in the operating room. First, in the ICU, these agents are administered to critically ill patients with significant, often multiple, organ system dysfunction. These patients are receiving multiple medications including nutritional support, are often mechanically ventilated, and may have profound alterations in drug metabolism and receptor regulation and function. These patients are not the usual population of relatively healthy, young surgical patients chosen for clinical studies involving new anesthetic or paralytic agents[1] (Table 57-1). Elimination half-life, volume of distribution, and drug clearance may be markedly altered in the critically ill population.[2-4] This is particularly true when dealing with neonatal, pediatric, or geriatric patients. Second, in the ICU, these agents are often administered over days to weeks, whereas in the operating room they are utilized for much shorter periods of time. Finally, many of these agents are administered by continuous infusion in the ICU, while in the operating room administration is often by intermittent injection.

The perception of pain is an inherently subjective experience, and thus, any rating system is inexact.

Patients who are not able to communicate because of endotracheal intubation, sedation, or administration of neuromuscular blocking agents may manifest pain by agitation or changes in heart rate, blood pressure, or respiratory pattern.

Concerns regarding addiction and abuse have historically led to inappropriate undermedication and withholding of opioids.

Because of these differences, initial information regarding new sedative or paralytic agents should be treated with some element of skepticism prior to application in the care of critically ill patients. Alterations in the administration and pharmacokinetics of drugs used in critically ill patients may lead to a propensity for prolonged action and, in some instances, an increased incidence and severity of side effects. These issues must be borne in mind whenever consideration is given to using a relatively new agent, devised for short-term use in the operative patient, in critically ill ICU patients.

ANALGESICS

Over the past decade, there has been renewed awareness of the necessity of providing effective pain management in the critically ill in the hope of achieving improved patient outcome(s). Pain is an activator of the stress response, and can, therefore, secondarily affect the immune system. When activated by stress, the sympathetic and parasympathetic nervous systems influence endocrine function, which leads to the release of a number of hormones and mediators. Catecholamines, cortisone, glucagon, ADH, and renin-angiotensin-aldosterone are major mediators of this response.[5] In addition, release of cytokines, interleukins, and gamma-interferon is dramatically increased. Secondary inhibition of the T-cell antibody response, IL-2 production and diminished T-cell production can contribute to depression of the critically ill patient's immune system.[6]

Pain control in the ICU is of paramount importance. Control of pain with parenteral narcotics, nonsteroidal anti-inflammatory agents, and a variety of regional techniques are satisfactory methods to alleviate patient pain. However, not all pain experienced by critically ill patients is related to diagnostic or therapeutic procedures. It may be related to the disease

TABLE 57-1

DIFFERENCES BETWEEN PATIENT POPULATION IN THE OPERATING ROOM AND ICU THAT AFFECT ANALGESIC AND SEDATIVE DRUG CHOICES

OPERATING ROOM (CLINICAL STUDIES)	ICU (CLINICAL USE)
Younger patients	Older patients
Essentially healthy (usually one surgical issue)	Critically ill (multiple issues; ± multiple organ system dysfunction)
Few or no medications	Multiple medications
Usually well nourished	May be malnourished (± nutritional support)
Short-term mechanical ventilation	Long-term mechanical ventilation
Normal pharmacokinetics	Alterations in elimination half-life
Normal pharmacodynamics	Alterations in drug metabolism
	Changes in receptor function and volume of distribution and clearance

process, and thus, it is important to attempt to understand the etiology of pain before treatment. Adequate evaluation of pain and consideration regarding its significance are crucial.

Rating systems, such as the commonly used visual analogue scale (VAS) or the McGill pain questionnaire, have been utilized with variable success in this environment. Pain is a fiercely subjective experience, and thus, any rating system will be inexact. Pain usually consists of two components. There is a constant nociceptive component secondary to the injury or surgery, and there is acute incident pain related to the patient's coughing, deep breathing, or getting out of bed.[7] Complaints regarding pain and discomfort should be given serious attention, and effective control measures should be instituted as rapidly as possible. Patients who are not able to communicate because of endotracheal intubation, sedation, or administration of neuromuscular blocking agents may manifest pain by agitation or changes in heart rate, blood pressure, or respiratory pattern.

A past history of narcotic abuse or concerns about causing addiction should not be given undue weight by the physician. Concerns regarding addiction and abuse have historically led to inappropriate undermedication and withholding of opioids.[8] Conversely, in more than 30% of patients who have been intubated for prolonged periods and received narcotics and benzodiazepines in excess of recommended daily doses, an acute withdrawal state has been described.[9] When administering these types of agents for prolonged time periods, careful titration and avoidance of rapid drug weaning are necessary.

Opioids

There are five classes of opioid receptors: mu (μ), kappa (κ), delta (δ), sigma (σ), and epsilon (ε). Of these receptor classes, the μ, κ, and δ receptors are firmly established and have identifiable subtypes. Most of the opioids used in clinical medicine today cause effects at peripheral, spinal, or central sites and mediate their effect largely through the μ receptor. Nalbuphine hydrochloride and butorphanol tartrate are agonists/antagonists and are clinically relevant exceptions. Naloxone, a competitive antagonist, is nonselective for receptor type and is used in a variety of settings to reverse narcotic effect. It has tremendous utility as a rescue agent, since it will rapidly and reliably reverse the respiratory depressant and sedative effects of opioids; however, its short half-life (≤30 min) often obligates additional doses to prevent a recurrence of apnea or excessive sedation.

In critically ill patients, the clearance of narcotics is often decreased. Because of changes in the volume of distribution, the elimination half-life is variably affected[4] (Table 57-2). The administration of these agents must, therefore, be titrated to clinical effect, especially in regard to the patient's cardiovascular and respiratory function. There appears to be little difference in the magnitude of side effects associated with μ-receptor-selective opioids when parenterally administered at equianalgesic steady-state concentrations.[10] Issues related to ventilatory depression, sedation, hypoxemia, pruritus, hypotension, increased common bile duct pressure, and nausea are common to all μ-selective agents.[4]

There appears to be no difference in the magnitude of side effects associated with μ-receptor-selective opioids when parenterally administered at equianalgesic steady-state concentrations. Issues related to ventilatory depression, sedation, hypoxemia, pruritus, hypotension, increased common bile duct pressure, and nausea are common to all μ-selective agents.

Morphine is the narcotic most frequently administered in the critical care setting.[11,12] Morphine acts through stimulation of peripheral and central receptor systems; however, central effects predominate following parenteral administration. Although morphine may cause histamine release at higher doses, it has the advantage of being well known, inexpensive, and easy to administer. Morphine is metabolized in the liver via glucuronidation to morphine-3 and morphine-6-glucuronide, which are ultimately eliminated by the kidney. Although these metabolites possess weak analgesic properties, they are potent depressants of central respiratory drive. Morphine-6-glucuronide is thought to be responsible for the increased sensitivity to morphine observed in patients with renal failure; for this reason, morphine should be administered cautiously to these patients.[13]

Morphine may be administered intermittently, by continuous intravenous infusion, or via a patient-controlled analgesia (PCA) device. In a well-staffed and intensively monitored location such as the ICU, there should be no need to administer narcotics on a regular basis via the intramuscular route. Morphine may also be administered via neuraxial techniques, as discussed later in this chapter. There is good evidence that morphine has direct peripheral actions.

In a well-staffed and intensively monitored location such as the ICU, there should be no need to administer narcotics on a regular basis via the intramuscular route.

TABLE 57-2

OPIOID USE IN CRITICALLY ILL ADULT PATIENTS

OPIOID	ROUTES OF ADMINISTRATION	ELIMINATION HALF-LIFE (H)	INTERMITTENT OR BOLUS DOSE (IV)	CONTINUOUS INFUSION RATE (IV)
Morphine	IV, IM, SC, continuous infusion, PCA	2–4	2–5 mg	1–5 mg/h
Fentanyl	IV, continuous infusion, skin patch	3–6	25–100 μg	50–150 μg/h
Meperidine	IV, IM, SC, PCA	3–4	12.5–50 mg	N/A
Nalbuphine	IV, IM	5	5–10 mg	N/A
Butorphanol	IV, IM	2.5–3.5	1.5–3 mg	N/A

IV intravenous; *IM* intramuscular; *SC* subcutaneous; *PCA* patient-controlled analgesia; *N/A* not available

It has been shown to have local analgesic actions in animal and clinical studies, although this method of administration has found little clinical application in critically ill patients.[13]

Fentanyl is a narcotic with 50–100 times the potency of morphine. It has a rapid onset of action and no active metabolites. It is a μ-selective agonist with little effect on other opiate receptors and produces profound dose-dependent analgesia. At high doses, it can produce loss of consciousness and muscle rigidity. It has a rapid redistribution half-life, measured in minutes, and for that reason is usually administered by continuous infusion in critically ill patients. With high doses, or prolonged administration, there will be saturation of lipophilic redistribution sites, accumulation of drug, and extended clinical effects. Once the lipophilic redistribution sites are saturated, the duration of action of fentanyl is determined by an elimination half-life of approximately 3–6 h. The elderly (>60 years of age) may have a prolonged terminal half-life that is roughly two to three times that of younger individuals.[14] Prolonged elimination or decreased metabolism of fentanyl may be observed in patients with significant hepatic dysfunction. Fentanyl does not trigger histamine release, does not cross-react in patients with morphine allergy, and its pharmacokinetics are not altered by renal failure. It has been recommended as the analgesic agent of choice in critically ill, hemodynamically unstable patients.[15] Similar to morphine, it may also be administered via a neuraxial technique. The executive summary of practice parameters published by the Society of Critical Care Medicine for the administration of intravenous analgesia and sedation in critically ill adults recommends 1–2 μg/kg/h for fentanyl. These doses may be appropriate for initiation, but titration to effect will be necessary in most patients.[15]

The executive summary of practice parameters published by the Society of Critical Care Medicine for the administration of intravenous analgesia and sedation in critically ill adults recommends 1–2 μg/kg/h for fentanyl. Although these may be appropriate initiation doses, titration to effect will be necessary in most patients.

Meperidine has a rapid onset of action when administered intravenously. It binds to both the μ and κ receptors. Through its effect on the κ receptor, it acts as a potent suppressor of shivering and thus prevents shivering-induced increased metabolic demand.[16] Normeperidine, its major metabolite, may accumulate in patients with renal failure and act as an eleptogenic trigger. Meperidine at doses greater than 5 mg/kg has been associated with myocardial depression, and for that reason, this agent should not be used as part of an anesthetic technique involving high-dose narcotic administration.[17] For all these reasons, meperidine is used infrequently in the critically ill patient.

Mixed agonist–antagonist opioids such as nalbuphine and butorphanol have an effect at the μ-receptor, but are less potent than agents such as morphine or fentanyl. In the presence of a potent opioid, these agents may act as μ-receptor antagonists while exerting an agonist effect on other classes of opioid receptors. For example, nalbuphine has the characteristics of a μ antagonist when given following morphine administration, but has an agonist effect at the κ receptor.[18] Like meperidine, it has a significant suppressive effect on shivering, presumably mediated via the κ receptor.[19]

Lower efficacy opioids, such as nalbuphine and butorphanol, partially depress respiratory drive as opposed to higher efficacy narcotics, which in large doses may completely suppress it. For this reason, lower efficacy agents may be combined with more potent opioids, in postoperative settings, to moderate opioid side effects while not completely negating the antinociceptive effect.[18]

Additional potent μ agonists are also available, and include alfentanil, sufentanil, and remifentanil. These agents are used primarily in the delivery of anesthetic care, are expensive, and have little documented advantage over fentanyl. The one exception is remifentanil, which, because of an ester functional group, is susceptible to hydrolysis by blood and tissue esterases; this results in a very rapid breakdown of the drug. These agents have not yet found routine application in the ICU.[8]

PCA allows for consistent therapeutic narcotic blood levels by enabling the patient to time analgesic drug administration and the unit dose, while safeguarding a lockout time between doses and total cumulative dose allowable; parameters set by the physician.

Patient-Controlled Analgesia

PCA is an important analgesic delivery technique. All narcotics have threshold plasma concentrations at which they are effective. PCA allows for consistent therapeutic narcotic blood levels by enabling the patient to choose, within limits, the time of analgesic administration. Dose, lockout time between successive doses, and total cumulative dose are set by the physician. This technique may involve both continuous infusion and concomitant patient control of the interval between unit doses. It is used to provide pain relief following surgery, in

Initial settings for a Morphine-PCA in an adult patient would include a bolus dose of 0.03–0.1 mg/kg; unit dose, 0.5–2.0 mg; lockout time, 6–10 min between doses; and a cumulative 4 h dose ≤20 mg.

patients with cancer, and in the critically ill. However, in many critically ill patients, this technique is not appropriate because of agitation, primary or secondary changes in cognitive function, or severity of illness. Initial settings for a Morphine-PCA in an adult patient would include a bolus dose of 0.03–0.1 mg/kg, unit dose of 0.5–2.0 mg, lockout interval of 6–10 min between doses, and a cumulative 4 h dose of ≤ 20 mg.

Nonsteroidal Anti-Inflammatory Drugs

The nonsteroidal anti-inflammatory agent ketorolac tromethamine is available in parenteral form. Like other nonsteroidal anti-inflammatory drugs (NSAIDs), its primary mode of action is inhibition of prostaglandin-mediated amplification of pain pathways. Ketorolac at 10–30 mg intramuscularly has been reported to have the analgesic equivalence of 10 mg of morphine.[20] Ketorolac is also commonly injected intravenously; the dosage is 15–30 mg every 4–6 h. It is recommended that the duration of therapy should not exceed 5 days.

Ketorolac at 10–30 mg intramuscularly has been reported to have the analgesic equivalence of 10 mg morphine.

Ketorolac has the usual NSAID-related adverse effects; it can cause or exacerbate peptic ulcers and gastrointestinal bleeding and is contraindicated in patients with these problems. Antiplatelet effects are a concern and, as with many NSAIDs, are usually reversible within 24–48 h. There may be effects on renal function because NSAIDs block prostaglandin-mediated autoregulation of renal blood flow. Thus, this agent should be avoided in patients with advanced renal impairment or those at increased risk for acute renal injury; hypovolemia should be corrected before its administration. Because this agent does not have the side effects commonly seen with the narcotics, it may be a useful adjunct to therapy in combination with opioids. It should not be administered to patients with allergies to aspirin or other NSAIDs.

Regional Techniques

Neuraxial

Neuraxial techniques include spinal or epidural anesthesia or analgesia. Neuraxial administration of a local anesthetic, a narcotic, an alpha-2 agonist such as clonidine, or a combination of these agents can dramatically reduce or eliminate pain in the thorax, abdomen, and/or lower extremities.

Epidural Local Anesthetic

Intermittent or continuous administration of a local anesthetic via an epidural catheter blocks sympathetic, motor, and sensory neurons, and thus, provides complete anesthesia or profound analgesia without the risk of narcotic-mediated respiratory depression. This technique is commonly used in the operating room and obstetrical suite. Distribution of the local anesthetic and subsequent pain relief are dependent on the anatomic region chosen (thoracic or lumbar), correct placement of the catheter, and the concentration and volume of local anesthetic injected. Long-acting agents such as bupivicaine or ropivicaine are commonly used.

Contraindications to this technique include local skin lesions, sepsis, coagulation defects, or a history of recent drug administration that could adversely alter coagulation. Complications of epidurals stem from incorrect catheter placement and subsequent drug administration. Intrathecal injection of local anesthetic can cause total spinal blockade and profound hypotension; intravenous administration can lead to seizures and cardiac arrest. Infection or hematoma formation in the epidural space is extremely rare complications with appropriate technique and selection of patients.

Spinal and Epidural Narcotics

Analgesia after neuraxial administration of narcotics occurs through action on opioid receptors located in the dorsal horn of the spinal cord. Both intrathecal and epidural opiates act on the presynaptic and postsynaptic neurons in the substantia gelatinosa. Relatively small doses

of intrathecal and epidural narcotics produce profound analgesia with no autonomic, sensory, or motor blockade. The potency, onset of action, duration of effect, and likelihood of side effects are related to lipid solubility and narcotic concentration within the cerebrospinal fluid (CSF). The narcotics most commonly administered via the neuraxial method are morphine and fentanyl.

The narcotics most commonly administered via the neuraxial method are morphine and fentanyl.

Intrathecal administration of narcotics produces a drug concentration within the CSF that is agent-specific and dose-dependent. Fentanyl, because of its high lipid solubility, is absorbed rapidly into the spinal cord. Morphine penetrates the cord more slowly, and considerable amounts of the drug remain in the CSF with the potential for direct action. When morphine is used, the onset of drug effect is slower than with fentanyl, but pain reduction may last for 18–24 h following a single injection.

Epidural administration of narcotics involves larger doses of drug. Following diffusion of a small percentage of the administered dose across the dura, the action of the narcotic is mediated in the same way as via the intrathecal route. However, vascular absorption by the extensive venous plexus in the epidural space leads to blood levels that can be similar to those of an equivalent intramuscular dose.[21] It is possible that the profound pain relief experienced with the use of epidural narcotics reflects a synergistic action of spinal and central receptor systems.[13] The beneficial effects of this technique postoperatively have been reported to include better pain control, less sedation, earlier mobilization, and a decreased time to recovery.[22]

Complications of epidurals stem from incorrect catheter placement and subsequent drug administration. Intrathecal injection of local anesthetic can cause total spinal blockade and profound hypotension; intravenous administration can lead to seizures and cardiac arrest.

Side effects are related to the presence of opioids in the CSF or blood, are dose-dependent, and can be seen with any narcotic. Morphine, because of its water solubility and greater concentration in the CSF, has a higher incidence of side effects than fentanyl. Although numerous side effects have been described, the four classic effects are nausea and vomiting, pruritus, urinary retention, and respiratory depression.[21] Respiratory depression, the most serious and feared side effect, may occur within minutes of injection or be delayed for several hours. Clinically relevant early respiratory depression has not been reported with morphine. The incidence of respiratory depression requiring some type of intervention is reported to be approximately 1%.[21]

Delayed respiratory depression is typically related to the neuraxial administration of morphine and results from transport via the CSF to central opioid receptors in the ventral medulla.[21] This area of the central nervous system is critically important in the regulation of normal respiration. Delayed respiratory depression usually occurs 6–12 h following neuraxial administration of morphine and may be manifested by an insidious and progressive bradypnea, hypercapnia, and a depressed level of consciousness. Protocols for detection and treatment of respiratory depression should be developed and consistently followed at all institutions utilizing neuraxial narcotics.

All side effects seen with the intrathecal and epidural administration of narcotics are mediated via opioid receptors. Therefore, treatment involves parenteral administration of an opioid antagonist or an opioid agonist/antagonist. Side effects are easily treated in this manner. Pain relief has been variably reported to be maintained or antagonized in a dose-dependent fashion.[23] For that reason, naloxone should be titrated to effect, unless profound respiratory depression is present, as the goal is reversal of side effects with preservation of pain control. For nonlife-threatening side effects, 40–80 μg of intravenous naloxone would be an appropriate initial adult dose. Repetitive administration of naloxone, a naloxone infusion, or oral administration of naltrexone, a long-acting opioid antagonist, may be necessary as side effects can recur. Reversal of nausea and pruritus, with maintenance of analgesia, is also possible if an agonist/antagonist such as nalbuphine (initial adult dose, 5 mg) is administered.[24]

Addition of a narcotic to a local anesthetic and administration via an epidural can result in profound pain relief and obviate the need for any parenteral narcotics. Epidural administration of an opioid with or without a local anesthetic has been found to be efficacious following thoracotomy in patients with marginal pulmonary function and following abdominal surgery in patients with sleep apnea.[25]

Epidural administration of local anesthetics or opioids may be repetitive or continuous, if an epidural catheter is placed in the lumbar or thoracic epidural space. Administration of

narcotics directly into the CSF is equally effective, but an indwelling spinal catheter is infrequently used in the ICU.

Peripheral Nerve Blocks

Peripheral nerve blocks may be useful in controlling postoperative pain depending on the site of surgery. In thoracic surgery, blockade of the intercostal nerves with a local anesthetic, either at the time of surgery or percutaneously in the ICU, will reduce pain and the likelihood of respiratory depression by decreasing the need for parenteral narcotics. Bupivicaine 0.5% in doses of 2–3 mL per intercostal nerve can be placed at the level of incision and two levels above and below the incision. Discomfort from thoracostomy tubes can be alleviated by intercostal nerve blockade at the level of insertion.

Interpleural anesthesia allows multiple intercostal nerves to be blocked without multiple needle injections. This technique involves placement of an interpleural catheter, which may be introduced percutaneously or at the time of surgery. The patient's position is an important factor in the action of the local anesthetic and clinical result. With the patient in the supine position, a continuous infusion of a local anesthetic "bathes" the posterior pleural space and results in continuous blockade of multiple intercostal nerves. Use of this technique may be limited by the loss of local anesthetic if a thoracostomy tube is in place. A related technique involves placement of a catheter in an extrapleural position. Following an intrathoracic procedure, a catheter is introduced superficial to the parietal pleura and parallel to the vertebral bodies. Infusion of local anesthetic into the catheter results in blockade of multiple intercostal nerves. One advantage to this technique is avoidance of drug loss via the thoracostomy tube.[26] Pneumothorax and the systemic toxicity of local anesthetics are potential complications associated with these nerve blocks.

Peripheral nerve blocks and regional anesthesia may also be used in the care of critically ill patients who suffer penetrating and nonpenetrating injuries to the extremities.[27,28] These blocks may dramatically reduce agitation and anxiety due to more effective pain control and allow for lower cumulative doses of parenteral narcotics and sedative-hypnotics. The avoidance of excessive sedation should allow for earlier ambulation, and with enhanced peripheral blood flow, often seen with peripheral nerve blocks, may decrease the incidence of deep venous thrombosis (DVT).

Injuries to an extremity may be treated with a single-dose technique. This involves the administration of local anesthetic near the sheaths surrounding the nerve or plexus. In this manner the brachial plexus, axillary nerve, sciatic nerve, femoral nerve, popliteal nerve, or the nerves innervating the ankle may be blocked. The duration of blockade of the plexus or peripheral nerve will be significantly enhanced by the insertion of an infusion catheter adjacent to the neurovascular bundle, which permits continuous administration of local anesthetics and/or opioid mixtures. These catheters typically can remain in place for 4–5 days, assuming there is no clinical evidence of inflammation or infection.[29-32]

Consideration of peripheral nerve blocks should be tempered by the realization that their use in an ICU setting may be fraught with difficulty.[33] The actual procedure may be technically difficult if the patient is ventilator dependent and/or there are other positioning constraints; an uncooperative patient is a relative contraindication to peripheral nerve blockade. Additionally, a significant percentage of ICU patients receive some form of anticoagulation. It is imperative to evaluate the patient's coagulation status prior to proceeding with any nerve block or catheter insertion. Likewise, the patient's medication list should be carefully reviewed since the clinical effect of some anticoagulant medications may not be readily detected through routine coagulation tests.[34]

If the PT and INR are ≥1.4 times the normal range for the patient, or the platelet count is significantly decreased, regional techniques are generally not recommended. This is also true for patients receiving low molecular weight heparin for DVT prophylaxis. Additional factors to consider are the presence of preexisting nerve injury, diabetes mellitus with peripheral neuropathy, peripheral vascular disease, cardiac impairment, hepatic and renal dysfunction, and the volume status of the patient.

The term cryoanalgesia refers to a method of pain relief achieved through the application of extreme cold to a peripheral nerve. This technique produces a prolonged period of

The recommended guidelines for treatment of local anesthetic-induced cardiac arrest with intralipid therapy include initial bolus of 1.5 mL/kg of 20% emulsion (Intralipid, KabiVitrum, Canada Inc., Toronto Canada) followed by continuous infusion of 0.25–0.5 mL/kg/min. If the initial bolus does not result in return of spontaneous circulation within 10 min, the bolus dose may be repeated once or twice as needed.

analgesia, from several weeks to up to 6 months, but does not anatomically disrupt the nerve and thus allows for eventual return of nerve function.[35] Clinically, it has found greatest application in the blockade of the intercostal nerve(s) internally, usually just before thoracotomy closure.

The term cryoanalgesia refers to a method of pain relief achieved through the application of extreme cold to a peripheral nerve.

One of the most severe complications of any type of regional anesthesia is the inadvertent intravascular injection of a local anesthetic agent. The interruption of electric impulses by local anesthetic agents is accomplished by a similar mechanism in peripheral nerves, the CNS, and cardiac tissue. Thus, an intravascular injection can result in early symptoms of tinnitus and muscle twitching and may progress to seizure activity. A rapid and lethal outcome from direct cardiac toxicity may also be seen with larger doses and/or more potent local anesthetics.

Animal studies have shown promising results in regard to the reversal of this direct cardiac toxicity through infusion of lipids.[36-38] Recently, it has been reported that emergent infusion of 20% Intralipid can reverse this cardiac toxicity in humans.[39,40] Rosenblatt et al. reported a patient who experienced cardiac arrest immediately following injection of bupivicaine and mepivicaine for brachial plexus block. The patient was unresponsive to 20 min of ACLS-guided resuscitation techniques, but responded to a single bolus of 20% Intralipid. The patient was continued on a continuous infusion of 20% Intralipid and ultimately recovered completely. The proposed mechanism of rescue includes a "lipid sink" into which the local anesthetic is drawn; it is later eliminated from the body. Alternatively, the lipids may provide a source of fatty acids that reverse local anesthetic toxicity within the mitochondria.[41]

The recommended guidelines for treatment of local anesthetic-induced cardiac arrest with Intralipid therapy include initial bolus of 1.5 mL/kg of 20% emulsion (Intralipid, KabiVitrum, Canada Inc., Toronto Canada) followed by continuous infusion of 0.25–0.5 mL/kg/min. If the initial bolus does not result in return of spontaneous circulation within 10 min, the bolus dose may be repeated once or twice as needed. To date, no adverse responses to lipid reversal of local anesthetic toxicity have been reported.[42,43]

SEDATIVE/HYPNOTICS

Critically ill patients frequently require anxiolytics or sedatives to modify distress and mental discomfort and to facilitate compliance with life-sustaining treatment (Table 57-3).

Critically ill patients frequently require anxiolytics or sedatives to modify distress, for mental discomfort, and to facilitate compliance with life-sustaining treatment.

The adequacy of sedation is most often assessed clinically. Sedation scales including the Ramsay scale, the COMFORT scale for pediatric patients, the Sedation Agitation Scale (SAS) or the Motor Activity Assessment Scale (MAAS) have found varying degrees of acceptance and utility.[44] Neurophysiologic monitoring devices offer the hope of an objective method of assessing and monitoring sedation; some have been found to correlate well with the level of responsiveness and may one day find routine applicability within the ICU.[45]

Benzodiazepines

The ideal sedative/hypnotic would be inexpensive, and have anxiolytic and analgesic properties, a rapid onset of action, a short half-life with no accumulation of active metabolites, and insignificant cardiovascular and respiratory effects. Although the perfect agent does not yet exist, the group of drugs known as benzodiazepines (BZDs) is closest to the ideal. Because these drugs are used daily in the ICU, it is helpful to have some understanding of their mechanism of action.

BZDs exert their pharmacologic actions by enhancing GABA-mediated inhibition of neuronal transmission.

The discovery in 1977 of specific membrane-binding sites for the BZDs was the initial step into the insight we now have regarding how these drugs function.[46,47] BZDs exert their pharmacologic actions by enhancing γ-aminobutyric acid (GABA)-mediated inhibition of neuronal transmission. The GABA receptor–chloride ionophore complex is composed of multisubunit proteins that when activated, form a selective channel, allowing chloride to enter the cell (Fig. 57-1). This free flow of chloride hyperpolarizes the neuron and inhibits neural transmission. A number of drugs modulate GABA receptor-regulated chloride

BZDs facilitate the inhibitory effect of GABA on neuronal transmission at limbic, thalamic, hypothalamic, and spinal levels, resulting in sedation, amnesia, anxiolysis, and muscle spasm reduction; they have no analgesic effects.

TABLE 57-3

SEDATIVE/HYPNOTIC USE
IN CRITICALLY ILL ADULT PATIENTS

AGENT	ROUTES OF ADMINISTRATION	ELIMINATION HALF-LIFE (H)	INTERMITTENT DOSE	INFUSION RATE (μG/KG/MIN)	ACTIVE METABOLITE	ONSET
Diazepam	IV	20–70	2–10 mg q2–4 h	N/A	Desmethyldiazepam	Slow
Midazolam	IV, continuous infusion	1–4	1–4 mg q1–3 h	0.25–2.0	1-Hydroxymidazolam; 4-hydroxymidazolam	Fast
Lorazepam	IV, continuous infusion	10–20	1–4 mg q1–6 h	0.2–0.5	No	Slow
Propofol	Continuous infusion	1–7 (rapid awakening secondary to redistribution)	N/A	10–100	No	Fast

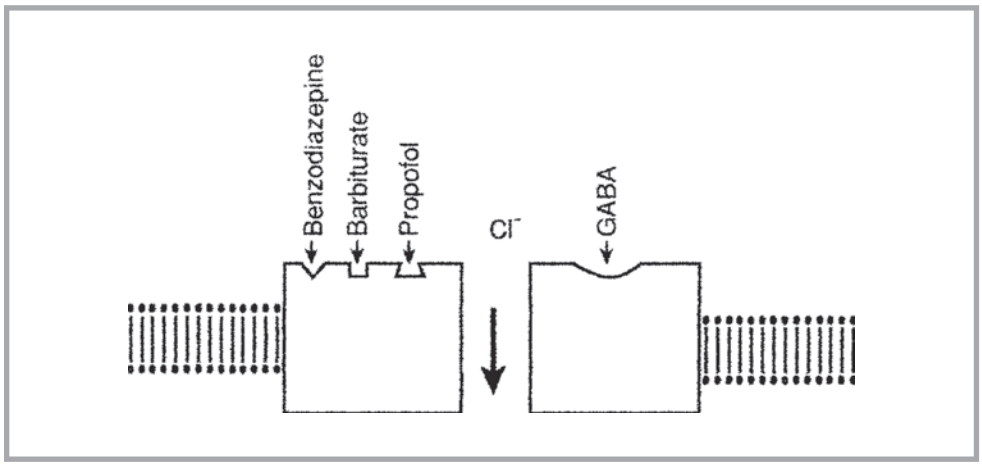

FIGURE 57-1

The action of various agonists on the γ-aminobutyric acid (GABA) receptor complex results in an increased affinity of the receptor for GABA and increases the average time the channel remains open.

channels. BZDs, barbiturates, and propofol react with discrete, modulatory receptor sites within the GABA receptor–chloride channel complex. The end result of BZD action on the GABA receptor is to increase the affinity of the receptor for GABA and to produce a modest increase in the average time the channel stays open. BZDs, thus facilitate the inhibitory effect of GABA on neuronal transmission at limbic, thalamic, hypothalamic, and spinal levels, resulting in sedation, amnesia, anxiolysis, and muscle spasm reduction; they have no analgesic effects.

It should be emphasized that the GABA receptor–chloride channel complex is unusual in that it has the ability to respond not only to agonists (BZD, barbiturates, propofol) and competitive antagonists (flumazenil), but also to inverse agonists (picrotoxin, bicuculline). The action of an inverse agonist is to decrease the inhibitory effect of GABA. In animal experimentation, these inverse agonists have prominent convulsant effects. The competitive antagonist flumazenil will reverse the action of agonists and inverse agonists by binding tightly to the BZD receptor, yet will produce no clinical effect itself. Thus, evidence strongly suggests that there is an agonist–antagonist–inverse agonist continuum in terms of the action of various substances on this receptor complex.[48] This information regarding BZD receptor kinetics gives insight into the withdrawal symptoms described with this class of agents.[49] All clinically available BZDs interact with the GABA receptor complex in a qualitatively similar fashion.

Clinically, in the critical care setting, BZDs are used for anxiolysis, sedation, treatment of alcohol withdrawal, and often as initial therapy for control of agitation. Any of the BZDs can be associated with a paradoxical or disinhibitory reaction, causing the patient to become uncooperative or agitated. The three BZDs used most frequently in the critical care setting are diazepam, lorazepam, and midazolam.[50,51] All may be administered intravenously and any of them can cause dose-dependent respiratory depression and decreased blood pressure secondary to a central sympatholytic effect.[4] The time course and intensity of their clinical effects will vary, depending in part on the sensitivity of the patient, the amount of drug, and whether administered as a bolus or via continuous infusion. The other clinical differences noted between the different agents in this class are due to variations in the rates at which the agents penetrate the CNS and their metabolic profiles.

Clinically, in the critical care setting, BZDs are used for anxiolysis, sedation, treatment of alcohol withdrawal, and often as initial therapy for control of agitation.

Diazepam, with a half-life of 30 h for the parent compound, up to 200 h for active metabolites, and decreased clearance in the critically ill, is used less frequently than in the past. After a single dose of diazepam, its pharmacologically active metabolite, desmethyldiazepam, is usually not present in sufficient concentration to have prolonged clinical effect. During prolonged administration, production of desmethyldiazepam can be extensive and, because of its longer half-life, can exceed the concentration of the parent compound. It is technically difficult to administer diazepam via continuous infusion as a dedicated line and syringe pump are required. However, because it is inexpensive, has a rapid onset of action, and when used intermittently, has a relatively short clinical effect, it still has a role in treatment of the critically ill.

Midazolam has found wide application as a short-acting sedative for endoscopic procedures, angiography, and cardioversion.

Midazolam, a water-soluble agent with a half-life of 1.5–3 h, was the first BZD to be administered via continuous intravenous infusion. Like diazepam, it is highly lipophilic, and for that reason, has a rapid onset of clinical effect. Midazolam has found wide application as a short-acting sedative for endoscopic procedures, angiography, and cardioversion. In patients with inadequate intravascular volume or compromised cardiac function, rapid administration may lead to hemodynamic instability and respiratory depression. Midazolam is eliminated almost exclusively by hepatic hydroxylation and then conjugated with glucuronic acid; its major metabolite is α-hydroxy-midazolam.[3]

In spite of a short half-life, prolonged sedation in critically ill patients has been reported with midazolam. An increase in the volume of distribution and a prolongation in elimination half-life have been demonstrated in critically ill patients and contribute to this effect.[3] Midazolam has a hepatic extraction ratio of 30–70%, and a decrease in hepatic blood flow could reduce its clearance.[3] Additionally, conjugated metabolites have been found to have substantial pharmacologic effect and may accumulate with prolonged administration and in patients with renal failure.[52]

Because lorazepam is less lipid soluble than midazolam or diazepam, maximum effects may not be seen for 15–30 min.

Lorazepam may also be administered via continuous infusion; solubility issues have been resolved. Lorazepam has a half-life of 10–20 h, but has no active metabolites. Because lorazepam is less lipid soluble than midazolam or diazepam, maximum effects may not be seen for 15–30 min. Although this may be a disadvantage in patients who need rapid sedation, associated cardiovascular changes are usually less pronounced. Although lorazepam has a longer half-life than midazolam, its duration of effect is shorter following cessation of continuous infusion, and it is generally believed to be more cost-effective for long-term sedation.[53] The greater duration of effect with midazolam in critically ill patients is attributed to altered drug kinetics and accumulation of active metabolites.[53] A continuous infusion of any BZD administered for an extended period of time should be tapered rather than abruptly discontinued. The clinical practice guidelines of the Society of Critical Care Medicine for the administration of intravenous analgesia and sedation in critically ill adults recommend 0.02–0.06 mg/kg every 2–6 h for lorazepam as an appropriate initiation dose; however, titration to clinical effect is necessary.[15]

Hepatic biotransformation accounts for the majority of BZD clearance. The two principal pathways involved are oxidation (diazepam, midazolam) and glucuronide conjugation (lorazepam). The oxidative pathway is most susceptible to impairment in the elderly or cirrhotic patient, which has led to the recommendation that lorazepam be considered the BZD of choice in these patients.

Zolpidem (Ambien), a compound structurally dissimilar to the BZDs, exerts its effect via action on the BZD recognition site of the GABA receptor complex. It is indicated in the short-term treatment of insomnia and causes less sleep disturbance compared to the BZDs. It is available in tablet form only.

Flumazenil, an imidazobenzodiazepine derivative, binds in a competitive and reversible manner to the BZD receptor on the GABA receptor–chloride ionophore complex. Administration of 1 mg or less usually reverses the effects of the BZDs and may be useful following iatrogenic oversedation. A dose of up to 3 mg is appropriate to emergently reverse a drug overdose involving the BZDs. The clinical effects of this agent are evident within minutes of administration. Resedation may occur within several hours or less depending on which BZD and what amount is being antagonized. Convulsions are the most common serious adverse effects reported and usually occur in patients who are chronically dependent on BZDs, use them to control seizures, or have ingested large doses of other drugs.

Propofol

Propofol is an alkylphenol that is virtually insoluble in aqueous solution. It is commercially prepared in an oil-in-water emulsion, which consists of propofol, soybean oil, glycerol, and egg phosphatide. The use of propofol is contraindicated in patients with known or suspected hypersensitivity to any of its components, especially egg products.

Although propofol may be administered as a bolus for short procedures, such as endotracheal intubation or cardioversion, it is most commonly administered in the ICU as a continuous infusion for sedation in intubated, mechanically ventilated patients.[54] Over the past decade,

continuous infusions of propofol have gained in popularity. Reasons for this surge in use include ease of titration, short duration of action, and enhanced patient-ventilator synchrony. As it is a potent respiratory depressant and will blunt protective airway reflexes, it should be used with extreme caution in patients who are not intubated and mechanically ventilated. Because of a negative effect on cardiac output and reduction in systemic vascular resistance, hypotension may be seen with propofol use. For that reason, it should be used with caution in patients with hypotension, hypovolemia, or other forms of cardiovascular instability.

Propofol has a rapid onset of action, but a brief duration of effect due to a short redistribution half-life; this rapid redistribution occurs because propofol is extremely lipophilic. It is metabolized in the liver, but its elimination rate exceeds hepatic blood flow. Thus, some degree of "extrahepatic" metabolism is thought to occur. Following termination of a short-term infusion, levels of propofol in the blood decrease rapidly, with clinical emergence usually occurring within 5–10 min. Prolonged administration of propofol is quite different from short-term administration. Following prolonged administration, tissue stores of propofol are significantly increased and the terminal half-life may be on the order of 1–3 days; clinical effects and time to awakening may also be prolonged. For that reason, it is appropriate to decrease the infusion rate (titrate to clinical effect) if the infusion is continued for extended periods of time.

Since it exerts its effect via the GABA receptor complex, propofol does have some amnestic and anticonvulsant effects. However, single-drug therapy with propofol has been associated with patient recall during therapeutic paralysis in a surgical ICU, and thus, it seems prudent to administer a BZD or narcotic with it.[55] When combined with opioids, the deep sedation possible with propofol infusion may obviate the need for neuromuscular blockade. Long-term infusions of propofol may foster the development of drug tolerance, or downregulation within central GABA receptors. Hence, there is a risk that seizure activity may follow the abrupt cessation of an infusion after prolonged propofol use. For this and other reasons, it seems wise to wean this agent if it has been used for an extended period of time.

Propofol Infusion Syndrome (PRIS) is a rare and often fatal group of metabolic derangements reported in both pediatric and adult patients receiving long-term propofol infusions; it has also been reported during prolonged propofol anesthesia. It is characterized by metabolic acidosis, cardiac and renal failure, hyperkalemia, and rhabdomyolysis. It is believed to result from propofol's impairment of free fatty acid oxidation and inhibition of oxidative phosphorylation in the mitochondria; catecholamines exacerbate this process. It has most often been associated with prolonged, high-dose infusions (>5 mg/kg/h for over 48 h).[56-58]

Propofol provides approximately 1.1 kcal/mL, which should be taken into account when it is administered in association with enteral or parenteral nutrition.[59] Long-term administration may result in elevations in serum triglycerides, amylase, and lipase; a chemical pancreatitis may occur. When using propofol over an extended period, a serum triglyceride level should be obtained regularly.[59] Propofol may offer weak antiemetic properties compared to other sedative-hypnotic drugs.

When handling propofol, strict aseptic technique is mandatory; it has been reported to support the rapid growth of microorganisms. As a result of concerns over contamination, it is recommended that the drug be used within 6 h of opening. If propofol is infused directly from a spiked vial, the infusion must be completed within 12 h, or the infusion tubing, and any remaining propofol discarded. Long-term infusions are best delivered through a dedicated central venous catheter as administration via a peripheral vein is often associated with pain at the infusion site.[60]

The executive summary of the Society of Critical Care Medicine practice parameters for the administration of intravenous analgesia and sedation in critically ill adults recommends 0.044 mg/kg every 2–4 h for lorazepam as an appropriate initiation dose; however, titration to clinical effect is necessary in every patient.

The oxidative pathway is most susceptible to impairment in the elderly or cirrhotic patient, which has led to the recommendation that lorazepam be considered the BZD of choice in these patients.

When combined with opioids, the deep sedation possible with propofol infusion may obviate the need for neuromuscular blockade.

Agitation is common among the critically ill and its etiology is multifactorial; ideally, it requires a definitive diagnosis before initiation of therapy. It is important to realize that sedating a patient experiencing pain without first providing adequate analgesia will induce agitation.

Ketamine

Ketamine, a phencyclidine derivative, is a rapid-acting, dissociative anesthetic agent with analgesic properties. It acts on both the *N*-methyl-D-aspartate (NMDA) receptor and the μ opiate receptor. Its central sympathomimetic effects may be efficacious in agitated patients with bronchospasm and/or hemodynamic instability.[61] However, it is unlikely to add significantly to the effects of standard asthma treatment.[62] Ketamine also has potential for direct negative inotropic effects, which preclude its use in patients with severely impaired left ventricular function.[63] It should also be used with some element of caution in patients with underlying

atherosclerotic heart disease or valvular stenosis who could be susceptible to rate-induced ischemia. Ketamine is commonly administered with a BZD to prevent psychomimetic reactions.[4] The combination of ketamine and midazolam may avoid the inhibition of intestinal motility that is commonly observed with sedation regimens that include opioids.[64,65]

Ketamine is infrequently used in patients with significant CNS injury; it causes an increase in cerebral blood flow, can lead to increased intracranial pressure, and may lower the seizure threshold. Other deleterious effects include increased salivation, heart rate, blood pressure, and visual hallucinations.

Dexmedetomidine

Dexmedetomidine, the dextro-isomer of medetomidine, is an alpha-2 agonist compound that offers sedative and analgesic properties combined with an ultrashort duration of action. It binds more avidly to the alpha-2 adrenoreceptor than clonidine; approximately an eightfold greater affinity. Both its distribution half-life (6 min) and its terminal elimination half-life (2 h) are considerably shorter than those of clonidine. In addition, dexmedetomidine is associated with little respiratory depression, minimal hemodynamic perturbations, and marked attenuation of hormonal response to stress. Its role in the stress response remains to be fully elucidated, but offers the theoretical advantage of decreased myocardial ischemia in the perioperative period.[66]

Additionally, renal function as demonstrated by increased diuresis and natriuresis may be improved.

Typical infusion rates are 0.2–0.7 μg/kg/h for ≤24 h. The results of pharmaco-economic analysis remain controversial. The acquisition cost by the pharmacy is considerably higher than other agents, but may be offset by the beneficial effects on the stress response, as well as a more rapid emergence. Deleterious side effects include progressive hypotension and marked bradycardia. Hepatic insufficiency or liver failure may significantly prolong its duration of action.[67,68]

Inhalational Agents

Inhalational anesthetic agents administered via ventilator-mounted vaporizers may be used for sedation in the ICU. Rapid reversal of sedation is due to excretion of the drug via the respiratory tract and is one of the attractive features of inhalational agents in this setting. The use of these drugs holds promise, but more work is needed regarding long-term administration in critically ill patients. Halogenated inhalational agents may also be used in the critical care setting to treat status asthmaticus, status epilepticus, and for emergent control of intracranial and systemic hypertension.[69-71]

CONTROL OF AGITATION

Agitation is common among the critically ill, and its etiology is multifactorial (Table 57-4). Ideally, agitation should have a definitive diagnosis before initiation of therapy. It is important to realize that sedating a patient experiencing pain without first providing adequate analgesia will induce agitation. If a cause for agitation is found, therapy will, at least in part,

TABLE 57-4

CAUSES OF AGITATION IN THE CRITICALLY ILL

Sepsis	Subdural hematoma
Seizures	Hypertensive encephalopathy
Meningitis/encephalitis	Anxiety disorders
Delirium tremens	Cerebrovascular accident
Drug reactions	Thyroid disease
Hepatic encephalopathy	Uremic encephalopathy
Hypoglycemia	Hypoxia/hypercapnia
Hyponatremia	Steroid psychosis
Intracranial bleed	ICU psychosis

ICU intensive care unit

involve treatment of the underlying cause. If no cause for agitation is found, there is still a need to treat the patient to prevent self-injury or injury to health care professionals. If nonspecific agitation cannot be adequately controlled with BZDs alone, other drugs are used, either alone or in combination with the BZDs.

Haloperidol

Intravenous haloperidol has become a mainstay in the management of agitation in the ICU, despite a lack of approval by the FDA for this route of administration.[72] Haloperidol, a butyrophenone, has been shown to induce a state of apathy and mental detachment in patients experiencing agitation or delirium. This agent is potent, has a rapid onset of action, and has few negative effects on respiration or hemodynamics. Thus, it can be used in spontaneously breathing patients who are not intubated or supported by mechanical ventilation.

Haloperidol is a neuroleptic with an onset of action of 5–20 min and a terminal half-life of 20–50 h. The appropriate dose of haloperidol remains controversial, although a wide range of recommendations exist. A reasonable starting dose is 2–5 mg, with a doubling of the dose every 10–20 min until adequate control of agitation and effective sedation is achieved. The suggested maximum single dose of haloperidol is 40 mg.[73,74] The drug is metabolized in the liver and has no active metabolites.

A reasonable starting dose is 2–5 mg, initially with a doubling of the dose every 10–20 min until sedation is achieved. The suggested maximum single dose of haloperidol is 40 mg.

Neuroleptic malignant syndrome (NMS) is a potentially fatal reaction to neuroleptic agents. Haloperidol or the phenothiazines, alone or in combination, may trigger NMS. The signs and symptoms include muscle rigidity, hyperthermia, tachycardia, hypertension, rhabdomyolysis, mental status changes, and acidosis.[72] NMS may be confused with malignant hyperthermia, pheochromocytoma, thyroid storm, or sepsis. Therapy of NMS includes discontinuation of the offending agents, administration of intravenous dantrolene or a neuromuscular blocking agent, and bromocriptine. Although extrapyramidal side effects are observed less frequently when haloperidol is administered intravenously, they still may occur. Akathisia should be considered in patients who continue to move in a repetitive manner despite adequate treatment. Lorazepam or dopaminergic agents such as bromocriptine may be helpful in this setting. The administration of haloperidol may also rarely be associated with torsades de pointes and laryngospasm.

Haloperidol may be used alone, or in combination with lorazepam. A reasonable initial dose in an adult patient is haloperidol 5 mg and lorazepam 0.5 mg, in association with a one-time administration of opioid. The dose of haloperidol and lorazepam is then repeated or increased every 20–30 min until the patient is sedated. Once sedation is achieved with this type of combination therapy, subsequent doses and scheduling of each medication and intervals of administration depend on the recurrence of agitation.

Haloperidol may be used alone, or in combination with lorazepam. A reasonable initial dose in an adult patient is haloperidol 5 mg and lorazepam 0.5 mg, in association with a one-time administration of opioid.

Intermittent doses of analgesics or a continuous narcotic infusion may be combined with the sedative/hypnotics to control agitation. It is important to note that the combination of sedative/hypnotics and analgesics is synergistic rather than simply additive.[75] For that reason, the combination of an analgesic with one or more sedative-hypnotic agents may allow for a greater likelihood of successful sedation, uncomplicated by significant cardiovascular side effects. Careful titration to effect should mitigate the potential for oversedation.[4,60,61]

It is important to note that the combination of sedative/hypnotics and analgesics is synergistic rather than simply additive.

Risperidone

Over the past several years, clinicians have sought additional treatments for the control of agitation in the ICU patient. Risperidone is an antipsychotic agent and has been approved by the FDA for use in the treatment of acute mania, bipolar disorders, aggression/irritability with autistic disorder, and acute schizophrenia.[76] It has undergone investigational off-label use in the control of agitation, behavioral symptoms associated with senile dementia, treatment of Tourette's disorder, and management of pervasive developmental disorders.[77]

Risperidone is a benzisoxazole, atypical antipsychotic with mixed serotonin-dopamine antagonist activity. It binds with high affinity to serotonin 5-HT_2-receptors in the CNS, as well as in the peripheral nervous system. Risperidone binds with less affinity to dopamine-D_2 receptors. The addition of serotonin antagonism to dopamine modulation is hypothesized

to enhance control of acute agitation and psychosis. Risperidone is rapidly and well absorbed from the GI tract; the rate of absorption is not affected by enteral feedings. At present, it is not approved for intravenous administration; however, it can be given intramuscularly.

Risperidone may cause anticholinergic side effects, extrapyramidal symptoms (including pseudoparkinsonian features), and orthostasis. Risperidone should be used with caution in patients who are hypovolemic. In particular, dehydrated geriatric patients may be at increased risk of cerebrovascular accident and death. It should be used with care in any patient with preexisting CNS depression, since it can be moderately sedating. In addition, its use should be curtailed or avoided in patients who exhibit any significant degree of hepatic or renal impairment. Finally, its use in patients with preexisting Alzheimer's and/or Parkinson's disease remains controversial.[78] Therefore, it should be utilized with caution, careful follow-up, and clinical monitoring.

If control of agitation is still needed after intermittent administration of a BZD alone or in combination with analgesics, haloperidol, or risperidone, other choices are available; these include, but are not limited to, continuous infusions of lorazepam, midazolam, propofol, or ketamine.[79] Mechanical ventilation, with or without the use of neuromuscular blocking agents, may be necessary on occasion in an individual patient.

SUMMARY

Most patients admitted to an ICU will receive some combination of sedative/hypnotics and analgesics. There is no reason to allow critically ill patients to experience fear, anxiety, or pain. Often, multiple agents and techniques are employed. An understanding of how critical illness affects the pharmacokinetics and pharmacodynamics of these agents is vital. Although multiple tools are available to assess the degree of this emotional and physical discomfort, they lack routine clinical applicability in the care of the critically ill.

Morphine is the agent of choice for analgesia in the critically ill patient. If hemodynamic instability or allergy to morphine exists, fentanyl is an excellent alternative analgesic. Lorazepam is the sedative/hypnotic agent recommended for anxiolysis or sedation. It may be administered by intermittent injection or continuous infusion. Midazolam or propofol are reasonable alternative choices.

Agitation has multiple etiologies and should be investigated fully. Appropriate diagnosis will lead to appropriate care; however, treatment of agitation is crucial in the prevention of injury to the patient and health care personnel. Haloperidol with or without concomitant administration of a BZD is an appropriate first choice.

REVIEW QUESTIONS*

1. **The following opioids demonstrate significant action at the μ and κ receptors:**
   - **A.** Morphine
   - **B.** Meperidine
   - **C.** Fentanyl
   - **D.** Nalbuphine

2. **The following are potential causes of agitation in the critically ill patient:**
   - **A.** Sepsis
   - **B.** Alcohol withdrawal
   - **C.** Hypoglycemia
   - **D.** Hypertensive encephalopathy

3. **Which of the following are potential side effects of the epidural or spinal administration of narcotics?**
   - **A.** Nausea and vomiting
   - **B.** Pruritus
   - **C.** Urinary retention
   - **D.** Respiratory depression

4. **Which of the following sedative/hypnotics produce active metabolites following their breakdown within the liver?**
   - **A.** Diazepam
   - **B.** Propofol
   - **C.** Midazolam
   - **D.** Lorazepam

* Note: More than one answer may be correct.

5. **The intravenous administration of haloperidol may be associated with:**
   - **A.** Neuroleptic malignant syndrome
   - **B.** Torsades de pointes
   - **C.** Laryngospasm
   - **D.** Hypokalemia

6. **Propofol is a sedative/hypnotic agent which may:**
   - **A.** Cause a burning sensation at the site of intravenous injection
   - **B.** Result in acute refractory bradycardia or asystole
   - **C.** Induce sudden onset of apnea
   - **D.** Support bacterial growth

7. **Ketamine, a PCP derivative, acts primarily via which of the following receptor(s)?**
   - **A.** Central GABA receptor
   - **B.** The μ receptor
   - **C.** The NMDA receptor
   - **D.** The κ receptor

8. **Dexmedetomidine, an alpha-2 agonist, possesses which of the following characteristics?**
   - **A.** Minimal respiratory depression
   - **B.** Attenuation of hormonal responses to surgical stress
   - **C.** Progressive hypotension with marked bradycardia
   - **D.** Prolonged duration of action in the setting of hepatic failure

9. **Neuraxial analgesia is contraindicated under which of the following circumstances:**
   - **A.** Patients receiving low molecular weight heparin for DVT prophylaxis
   - **B.** Those who are fully anticoagulated with coumadin
   - **C.** Patients receiving unfractionated (mini-dose) heparin for DVT prophylaxis
   - **D.** Those taking clopidogrel, but who have not received it within the previous 24 h

10. **Severe local anesthetic toxicity may result in the following critical events:**
    - **A.** Cardiac arrest
    - **B.** Bronchospasm
    - **C.** Convulsions
    - **D.** Nephrotoxicity

ANSWERS

1. The answer is B and D. There are five classes of opioid receptors; mu (μ), kappa (κ), delta (δ), sigma (σ), and epsilon (ε). Morphine and fentanyl mediate their effect largely through the μ receptor. Nalbuphine hydrochloride is considered an agonist/antagonist because although it has a weak intrinsic agonist effect at the μ receptor, it acts as an antagonist in the presence of a potent μ receptor agonist such as morphine. Meperidine and nalbuphine both act on the κ receptor in addition to their action on the μ receptor. κ receptor agonists suppress shivering and thus avoid increasing metabolic demand.
2. The answer is A, B, C, D. All these conditions may lead to agitation. If a cause for agitation is found, therapy will, at least in part, involve treatment of the underlying cause. While that treatment is ongoing, it is important to note that there may still be a need to treat the patient with sedatives and analgesics, or haloperidol, to prevent self-injury or injury to health care personnel.
3. The answer is A, B, C, and D. Although there are a number of side effects described with the epidural or spinal administration of opioids, the four symptoms named (nausea and vomiting, pruritus, urinary retention, and respiratory depression) are considered the classic side effects. All these side effects are mediated by opioid action and can be effectively treated with naloxone. Titration with naloxone is recommended in an attempt to maintain pain relief while reversing nonemergent side effects. Profound respiratory depression is rare and should be treated immediately.
4. The answer is A and C. Diazepam and midazolam have potent, active metabolites, which, to some extent, have limited their use in the critically ill patient. Although lorazepam has a longer elimination half-life than midazolam, its duration of effect has been reported to be shorter following discontinuation of a continuous infusion. The prolonged effect of midazolam is believed due to altered drug kinetics and an accumulation of active metabolites in critically ill patients. Propofol has no active metabolites and is rapidly redistributed to lipophilic sites following discontinuation of administration.
5. The answer is A, B, and C. Neuroleptic malignant syndrome, torsades de pointes, and laryngospasm are considered rare but potential complications of the intravenous administration of haloperidol.
6. The answer is A, B, C, and D. Propofol is an oil-in-water emulsion which is used as an intravenous sedative and hypnotic agent. It may cause a burning sensation at the site of peripheral injection. It may result in acute refractory bradycardia, asystole, and sudden onset of apnea. Because of its ability to support bacterial growth, recommendations regarding preparation and the application of strict aseptic technique must be followed.
7. The answer is C. The mu (μ) and kappa (κ) receptors are opiate receptors. Benzodiazepines act via the central GABA receptor.
8. The answer is A, B, C, and D. Useful characteristics include minimal to no respiratory depression and attenuation of hormonal response to stress. Progressive hypotension and marked bradycardia are possible complications; hepatic insufficiency will prolong the action of this agent.
9. The answer is A, B, and D. Epidural hematoma is a feared and potentially catastrophic complication of neuraxial techniques. Certain antiplatelet agents, LMWH, and oral anticoagulants may increase risk; there is no contraindication to neuraxial blockade if mini-dose heparin is being administered for DVT prophylaxis.

The American Society of Regional Anesthesiology has specific recommendations for anticoagulation and regional anesthesia (Second Consensus Conference on Neuraxial Anesthesia and Anticoagulation 25–28 April 2002).

10. The answer is A and C. The primary target organ for local anesthetic toxicity is the CNS, and convulsions may be seen. More potent local anesthetics, such as bupivacaine, are more cardiotoxic than less potent agents, such as lidocaine. Local anesthetic toxicity may be manifested by a progressive blockade of the sodium channel resulting in cardiac arrest. Rescue therapy has been successful with 20% Intralipid, a commonly available intravenous lipid emulsion.

Use of Neuromuscular Blocking Agents in the Intensive Care Unit

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the pharmacokinetics and pharmacodynamics of various neuromuscular blocking (NMB) agents.
- Understand the complications associated with the prolonged use of NMB agents in the critically ill patient and how to minimize them.
- Recognize the potential for interaction among commonly used drugs and NMB agents.
- Make recommendations regarding the use and dose of NMB agents in the critically ill.
- Understand the need for routine and effective sedation and analgesia in the critically ill patient receiving NMB agents in order to prevent awareness and pain.
- Understand the need for evaluation and monitoring of neuromuscular function in the critically ill patient receiving NMB agents.

In the mid-1980s, the two intermediate-duration NMB agents, atracurium and vecuronium, were introduced into practice; within a few years, these accounted for the majority of NMB agent use in critically ill patients.[1] In association with the introduction of these new agents, there was an expansion of the indications for muscle paralysis in this country, which was at least partially related to new ventilatory modes and technologic advances that necessitated cooperative, sedate, or immobile patients. These new indications for an immobile patient, coupled with an expanded knowledge of available NMB agents, led to a dramatic increase in the use of muscle paralysis in the intensive care unit (ICU).[1] In association with this increased use has come a growing awareness of the potential for severe complications and side effects.

It cannot be overemphasized that NMB agents do not have sedative, amnesic, or analgesic effects.[2] Therefore, it is mandatory to administer, concurrently with NMB agents, medications that have those effects. Adequate dosing with a combination of benzodiazepine and narcotic is optimal.[3] Propofol infusions in the dosages commonly used in the ICU may lack amnesic action and provide no analgesia. In this chapter, we review the pharmacology, indications for use, monitoring, and complications of NMB agents used in the management of the critically ill.

It cannot be overemphasized that neuromuscular blocking (NMB) agents do not have sedative, amnesic, or analgesic effects.

PHYSIOLOGY OF NEUROMUSCULAR BLOCKADE

Transmission of the nerve cell action potential across the synaptic cleft and initiation of a muscle cell action potential is accomplished in the following manner. Acetylcholine is synthesized from acetate and choline and stored in vesicles in the motor nerve ending in close proximity to the nerve cell membrane and opposite the area of the muscle cell with the highest density of nicotinic acetylcholine receptors. A nerve cell action potential initiates an influx of calcium, which allows exocytotic release of acetylcholine into the synaptic cleft. Acetylcholine then diffuses across the synapse and interacts with acetylcholine receptors (Fig. 58-1).

The nicotinic acetylcholine receptor is present at three locations: postsynaptic junctional, extrajunctional, and a presynaptic receptor on the nerve ending.[4] The postsynaptic junctional receptors are present in high density at a specialized area of muscle membrane located at the juncture of the primary and secondary synaptic clefts, close to the nerve ending. These receptors are composed of five protein subunits that span the muscle cell membrane. Arranged in a tube-like structure, the receptor complex allows passage of ions through the muscle cell membrane and down their respective concentration gradients when properly stimulated. The two alpha subunits carry recognition sites for agonists and antagonists. Both alpha subunits must bind acetylcholine simultaneously to induce a conformational change in receptor structure. With the opening of this five-subunit receptor, sodium and calcium move into the muscle cell, potassium moves out of the cell, and a miniature end-plate potential is generated. If an adequate number of receptors are stimulated, miniature end-plate potentials summarize to exceed the threshold potential and generate an action potential. The action potential activates the adjacent voltage-dependent sodium channels and spreads throughout the muscle fiber, triggering the contraction process. Stimulation of presynaptic receptors causes mobilization of additional acetylcholine for future neuromuscular transmission. Extrajunctional receptors are a concern to the clinician only if they proliferate because of dysfunction of nerve or muscle. Acetylcholine, after diffusing off the receptor, is rapidly hydrolyzed by the enzyme acetylcholinesterase, which is present within the synaptic cleft.

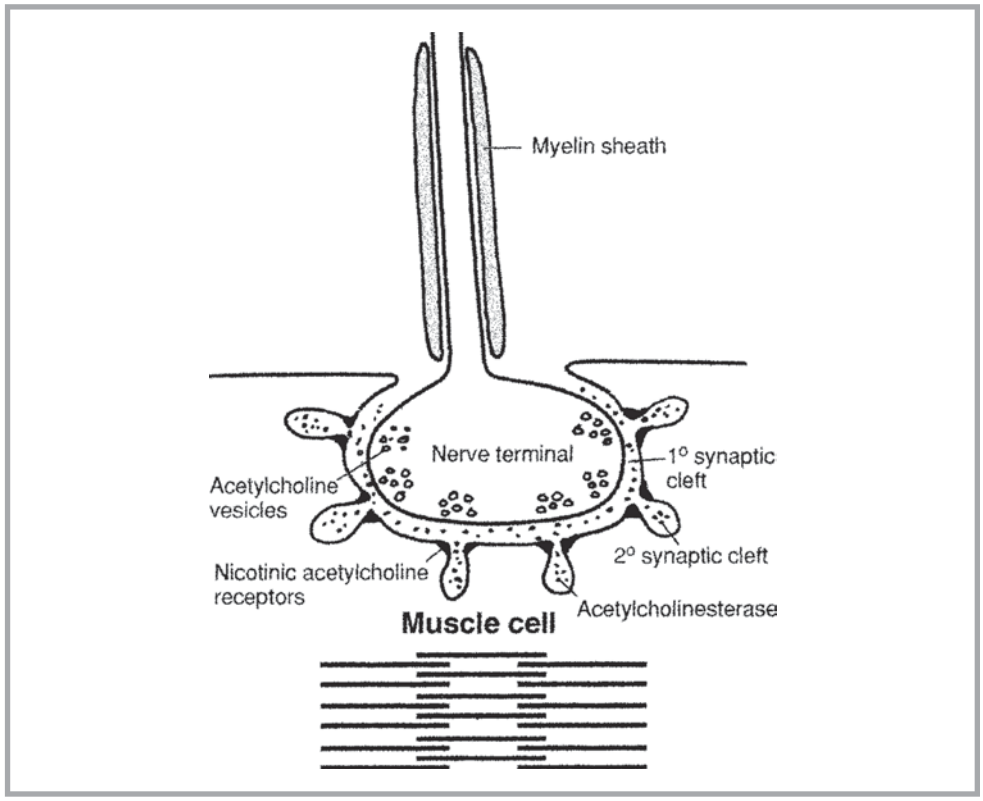

FIGURE 58-1

Neuromuscular junction.

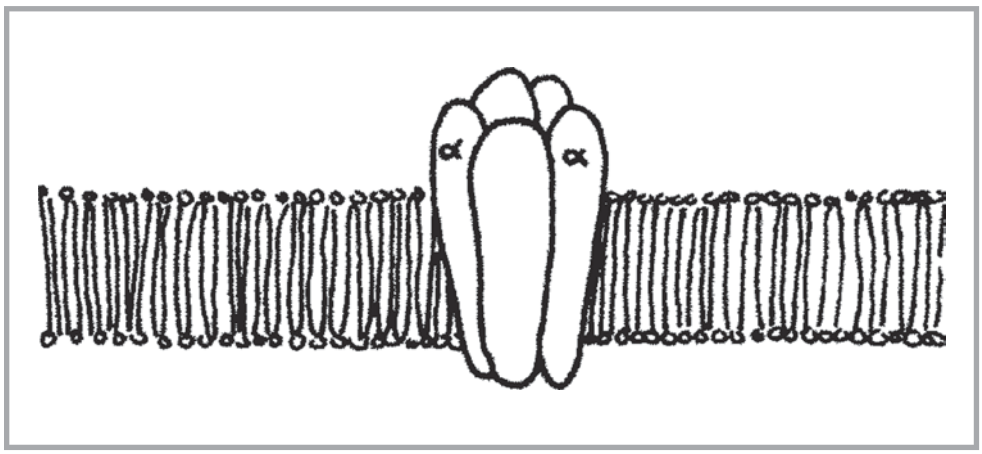

FIGURE 58-2

The nicotinic acetylcholine receptor is composed of five subunits. Both alpha subunits must bind acetylcholine simultaneously to open the ion channel.

Depolarization of the muscle membrane must occur for muscle contraction to take place. Nondepolarizing NMB agents prevent depolarization of the muscle membrane, and thus, cause muscle paralysis, primarily by competitive inhibition at one or both of the alpha subunits of the postsynaptic nicotinic acetylcholine receptor (Fig. 58-2).

Depolarizing NMB agents also bind to both alpha subunits to exert an effect, but they act as agonists. Because these drugs have a longer duration of action than acetylcholine, the muscle fiber, following an initial contraction (fasciculation), remains persistently depolarized and flaccid.

It should be noted that there exists a wide margin of safety in the number of postsynaptic nicotinic acetylcholine receptors. Only a small fraction of receptors need be stimulated to produce depolarization and muscle contraction. For that reason, 70–75% of postsynaptic receptors must be occupied by nondepolarizing NMB agents before clinical blockade is detectable. Clinically relevant neuromuscular paralysis, thus, occurs over a narrow range of receptor occupancy (i.e., 70–100%).

TYPES AND CLASSES OF NMB AGENTS

Depolarizing NMB Agents

Succinylcholine is the only depolarizing NMB agent utilized clinically within the United States. It has a very short time to onset, a short duration of action, and is inexpensive. When administered to adults in an intravenous dose of 1–1.5 mg/kg, onset occurs in 60–90 s; spontaneous ventilation is resumed in 8–9 min.[5] It is used most often in situations that require rapid control of the airway. Once the airway has been successfully controlled, if there is an ongoing need for neuromuscular blockade, a nondepolarizing agent is administered (Table 58-1).

Succinylcholine is the only depolarizing NMB agent utilized clinically within the United States.

The side effects of succinylcholine include a transient, but potentially hazardous, increase in serum potassium levels. This increase in serum potassium is mediated by the simultaneous opening of large numbers of nicotinic acetylcholine receptors and is on the order of approximately 0.5 mEq/dL.[6] In patients with normal nicotinic acetylcholine receptor density, this becomes a concern only if high levels of potassium exist at the time of drug administration, as might be the case in a patient with renal failure. However, in patients who have suffered denervation injuries, massive increases in the number of extrajunctional nicotinic acetylcholine receptors can result in life-threatening hyperkalemia if succinylcholine is administered.[4] Both upper and lower motor neuron lesions are contraindications to the use of succinylcholine, depending on the time from injury. Succinylcholine should not be administered to patients beyond 48 h from the time of injury and remains contraindicated for 6–12 months.

In patients who have suffered denervation injuries, massive increases in the number of extrajunctional nicotinic acetylcholine receptors can result in life-threatening hyperkalemia if succinylcholine is administered.

Succinylcholine is one of the classic triggers for malignant hyperthermia and should not be administered to patients with a personal or family history of this disorder.

TABLE 58-1

NMB AGENTS USED IN ICU CLINICAL PRACTICE

CLASS	AGENT	BOLUS OR INTERMITTENT INJECTION IN ADULTS (mg/kg)	ONSET (MIN)	DURATION OF ACTION	INFUSION RATE (mg/kg/H)	RECOVERY TIME (MIN)
Depolarizing	Succinylcholine	1–1.5	1–1.5	Ultrashort	N/A	7–9
Nondepolarizing (aminosteroid)	Pancuronium	0.1 every 90–min	3–5	Long	N/A	60–100
Nondepolarizing (aminosteroid)	Vecuronium	0.1 every 35–40 min	2–3	Intermediate	0.05–0.1	20–40
Nondepolarizing (aminosteroid)	Pipecuronium	0.09–0.1 every 90–100 min	3–5	Long	N/A	60–120
Nondepolarizing (aminosteroid)	Rocuronium	0.6–1.0 every 25–30 min	1–1.5	Intermediate	N/A	30–60
Nondepolarizing (benzylisoquinolinium)	Atracurium	0.4–0.5 every 25–30 min	2–3	Intermediate	0.4–1.0	30–45
Nondepolarizing (benzylisoquinolinium)	Cisatracurium	0.15–0.2 every 25–30 min	2–3	Intermediate	0.03–0.6	40–45
Nondepolarizing (benzylisoquinolinium)	Doxacurium	0.025 every 90–100 min	4–6	Long	N/A	100–160

Direct muscle injury, extensive burns, and a recent history of chronic administration of nondepolarizing NMB agents are also contraindications.[6] Cardiac arrest, secondary to hyperkalemia following succinylcholine administration, has been reported in ICU patients with no risk factors other than immobilization due to confinement.[7]

Succinylcholine is one of the classic triggers for malignant hyperthermia and should not be administered to patients with a history, or family history, of this disorder. Other side effects include cardiac dysrhythmias, masseter spasm, and increased intraocular, intracranial, and intragastric pressure. Diffuse muscle pain may occur following succinylcholine administration.

Nondepolarizing NMB Agents

The nondepolarizing compounds used commonly within both the operating theater and the critical care unit are organized by structure into two major groups: the aminosteroid compounds and the benzylisoquinolinium compounds. Agents in both groups are quaternary ammonium compounds that contain a positively charged nitrogen atom capable of binding to the alpha subunit(s) of the nicotinic acetylcholine receptor[8] (Fig. 58-3).

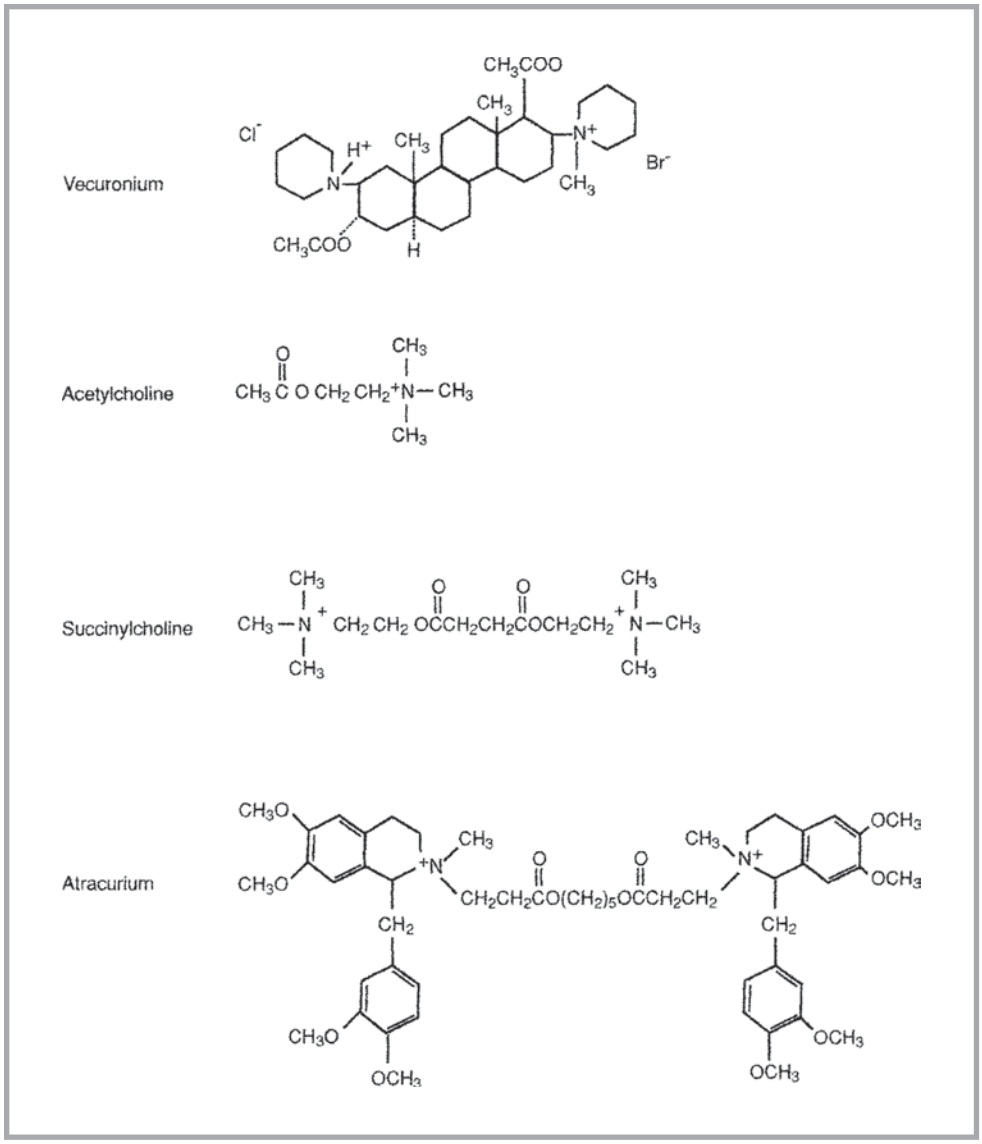

FIGURE 58-3

Acetylcholine, succinylcholine, atracurium, and vecuronium.

Aminosteroid Compounds

The aminosteroid compounds contain a steroid skeleton within their structure. Currently available members of this group include pancuronium, vecuronium, pipecuronium, and rocuronium.

Pancuronium is a synthetic NMB agent that has classically been administered by intermittent injection because of its relatively long duration of action (approximately 100 min following an intubation dose of 0.1 mg/kg). The vagolytic action of pancuronium causes an increase in heart rate, and for that reason, it may be unsuitable in patients with coronary artery disease. Excretion is accomplished primarily by renal routes, although hepatic elimination plays a role; it is contraindicated in patients with significant organ dysfunction. Pancuronium has an active metabolite, 3-hydroxypancuronium, with 30–50% of the potency of the parent compound.

The vagolytic action of pancuronium causes an increase in heart rate, and for that reason, it may be unsuitable in patients with coronary artery disease.

A great deal has been learned about the use of vecuronium in critical care since its introduction in 1984. It is a NMB agent with an intermediate duration of action, often administered by continuous infusion. After a single dose of 0.1 mg/kg, it has a duration of effect of 30–40 min. Vecuronium has a safe cardiovascular profile and does not affect heart rate or blood pressure. Like pancuronium, it has an active metabolite, 3-desacetylvecuronium, with 80% of the potency of the parent compound. This agent, its metabolism, and its complications are described later in greater detail.

Vecuronium has a safe cardiovascular profile and does not affect heart rate or blood pressure.

Pipecuronium and rocuronium are newer members of this group and have not as yet found routine use among intensivists. Pipecuronium is a long-acting agent similar to pancuronium in structure, potency, and duration of effect, but without the vagolytic actions of pancuronium. It is also primarily eliminated via the renal route. There appears to be little difference, other than cost, in long-term administration of pancuronium versus pipecuronium in the critical care setting.

Rocuronium is intermediate in duration of action (30–60 min). Although similar to vecuronium in pharmacokinetics, it has a more rapid onset of action and a lack of active metabolites. Its time to onset makes it the most attractive alternative to succinylcholine when a nondepolarizing NMB agent is indicated for rapid tracheal intubation.[9] When administered continuously over several days in critically ill patients, plasma clearance decreases, volume of distribution increases, and terminal half-life is prolonged.[10]

Benzylisoquinolinium Compounds

Clinically relevant compounds in this group include atracurium, cisatracurium, and doxacurium. D-tubocurarine, metocurine and mivacurium have either fallen into disuse or been withdrawn from the market. These agents are esters, and metabolism via ester hydrolysis occurs, to some extent, with each member of the group; some (atracurium and cisatracurium) also undergo a nonorgan-based degradation known as Hofmann elimination. Histamine release, and its effect on cardiac and respiratory function, has been a relatively consistent concern over the years with this group of agents.

Atracurium is a NMB agent with an intermediate duration of action. Histamine release occurs with bolus administration and can be associated with skin flushing, hypotension, or bronchospasm. This agent is usually administered by continuous infusion in a critical care setting. Atracurium is best known for its rapid spontaneous metabolism, which is largely independent of organ function. It has no active metabolites. Atracurium is metabolized by Hofmann elimination (nonenzymatic degradation at normal body temperature and pH) and ester hydrolysis to yield laudanosine and a monoacrylate metabolite. Concern has been expressed regarding its metabolite, laudanosine, which has been reported to cause seizure activity in animal models. The initial lack of enthusiasm for the use of this agent in the ICU may have been the result of fear regarding a possible association between atracurium administration and seizure activity in humans.[1,11] However, there appears to be no clinical relevance to this concern.[12,13]

Atracurium is best known for its rapid spontaneous metabolism, which is largely independent of organ function.

Cisatracurium besylate is a purified form of one of the isomers of atracurium. Cisatracurium has a NMB profile similar to that of atracurium with the following exceptions. It is approximately three times more potent than atracurium, has a slower onset of action, and is devoid

Cisatracurium besylate is a purified form of one of the isomers of atracurium.

of the dose-related histamine-releasing effects that plague atracurium.[14] Its rapidity of metabolism, independent of organ function, mirrors that of atracurium. Mean recovery time, comparable to that of atracurium, is approximately 45 min following cessation of infusion.[15] Potential dose-related side effects, such as the accumulation of laudanosine, would be even less likely than with atracurium, because a lesser amount of agent is administered.[15] Cisatracurium has become preferred over atracurium in the critically ill patient because of its lack of histamine release, increased potency, and decreased cost. The safety of cisatracurium and its lack of active metabolites make it a reasonable choice for use in critically ill patients.[16]

Doxacurium is a long-acting NMB agent, devoid of histamine-releasing side effects. It is similar to pancuronium in its elimination half-life and dependence on renal clearance, but does not cause tachycardia or have other hemodynamic effects. Doxacurium has a slow onset of action and a long duration of effect. It is used infrequently in a critical care setting, and there is limited information regarding administration by infusion.[17]

Reversal of Neuromuscular Blockade

Reversal of neuromuscular blockade is usually accomplished in an ICU setting by discontinuing the NMB agent and allowing metabolic breakdown to result in the recovery of function. However, in some settings, pharmacologic reversal of the effects of these agents may be necessary and appropriate.

Acetylcholinesterase inhibitors are commonly used to reverse the paralytic effects of NMB agents. Acetylcholinesterase inhibitors increase the concentration of acetylcholine at the neuromuscular junction, reversing the neuromuscular blockade by a competitive mechanism. In the operating room the most frequently used acetylcholinesterase inhibitor is neostigmine; the reversal dose for neostigmine is 70 μg/kg, to a maximum dose of 5 mg. Because these drugs have a pharmacologic ceiling effect, they cannot reverse profound neuromuscular blockade.[18] Neostigmine should be administered only after demonstration of partial recovery by the reappearance of at least one twitch in a train-of-four (TOF) stimulus. Premature administration of the reversal agent before achieving some degree of spontaneous recovery should not be attempted as it will not accelerate recovery. [18]

The increase in acetylcholine levels seen with the administration of an acetylcholinesterase inhibitor is not limited to the neuromuscular junction and can result in unwanted side effects (bradycardia, bronchospasm, and increased peristalsis), which can be blocked or minimized by the simultaneous administration of a muscarinic antagonist. Glycopyrrolate is commonly used at a dose of 10 μg/kg, with a minimum dose of 0.2 mg. Glycopyrrolate causes tachycardia and xerostomia.

Sugammadex, a novel agent for the reversal of neuromuscular blockade, is a modified gamma-cyclodextrin compound that selectively binds aminosteroid NMB agents, forming a 1:1 complex in the plasma, which results in a lower effective concentration at the receptor site.[19] The Sugammadex-steroid NMB agent complex does not have NMB effects and is excreted through the kidney.[19] Sugammadex was developed to specifically bind rocuronium; however, it binds other aminosteroid agents, including vecuronium. The action of Sugammadex is independent of cholinergic receptors and has been shown to be effective and well tolerated in humans. Unlike acetylcholinesterase inhibitors, Sugammadex does not require simultaneous administration of an anticholinergic agent, and effectively reverses profound neuromuscular blockade.[19] Sugammadex is currently being evaluated by the Food and Drug Administration for use in the USA (Fig. 58-4).

Unlike acetylcholinesterase inhibitors, Sugammadex does not require simultaneous administration of an anticholinergic agent, and effectively reverses profound neuromuscular blockade by selectively binding aminosteroid NMB agents.

INDICATIONS FOR ADMINISTRATION OF NMB AGENTS

Indications for administration of NMB agents can be categorized as short-term, to facilitate procedures, or long-term, as therapeutic interventions.

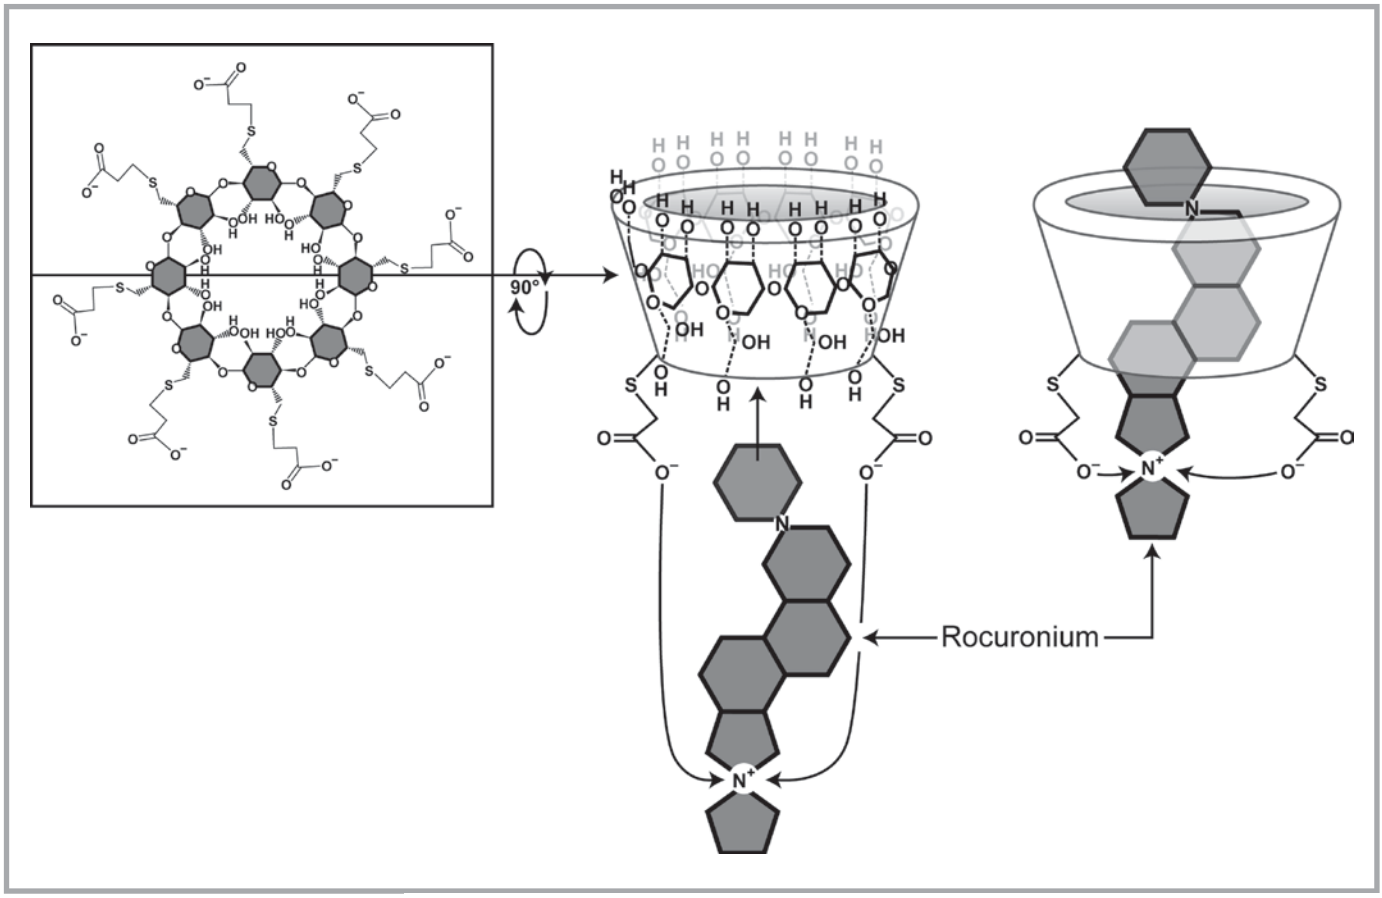

FIGURE 58-4

Sugammadex, a modified gamma-cyclodextrin compound, has a lipophilic core and a hydrophilic periphery which permits encapsulation of the rocuronium molecule. The intense binding effectively renders the NMB agent unavailable to bind to nicotinic acetylcholine receptors (Illustration by Alice Y. Chen).

An appropriate indication must exist for the use of a NMB agent.

Indications for administration of NMB agents can be categorized as short-term, to facilitate procedures, or long-term, as therapeutic interventions.

Facilitation of mechanical ventilation is the most common indication for long-term administration of NMB agents.

In patients with respiratory failure and in patients who need urgent or rapid control of the airway, these drugs are often used to facilitate endotracheal intubation. Additionally, some diagnostic studies, such as magnetic resonance imaging or computed axial tomography, may require absolute immobility for successful completion (Table 58-2). To ensure patient safety and successful completion of a diagnostic or therapeutic procedure, such as bronchoscopy, endoscopy, or transesophageal echocardiography, short-term use of NMB agents may be indicated. Additionally, in some settings, patient transport may be an appropriate indication. In these settings, the duration of use is measured in minutes or perhaps hours, and airway control with some form of assisted ventilation is mandatory.

TABLE 58-2

INDICATIONS FOR USE OF NEUROMUSCULAR BLOCKING (NMB) AGENTS

SHORT TERM	LONG TERM
Endotracheal intubation	Facilitation of medical ventilation (synchrony, inverse ratio ventilation, permissive hypercapnia)
Diagnostic studies	Tetanus
Therapeutic procedures	Infant respiratory distress syndrome
Patient transport	Acute respiratory distress syndrome
	Agitation (with concurrent sedative and analgesic treatment)
	Ventilatory support in association with increased intracranial pressure

Facilitation of mechanical ventilation is the most common indication for long-term administration of NMB agents. These agents may allow improvement in the interface between patients and innovative ventilatory modes, such as inverse ratio ventilation, high-frequency oscillatory ventilation, and permissive hypercapnia.[20] NMB agents are now used in at least 13% of critically ill patients requiring mechanical ventilation.[21] Additional indications include the treatment of tetanus, infant respiratory distress syndrome, acute respiratory distress syndrome, and adult patients requiring high inspired oxygen concentrations in association with the prone position.

In critically ill patients with neurologic dysfunction and increased intracranial pressure, NMB agents allow suctioning of airway secretions without provoking coughing or dysnchrony with the ventilator. Either of these responses to routine pulmonary toilet could increase intracranial pressure to potentially dangerous levels.[22]

Neuromuscular blockers should be avoided, if at all possible, in the septic patient due to the risk of prolonged neuromuscular blockade after discontinuation.[23]

CLINICAL USE OF NMB AGENTS

The use of NMB agents to control agitation, assure immobility, or allow synchronization with the ventilator should not be undertaken until a careful examination of the patient has excluded other causes of patient-ventilator dyssynchrony. Additionally, the use of NMB agents to facilitate ventilation should be undertaken only after attempts to control the patient with adjustments in ventilator settings, and various combinations of sedative/hypnotics and analgesics have failed. It has been the experience of the authors that NMB agents are often utilized for control of agitation following an inadequate trial of analgesics and sedative/hypnotics. The combination of various sedative/hypnotics with analgesics has the useful property of synergism and allows a much lower dose of each individual agent than would be possible if their effects were simply additive.[24] This approach is analogous to using multiple chemotherapeutic agents for cancer treatment; it allows maximization of individual drug effect while minimizing unwanted side effects. Involvement of an anesthesiologist may be helpful in tailoring an appropriate combination of sedative/hypnotics and analgesics; in the operating room, this technique of using small amounts of various agents to maximize their effect, while minimizing the side effects of each agent, is known as balanced anesthesia. Some patients will require administration of NMB drugs for control of agitation,[25] but with appropriate use of sedative/hypnotics and analgesics, this number can be minimized.

The use of NMB agents to control agitation, assure immobility, or allow synchronization with the ventilator should not be undertaken unless manipulation of the ventilator settings and attempts to control the patient with various combinations of sedative/hypnotics and analgesics fail.

The choice of NMB agent and the method of its administration should be considered. It is premature to state that one particular NMB agent, or even one particular class of agent, is clearly superior to another; there does not appear to be strong evidence favoring one class of agent over another in regard to complications. However, in patients with organ dysfunction, benzylisoquinolinium agents appear to have an advantage over the aminosteroid compounds, presumably based on pharmacokinetics.[26]

It is premature to state that one particular NMB agent or even one particular class of agent is clearly superior to another.

NMB agents may be administered by intermittent injection or continuous intravenous infusion. Some clinicians believe that intermittent bolus administration may place a patient at lesser risk because it allows monitoring and titration of drug in addition to periods of normal neuromuscular function.[27] However, there is no clear evidence that one method of administration is superior to another.

If the use of a NMB agent is instituted, it should be utilized for the shortest possible time. Discontinuation of NMB agent administration should occur at least every 24 h as this may decrease the incidence of complications[28], it will certainly help prevent overdose or accumulation of active metabolites and allow early recognition of prolonged blockade. It also provides a daily opportunity for a physical and neurologic examination and evaluation of the need for ongoing mechanical ventilation.[29]

Discontinuation of NMB agent administration should occur at least every 24 h as this may decrease the incidence of complications. It will certainly help prevent overdose or accumulation of active metabolites and allow early recognition of prolonged blockade.

Patients receiving NMB agents have an increased incidence of pulmonary embolus.

Care of the Patient Receiving NMB Agents

In addition to the complications noted above, there are potential problems common to all patients who receive NMB drugs long-term. There is an increased incidence of pulmonary embolus in

patients receiving NMB agents, which may result from the severity of illness of these patients or their marked degree of immobility. Prophylactic measures should be routinely employed in an attempt to prevent this complication. Bedside range-of-motion therapy may help prevent or minimize disuse atrophy and ligamentous joint calcification. Issues regarding eye care and protection, prevention of soft tissue injury and pressure necrosis, and adequate sedation should be adequately and consistently addressed in all patients receiving NMB agents. These patients cannot move or communicate with health care personnel in any way. Hypoxemia will result from loss of airway, disconnection from the ventilator, or ventilator malfunction. Therefore, all monitoring devices and alarm systems must be operational, and any alarm must be investigated immediately. An adequate and up-to-date nursing care policy and protocol is an extremely important tool that will help ensure consistency of care.[30] In-service training of ICU nursing personnel at regular intervals is also crucial to the care of patients receiving NMB agents.

Issues regarding eye care and protection, prevention of soft tissue injury and pressure necrosis, and adequate sedation should be adequately and consistently addressed in all patients receiving NMB agents.

Monitoring of the Patient Receiving NMB Agents

When the effective dose of a particular drug varies among patients, some type of assessment of therapy must take place. This assessment may simply entail observing for an adequate clinical response; if that is not forthcoming, and if there are no significant side effects, additional medication is administered. If there are potential adverse effects, the clinician may choose to measure drug levels or to monitor for adverse effects in some other manner. Because only a few medical centers are capable of accurate measurement of plasma levels of NMB agents and their active metabolites, we must use some clinical measurement of drug effect in an attempt to achieve neuromuscular blockade while minimizing adverse sequelae.

Neuromuscular function is usually evaluated in the ICU by a peripheral nerve stimulator.[31] The ratio of a single twitch to that of a control twitch reflects the extent of receptor occupancy in that muscle by a nondepolarizing NMB agent (i.e., 80% reduction in twitch height is equivalent to 80% blockade). When using TOF stimulation, four electric stimuli are administered to a peripheral nerve in rapid sequence. Usually the response of the adductor pollicis brevis muscle (adduction of thumb) to percutaneous supramaximal stimulation of the ulnar nerve is chosen for TOF monitoring. However, other sites and other types of monitoring may be useful in the critical care arena. Successive twitches disappear as progressively greater degrees of neuromuscular blockade are achieved. Good correlation exists between the degree of neuromuscular blockade and the number of responses to TOF stimulation. Over the range of 75–100% blockade, the fourth, third, second, and first twitch become inappreciable, in that order; spontaneous recovery occurs predictably in reverse order (Fig. 58-5).[32]

Neuromuscular function is usually evaluated in the ICU by a peripheral nerve stimulator.

Emphasis must be placed on appropriate training in the use of a twitch monitor. Although TOF stimulation is a relatively simple procedure, there are potential problems associated with its performance. Two common problems are imprecise placement of the electrodes and failure to recognize the variation in response to TOF stimulation that is due to increased tissue thickness between electrodes and nerve (often seen in edematous patients). Placement of the electrodes at the level of the wrist and over the ulnar arterial pulse (the ulnar nerve is adjacent to the artery) is helpful. Wrapping an edematous extremity for several minutes before TOF stimulation can be useful in solving the second problem. Ongoing training and quality assurance activities should be instituted to maintain an acceptable level of expertise in the use of NMB agents and TOF monitoring.

Ablation of greater than three twitches to TOF stimulation at the ulnar nerve is usually unnecessary in the critically ill patient.

Monitoring the degree of neuromuscular blockade with a twitch monitor is reasonable, cost-effective, and likely to lessen the possibility of prolonged muscle weakness or persistent paralysis.

The diaphragm is the most resistant of all muscles to the action of NMB agents, requiring 1.4–2.0 times as much agent as the adductor pollicis brevis muscle for identical degrees of paralysis.[33] Because the diaphragm will continue to show activity in the face of complete blockade, as measured by ulnar nerve TOF stimulation, more sensitive techniques may be employed. In the operating room, where access to the ulnar nerve may be restricted, it has long been known that TOF stimulation may be applied to the facial nerve and the response monitored at the orbicularis oculi muscle. When TOF stimulation of the facial nerve is compared to stimulation of the ulnar nerve, onset of neuromuscular blockade and time to recovery are similar at the diaphragm and the orbicularis oculi muscle, but not at the adductor pollicis brevis muscle.[34] Therefore, the response of the orbicularis oculi to facial nerve stimulation depicts the degree of neuromuscular block of the diaphragm better than the response of the adductor pollicis to ulnar nerve stimulation and is perhaps more clinically relevant in the critically ill.

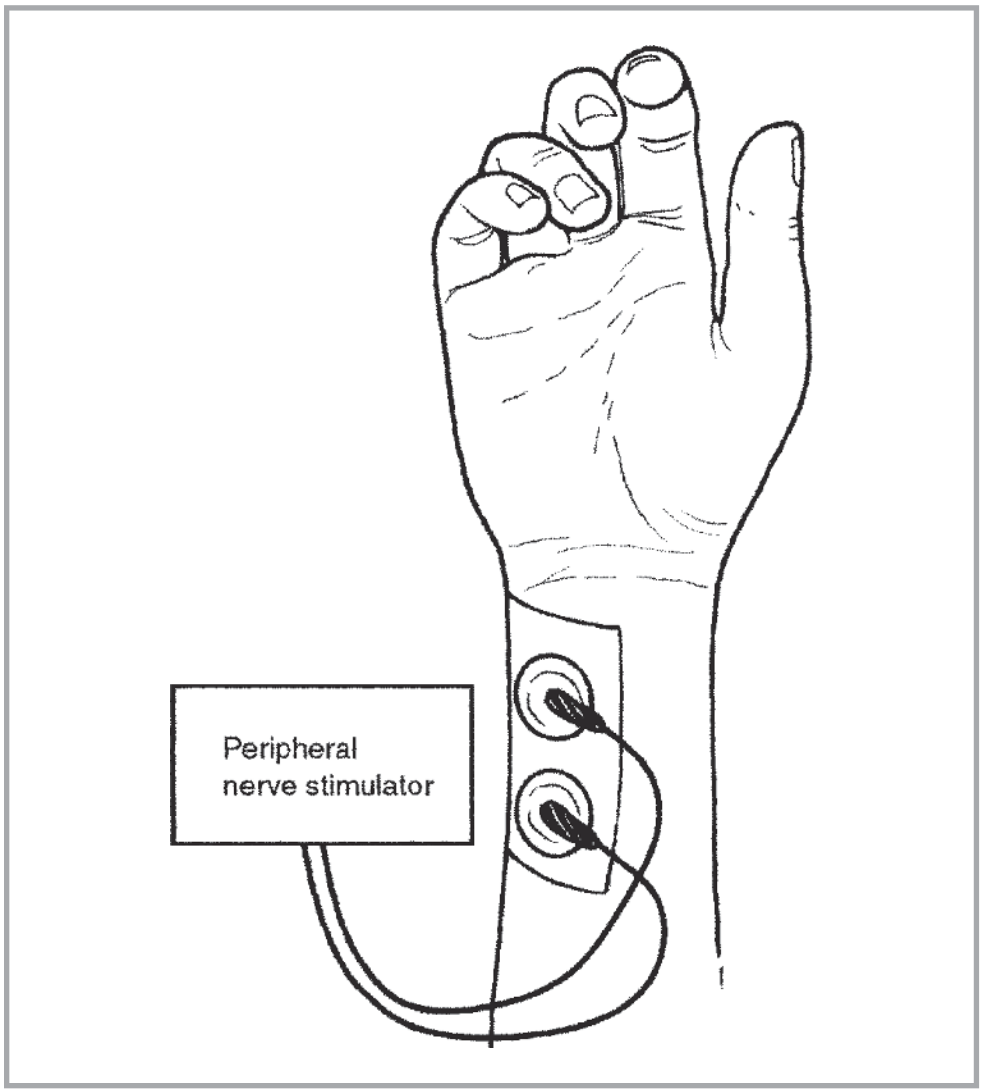

FIGURE 58-5

Proper placement of train-of-four (TOF) twitch monitor electrodes over ulnar nerve.

Ablation of more than three twitches to TOF stimulation at the ulnar nerve is usually unnecessary in the critically ill patient.[35] However, if it is deemed essential to stop all diaphragmatic motion, it will be necessary to increase the degree of neuromuscular blockade to the point where there is no response to TOF stimulation, regardless of monitoring site. Thus, when diaphragmatic paralysis is required, a dilemma in monitoring occurs. In such situations use of the posttetanic count[36], rather than TOF stimulation, may enable the critical care practitioner to estimate the amount of time necessary for recovery from neuromuscular blockade, and thus, more appropriately titrate drug administration. Posttetanic count requires administration of a tetanic stimulus (50 Hz for 5 s) followed a few seconds later by a TOF pattern. It allows accurate prediction of the duration of no response to TOF stimulation because mobilization of acetylcholine from reserve stores will outlast the period of tetanic stimulation (posttetanic facilitation). In the absence of organ dysfunction, a positive muscular response to a posttetanic TOF stimulation in a patient receiving vecuronium usually indicates that the patient will become responsive to routine TOF monitoring within 20 min.

Monitoring the degree of neuromuscular blockade with a twitch monitor is reasonable, cost-effective, and likely to lessen the possibility of prolonged muscle weakness or persistent paralysis. It has been postulated that clinical neurological evaluation may be just as effective as the use of the nerve stimulator[28]. Interestingly, recent clinical trials evaluating the utility

of TOF monitoring have produced conflicting results. Sessler[26] suggests that this is related to the NMB agent studied. Those studies involving benzylisoquinoliniums found little added value to TOF monitoring beyond that offered by clinical evaluation.[37] Those involving aminosteroid compounds found just the opposite; reconciliation of these disparate results may be related to differing metabolic pathways. TOF monitoring has found broad applicability in the ICU because of its low cost, low risk, and recommendation by the SCCM task force.

COMPLICATIONS FROM PROLONGED USE OF NMB AGENTS

Critically ill ventilated patients are commonly found to be weak.[38] There are a variety of reasons causally related to this weakness; sepsis, multiple organ system dysfunction, systemic inflammatory response syndrome (SIRS), nutritional issues, deconditioning and administration of NMB agents have all been implicated.

Overall, in critically ill adults, there is approximately a 10% incidence of prolonged neuromuscular weakness, of varying duration, following the use of NMB agents.

The use of NMB agents with or without concomitant administration of corticosteroids has been linked with the development of severe weakness or even paralysis. Reports of prolonged muscle weakness or paralysis associated with administration of new NMB agents appeared with increasing frequency beginning in the late 1980s. A variety of etiologic mechanisms were proposed. One broad approach to categorizing these reports divided causative factors into pharmacokinetic based, usually persisting for days to weeks, and neuromuscular function based, persisting for weeks to months.[39] Overall, in critically ill adults, there is approximately a 10% incidence of prolonged neuromuscular weakness, of varying duration, following the use of NMB agents.[28]

Pharmacokinetic Causes

In some instances, a prolonged effect of NMB agents is caused by therapeutic overdose.

In some instances, a prolonged effect of NMB agents is due to therapeutic overdose.[40] If monitoring is not performed, performed improperly, or misinterpreted, critically ill patients may be at increased risk for relative or absolute drug overdose even if state-of-the-art administration guidelines are followed. Patients with prolonged paralysis have often received significantly more muscle relaxant than patients whose recovery was not prolonged.[41] Overdosing of muscle relaxants may be avoided, and an adequate degree of paralysis maintained, by titrating administration of NMB agents with appropriate monitoring of neuromuscular function.[42]

Hepatic and/or renal dysfunction has been implicated as a cause of prolonged drug effect following the discontinuation of NMB agents.

Hepatic and/or renal dysfunction has been implicated as a cause of prolonged drug effect following the discontinuation of NMB agents. The prolonged duration of action of vecuronium in critically ill patients with renal failure has been well documented; this has been ascribed to the inability, in patients with renal failure, to excrete the pharmacologically active metabolite, 3-desacetylvecuronium.[43] The association of renal failure and the prolonged action of vecuronium has been further linked with the presence of metabolic acidosis and elevated magnesium concentrations.[44]

The pharmacokinetics and pharmacodynamics of 3-desacetylvecuronium have been clarified. It appears that 3-desacetylvecuronium has 80% of the potency of vecuronium and that the liver, not the kidney, is the primary organ of elimination for this metabolite. The reason that patients with chronic renal failure have a markedly decreased clearance of 3-desacetylvecuronium, and thus a prolonged drug effect, is related to an associated decrement in hepatic function. The uremia of renal failure has been implicated as a cause of this decreased hepatic clearance. Renal failure, thus, secondarily prolongs neuromuscular blockade by markedly decreasing hepatic clearance of 3-desacetylvecuronium.[45] Vecuronium and 3-desacetylvecuronium are not removed by hemodialysis.[27]

Interestingly, the action of 3-desacetylvecuronium is clinically relevant even in patients with normal hepatic and renal function and has been found to contribute to the cumulative effect associated with repetitive vecuronium dosing.[46] This cumulative effect further

illustrates the need for routine and competent monitoring of neuromuscular function. Although the issue of active metabolites is commonly associated with vecuronium, it has been observed with other aminosteroid NMB agents.

Severe electrolyte disorders (e.g., hypermagnesemia, hypocalcemia, hypophosphatemia, and hypokalemia) may produce weakness alone or in combination with NMB agents. A number of drugs may potentiate neuromuscular blockade: clindamycin, metronidazole, tetracycline, furosemide, anticholinesterase drugs, and many antiarrhythmic agents. In addition, corticosteroids are known to interact with nondepolarizing agents.

Severe electrolyte disorders (e.g., hypermagnesemia, hypocalcemia, hypophosphatemia, and hypokalemia) may produce weakness alone or in combination with NMB agents. Additionally, a number of drugs may potentiate neuromuscular blockade: clindamycin, metronidazole, tetracycline, furosemide, anticholinesterase drugs, and many antiarrhythmic agents. In addition, corticosteroids are known to interact with nondepolarizing agents.

Neuromuscular Causes

Not all instances of prolonged effect of NMB agents are explained by overdose or alterations in pharmacokinetics (Table 58-3). Another major pattern of prolonged paralysis is that of acute myopathy, often referred to as acute quadriplegic myopathy, which becomes apparent only as transmission resumes across the neuromuscular junction.[47] There also appears to be a broad category of persistent paralysis that is secondary to physiologic disruption of neuromuscular transmission.[7]

The acute myopathy described following prolonged use of NMB agents in critical care has been documented in multiple case reports and patient series.[39,48] This myopathy is usually described in critically ill patients with nonneuromuscular disorders who have been treated for longer than 24–48 h with a NMB agent.[49,54] Increasing duration of therapy and total cumulative dose may increase the likelihood of this complication, as will simultaneous administration of corticosteroids.[41,50–52] The association of NMB agents and corticosteroids is believed responsible for the 30–40% incidence of myopathy in intubated paralyzed asthmatics.[50,52]

Another major pattern of prolonged paralysis is that of acute myopathy, which becomes apparent only as transmission resumes across the neuromuscular junction.

This acute myopathy is associated with a variable increase in creatine phosphokinase (CPK), myoglobinuria (which may lead to acute renal failure), and weakness, which in its most extreme form is manifested as flaccid paralysis and areflexia. Cognition and sensation are normal in these patients. Proximal musculature may be more severely affected than distal, and recovery is slow. Prolonged physical therapy and an extended stay at a rehabilitation center are often necessary.

This acute myopathy is associated with a variable increase in CPK, myoglobinuria (which may lead to acute renal failure), and weakness, which in its most extreme form is manifested as flaccid paralysis and areflexia.

The characteristic pathology involves atrophy of type I and type II fibers with preservation of muscle cell structure, no inflammation, and loss of thick myosin filaments. In animal studies involving steroid administration and surgical denervation of musculature, a severe myopathy with similar pathologic lesions of the thick myosin filaments has been described. The common factor appears to be some type of denervation (anatomic or pharmacologic) in association with the parenteral administration of large doses of steroids.

This myopathy was initially reported with the aminosteroid NMB agents, which accounted for the majority of therapeutic paralysis in the late 1980s and early 1990s.[1] However, as nonsteroidal NMB agent use increased, it became clear that they also cause complications. Atracurium, cisatracurium, and doxacurium have each been associated with the development of myopathy.[53–55] Apparently the initial lack of association with prolonged paralysis resulted from a lesser experience with this group of drugs, rather than specific properties of the benzylisoquinolinium NMB agents.

In addition to an acute myopathy, there is the distinct possibility of an as yet uncharacterized neuromuscular transmission deficit(s).

TABLE 58-3

CATEGORIES OF PROLONGED PARALYSIS FOLLOWING USE OF NMB AGENTS

Overdose and/or the presence of active metabolites
Acute myopathy (also known as acute quadriplegic myopathy)
An uncharacterized neuromuscular transmission deficit(s) or a deficit in muscle proteins that support muscle action potential generation
One or more of the above in combination
Any of the above in association with other neuromuscular complications of critical illness including interactions with drugs that affect neuromuscular function

In addition to an acute myopathy, there is the distinct possibility of an as yet uncharacterized neuromuscular transmission deficit(s). In some patients, neuromuscular junction dysfunction has been documented with nerve conduction studies.[56] Unfortunately, this information is not meaningful unless plasma levels of the parent compound and its metabolites are measured and found to be clinically irrelevant. Otherwise, it is difficult to separate overdose or accumulation of active metabolites from a pathophysiologic alteration in neuromuscular transmission.

Although not all reports regarding persistent neuromuscular blockade resolve the issue of residual drug effect, it is probable that in some patients there is a persistent dysregulation of the nicotinic acetylcholine receptor following prolonged exposure to NMB agents. Many ICU patients demonstrate increasing requirements for NMB agents to maintain a constant level of blockade. A relationship between this observation and an increase in nicotinic acetylcholine receptors has been postulated.[57] Also, infusions of D-tubocurarine have been demonstrated to accentuate burn-induced upregulation of postsynaptic nicotinic acetylcholine receptors.[7] Given what we know regarding the effects of agonist and antagonist therapy on the much-studied cardiac beta receptors, it seems quite likely that similar changes will be found involving the nicotinic acetylcholine receptor or some other muscle protein involved in generating the muscle action potential.[58] It is possible that changes in the nicotinic acetylcholine receptor density, function, or ability to propagate excitation to muscle membranes are common to many, if not all, patients with prolonged muscle weakness following NMB agent administration.[7,58]

Other reports of neuromuscular dysfunction following the use of NMB drugs implicate disuse atrophy, critical illness polyneuropathy, or toxic neuromyopathy. Part of the difficulty in evaluating these reports is that it is likely more than one pathologic process is active. The polyneuropathy of critical illness is not uncommonly seen in patients with sepsis, SIRS, and multiple organ failure. It is also common for patients with these disease entities to receive NMB drugs. It should not surprise us if there are reports of patients with both critical illness polyneuropathy and severe complications secondary to the use of NMB agents. Additionally, an animal model of sepsis implicated cross-reactive antibodies (initially produced against bacteria) in the downregulation of nicotinic acetylcholine receptors, leading to impaired neuromuscular function.[48] Thus, in some situations sepsis may play a role in the development of neuromuscular dysfunction.

NMB agents have a significant profile of adverse effects and should be used with great caution, for the shortest possible period of time, and only if various combinations of sedatives and analgesics have failed to achieve a cooperative patient.

In conclusion, it seems that most reports of prolonged paralysis can be categorized in one of five groups: (1) overdose and/or the presence of active metabolites; (2) acute myopathy; (3) an uncharacterized neuromuscular transmission deficit or a deficit in muscle proteins that support muscle action potential generation; (4) one or more of these in combination; or (5) any of these in association with other neuromuscular complications of critical illness, including critical illness polyneuropathy and/or interactions with drugs that affect neuromuscular function.

SUMMARY

A small percentage of critically ill patients will be administered a NMB agent for an extended duration. These agents have a significant profile of adverse effects and should be used with great caution, for the shortest possible period of time, and only if various combinations of sedatives and analgesics have failed to achieve a cooperative patient. Adequate monitoring and cessation of NMB agent administration every 24 h are recommended. It is vital that all personnel involved in the care of patients receiving NMB agents understand their actions, potential complications, and the methods that can be utilized to avoid or decrease the likelihood of a prolonged effect.

REVIEW QUESTIONS*

1. **NMB agents: (single best answer)**
   - **A.** Act in part by direct interference with the actin and myosin filaments
   - **B.** Have both analgesic and amnestic effects
   - **C.** In sufficient doses, will completely paralyze smooth muscle
   - **D.** Exert an effect via recognition sites on the alpha subunits of the nicotinic acetylcholine receptor

2. **Vecuronium bromide**
   - **A.** Is a nondepolarizing NMB agent
   - **B.** Has been associated with the development of myopathy following long-term use in the critically ill patient
   - **C.** Is classified as intermediate in the duration of action
   - **D.** Is eliminated via hepatic and renal routes

3. **Cisatracurium**
   - **A.** Is an isomer of atracurium
   - **B.** Is classified as an aminosteroid
   - **C.** Is more potent than atracurium
   - **D.** Is primarily eliminated via the hepatic route

4. **Which of the following potentiate the action of NMB agents?**
   - **A.** Hypermagnesemia
   - **B.** Hypokalemia
   - **C.** Hypocalcemia
   - **D.** Hyperphosphatemia

5. **Reasonable strategies to minimize the potential for complications related to long-term use of NMB agents in the critically ill patient include:**
   - **A.** Stopping administration of the NMB agent at least once every 24 h
   - **B.** Using only NMB agents from the aminosteroid group
   - **C.** Monitoring drug effect with a TOF twitch monitor
   - **D.** Education of all personnel involved in the care of patients receiving NMB agents as to potential side effects and complications

6. **What is not an indication for the use of NMB agents? (single best answer)**
   - **A.** Management of ventilation
   - **B.** Treatment of pain and anxiety
   - **C.** Management of increased ICP
   - **D.** Treatment of muscle spasm

7. **What is a contraindication to the use of succinylcholine? (single best answer)**
   - **A.** Low potassium serum levels
   - **B.** History of neuroleptic malignant syndrome
   - **C.** Burn injury sustained 2 days prior
   - **D.** Concomitant administration of steroids

8. **Match the NMB agent with its side effect or action (single best answer)**
   - **A.** Pancuronium-vagolytic effect
   - **B.** Rocuronium-hyperkalemia
   - **C.** Succinylcholine-Hoffman elimination
   - **D.** Atracurium-malignant hyperthermia trigger

9. **A 65-year-old male with a recent onset of hemiplegia is admitted to the ICU for management of congestive heart failure. The patient evidences progressive dyspnea and desaturation; endotracheal intubation and mechanical ventilation is indicated. The patient is considered to have a full stomach (large meal 4 h prior). Which of the following is the most appropriate NMB agent to use (in conjunction with an induction agent) for intubation? (single best answer)**
   - **A.** Vecuronium
   - **B.** Succinylcholine
   - **C.** Atracurium
   - **D.** Rocuronium

10. **Choose the nerve/muscle pair that upon stimulation best reflects the degree of diaphragmatic neuromuscular blockade (single best answer)**
    - **A.** Ulnar nerve-adductor pollicis muscle
    - **B.** Median nerve-flexor pollicis brevis muscle
    - **C.** Ulnar nerve-abductor pollicis brevis muscle
    - **D.** Facial nerve-orbicularis oculi muscle

ANSWERS

1. The answer is D. The postsynaptic nicotinic acetylcholine receptors are present in high density at a specialized area of the skeletal muscle membrane located at the juncture of the primary and secondary synaptic clefts. The two alpha subunits carry the recognition sites for agonist and antagonist drug action. NMB agents have no analgesic or amnestic effects.
2. The answer is A, B, C, and D. Vecuronium bromide is a nondepolarizing NMB agent with an intermediate duration of action. It has been associated with the development of myopathy following long-term use in critically ill patients. The likelihood of developing such a myopathy is increased with the concurrent administration of corticosteroids. Metabolism and elimination are dependent on hepatic and renal routes.
3. The answer is A and C. Cisatracurium besylate is a purified form of one of the isomers of atracurium and is a benzylisoquinolinium compound. It is approximately three times more potent than atracurium, and its metabolism is independent of organ function.

* More than one answer may be correct unless otherwise noted.

4. The answer is A, B, and C. Severe electrolyte disorders, such as, hypermagnesemia, hypocalcemia, hypophosphatemia, and hypokalemia, may produce weakness alone or in combination with NMB agents.
5. The answer is A, C, and D. Prolonged paralysis has been described with NMB agents from the amino steroid and benzylisoquinolinium groups. Several clinical studies have indicated that monitoring of drug effect with a TOF nerve stimulator and cessation of drug administration every 24 h may reduce the likelihood of prolonged paralysis. It is vital that all personnel involved in the care of patients receiving NMB agents understand their actions, potential complications, and the methods that can be utilized to avoid or decrease the likelihood of a prolonged effect.
6. The answer is B. NMB agents do not have analgesic or anxiolytic effects.
7. The answer is C. Burn injuries are associated with upregulation of nicotinic acetylcholine receptors. There is a risk of a significant and life-threatening hyperkalemic response to the administration of succinylcholine in this patient.
8. The answer is A. Pancuronium is a nondepolarizing NMB agent relaxant that produces an increase in heart rate due to a vagolytic action. Succinylcholine side effects include a transient increase in potassium, increased intraocular pressure, and muscle pain. Succinylcholine is also a malignant hyperthermia triggering agent. Atracurium is metabolized by Hofmann elimination (nonenzymatic degradation at normal body temperature and pH) and ester hydrolysis.
9. The answer is D. This patient needs urgent endotracheal intubation and mechanical ventilation. The main concerns are aspiration risk (full stomach) and recent onset of hemiplegia. A rapid sequence induction/intubation is indicated to minimize the risk of aspiration; only succinylcholine and rocuronium have a sufficiently rapid onset of action. Succinylcholine is contraindicated because of the risk of hyperkalemia secondary to the increased number of extrajunctional nicotinic acetylcholine receptors in a patient with a recent upper motor neuron lesion.
10. The answer is D. The orbicularis oculi response to facial stimulation is a closer approximation of diaphragmatic muscle paralysis than the response of the adductor pollicis to ulnar nerve stimulation.

Prophylactic Regimens in the Intensive Care Unit

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Identify risk factors associated with the development of deep vein thrombosis and its consequence, pulmonary embolism.
- Understand the indications and contraindications for medical, mechanical, and inferior vena cava filter prophylaxis, and describe the available methods for each.
- Identify the major physiologic mechanism associated with stress-induced gastritis and ulceration, and identify the risk factors associated with this condition.
- Know the methods used for prophylaxis of stress-induced gastritis and ulceration and the potential complications of the medical therapies used for this condition.
- Identify the nosocomial infections common in the intensive care unit and the causative organisms responsible.
- Discuss the various risk factors associated with the development of iatrogenic or preventable infection in critically ill patients.
- Employ a variety of effective prophylactic regimens to nosocomial infection in the intensive care unit: healthcare/ventilator associated pneumonia (VAP), catheter-related bloodstream infection, and genitourinary tract infection in critically ill patients.

DEEP VENOUS THROMBOSIS PROPHYLAXIS

The prevention of deep vein thrombosis of the lower extremities, by definition, will reduce the frequency of pulmonary embolism. Pulmonary embolism is not a disease; it is merely a complication of deep vein thrombosis. Therefore, if venous thrombosis can be prevented, pulmonary embolism will be prevented.

A number of clinical conditions, diseases, and laboratory findings have been associated with an apparent predisposition for the development of deep vein thrombosis. For most intensive care unit patients, one or more of these conditions exist. Many of these risk factors have

been found to be associated with one or more thrombogenic alterations responsible for the development of a hypercoagulable state, venostasis and/or vascular intimal injury. Risk factors are cumulative in their effect; with generally more than one factor present (Table 59-1).[1] Thromboembolic risk after surgical and nonsurgical trauma is related to the severity, site and extent of the trauma, the length of the surgery, the age of the patient, a previous thromboembolic episode, and length of immobilization. Five independent risk factors for thrombosis in trauma patients have been identified: older age, need for blood transfusions or surgery, fracture of the pelvis or leg, and spinal cord injury.[2] The posttraumatic setting is a paradigm for the hypercoagulable state. Increased coagulability as a result of tissue thromboplastin release into the blood, vessel endothelial damage, stasis of blood flow resulting from immobilization, and reduced fibrinolysis have all been identified.

Indications

Roughly two thirds of patients who die of massive pulmonary embolism die within the first hour following hospitalization.[3] No treatment modality can have an impact comparable to appropriate deep venous thrombosis (DVT) prophylaxis. The use of appropriate prophylaxis in high-risk patient groups will reduce the incidence of deep vein thrombosis significantly. The ideal preventative method should be effective, safe, associated with minimal clinically relevant side effects, easily administered and monitored, and cost-effective for the specific patient. Given the complex nature of the patient in the medical intensive care unit, there have been few large clinical trials comparing individual methods of venous thromboembolic prophylaxis. Either pharmacologic or mechanical methods may be used, and sometimes a

combination of methods must be employed for a specific patient. There is no single method that is appropriate or efficacious for every clinical situation.

The American College of Chest Physicians has established a general approach to prophylaxis. Simply stated, single modality therapy should be used in patients at a low or medium risk, while multiple modalities or special interventions should be reserved for patients at high risk for venous thromboembolic disease.[1] Medical patients who are mobile and patients undergoing minor surgery have a low risk for DVT and do not require medication for thromboprophylaxis, but do benefit greatly from early and aggressive ambulation. Most general surgical and medical patients who are at bed rest have a moderate risk for DVT (10–40%) and should receive thromboprophylaxis with unfractionated heparin or low-molecular weight heparin (LMWH) or fondaparinux at recommended doses. Surgery patients at high risk for DVT (40.80%) include those who undergo bariatric surgery, spinal cord surgery, hip and knee arthroplasty, hip fracture surgery, and surgery for major trauma. Recommended DVT prophylaxis for this high-risk group involves the appropriate regimen of either LMWH and fondaparinux or warfarin. Importantly, any moderate or high-risk patient with an additional risk for bleeding should not receive medical prevention, but mechanical thromboprophylaxis.

Methods

A variety of preventative measures have proven effective in reducing lower extremity deep vein thrombosis in critically ill patients. The methods can be divided into medical, mechanical, and inferior vena cava filters.

Medical Prophylaxis

Low-Dose Unfractionated Heparin

Pulmonary embolism is potentially fatal; therefore, the best therapy is prevention.

Low-dose unfractionated heparin (LDUH), LMWH, or fondaparinux can be used as monotherapy for the prophylaxis of thromboembolism in all but the highest risk patients.

The method of prophylaxis traditionally used in both medical and surgical patients is low-dose subcutaneous unfractionated heparin (LDUH). Heparin acts as an anticoagulant by binding with its plasma cofactor antithrombin III and primarily inhibiting thrombin and factor Xa activity. Heparin/antithrombin III complex additionally influences the activity of kallikrein, factors IXa, XIa, and XIIa. At low doses used for the prevention of venous thrombosis, heparin inhibits thrombus formation with a minimal risk for bleeding as compared to higher intravenous doses required for therapeutic anticoagulation. Low-dose unfractionated heparin is indicated for those medical patients who are at moderate-to-high risk for deep vein thrombosis formation and are not actively bleeding or at risk of major bleeding. Often, LDUH is used in combination with sequential compression devices applied to the lower extremities in patients who are critically ill and who may be at highest risk for thrombus formation. LDUH has been shown to be effective at preventing thrombus formation in patients who undergo general surgery, including thoracoabdominal and gynecologic procedures. However, this form of prophylaxis has not proved to be equally effective in all patient groups. For example, limitations have been recognized in the following subgroups: trauma surgery,[4] major orthopedic procedures including repair of femoral fractures, reconstructive operations of the hips and knees, and following prostate surgery and cystectomy.

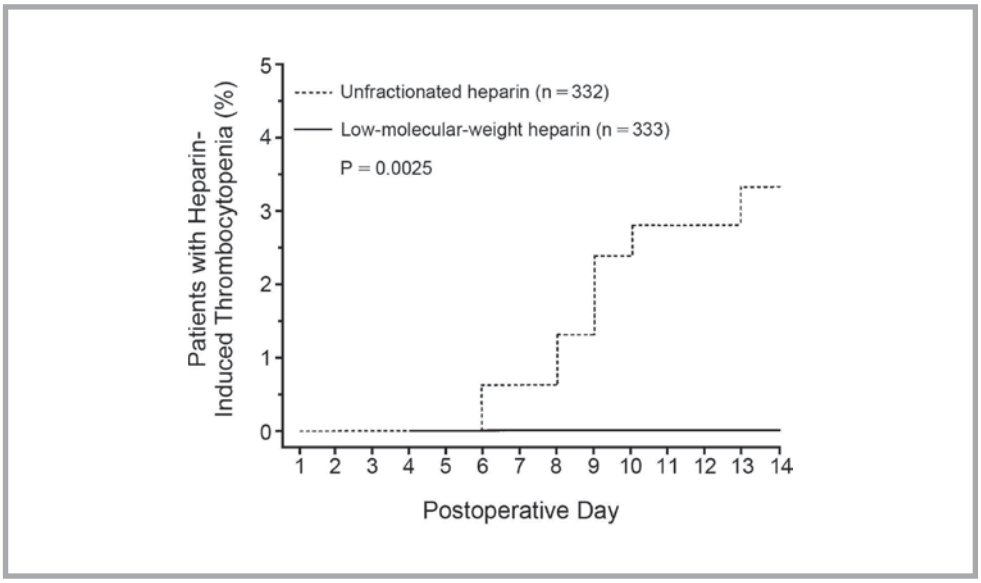
Prophylaxic LDUH is safe at both q 12 h and q 8 h dosing with less than 1% risk of serious bleeding or hematoma.

Lower incidence of Type II HIT has been shown with LMWH preparations and fondaparinux as compared with LDUH.

Based on current recommendations, patients at low risk for venous thrombosis following minor surgical procedures require no more than 5,000 units of LDUH every 12 h by subcutaneous administration. However, patients at moderate or severe risk for VTD require three times daily dosing to achieve both appropriate VTD prophylaxis as well as similar efficacy with LMWH preparations and fondaparinux.[5] In a large metaanalysis, LDUH at 5,000 units every 8 h was shown to be more efficacious in preventing deep vein thrombosis without increasing the occurrence of wound hematoma or adverse bleeding events.[5] The benefits of LDUH are its proven efficacy, ease of administration, and relatively low cost. Its risks are low, with estimates of serious bleeding less than 1% and of heparin-induced thrombocytopenia (HIT) less than 3%.[6] Laboratory tests of coagulation status are not routinely monitored; however, it is not uncommon in critically ill patients receiving 15,000 U/day of

FIGURE 59-1

Timing and increased incidence of HIT in patients treated with low-dose unfractionated heparin as compared to low-molecular weight heparin following hip replacement surgery. The platelet count was less than 150,000 between post-op days 5 and 14, along with the detection of heparin-dependent IgG. (adapted from Warkentin et al.[7] Copyright 1995 Massachusetts Medical Society. All rights reserved).



subcutaneous unfractionated heparin to experience elevations in their activated partial thromboplastin time (aPTT). Complete blood count monitoring is essential given the two main complications of heparin therapy – clinically significant internal bleeding and HIT. HIT, in this case Type II HIT, is an autoimmune process in which IgG that typically develops 5–10 days following exposure to heparin bind to and activate platelet factor 4 leading to clinically significant and usually severe episodes of arterial and/or venous thrombosis. The incidence of Type II HIT is approximately 2.6% in patients treated for more than 4 days.[6] Suspicion of HIT should develop when the platelet count drops below 150,000 or by less than 50% five days following the initiation of therapy. A rapider onset may be seen in patients who have been previously exposed to heparin products. A lower incidence of heparin-induced IgG and clinically relevant episodes of thrombosis in patients receiving LMWH and possibly fondaparinux makes these medications an attractive alternative (Fig. 59-1).[7,8]

Low-Molecular Weight Heparin and Fondaparinux

LMWH is derived from unfractionated heparin and exerts its antithrombotic effects primarily through inhibition of factor Xa. The advantages of LMWH stem from its pharmacokinetics. LMWH has an active half-life that is twice as long as that of unfractionated heparin with a four times greater bioavailability, allowing for once-daily dosing. LMWH may have a reduced tendency to induce bleeding and a lower incidence of HIT. The effectiveness, and in some cases, superiority of LMWH to LDUH have been shown in several surgical patient populations including general, urologic, obstetric, bariatric, and orthopedic surgeries, as well as general medical patients at risk.[1] The main disadvantages between LMWH as compared to LDUH are increased cost and renal clearance of LMWH. When used, LMWH should be dose adjusted in patients with chronic renal insufficiency, and should be avoided in patients with acute renal dysfunction, whose degree of effective renal clearance is unpredictable. LMWH is more expensive than LDUH, though the overall cost:benefit ratio of the two drugs is debatable beyond the scope of this chapter.

Selected surgical patients from orthopedics, urology, and trauma have shown reduced incidence of DVT with the use of LMWH products as compared to LDUH. The use of LMWH is contraindicated in patients receiving epidural or spinal anesthesia.

High-risk orthopedic patients have benefited from anticoagulant prophylaxis for up to 35 days postoperative.

There are several different LMWH preparations available for use. Enoxaparin is best studied in the literature and carries several US FDA prophylactic indications that other formulations do not. The prophylactic dose and duration of LMWH depend on the clinical situation as summarized in Table 59-2. The majority of patients are treated until their degree of immobilization or risk of DVT is diminished ~7 days postoperative. However, orthopedic patients who underwent total hip repair, total knee repair, or hip fracture surgery have been shown to have both silent and symptomatic DVT diagnosed after postoperative day 7, despite

TABLE 59-2

FDA APPROVED DOSING OF LMWH PREPARATIONS AVAILABLE IN THE UNITED STATES (DURATION OF THERAPY MODIFIED TO REFLECT UPDATED ACCP GUIDELINES[1])

LOW-MOLECULAR WEIGHT HEPARIN PREPARATIONS: INDICATION, DOSING, AND TREATMENT DURATION

	Indication	*Dose*	*Duration*
Enoxaparin	Total hip replacement	30 mg SC q 12 h	12–24 h postsurgery until INR therapeutic or no further risk DVT (10–35 days)
		40 mg SC daily	9–15 h pre-op until INR therapeutic or no further risk DVT (10-35 days)
	Total knee replacement	30 mg SC q 12 h	12–24 h postsurgery until risk is diminished (10–35 days)
		40 mg SC daily	9–15 h pre-op until risk is diminished (10–35 days)
	Abdominal surgery	40 mg SC daily	2 h pre-op until risk is diminished (7–10 days)
	Medical illness	40 mg SC daily	Until risk is diminished
	Elective neurosurgery	40 mg SC daily	Within 24 h post-op until risk is diminished no less than 7 days
Dalteparin	Total hip replacement	2,500 IU SC and 5,000 IU SC daily	2,500 IU 2 h pre-op then again the evening of surgery followed by 5,000 IU SC daily until no further risk DVT or INR therapeutic

SOURCE: data from Geerts et al[1]

prophylactic anticoagulation. Trials that have extended the duration of therapy to both 15 and 35 days have shown significant reductions in the incidence of DVT in high-risk orthopedic patients at later dates.[1] Though not an approved indication, trauma patients had a beneficial reduction in DVT following treatment with enoxaparin at 30 mg every 12 h started at least 36 h following admission to the hospital provided hemostasis had been achieved.[4]

The risks of LMWH are similar to unfractionated heparin. It is not recommended in patients with active bleeding or in documented cases of HIT. Additionally, LMWH should not be used in patients with epidural or spinal anesthesia given the risk of epidural or spinal hematoma and subsequent spinal cord compromise. Renal insufficiency is an additional absolute or relative contraindication to enoxaparin therapy with clinical trials involving surgical patients excluding patients with a creatinine >3.4 mg/dL,[4] and a stricter cut-off was established in medical efficacy studies of 1.7 mg/dL.[9] In patients with renal insufficiency, careful dosing adjustments should be made based on the creatinine clearance, and the manufacturer's dosing instructions should be followed carefully.

Fondaparinux is a synthetic pentasaccharide with a similar structure to heparin that binds antithrombin and inhibits factor Xa. Fondaparinux has been shown to be as effective, if not superior to enoxaparin in the prevention of VTD in high-risk orthopedic patients.[10] Fondaparinux additionally shares a similarly prolonged half-life and enhanced bioavailability allowing for once-daily dosing of 2.5 mg subcutaneously for prophylactic indications. Similar to LMWH, the medication is cleared by the kidney requiring caution in patients with renal disease. Additionally, there is an increased risk of bleeding in patients less than 50 kg who receive fondaparinux prophylaxis for high-risk orthopedic surgery. Though they share several similarities based on their chemical structure, one benefit of fondaparinux compared to both LMWH and UFH is the decreased risk of HIT. Fondaparinux is smaller than unfractionated and LMWH. The smaller size is believed to have a lower degree of immunogenicity with regard to antibody formation against platelet factor 4/heparin complex. In a direct comparison with enoxaparin, both medications led to the development of IgG antibody specific for PF4/heparin. Despite the presence of PF4/heparin, antibody no detectable in vitro activity against PF4/fondaparinux complex was noted. Along with a lack of in vitro reactivity, antibody formation due to fondaparinux was not associated with clinical thrombocytopenia.[8] Subsequent case reports of Type II HIT have been reported with fondaparinux use and the

medication should not be considered a safe alternative in patients diagnosed with or a prior history of HIT.

Direct thrombin inhibitors (argatroban, bivalirudin, and hirudin) do not play a role in prophylaxis of venous thromboembolic disease; however, their use is essential for the appropriate treatment of HIT with suspected or proven thrombosis.

Danaparoid sodium, which has been discontinued in the United States, is another antithrombotic agent that can be used for prophylaxis against the formation of DVT in patients who are undergoing elective hip replacement surgery. This medication is not a LMWH, but is actually a combination of heparin, dermatan, and chondroiton sulfate. This particular antithrombotic acts in a way similar to that of LMWH. Danaparoid prevents fibrin formation by inhibiting the formation of thrombin by antifactor Xa and IIa activity. Danaparoid sodium is administered by subcutaneous injection beginning 1–4 h preoperatively at 750 U and then continued twice daily until the risk of thrombosis formation has diminished. Danaparoid sodium seems to have less effect on platelets, with a lower incidence of HIT. It has been shown to have a low cross-reactivity with antiplatelet antibodies in individuals who have developed HIT in the past. Therefore, danaparoid sodium is used in individuals who require thrombosis prophylaxis and who cannot tolerate unfractionated heparin or LMWH because of prior development of thrombocytopenia.

Low-Dose Warfarin

Low-dose warfarin is another prophylactic option for patients undergoing elective total hip or knee replacement surgery, hip fracture surgery, and certain general surgery patients, particularly those who are at highest risk for the development of deep vein thrombosis. However, the use of warfarin is more cumbersome than heparin because it requires some dosage titration and monitoring of the prothrombin time and international normalized ratio (PT/INR). Furthermore, certain drug interactions and diet can potentiate or reduce the effect of warfarin on the coagulation cascade. Warfarin works by inhibiting the production of vitamin K-dependent coagulation factors, namely VII, IX, and X, and prothrombin, as well as the naturally occurring anticoagulants protein C and protein S. When long-term prophylaxis is indicated in high-risk patients, orthopedic surgery most commonly, warfarin therapy may be appropriate.

The initial dose of warfarin is 10 mg orally followed by a daily dose of 2.5 mg. The dosage is adjusted to achieve an elevated PT with an INR 2–3 times the normal laboratory value. Frequent monitoring of blood levels and patient education are necessary to prevent either subtherapeutic or excessive dosing of warfarin.

Mechanical Prophylaxis

Intermittent Pneumatic Compression Devices (IPCDs)

Intermittent pneumatic compression devices (IPCDs) are effective prophylaxis for deep vein thrombosis in patients undergoing surgery at risk for perioperative bleeding.

IPCDs have typically been used as mechanical prophylaxis in medical and surgical intensive care units in patients at high risk for venous thromboembolic disease who have a contraindication to chemical prophylaxis due to active bleeding, or a high perioperative risk of bleed. There are two methods of IPCDs commonly used in routine clinical practice. Traditional IPCDs are applied from calf to thigh and provide rhythmic external compression with 35–40 mmHg pressure for about 10 s every 1–2 min. In postoperative patients who cannot tolerate full leg devices due to trauma, vein harvesting, and/or orthopedic procedures, compact "foot pump" or plantar inflatable devices are applied at the level of the foot and ankle and use a lower number of inflatable chambers with higher pressures (~130 mmHg) at approximately 20 s intervals. They are an acceptable alternative to the full length device when these are not an option. In addition to mechanically accelerating blood flow, these devices may enhance blood fibrinolytic activity. The proposed mechanism is a reduction in plasminogen activator inhibitor-1, with a resultant increase in local tissue plasminogen activator activity.[11] Both devices should be used at all times when the patients are nonweight bearing or immobilized. However, patient comfort is a concern and may contribute to noncompliance with poorer efficacy. Additionally, patients with peripheral vascular disease, lower extremity wounds due to arterial or venous insufficiency, or known history of DVT are not appropriate candidates. Either alone or in combination with LMWH, IPCDs are effective

prophylaxis for deep vein thrombosis in patients undergoing general surgery, major knee and hip surgery, select neurosurgical procedures, open urologic procedures, gynecologic surgery, and trauma.[1,12] These devices have been shown to be useful prophylactic measures in patients with moderate-to-high thrombotic risk and as adjunctive therapy in the highest risk population.

Graded Compression Stockings (GCSs)

Graded compression elastic stockings can improve venous return from the lower extremities, and when properly fitted and worn preoperatively, they provide a safe, simple, and inexpensive method for preventing deep vein thrombosis, especially in low-risk patients. These stockings apply graduated compression, i.e., compression that is greatest in the lower part of the calf and steadily diminishes up the leg. When used in combination with low-dose unfractionated heparin, intermittent pneumatic compression and graded compression elastic stockings enhance each other's effectiveness at reducing the incidence of lower extremity deep vein thrombosis during a variety of surgical interventions. However, GCSs need to fit and be worn appropriately for both patient comfort and to prevent a "tourniquete" effect, which commonly happens when the stockings are either too small or are not extended completely to their full length. Appropriate use and fit are essential in ICU patients receiving heavy sedation or paralytics who are unable to communicate discomfort or pain.

Temporary Inferior Vena Cava Filters

Inferior vena cava filters have been shown to substantially reduce the risk of fatal pulmonary embolism in certain clinical scenarios including documented iliofemoral vein thrombosis and a contraindication to anticoagulation, development of pulmonary embolism despite full anticoagulation, a large free-floating thrombus, and a high-risk condition for fatal pulmonary embolism. Such high-risk conditions include patients with severe cardiopulmonary disease, trauma, solid tumor malignancy with associated hypercoaguable state, neurologic or musculoskeletal deficit resulting in limb immobility and patients with both CNS malignancy, either primary or metastatic, and associated limb immobility. Removable or temporary IVC filters are a recent, effective option for prevention of pulmonary embolism with low complication rates.[13,14] They are appropriate for patients with given risk factors mentioned above, who are at high risk for both DVT/PE and a major bleeding complication on prophylactic anticoagulation.[13,14]

STRESS-RELATED MUCOSAL DISEASE AND GASTRIC ULCER PROPHYLAXIS

In 1938, Cushing described an association between head injury and gastrointestinal hemorrhage. A similar association between severe burns and duodenal ulceration was described by Curling in 1942. These discoveries were followed by an understanding of the protective process or mucosal barrier associated with the gastric or duodenal epithelium, which maintains its integrity despite constant assault from what the individual eats and hydrochloric acid and pepsin. In the past, it was not uncommon for major gastrointestinal hemorrhage to occur in seriously ill people. However, over the past 10–20 years, the incidence of upper gastrointestinal hemorrhage in seriously ill patients has dramatically declined because of the widespread use of histamine type-2 receptor antagonists (H2RAs), proton pump inhibitors (PPIs), antacids, sucralfate, and early use of enteral feeding, all of which are likely responsible for this improvement.

The incidence of stress gastritis and ulceration collectively referred to as stress-related mucosal disease (SRMD) in the intensive care unit varies from as low as 6% to as high as 100% when endoscopy and/or gastric heme-occult testing is used to identify its presence.[15]

Mortality in patients who have hemodynamically significant bleeding, though only seen in approximately 1.5% of ICU patients, approached 50%.[16] Gastric perforation can occur, and the incidence of nosocomial septicemia related to stress-related mucosal damage remains unknown.

Pathophysiology

Overt stress-induced gastrointestinal bleeding occurs in 10–20% of intensive care unit (ICU) patients.

Patients with coagulopathy and requiring prolonged mechanical ventilation were prospectively shown to be at high risk for stress-related mucosal disease.

Decreased gastric mucosal blood flow is the primary casual factor of stress-induced gastritis.

The gastric mucosa is composed of epithelial cells with tight junctions capable of secreting bicarbonate as well as mucus (Fig. 59-2). Theories behind the pathogenesis of stress-related mucosal damage relate to disruption of these tight junctions, destruction of the underlying epithelial cells, and impairment of blood flow necessary for mucosal and bicarbonate production, as well as epithelial regeneration. Endogenous prostaglandins play a role by stimulating blood flow, enhancing the regeneration of epithelial cells, inducing mucus and bicarbonate production, and suppressing gastric acid production. Although gastric acid is crucial to the development of stress gastritis and ulceration, shock with decreased mucosal blood flow actually decreases acid production, but this reduction in blood flow leads to a decreased synthesis of mucus, bicarbonate, and a variety of prostaglandins, and to epithelial cell regeneration. Therefore, this reduction in mucosal blood flow is thought to be essential to the development of stress-related gastric mucosal damage. However, in certain clinical conditions such as burns, central nervous system trauma, and severe infection, gastric acid secretion may be markedly increased.

Indications

Not all patients in the intensive care unit require stress ulcer prophylaxis. Historically, a variety of clinical conditions have been considered high risk for stress ulcer-related bleeding

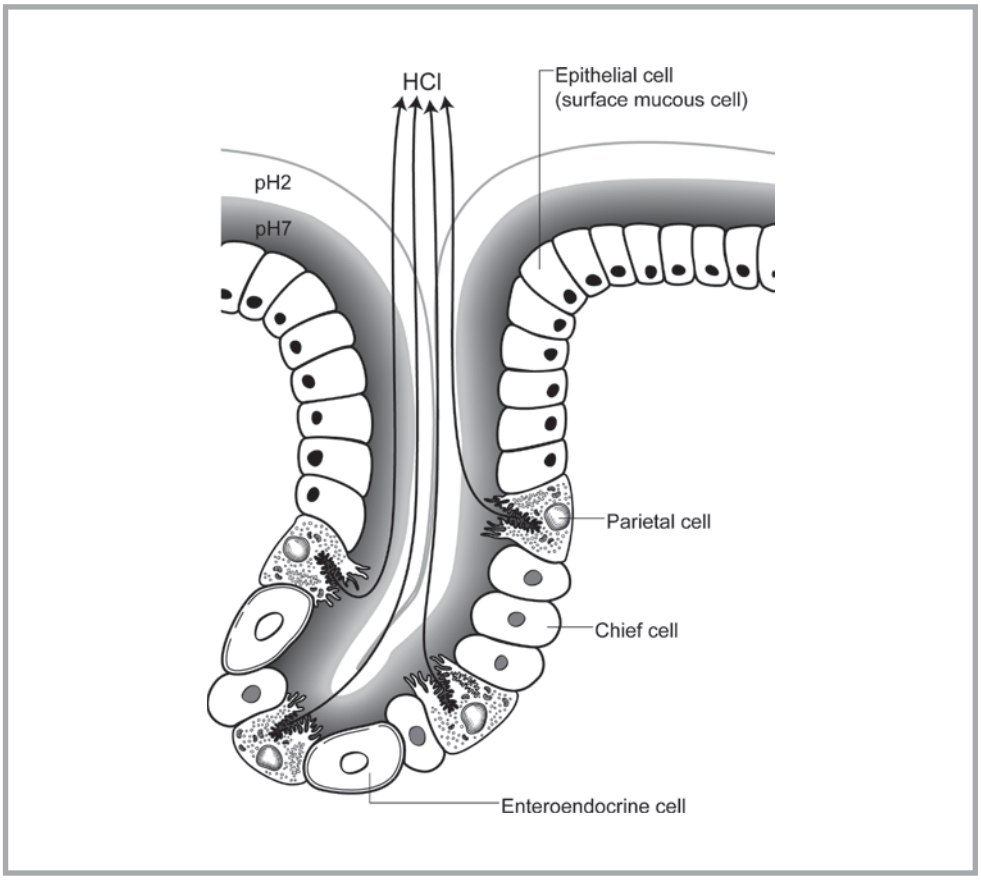


FIGURE 59-2

Production of HCl by parietal cells in the gastric mucosa and transport to the gastric lumen. A protective layer of mucus preserves a pH of 7 near the cell surface, whereas the intraluminal pH is 2 (illustration by Alice Y. Chen).

prophylaxis. These conditions include head injury, thermal injury involving at least 30% of the body surface area, emergent or major surgery, severe multisystem trauma, shock and multiorgan failure, coagulopathy, mechanical ventilation for longer than 48 h, ongoing therapy with a variety of ulcerogenic drugs, and a history of ulcer-related bleeding. A large trial involving approximately 2,200 ICU level patients identified two important independent risk factors for overt GI bleed, namely, respiratory failure requiring mechanical ventilation for more than 24 h and coagulopathy.[16] Recent evidence-based guidelines further defined coagulopathy as either a reduction in the platelet count to less than 50,000 INR greater than 1.5 or an activated partial thromboblastin time (aPTT) roughly double the normal lab value.[17] Additional factors associated with risk for GI bleeding included recent history of GI bleed, sepsis, prolonged ICU stay greater than 1 week, and high levels of corticosteroid therapy.[17]

Endoscopically, stress ulcerations are superficial erosions in the gastric mucosa, distinctly different from the lesions of peptic ulcer disease, which are deeper craters that can erode through the entire width of the gastric wall. Sometimes not just erosions but actual ulcerations are associated with this condition. These gastric ulcers are generally found on the lesser curvature of the fundus of the stomach; they are often associated with clinically relevant hemorrhage. Rarely, hemorrhage from an exposed artery in the ulcer crater may occur.

Gastric acid suppression has been associated with a slight increased risk of nosocomial pneumonia. This risk is based on the theory of gastric reflux contamination of the oral cavity and subsequent migration or aspiration of colonizing bacteria, commonly aerobic gram-negative rods into the lower airway. Increased gastric growth and colonization of bacteria has been shown at gastric pH >4.0, which is achieved with the use of acid suppression and continuous tube feeding. This risk can be eliminated if stress ulceration prophylaxis is not given when not needed. Furthermore, by elevating the head of the patient to 30°, the risk of gastric content reflux and potential aspiration is minimized. Some advocate the use of enteral feedings as a way of not only reducing stress ulceration, but also minimizing the further risk of nosocomial pneumonia. A contrary argument suggests that the elevated pH achieved with enteral feeding alone is sufficient to enhance bacterial colonization and that further acid suppression contributes little other than providing a suitable environment for bacterial growth. The use of acid reduction therapy and risk of nosocomial/ventilator associated pneumonia (VAP) will be discussed later in this chapter.

Methods

Prophylactic efficacy for medications has been evaluated by the incidence of clinically recognized bleeding. Therapies that have been recognized as effective for reducing the incidence of overt bleeding from stress ulceration include antacids, H2RAs, sucralfate, PPIs, prostaglandin inhibitors, and enteral feeding.

The principal mechanism for the development of stress-related mucosal damage is impaired mucosal blood flow. Therefore, the most important preventative strategy includes measures that preserve an adequate mesenteric blood flow. The best strategy is to maintain appropriate systemic blood pressure, hemoglobin, and cardiac output so that oxygen transport to the bowel is optimal.

Antacids

Antacids are rarely used for stress-induced gastritis prophylaxis.

Knowing the role of hydrochloric acid in the development of stress-related mucosal damage led to the hypothesis that antacids could be given to neutralize gastric acid, and thus, reduce the incidence and severity of stress gastritis and ulceration. When the gastric pH was kept above 4 by antacid therapy, this form of prophylaxis was deemed successful. However, large volumes of antacid therapy are frequently required, and an intensive degree of work by nurses is required to accomplish this feat. Furthermore, diarrhea is a bothersome adverse effect. Considering these negatives, there is no advantage of using antacids over other therapies that neutralize gastric acid, such as H_2 blockers, PPIs, and sucralfate. Furthermore, antacids that include aluminum, magnesium, or calcium reduce the absorption of a variety of different medications, including digoxin, iron, prednisone, phenytoin, thyroxine, and

multivitamins. For these reasons, antacids are rarely used for stress gastritis and ulceration prophylaxis in the intensive care unit.

Sucralfate

Sucralfate, H2RAs, PPIs, and antacids prevent stress-induced gastritis when compared to placebo.

Sucralfate is a product of sucrose octasulfate and aluminum hydroxide. Its therapeutic action appears to be related to its ability to bind to exposed epithelial cells and ulcer craters, forming a protective barrier. It may also work by stimulating prostaglandin synthesis, enhancing the absorption of pepsin, and stimulating epidermal growth factor. The medication is administered either orally or via a nasogastric tube at a dose of 1 g every 6 h. This medication is safe, inexpensive, and easy to administer, requiring less volume than antacid therapy. Sucralfate has been shown to be as effective as antacid therapy and H2RA therapy; however, there is somewhat conflicting evidence concerning comparisons between sucralfate and H2RAs. In a prospective, head-to-head comparison involving roughly 1,200 patients, Cook et al [18] showed significantly more clinically relevant episodes of GI bleeding with sucralfate (3.8%) as compared to ranitidine (1.7%). This did not translate into a difference in mortality. This study also showed a nonsignificant trend toward a possible increase in VAP with ranitidine.[18] The lower rate of clinically relevant GI bleeding with H2RA therapy was shown in a subsequent metaanalysis done by the same author.[19] Several comparison trials with varied study designs and smaller patient populations have shown conflicting results, with the suggestion that sucralfate is as effective at preventing bleeding and does lead to fewer cases of VAP.[20,21] Along with a slight increased risk of GI bleeding, a disadvantage of sucralfate is that it potentially can interfere with the absorption of a large variety of medications, including ciprofloxacin, warfarin, phenytoin, ranitidine, theophylline, and ketoconazole. Therefore, these medications must be given at least 2 h before the enteral administration of sucralfate. Sucralfate requires acid for dissolution and tissue binding, and is ineffective if administered concurrently with H2RAs.

Histamine-2 Receptor Antagonists

Histamine receptor blocker therapies are highly effective and safe for the prevention of stress-related mucosal disease.

Perhaps the most popular method of preventing stress-related mucosal injury is to inhibit gastric acid production with H2RAs. All histamine antagonists are equally effective in reducing the incidence of stress ulcer bleeding. In the critically ill patient, these medications can be given intravenously; however, oral therapy is as effective. Several different H2RAs are available, including cimetidine, ranitidine, and famotidine. Cimetidine is not as widely used as famotidine and ranitidine due to its side effect profile and inhibition of cytochrome P450, with potential drug interactions.[22] Both famotidine and ranitidine can be administered twice daily as bolus therapy intravenously or by the enteric route. There is no advantage to continuous intravenous infusion in preventing SRMD.

As mentioned, H2RAs do have side effects and potential drug interactions. Delirium and confusion are commonly encountered in the ICU. Intravenous H2RAs may contribute to both in the elderly. Thrombocytopenia, though common in the intensive care unit, is another possible side effect of H2RA therapy. Famotidine seems to have the lowest adverse-effect profile.

Proton Pump Inhibitors (PPIs)

Orally administered PPIs, theoretically, should reduce the risk of bleeding from stress-related mucosal damage. PPIs prevent release of H+ in activated parietal cells that is both vagally and histamine-mediated. Despite inhibiting the final pathway of acid release in the stomach as compared with the selective H2RAs, there are no data to suggest that PPIs have any additional benefit over H2RA therapy in preventing SRMD.[23,24] PPIs, however, play a major role in the treatment of documented or suspected upper gastrointestinal bleeding, peptic ulcer disease, gastroesophageal reflux disease, and erosive esophagitis in the intensive care unit.

Enteral Nutrition

Enteral feedings have been shown to reduce the risk of stress ulcer bleeding, and at the same time, to provide daily nutritional requirements. It is thought that nutritional feeding only neutralizes gastric acid, but it also maintains the integrity of the mucosa of the gastrointestinal tract. If enteral feedings are being used, other protective measures are not necessary for the majority of patients, with the exception of high-risk patients, to prevent the development of stress ulceration.

Prostaglandins

Misoprostol, a prostaglandin, has both antisecretory and mucosal protective properties. Therefore, it reduces gastric acid secretion and protects the gastroduodenal mucosa from ulceration. Furthermore, this medication likely increases mucosal bicarbonate and actual mucosal mucus production and may stimulate the production of new mucosal epithelial cells. Misoprostol's efficacy at preventing stress ulcer bleeding is unclear. It has been used to protect against gastric ulcer formation in patients taking nonsteroidal antiinflammatory drugs.

NOSOCOMIAL INFECTION PROPHYLAXIS

Recently, the results of a very large European trial that evaluated the prevalence of infection in the intensive care unit reported that approximately 20% of the patients had intensive care unit-acquired infection.[25] The majority had infection of the lower respiratory tract, followed by urinary tract infections and bacteremia. Seven risk factors for the development of infection in the intensive care unit were identified (Table 59-3).[25]

When infection was present, the likelihood of death also increased, but the study identified that nearly 30% of the patients could have had their infection prevented through programs that stress surveillance.

The major pathogens in nosocomial pneumonia are *Staphylococcus aureus* and a variety of enteric gram-negative rods.

Maintaining the semirecumbent position, following pulmonary toilet measures, and minimizing sedation reduce the risk of nosocomial pneumonia.

Nosocomial Pneumonia

Nosocomial and VAP in the intensive care unit is common, accounting for approximately half of all nosocomial infections in critically ill patients. Also, it is the most fatal of the nosocomial infections, with a mortality that may approach approximately 50%, despite aggressive therapy and a variety of new, broad spectrum antibiotics. Nosocomial pneumonia generally occurs by aspiration of oropharyngeal contents into the airways, but it can also occur by bacterial spread from another focus. Risk factors for the development of nosocomial pneumonia that have been identified include aspiration of bacteria from the oropharynx, colonization of the oropharynx with virulent nosocomial pathogens, the supine position, the presence of a nasogastric tube, and possibly reflux of bacteria from gastric colonization. In healthy adults, the normal bacterial colonization of the pharynx, upper respiratory, and gastrointestinal tracts consists of mixed, predominantly anaerobic bacteria. Following admission to the hospital and ICU, over a period of roughly 24–48 h, the normal colonization of

the pharynx and upper respiratory tract evolves to include predominantly virulent species of bacteria commonly associated with nosocomial infection including aerobic gram-negative rods and *Staphylococcus* species, most notably methicillin resistant *S. aureus* strains (MRSA). The gram-negative rods include *Pseudomonas, Proteus, Haemophilus, Escherichia coli,* and *Acinetobacter. Legionella* and *Pneumococcus* may also be found.[26]

As discussed earlier, in critically ill patients with appropriate risk factors, PPIs and H2RAs effectively raise the pH of the stomach to prevent gastrointestinal bleeding. When gastric acidity is suppressed, bacteria of the stomach and GI tract that would normally be inhibited by the acidic environment persist, which assists virulent bacterial colonization. This gastric colonization provides another reservoir for bacteria that eventually may migrate to the esophagus, pharynx, then upper and lower respiratory tract. With the presence of a nasal/oral gastric tube, there is an additional facilitated pathway from the stomach to the respiratory tract.[26]

Currently, major issues in nosocomial pneumonia focus on the problems associated with documenting true infection and isolating the responsible pathogens. However, this section focuses on preventive interventions only. Patients who are at high risk for stress ulceration should receive preventative acid lowering therapy. Nasal/oral gastric tubes should be left in place only so long as necessary. The patient should be maintained in the semirecumbent position, no lower than 30°, to minimize esophageal reflux and subsequent aspiration. Patients who are able to perform incentive spirometry have a lower risk for the development of nosocomial pneumonia. Therefore, minimizing sedation and opiate medication so that pulmonary toilet maneuvers, including an effective cough, can be accomplished is an important prophylactic measure.

Combinations of both topical enteral and parenteral antibiotics have been used to sterilize the above mentioned anatomic regions involved in the pathogenesis of nosocomial pneumonia. Topical antibiotics can be administered both directly to the oropharynx and via a feeding tube to the upper gastrointestinal tract. The topical antibiotic combinations have broad coverage including gram-negative, gram-positive, and fungal coverage. Selective oral decontamination with topical antibiotic cocktails has been shown to reduce bacterial colonization and the diagnosis of VAP in mechanically ventilated patients.[27,28] However, the impact of this intervention on mortality of VAP and antibiotic resistance is not clear.

As mentioned, a bacteremic etiology of nosocomial pneumonia must be recognized. The bacteremia may come from a variety of sources, including intravenous line or arterial line sepsis, and from translocation of bacteria through the bowel (Fig. 59-2). In critically ill patients, a variety of protective mechanisms that limit the movement of bacteria from the bowel into the bloodstream become defective. Therefore, translocation of bacteria can occur. With bowel microbial overgrowth and disruption of the surface mucosa, bowel microbes can leak into the bloodstream, and in the absence of effective lymphatic protective mechanisms, bacteremia can occur. With bacteremia, nosocomial pneumonia can occur. Theoretically, controlling or limiting the burden of bacterial colonization from virulent organisms in the gut should reduce nosocomial pneumonia by preventing both seeding of the bloodstream and migration to the upper airway and subsequent lower respiratory tract infection. Therefore, selective decontamination of both the oropharynx and gut with topical antibiotics has been attempted to reduce the incidence of nosocomial infection, including pneumonia. Though interventions and diagnostic techniques varied between studies, a metaanalysis published in 1991 showed a reduction in VAP without a mortality benefit using selective digestive decontamination.[29] However, two subsequent large, randomized studies using a combination of topical tobramycin, colistin, and amphotericin B with and without additional parenteral cephalosporin refuted this benefit.[30,31] Neither study showed a benefit in mortality or infection rate. Additionally, when infection was diagnosed, there was no correlation found between the causative organism and colonization of the oropharynx or gut. Since then, efforts have been made to assess the viability of oral and digestive decontamination in different patient populations in the ICU with varied results. For example, different combinations of topical broad spectrum antibiotic have been successful in reducing tracheobronchial bacterial colonization and VAP incidence.[27,28,32] However, neither intervention had an impact on relevant clinical endpoints length of ICU stay, duration of mechanical ventilation, and mortality. Additionally, selection of resistant organisms is of both theoretical and actual

concern in centers where incidence of resistant organisms is high to begin with.[31] At present, with no proven benefit in mortality or other clinical endpoints and the possibility of antibiotic resistance, selective decontamination is not used routinely in the intensive care unit. This may change, however, as a recent large unblinded study involving roughly 6,000 patients was able to show an adjusted reduction in mortality and incidence of bacteremia with selective digestive and oral decontamination for 4 days following admission to the intensive care unit.[33] Additionally, there was no influence on emerging antibiotic resistance. Though a largely positive study, the influence these findings may have on changing standard of care is debatable.

The endotracheal tube itself has become an important device with regard to the prevention of nosocomial pneumonia. Pathologic organisms can use both the internal and external portion of the endotracheal tube to gain access to the lower respiratory tract. First, the internal portion of the tube provides a direct external pathway between the patient and the ventilator circuit. The ventilator or external circuit consists of the following: the ventilator, a humidifier or heat and moisture exchange filter, expiratory and inspiratory circuit tubing, a nebulization chamber or insertion site for metered dose inhalers, and an in-line suction device to aspirate secretions from the trachea and proximal bronchi with a distal connection to a suction source. Several regions of the respiratory circuit are prone to colonization of nosocomial organisms, including fluid condensate in the ventilator tubing, and both fluid condensate and medication left inappropriately in the nebulized medication reservoir for extended periods of time while medication is no longer being delivered. The outer surfaces of the entire ventilator circuit become colonized by bacteria as well. Contact with the circuit by healthcare professionals contributes to cross contamination when poor hand-washing and disposable gloves are not strictly used between patients. Subsequent disruption of the ventilator circuit likely permits translocation and subsequent colonization of the internal circuit, which may lead to VAP. This has been shown in several trials that hypothesized that frequent changes of the ventilator circuit tubing would be beneficial by replacing "dirty" equipment. However, rather than reducing the incidence of VAP, frequent changes of "sterile" tubing were shown to be more harmful or of no benefit.[34,35] It is believed that frequent disruption of the circuit that exposes the internal surfaces to colonizing bacteria leads to subsequent migration via the tube into the lower respiratory tract. If the ventilator circuit is functioning appropriately and the patient is clinically stable, there is no need to disrupt the ventilator circuit or the in-line suction apparatus. The use of both endotracheal tubes impregnated with antibiotics and antibiotics by nebulization has been shown to reduce the number of colonizing organisms with varied effect on the influence of nosocomial pneumonia.[36,37] However, a recent, multicenter study of silver-coated endotracheal tubes showed a significant decrease in both the incidence and time to the onset of VAP. Patients with the silver-coated tube showed a roughly 50% reduced risk of developing VAP during the first 10 days of intubation as compared with uncoated tubes. Unfortunately, there were no differences with regard to the duration of mechanical ventilation or mortality.[38]

A second pathway for inoculating the respiratory tract involving the endotracheal tube is by migration of densely colonized secretions that pool in the subglottic region above the endotracheal tube cuff on the outside of the tube. While the cuff remains inflated, secretions and bacteria can descend into the respiratory tract by migrating through internal folds of the cuff that do not maintain a tight seal with the tracheal wall. There are two methods being employed to prevent this migration. The first is to reduce the amount of secretions by using a suction catheter built-in to the endotracheal tube above the cuff.[39,40] The second involves manipulating both the cuff material and the pressure within the cuff once inflated to reduce or eliminate the number of folds or channels that exist once the cuff is inflated.[41,42] Both methods have had success in preventing the migration of secretions and reducing VAP, though neither in a large scale clinical trial. Additional obstacles to both methods involve potential damage to the trachea. Higher cuff pressures have been associated with tracheal ischemia and mucosal damage. Subglottic suction catheters, especially when used continuously, have caused significant tracheal ulceration and bleeding.

Regardless of the infectious etiology or pathway, avoidance of endotracheal intubation remains the best method of prevention. The use of noninvasive positive airway pressure to

spare the patient from endotracheal intubation in selected patients has been shown to decrease the incidence of nosocomial pneumonia. A variety of methods are used for noninvasive mechanical ventilation in critically ill patients, most commonly being continuous and bi-level positive airway pressure (CPAP and BiPAP) via a face mask.

Catheter-Related Bloodstream Infection (CRBSI)

Central venous catheterization and pulmonary artery catheterization are independent risk factors for nosocomial infection in the intensive care unit. This section is meant to encompass temporary central venous catheters most commonly used in the intensive care unit with an expected duration of use <30 days, most commonly triple lumen and veno-venous hemodialysis catheters. Hospital wide, the annual incidence of CRBSI is roughly 250,000 cases.[43] Nosocomial septicemia can double the length of stay in the intensive care unit and can substantially increase the chance of death. The diagnosis of catheter-related infection is difficult because the catheter site often does not demonstrate any signs of local infection. Catheter-related infection should be included in the differential diagnosis when the patient manifests an unexplained fever and an indwelling vascular catheter has been in place and in use prior to the onset of fever. The present Centers for Disease Control (CDC) criteria for a CRBSI includes growth of an organism from a peripherally drawn blood culture with clinical signs of infection and semiquantitative, or quantitative growth of the same organism from a segment of the catheter or culture drawn from the catheter.[44] The CDC recognizes two additional diagnostic protocols that allow the catheter to remain in use while the source of infection is being sought. Both include a comparison between blood cultures drawn peripherally and those drawn from the catheter. In the first method, quantitative cultures drawn from a CVC that are 5–10-fold higher than simultaneously peripherally drawn blood cultures are indicative of a CRBSI. The second method, rather than focus on quantitative growth, uses early growth of an organism from CVC-drawn blood as compared to a simultaneously drawn peripheral culture that detects initial growth more than 2 h later. Both diagnostic methods allow tunneled catheters, or temporary catheters in patients with limited vascular access to remain in place. Neither method is routinely available in most clinical laboratories.[44,45]

Most catheter-related infections are caused by nosocomial organisms: *Staphylococcus* species, gram-negative rods, *Enterococcus,* and yeast species.

Strict aseptic catheter insertion technique minimizes the risk of line sepsis.

The most common organisms cultured are coagulase-negative *Staphylococcus, S. aureus,* gram-negative rods, and *Candida* species.

From a preventative standpoint, there are several risk factors associated with developing a CRBSI and appropriate steps or interventions the healthcare practitioner should use to decrease those risks. Risk factors for catheter-related infection include the duration of catheterization and its site or location, with femoral and internal jugular catheters having the highest rate of infection and subclavian catheters the lowest. Negative risk factors include rigid aseptic insertion technique and careful sterile dressing changes when required. Catheters impregnated with antibiotics, particularly when placed using a tunneled technique, have the lowest incidence of infection and colonization.[43,46,47] However, the use of antibiotic impregnated catheters is not routine as both the cost and possible selection of antibiotic-resistant organisms are a concern.

The catheter-related infection, when occurring within the first week, originates from the skin and tunnels down the site of entry along the external portion of the catheter into the blood vessel before settling on the catheter tip. Catheters in use for more than a week may additionally develop infections that originate from the catheter's hub and migrates via the internal lumen to reach to vasculature. Careful handling and management of the CVC by the healthcare provider can limit these later hub-related infections. Bacteremia from any etiology can potentially seed any foreign body, including catheters. For example, translocation of bacteria from the bowel into the bloodstream in the presence of a foreign body, such as a catheter, can lead to colonization of the catheter tip and a persistent nidus of infection. Colonization of the skin and hub by virulent organisms along with bacteremia unrelated to the CVC site play a role in the etiology of catheter-related infection.

From a prophylaxis standpoint, the use of a multidisciplinary, evidence-based approach using accepted guidelines to prevent CVC infection by dictating standard procedures both at the time of line insertion and during daily reassessment and care of the CVC can lead to a significant reduction in the number of CVC infections. In a 2006 study published by Pronovost et al, five basic interventions used in nonemergent placement of a CVC led to a

TABLE 59-4

PRECAUTIONS SHOWN TO SIGNIFICANTLY REDUCE THE NUMBER OF CATHETER-RELATED BLOODSTREAM INFECTIONS

Strict hand washing before and following each patient interaction
Full barrier precautions and aseptic technique at the time of CVC insertion
Use of chlorhexidine topical antiseptic to prepare the skin at planned insertion site
Avoiding femoral vein placement of catheter
Daily assessment of need for CVC with removal of the catheter when no longer necessary

SOURCE: data from Pronovost et al[48]

significant reduction in the number of CVC infections (Table 59-4).[48] To further assist in implementing these goals and improving outcomes, additional measures included a dedicated central line cart containing all necessary supplies to complete the procedure, continuing education on infection control practices including a checklist to be used at the time of the procedure to ensure standards are being met. Once the catheter is inserted, use of a chlorhexidine impregnated dressing that cover the skin directly surrounding the catheter insertion site and releases medication over a 10-day period has been shown to reduce both bacterial colonization and bloodstream infection.[49] Transparent semipermeable polyurethane dressings, in addition to the impregnated dressing, are useful in that they allow visualization of the skin without removing the existing dressing. There are similar colonization and bloodstream infection rates between dry sterile gauze and polyurethane dressings.[50]

The routine replacement of indwelling vascular catheters to prevent infection cannot be recommended. Replacing a catheter over a guide wire should only be done to replace a malfunctioning catheter, to change a PA catheter cordis to a smaller lumen CVC, or for diagnostic purposes in patients with limited options for venous access when a CRBSI is suspected. Routine site changes in otherwise stable patients who do not have evidence of CRBSI have not been shown to reduce the incidence of catheter-related infection; however, when the catheter site is changed, there is a risk for catheter-associated complications.[51,52]

There are certain indications for replacing vascular catheters. Obviously, when the catheter site is erythematous and pus is identified, the catheter should be removed and a new insertion site should be selected. When a catheter has been inserted emergently without strict aseptic technique, a new site selection for catheterization should be considered. In cases of documented or highly likely CVC infection, a new site is recommended to adequately treat the infection.

Handling of the CVC following insertion is another pathway of infection that originates in the catheter's hub as mentioned earlier. Infection can be introduced to the body due to repeated use of the CVC hubs for medications, blood draws, TPN, or flushing. Minimizing catheter flushing, including unnecessary blood draws, has been shown to reduce CRBSI. Additionally, routine changes of the infusion lines attached to the catheter should be changed approximately every 72 h and even more frequently when nutrient rich infusions like blood products and TPN have been infused.[53]

Urinary Tract Infection

Urinary catheters are responsible for nearly all nosocomial urinary tract infections.

Urinary tract infection accounts for 15–30% of all nosocomial infection, and for approximately 15% of nosocomial infection in the intensive care unit. Of these, 80% is associated with indwelling urinary catheters. Bacteriuria is the accepted precursor of urinary tract infection and potentially urosepsis. Risk factors for bacteriuria include diabetes mellitus, colonization of the catheter and drainage bag, and duration of urinary catheterization. There is a 5% per day increase in bacteriuria with urinary catheterization with rates as high as 50% by 5 days.[54] Bacterial migration along the catheter is the presumed mechanism for the link between catheters and urinary tract infections. Also, the protective lining of the bladder, which in part involves *Lactobacillus* organisms, seems to be disrupted in patients who have chronic urinary bladder catheterization and are chronically ill.

The common pathogens responsible for nosocomial urinary tract infections include *Escherichia coli, Enterococcus* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,*

and others. *Candida* species are also part of this picture. With long-term catheterization, both *Staphylococcus epidermidis* and *S. aureus* can be the cause of the urinary tract infection.

The diagnosis of complicated urinary tract infection is difficult due to the potential colonization of multiple causative organisms. Urine should be sent for both urinalysis and quantitative culture. The sample should be removed from the intraluminal port and not the collection bag. The presence of abundant leukocytes and bacteria on urinalysis with a subsequent growth of $>10^5$ colony-forming units per milliliter is consistent with a complicated urinary tract infection.[55] Present guidelines do not recommend routine changing of indwelling catheters to prevent infection. However, in cases of presumed infection, changing or removing the catheter followed by repeat culture may allow specific isolation of the causative organism and guide antibiotic therapy. Removal of the catheter with repeat culture in an attempt to distinguish colonization from active infection is especially helpful in patients being empirically treated for highly resistant organisms that require antibiotics with significant adverse side effects.

Prophylaxis for intensive care urinary tract infections should include the following: the strict adherence to aseptic technique when the urinary catheter is inserted; when necessary, the use of antimicrobial-impregnated catheters; and appropriate daily catheter care which includes the prevention of contamination of the collecting system. Removal of the indwelling catheter when no longer necessary is an intervention that should be considered by the clinician on a daily basis. Early catheter removal has been shown in postsurgical patients to reduce the frequency of complicated urinary tract infection and to limit subsequent antibiotic use.[56] Urinary incontinence has been shown to be the most common indication for unnecessary placement of indwelling catheter in general medical patients.[57] Prolonged use of an indwelling catheter to monitor urine output in hemodynamically stable patients was a risk factor identified in the intensive care unit.

Funguria in the intensive care unit, most commonly Candida albicans and glabrata species, is of unclear clinical significance. In a large multicenter, prospective analysis of 861 patients with funguria ($>10^3$ cfu/mL growth of yeast), 22% had fever; however, only 2–4% had associated GU symptoms including flank pain, dysuria, frequency, hematuria, or urgency.[60] The fever could not be directly attributed to funguria. Candidemia was found in 7 (1.3%) of the patients, with only two deaths attributable to candidemia. Clinical Risk factors identified for candidemia are surgery, diabetes mellitus, urinary tract diseases, malignancy, malnutrition, trauma, neutropenia, and transplantation.[60] As this was an observational study, there were no treatment or intervention arms. However, it was noted that patients who did not undergo specific intervention were more likely to show resolution of funguria as those patients who either had catheter removal or antifungal therapy. Both the presence and persistence of funguria were associated with diabetes mellitus.

SUMMARY

Currently available prophylactic regimens can reduce the risk of deep vein thrombosis and pulmonary embolism by 50–70%. Medications can be employed with only minimal risk of complications including HIT and bleeding. Deep vein thrombosis prophylaxis should be tailored to the individual's estimated risk assessment.

Stress-induced gastric mucosal injury such that bleeding becomes clinically relevant is rarely encountered because the use of prophylactic measures has dramatically increased; however, many patients who receive stress ulceration prophylaxis likely do not need these medications, including the routine use of PPIs in patients without upper gastrointestinal bleeding. Prophylaxis should be directed to those patients who are at highest risk for the development of stress-related mucosal bleeding. Many prophylactic regimens are effective, but famotidine 20 mg intravenously or orally every 12 h appears to be safe, cost-effective, and with limited side effects.

More than 20% of patients admitted to the intensive care unit develop some form of nosocomial infection. Pneumonia, CRBSI, and urinary tract infection are the three major nosocomial infections against which we must guard. With meticulous care, certain prophylactic

techniques, and daily reevaluation of the individual patient including the need for mechanical ventilation, ability to wean, further requirement of central venous access etc., the rate of each of these infections can be reduced significantly with improved outcomes including avoidable healthcare costs and unnecessary morbidity for the patient.

REVIEW QUESTIONS

1. **In patients at the highest risk for thromboembolic disease, who are not given DVT prophylaxis, the rate of fatal pulmonary embolism is as high as:**
   - **A.** 1:20
   - **B.** 1:200
   - **C.** 1:2,000
   - **D.** 1:20,000

2. **Which of the following interventions has been shown to decrease the rate of nosocomial pneumonia?**
   - **A.** Elevating the head of the bed
   - **B.** Minimizing nasogastric tube duration during mechanical ventilation
   - **C.** Minimizing sedation
   - **D.** All the above

3. **Which of the following is not a reason to change or remove a central venous catheter?**
   - **A.** Erythema at the insertion site
   - **B.** Fever/leukocytosis without an obvious source and staphylococcal species growing from a peripherally drawn blood culture
   - **C.** A catheter in place for 8 days
   - **D.** A catheter that was placed emergently without aseptic technique

4. **Urinary tract infections account for 15% of all ICU nosocomial infections. Of these, 80% are catheter-related. Proven methods of prophylaxis include:**
   - **A.** Strict aseptic insertion
   - **B.** Antimicrobial-impregnated catheters
   - **C.** Prevention of contamination of the collecting system
   - **D.** Prevention of reflux of urine from the collecting system into the bladder
   - **E.** All the above

5. **True or False: Prophylactic doses of LMWH or unfractionated heparin can increase the risk of clinically significant bleeding.**

6. **Which of the following is not a risk factor for clinically significant stress gastritis?**
   - **A.** Mechanical ventilation
   - **B.** Coagulopathy
   - **C.** Acute head injury
   - **D.** Myocardial infarction

7. **All the following are acceptable forms of DVT prophylaxis in patients at moderate risk except:**
   - **A.** Low-molecular weight heparin
   - **B.** Intermittent pneumatic compression devices
   - **C.** Low-dose unfractionated heparin
   - **D.** Graded compression stockings

ANSWERS

1. The answer is A. Patients at the highest risk for thromboembolism include those with stroke, spinal cord injury, the elderly, victims of multiple trauma, and lower extremity fractures and surgery. In this group, the risk of fatal pulmonary embolism is between 1 and 5% if no prophylaxis is given. Additionally, the overall risk of pulmonary embolism is 5–10%, and the risk of proximal DVT is 10–20%. Given this potential for morbidity and mortality, it is imperative to treat accordingly with coumadin, LMWH, or a combination of low-dose unfractionated heparin plus intermittent pneumatic compression stockings.
2. The answer is E. Nosocomial pneumonia is the most common ICU-acquired infection; it also carries the highest morbidity (about 50%). Proven prophylactic methods include elevating the head of the bed 30–45° to reduce reflux and aspiration, minimizing the use of nasogastric tubes, which can be a conduit for aspiration and a source of sinusitis, minimizing sedation to allow for pulmonary toilet, and whenever possible, using noninvasive positive pressure ventilation instead of endotracheal intubation and mechanical ventilation. Using these methods can reduce the risk of nosocomial pneumonia by as much as 30%.
3. The answer is C. Line-related sepsis accounts for approximately 15% of all ICU-acquired infections, doubles the ICU length of stay, and adds to overall mortality. In light of this, many physicians favor changing central venous catheters on a regular basis such as every 3–7 days. This method of prevention has never been shown to be superior to changing lines only when clinically indicated. This practice also exposes the patient to the potential for procedure-related complications. Proven indications for changing a central venous catheter to a new site include erythema or pus at the insertion site, or when a CVC has been in used and a bacterium known to cause CRBSI is grown from a peripherally drawn blood culture.
4. The answer is E. Urinary tract infections account for 15% of all ICU-acquired infections. Of these, more than 80% are related to urinary catheters. Prophylaxis, therefore, centers on the proper care and insertion of these catheters. Methods to decrease infection rates include aseptic insertion technique, consideration of

antimicrobial-impregnated catheters, prevention of contamination of the collecting system, and when feasible, removal of the catheter. Employing these methods can reduce the risk of infection by as much as 30% over historical controls.

5. The answer is False. Prophylactic doses of LMWH or low-dose unfractionated heparin are exceptionally safe. Clinically significant bleeding resulting in hemodynamic instability or the need for blood transfusion is extremely rare, occurring in less than 1% of all treated patients. When considering the patient population in which these agents are being used (potential mortality as great as 5%), this becomes a clearly favorable intervention in patients at moderate-to-high risk for thromboembolism.
6. The answer is D. Stress gastritis is relatively common in the ICU. Clinically significant gastritis resulting in hemodynamic instability or the need for blood transfusion is less common, with an incidence of 10–20%. Studies of patients at risk for clinically significant stress gastritis found only four significant causes: head trauma, burns over 30% of the body, coagulopathy, and the need for mechanical ventilation for more than 24–48 h. Myocardial infarction can lead to gastritis, but has not been shown to result in clinically significant stress gastritis.
7. The answer is D. Patients at moderate risk for thromboembolic disease include patients more than 40 years of age, undergoing moderate nonorthopedic surgery, with a history of prior DVT, or with a cardiomyopathy or myocardial infarction. These patients clearly benefit from DVT prophylaxis with LMWH or low-dose unfractionated heparin. In this group, intermittent pneumatic compression devices are also acceptable, particularly in neurosurgical patients for whom heparin may be contraindicated. Graded compression stockings are only modestly effective at DVT prophylaxis, and therefore, are reserved for those patients with only a low risk for thromboembolic disease.

CHAPTER 60

ADITI G. SATTI, MELISSA DERR, AND MARY L. FORNEK

Rehabilitation in the Intensive Care Unit

CHAPTER OUTLINE

LEARNING OBJECTIVES

After studying this chapter, you should be able to:

- Understand the importance of the team approach and the process of care issues, which lead to successful implemention of rehabilitation in the ICU patient.
- Understand the main neuromuscular, respiratory, and psychological conditions that affect rehabilitation in the ICU.
- Develop a systematic approach for implementing early mobility of ventilated patients.
- Execute effective measures to prevent complications in ventilated patients in the ICU.

INTRODUCTION

The global advancement in ICU care has improved survival of the critically ill patient. This improved survival has led to longer ICU lengths-of-stay and an awareness of the number and diversity of secondary complications. A prolonged ICU stay and chronic critical illness are associated with weakness, deconditioning, decreased function, and quality-of-life. The goal of rehabilitation is to improve physical, psychological, and social function within the constraints of the patient's illness.

The goal of rehabilitation is to improve physical, psychological, and social function within the constraints of the patient's illness.

Acute respiratory distress syndrome (ARDS) is a common condition encountered in the ICU and is associated with long term psychological and functional disorders. In a study reviewing 109 survivors of ARDS, muscle fatigue and weakness were the major reasons

Muscle fatigue and weakness were the major reasons given for patient's persistent functional limitation.

CASE STUDY: PART 1

The patient, R.S., was a 54-year-old African American male with history of severe COPD; he was admitted with an acute exacerbation of COPD and hypoxemic respiratory failure. On admission, he was in acute respiratory distress, his respiratory rate was 37 breaths/min, pulse 136 beats/min, blood pressure 100/62 mmHg, and SpO_2 via pulse oximetry was 82%. On examination, R.S. had an increased work-of-breathing and was using accessory muscles. He had decreased air entry on lung exam. His initial chest X-ray showed hyperinflated lungs. The patient was intubated on admission and transferred to the ICU. During his stay he was treated with high-dose steroids for his COPD exacerbation and had to be sedated and paralyzed in order to maintain an oxygen saturation above 90% on ventilatory support. As the patient improved, the systemic corticosteroid dose was tapered and the sedation was weaned. Early in his hospital course, the patient was not a candidate for physical therapy due to his medical instability. At the present time, the patient's body is rotated every 2 h by the nurse. Multipodus boots and hand splints were placed on the patient to prevent joint contractures.

given for patient's persistent functional limitations. These functional limitations were evident in the lower than predicted distance walked in 6 min.[1] Survivors of prolonged ventilation also experienced a marked impairment in their physical quality-of-life, even though their mental health was preserved.[2] There is an increased need for rehabilitation following a stay in the ICU because of the harmful consequences of prolonged bed rest.

REHABILITATIVE ISSUES IN THE ICU PATIENT

Muscle atrophy, loss of force generation, and changes in type of muscle fibers all occur with bed rest.

It is not completely clear why weakness occurs in the ICU. The effects of deconditioning primarily come from studies done on healthy persons placed at bed rest in space programs and low-gravity research. Muscle atrophy, loss of force generation, and changes in type of muscle fibers all occur with bed rest. It has been found that even short periods of bed rest affect skeletal muscle performance. After 14 and 35 days, muscle force decreases by 15 and 25%, respectively. Thigh and calf muscle volumes also decrease significantly.[3] What happens to skeletal muscle with disuse is also true for the diaphragm. A study that evaluated diaphragm-biopsy specimens from subjects on mechanical ventilation for 18–69 h showed atrophy of both slow and fast-twitch muscle fibers.[4] This weakness contributes to an overall decrease in functional status and impairs ventilatory weaning.

Patients in the ICU are also at risk for developing neuromuscular weakness due to ICU treatments used to treat acute exacerbations of the underlying disease process. The greatest risk factor for critical illness myopathy (CIM) is the use of glucocorticoids and neuromuscular blocking agents (see Chap. 58). It is characterized by flaccid muscle weakness and failure to wean from the ventilator. CIM is usually reversible over weeks to months, but is associated with a prolonged hospital course.

Critical illness polyneuropathy (CIP) is another cause of neuromuscular weakness encountered in the ICU and may be confused with CIM. The physical findings are similar to those seen in myopathy, but also included sensory nerve dysfunction and decreased deep tendon reflexes; it is associated with severe sepsis.

The greatest risk factor for CIM is the use of glucocorticoids and neuromuscular blocking agents (see Chap. 58).

Patients may also develop compressive neuropathies affecting the ulnar and peroneal nerves. Proper positioning and frequent turning may limit the extent of these neuropathies. The remedy for all of these secondary disorders derives from treating the underlying medical conditions and intensive rehabilitation.

All patients admitted to the ICU suffer some element of deconditioning related to the need for bed rest and the catabolic nature of the underlying disease.

All patients admitted to the ICU suffer some element of deconditioning related to the need for bed rest and the catabolic nature of the underlying disease prompting admission. ICU patients who require sedation, neuromuscular blocking agents, corticosteroids, mechanical ventilation, and suffer from sepsis, shock, and/or renal failure represent patient groups who are at greatest risk for deconditioning; these patients require intensive, multidisciplinary whole body rehabilitation.

ICU patients are a special population of patients who benefit from early mobility. The ability to sit, stand, and ambulate not only improves their quality-of-life and functional status, but also mitigates the complications of immobility, such as deep venous thrombosis,

CASE STUDY: PART 2

R.S. had continued ventilator-dependent respiratory failure. He had a tracheostomy tube placed for comfort and mobility. Physical therapy was consulted in the ICU. The patient was assessed daily for any contraindications to physical therapy. The patient at this stage had passive range of motion performed by the nurses three times a day, and the patient's bed was put into a sitting position for a minimum of 20 min 3 times a day. The patient had severe weakness and CIM from the use of systemic glucocorticoids and neuromuscular blocking agents. The patient progressed to sitting in a chair and requested to sit for a minimum of 45 min/day. The patient was unable to wean from the ventilator and was transferred to the ventilator rehab unit (VRU) for further management. The patient met respiratory and nonrespiratory medical criteria for admission to the VRU tracheostomy, manageable secretions, stable ventilator settings, the presence of a gastrostomy tube for nutrition and was medically stable and cooperative.

pulmonary embolism, and decubitus ulcers. The ability to speak and eat also has a benefit on overall psychological well-being. These issues are extremely important and therapy should be instituted as early as feasible when caring for chronically ventilated patients.

Many studies have shown that patients doing arm and leg exercises have an improvement in the strength and endurance of respiratory muscles, decreased shortness of breath, and an improved quality-of-life. Keens et al[5] found that in cystic fibrosis patients undergoing intense upper extremity training, there was a 57% increase in ventilatory muscle endurance. Clanton et al[6] found that swimmers who did isometric upper extremity training had a 25% increase in mean inspiratory pressure and a 100% increase in ventilatory endurance compared to age-matched controls. Estenne et al[7] found that in C5–C6 quadriplegic patients, there was an increased expiratory reserve volume after undergoing 6 weeks of isometric pectoralis major muscle training. These studies have triggered an interest in the incorporation of upper extremity training in rehabilitation programs.

WHOLE BODY REHABILITATION

Whole body rehab should be an integral part of the care of a chronically ventilated patient.

We previously evaluated and reported the efficacy of aggressive whole body rehab in 49 chronically ventilated patients.[8] All patients had been ventilated for at least 14 days and none had neuromuscular disorders. Physical therapy was started on admission to our ventilator rehabilitation unit. The rehab program consisted of trunk control, active and passive extremity resistance training, and inspiratory muscle training (IMT). Deconditioning was assessed daily using a five-point motor score looking at strength and range of motion of all muscle groups. Our study showed that patients were initially very weak and debilitated, but had improvement in motor strength after a whole body rehabilitation program. All patients, initially bed bound, were able to sit and stand; and the majority (81%) were able to ambulate prior to discharge. It can be concluded from our study that whole body rehab should be an integral part of the care of a chronically ventilated patient.

Upper limb motor strength correlates inversely with weaning time.

The study also showed that there was significant correlation between upper limb motor strength and weaning time. This may be due to strengthening of the pectoralis muscles which have both inspiratory and expiratory functions. Past studies in different patient populations have shown an improvement in ventilatory mechanics (increased mean inspiratory pressure and expiratory reserve volume) with pectoralis muscle training.

Inspiratory Muscle Training

Strengthening the respiratory muscles by using IMT to facilitate weaning is also an important part of the rehabilitation program.

Using IMT to strengthen the respiratory muscles to facilitate weaning from mechanical ventilation is also an important part of the rehabilitation program.

IMT uses devices with different size diameters to provide flow or pressure resistance. An example of an IMT device can be seen in Fig. 60-1. The training program consists of the regular application of increasingly higher degrees of inspiratory resistance for brief periods

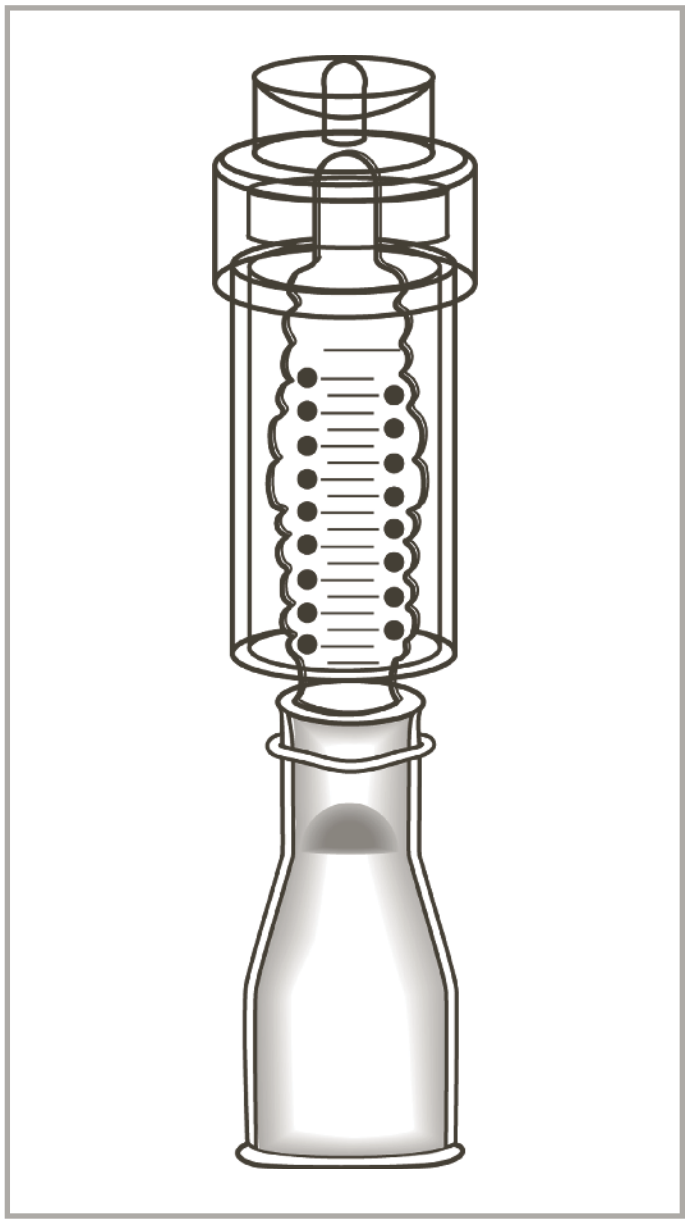

FIGURE 60-1

Threshold® IMT (illustration by Alice Y. Chen).

of time. In the study by Martin et al, nine out of ten patients undergoing IMT weaned successfully.[9]

The studies previously discussed indicate that strengthening of limb skeletal muscles and the respiratory muscles occurs with whole body rehabilitation, but is there an overall improvement in the patients' functional independence? In a study looking at functional status, 39 patients on prolonged mechanical ventilation were randomized to receive 6 weeks of physical therapy or standard care. Functional independence measure was used to assess a patient's ability to perform basic activities of daily living. A higher score meant more independence. At the end of 6 weeks, the physical therapy group had a significantly improved functional status compared to the control group that received standard care without dedicated physical therapy.[10]

Prolonged endotracheal intubation may result in injuries to the mouth, larynx, and trachea. Additionally, there are the risks of self-extubation, tube-malposition, and sinusitis; the physical discomfort associated with endotracheal intubation leads to the need for increased doses of sedative/hypnotics and opioids.

Early Tracheostomy to Facilitate Mobilization

Tracheostomy is among the most commonly performed surgical procedures in critically ill patients requiring ventilator support who fail to wean.[11] Prolonged endotracheal intubation

CASE STUDY: PART 3

While in the ICU, R.S. participated in an aggressive whole body rehabilitation program. An initial therapy assessment was done; the patient progressed from the sitting position in bed to sitting at the edge of the bed. The therapist assessed response to movement, vital signs, and strength against gravity, trunk control, and balance. The patient then progressed to out of bed to chair and to ambulation. The therapy program also emphasized upper extremity strength to facilitate weaning. The respiratory therapists were involved during all sessions to assist with the portable ventilator during ambulation and to ensure the patient was comfortable. Vitals signs were monitored throughout and the FiO_2 was adjusted by the therapist to maintain the patient's oxygen saturation.

may result in injuries to the mouth, larynx, and trachea. Additionally, there are the risks of self-extubation, tube-malposition, and sinusitis; the physical discomfort associated with endotracheal intubation leads to the need for increased doses of sedative/hypnotics and opioids.[12] The practice of early tracheostomy is controversial because studies demonstrating unequivocal benefit are lacking. Rumbak et al found that early tracheostomy (within 48 h) has advantages over delayed tracheostomy in critically ill patients who were predicted to require ventilation for greater than 14 days. Patients with early tracheostomy spent significantly less time in the ICU, less time on ventilatory support, and had significantly lower mortality and ventilator-associated pneumonia rates. Griffiths et al performed a systematic review of the literature and found that early tracheostomy (0–7 days after admission to the ICU) resulted in a shorter duration of artificial ventilation and length-of-stay in the ICU. Freeman et al performed an observational study, which found that the timing of tracheostomy appeared to be significantly associated with the duration of mechanical ventilation, ICU length-of-stay, and hospital length-of-stay, and recommended further study.

It is unclear if early tracheostomy facilitates early mobilization. The selection of tracheostomy tubes should be individualized for the patient. Small (4 or 6 mm in diameter), cuffless, or metal tubes provide the greatest comfort. Fenestrated tubes may improve voice quality, and cuffed tubes should be used in patients with swallowing dysfunction. The overall benefit of a tracheostomy is that it provides improved comfort, mobility, and speech. These functions facilitate rehabilitation and improvement in quality-of-life.

The overall benefit of a tracheostomy is that it provides improved comfort, mobility, and speech.

PSYCHOLOGICAL DYSFUNCTION

There is a high incidence of neuropsychiatric deficits in chronically ventilated patients. In 28 patients in a ventilator rehabilitation unit, there were deficits in all areas of cognition, including language, orientation, memory, and reasoning. Short-term memory deficits were the most common impairment. Impaired reasoning and long-term memory deficits were seen in 56 and 36% of patients, respectively.[13] There are a number of contributing factors; severity of illness, inability to communicate verbally, immobility and sedative medications.

There is a high incidence of neuropsychiatric deficits in chronically ventilated patients.

Short-term memory deficits were the most common.

SPEECH

Improving patient mobility, comfort, and the ability to communicate can improve psychological well-being. Most patients report that their inability to communicate is the most important factor contributing to the sense of fear and isolation. Speech therapists are an integral part of the multidisciplinary rehabilitation team. The use of an electrolarynx or one way-speaking valve can be individualized to assist in their speech. An example of a one-way speaking valve can be seen in Fig. 60-2.

SWALLOWING DYSFUNCTION

A tracheostomy tube provides the opportunity for oral nutrition, but patients on prolonged mechanical ventilation have a significant incidence of swallowing abnormalities. We

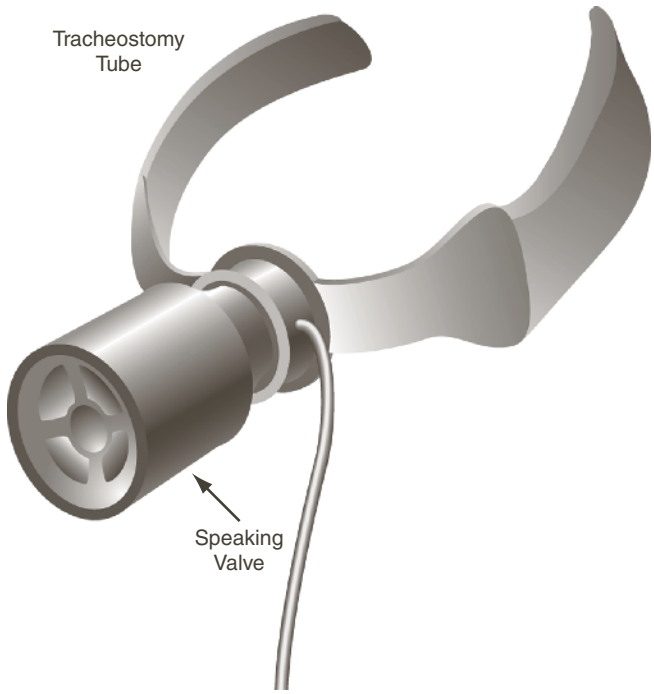
Patients on prolonged mechanical ventilation have an increased incidence of swallowing abnormalities.

CASE STUDY: PART 4

R.S. saw a progressive increase in his strength throughout his stay. He continued with inspiratory muscle strength training twice a day. As his strength improved, he was able to tolerate being off the ventilator for 16 h at a time and soon was on the ventilator only at night. He was evaluated by the speech therapist and given a one-way speaking valve. The ability to speak and interact with family members had a significant impact on his mood and quality-of-life. The patient initially had swallowing dysfunction and evidence of aspiration. Prior to discharge, the patient was able to eat solid foods and drink thick liquids. The patient's family was given instructions on caring for a tracheostomy and ventilator instructions prior to discharge.

FIGURE 60-2

One-way speaking valve (*arrow*) attached to end of a tracheostomy tube. (illustration by Alice Y. Chen).



previously examined the effects of chronic mechanical ventilation on swallowing function.[14] We found that 43% of patients receiving prolonged mechanical ventilation had evidence of aspiration on a modified barium swallow study. We stressed the importance of routinely ordering a modified barium swallow study in this patient group due to the high incidence of aspiration detected on patients with normal bedside examinations. Many factors may contribute to swallowing dysfunction including neuromuscular disorders, medications, underlying medical illness and laryngeal edema, or vocal cord injury from intubation and tracheostomy tube placement.[14] Speech therapists should evaluate swallowing, oral motor strength, and adequate cough and gag reflexes. The initial goal in a patient with swallowing dysfunction is to prevent aspiration. Proper patient positioning, alternate routes of nutrition, and assessment for other neurologic conditions contributing to swallowing dysfunction should be included in the management of these patients. The ability to eat, speak, and socially interact reengages the patient in normal human behavior, which is vital to their overall well-being.

SLEEP

Sleep deprivation may impair immunity and tissue repair and contribute to increased morbidity.

Other issues that contribute to psychological dysfunction in the ventilated patient are sleep deprivation, the inability to communicate, and social isolation. Patients admitted to the ICU are susceptible to sleep deprivation due to underlying illnesses, medications, and the ICU

environment itself; the ICU is a continuously noisy environment that provides the patient with unrelenting and often meaningless sensory input. Sleep deprivation may impair immunity and tissue repair, and contribute to increased morbidity. Steps to improve sleep such as creating a diurnal environment and minimizing interruptions should be taken.[15]

IMPLEMENTING AN EARLY MOBILITY PROGRAM

Initial Assessment

Initiation of the ICU mobility protocols begins upon admission to the ICU. The level of mobility for each patient is assessed on daily multidisciplinary rounds. A study looking at the safety of early activity showed that the majority of respiratory patients were able to participate in a physical therapy program in the ICU, while orally intubated, without adverse events (1%).[16]

The majority of respiratory patients were able to participate in a physical therapy program in the ICU, while orally intubated, without adverse event.

Specialized Unit Approach to Early Mobility

Protocols for mobility of the ventilated patient will differ among intensive care units; differing patient populations must be taken into consideration before implementing a program. The Temple ICU early mobility protocol can be seen in Table 60-1.

The cardiac intensive care unit (CICU) consists of postoperative cardiac patients who have a shorter length-of-stay than many other populations. These postoperative patients are routinely mobilized by nursing with or without the assistance of physical therapists.

The surgical intensive care unit (SICU) consists largely of trauma patients and general surgery patients; these patients are served by a number of physical therapy teams. The SICU may have general surgery patients who do not need physical therapy consults. Many of these patients do not have functional mobility issues; there mobility issues are related to pain and multiple invasive lines and/or tubes. Early mobilization of trauma patients may be delayed in order to rule out fractures and obtain weight bearing status. A standardized protocol for SICU patients is useful to coordinate care for this population.

The neurology and neurosurgical intensive care units (NICU, NSICU) mobility protocols differ due to the distinctly different patient populations in each unit. Physical therapy may become involved earlier in the care of these patients since extensive bedside exercise, beyond passive range of motion (PROM), has been shown to facilitate early return of motor function and cognition. Patients in the NSICU are often not mobilized due to invasive monitors, external ventricular drains, and head-of-bed elevation limitations due to ventriculostomies.

The medical respiratory intensive care unit (MRICU) is comprised of a varied population and includes ventilator-dependent patients with pneumonia, sepsis, multiple organ system dysfunction, immunosuppression, etc. Multidisciplinary teams round daily to discuss the mobility and rehabilitation plans for each ventilated patient. Coordination of care with Respiratory Therapy may be difficult in this unit since they have a heavy patient assignment. An increased number of portable ventilators will be required for these patients, as well as specially equipped rolling walkers with oxygen tank holders and seats.

The Burn Intensive Care Unit has not participated in the early mobility of the ventilated patient protocol due to the increased acuity and pain levels of their patients.

Rehabilitation Strategies

A daily assessment of the patient should be made to determine if there are any contraindications to physical therapy and early mobility. Some absolute contraindications are hemodynamic instability, acute proximal deep venous thrombosis or pulmonary embolism, uncontrolled heart failure, and unstable angina. The barriers and benefits to early mobility are listed in Table 60-2.

A daily assessment of the patient should be made to determine if there are any contraindications to physical therapy and early mobility.

A description of physical therapy techniques will be provided along with the evidence supporting their use.

TABLE 60-1

TEMPLE UNIVERSITY HOSPITAL EARLY MOBILITY PROTOCOL

ICU EARLY MOBILITY PROTOCOL

Once a patient responds to verbal stimuli, initiate activity by sitting the patient up with legs off the side of the bed. Progress as quickly as possible to standing, transferring to a chair, walking with assistance and walking independently.
Activity level of patient is assessed at least every 24 h and increased to the appropriate maximum tolerated mobility level
Activity should continue despite a patient's agitation or delirium, which often improves with reconditioning

All patients assessed daily in RN/PT rounds	*Not candidate for early mobility* if any *one* of the following apply	*Candidate for early mobility if*	*Progression of early mobility to sitting on edge of bed*	*Progression of early mobility to OOB, pivot, and sitting in chair*	*Ambulating in hallway*
Criteria	DVT being ruled out Femoral A-line Unstable surgical incisions PTT>100 secs or INR>4 Fractures being R/O'ed Cervical spine not cleared New onset neuro symptoms Severe thrombocytopenia Severe medical instability Combative Severe confusion DT's or withdrawal	Patient has stable BP and ET tube or trach And: unconscious, or chemically sedated, or awake but not following commands, or Hgb<7 gms or is on catecholamine drips or has symptomatic orthostasis SICU: if cervical collar ON and cleared by SICU attending patient is candidate	Conscious and follows commands with stable BP (no othostasis), ET tube, or trach no vasoactive drip changes 1 h prior to activity, and not on vent wean at time of activity Hgb>7gms And: needs assist to move in bed or lifts arms/legs against gravity Minimize or discontinue sedation and narcotics	Conscious and follows commands with stable BP (no othostasis), ET tube, or trach no vasoactive drip changes 1 h prior to activity, and not on vent wean at time of activity Hgb>7gms And: needs assist to move in bed or lifts arms/legs against gravity Minimize or discontinue sedation and narcotics	Conscious and follows commands with stable BP (no orthostasis), trach, no vasoactive drip changes 1 h prior to activity, and not on vent wean at time of activity Hgb>7gms And needs minimal assist to move in bed or lifts arms/legs against gravity Minimize or discontinue sedation and narcotics

CONTRAINDICATIONS AND BENEFITS TO AN EARLY MOBILITY PROGRAM

ABSOLUTE CONTRAINDICATIONS FOR EARLY MOBILITY AND WALKING PROGRAM	BARRIERS TO EARLY MOBILITY AND WALKING PROGRAM	POTENTIAL BENEFITS OF EARLY MOBILITY AND WALKING PROGRAM
Comatose, unresponsive patients	Lack of patient cooperation	Prevention of secondary complications of bed rest
Unstable angina	Bed rest culture	High level of satisfaction for nurses, patients, physicians, therapists, and family members
Uncontrolled heart failure	Age and level of function prior to ICU admission	Assistance with ventilator weaning process as strength, functional mobility, and endurance improve
Hemodynamic instability requiring high doses or multiple vasopressor drugs	Severity of disease and comorbidities	Decreased length of hospital stay and complications
Suspected or known dissecting aneurysm	Limited cardiac and pulmonary reserve	
Acute pulmonary embolus	Limited assessment of strength, mobility, and ability to bear weight	
Significant oxygenation dysfunction requiring > 0.7 FiO_2	Patients body weight	
Cerebral edema/uncontrolled ICP	Pain	
Significant neurological/ musculoskeletal dysfunction	Sedation	
Unstable fractures	Nutritional status	
	Sleep deprivation	
	Interdisciplinary cooperation	
	Staff availability to assist with mobility	
	Number of lines, tubes, monitoring, and life support equipment	

Positioning is a technique that is used to place patients in an optimal position to decrease V/Q mismatch. An example of the use of positioning is the placement of the patient in an upright, sitting position when weaning from the ventilator to increase lung volumes and decrease work-of-breathing. Initially, the head-of-the bed should be elevated to 30° with progression to 45°. As the patient adjusts to changes in posture, the bed should be configured into a chair position so that the patient can experience sitting upright with the legs in a dependent position for 1–2 h.

The goal of *active limb exercises*, such as sitting, standing, and walking, is to improve cardiopulmonary fitness and oxygen transport.

A patient is not a candidate for CLRT if they are ventilated, unconscious, have a femoral line, are combative or severely medically unstable, or have a $PaO_2/FiO_2 < 250$.

Continuous lateral rotational therapy (CLRT) uses specialized oscillating beds that turn patients. The goal is to prevent atelectasis and pooling of secretions. A study by Kirshenbaum et al compared the use of oscillating beds with that of conventional beds that required active turning of patients by nurses every 2 h.[17] This study found that there was a significantly lower rate of pneumonia in the CRT group. A patient is not a candidate for CLRT if they are ventilated, unconscious, have a femoral line, are combative or severely medically unstable, or have a PaO_2/FiO_2 ratio less than 250.

Manual hyperinflation is disconnection of the patient and manual delivery of a large tidal volume via an Ambu resuscitator bag. The goal is to improve compliance and decrease atelectasis. There are no studies to support its use and it may cause overdistension of alveoli and high airway pressures.

Percussion and vibration, also known as chest PT, are used to enhance clearance of secretions.

Percussion and vibration, also known as chest PT, is used to enhance clearance of secretions. This is usually performed by Respiratory Therapy and Registered Nurses. The level of evidence for these techniques can be found in Table 60-3.[18]

TABLE 60-3

LEVEL OF EVIDENCE FOR PHYSIOTHERAPY TECHNIQUES

ACTIVITY	TECHNIQUE	LEVEL OF EVIDENCE
Weaning process	Therapist directed protocols	A

Chest physiotherapy	Manual hyperinflation	B/C
	Percussion/vibration	C
Muscle retraining	Respiratory muscle	C
	Peripheral muscle	B/C

REHABILITATION PROGRAMS

The Ventilator Respiratory Unit (VRU) at Temple University Hospital is an example of a multidisciplinary rehabilitation program for long-term mechanically ventilated patients. It is an 18-bed noninvasive respiratory care unit in a tertiary care hospital and has provided care to over 2,000 patients with prolonged respiratory failure. One of the goals in the VRU is to achieve maximum functional status, despite the ongoing need of the patient for mechanical ventilation. The VRU is composed of a multidisciplinary team, each with a unique role. A summary of each team member's roles is provided in Table 60-4.

The physician provides the medical management of the patient and is the supervisor and coordinator of the appropriate treatment plan. The nurse provides education to the patient and family, and works toward transition of the patient to home. The nurse should evaluate the patient's mobility status daily and initiate patient activity. The physical therapist creates an individualized exercise program for each patient. The patient should have an initial assessment to determine functional deficits. The physical therapist will perform exercises which improve muscle strength, endurance, and range of motion. The occupational therapist's emphasis is on upper extremity strength and range of motion, which will aid in patient's activities of daily living. The therapist may provide boots, splints, or other specialized equipment to help with functional mobility. The speech therapist is responsible for assessing swallowing dysfunction and providing intervention for communication. The respiratory therapist will provide treatments as ordered by the physician. The therapist will also make sure that there is an appropriate ventilator setup for the patient, which is both comfortable and allows for mobility. The family will receive adequate respiratory teaching prior to discharge. The nutritionist will assess the patient's caloric needs and provide a dietary plan for each patient. The psychologist will assess a patient's cognition and meet with the family to discuss coping mechanisms and expectations on discharge. The social worker will make sure that the patient has a support system in place prior to discharge. Any financial issues and follow-up appointments should also be resolved. The pharmacist's role is to assist in implementing a sedation protocol and review all medications on a daily basis. They are also very helpful in reviewing your hospital's antibiogram and tailoring of antibiotics.[19]

SPECIAL CONSIDERATIONS

When implementing an early mobility protocol program, it is necessary to consider the individual needs of each patient. There is no standard guideline or technique used; rather the program should be customized for the patient. In order to be successful with such a program, the patient and staff must have the appropriate equipment to meet the needs for that particular level of mobility. Specialized equipment includes stretcher chairs, portable ventilators, walkers, and rollators.

When implementing an early mobility protocol program, it is necessary to consider the individual needs of each patient.

Portable ventilators are often required in the early stages of weaning to limit the strain on patients' cardiopulmonary system while focusing on their musculoskeletal function (Fig. 60-3). This equipment is typically used for ambulation and may require trials to ensure patient comfort with the machine prior to ambulation. A respiratory therapist must be present to manage the portable ventilator throughout the session and to ensure patient safety.

TABLE 60-4

SUMMARY OF MULTIDISCIPLINARY TEAM

FIGURE 60-3

Ambulation with a portable ventilator.

Rollators are a special version of a rolling walker with a seat used with the pulmonary disease patients. This type of walker allows a patient to rest when they are fatigued by folding down a seat. These walkers can be used at any level as they provide upper extremity weight bearing to allow for accessory muscle use to assist with breathing and provide an increased base of support to decrease the risk of falling.

SUMMARY

Skeletal muscle wasting occurs rapidly in the critically ill patient. The harmful consequences of this deconditioning stress the importance of early mobility and rehabilitation. Rehabilitation has been found to be safe and effective, but patients must receive individualized treatment plans, based on their age, disease process, and anticipated rate of recovery. The goal of restoring function, independence, and improving a patient's quality of life can best be accomplished using a multidisciplinary, multifaceted approach.

REVIEW QUESTIONS

1. **The functional limitation of ARDS survivors is mainly due to**
   - **A.** Muscle weakness
   - **B.** Severe dyspnea
   - **C.** Social isolation
   - **D.** Cognitive dysfunction

2. **What is the strongest risk factor for CIM?**
   - **A.** Older age
   - **B.** Steroids and paralytic agents
   - **C.** Underlying sepsis
   - **D.** Diabetes

3. **What had a strong correlation with shortened weaning time in the study by Martin et al?**
   - **A.** Whole body strength
   - **B.** Inspiratory muscle strength
   - **C.** Upper body strength

4. **Which of the following is a cognitive deficit found in patients who are chronically on mechanical ventilation?**
   - **A.** Orientation
   - **B.** Long-term memory
   - **C.** Short-term memory
   - **D.** All of the above

5. **What is an absolute contraindication to early mobility?**
   - **A.** Unstable angina
   - **B.** Morbid obesity
   - **C.** Multiple IV lines and tubes
   - **D.** Multiple comorbidities

ANSWERS

1. A. ARDS survivors have muscle wasting and weakness leading to significant morbidity. The cause for the weakness is multifactorial. These patients have a decreased 6-min walk distance and an impaired quality of life. Patient's lung volumes and spirometric measurements were within normal limits by 6 months. Patients also did not experience significant dyspnea or require oxygen.
2. B. CIM is characterized by flaccid muscle weakness and failure to wean from the ventilator. The strongest risk factor is the use of combination of glucocorticoids and neuromuscular blockers. This combination of medications is associated with a prolonged hospital course. It is reversible after the course of a few months and intensive rehab. It may be difficult to differentiate between CIP, which is associated with sepsis and affects sensory function.
3. C. In our study there was a strong correlation between upper limb strength and weaning time.[8] This was seen in other studies in different patient populations. This may be due to the strengthening of the pectoralis muscles, which have both inspiratory and expiratory function.
4. D. Patients on mechanical ventilation can experience all of the cognitive deficits including orientation, memory, language, and reasoning. Short-term memory is the most common deficit. All of these are contributors to a patient's general psychological dysfunction. Immobility, severity of illness, and inability to speak may contribute to psychological dysfunction. Altering reversible factors such as speech and immobility may benefit the patient. Also altering the environment and enhancing social interaction can benefit, as well as the use of anxiolytics and antidepressants.
5. A. The absolute contraindications to early mobility are listed in Table 60-2 and include unstable angina, uncontrolled heart failure, acute PE, unstable fractures, and hemodynamic instability. The other items listed are some barriers to early mobility, but should not preclude it. Early mobility can decrease the complications related to prolonged bed rest and decreased length of hospital stay.

Common Pharmacy Calculations in Adults

Ideal body weight (kg)

$IBW_{male} = 50 + (2.3 \times \text{height in inches over 60 in.})$

$IBW_{female} = 45.5 + (2.3 \times \text{height in inches over 60 in.})$

Adjusted body weight (kg)

ABW = 0.4 (actual body weight − ideal body weight)

Equivalent conversions

1 kilogram = 2.2 pounds	1 inch = 2.54 centimeters
1 kilogram = 1,000 grams	1 gram = 1,000 miligrams
1 milligram = 1,000 micrograms	1 microgram = 1,000 nanograms

Cockcroft and Gault calculation- used to estimate creatinine clearance

$$\text{CrCl} = \frac{(140 - \textit{age}) \times \text{ideal body weight (use ABW if obese)}}{\text{Serum Cr} \times 72} \text{ (females} \times 0.85)$$

Corrected serum calcium for albumin level

Corrected calcium = serum calcium + 0.8 (4−serum albumin)

Corrected phenytoin level for hypoalbuminemia and renal failure

Hypoalbuminemia

$$\text{Corrected serum phenytoin} = \frac{\text{C (observed)}}{(0.2 \times \text{albumin}) + 0.1}$$

C (observed) = observed serum phenytoin concentration in hypoalbuminemic patients

Renal failure

$$\text{Corrected serum phenytoin} = \frac{\text{C } (\textit{observed})}{(0.1 \times \text{albumin}) + 0.1}$$

C (observed) = observed serum phenytoin concentration in renal failure patients

APPENDIX B

KAZUMI MORITA

Dosages of Commonly Prescribed Antimicrobial Agents in the ICU

	USUAL DOSE	CrCl (mL/min)	DOSAGE ADJUSTMENT
Antibacterials			
Ampicillin	250 mg–2 g IV q4–6h	>50	250 mg–2 g IV q6h
		10–50	250 mg–2 g IV q6–12h
		<10	250 mg–2 g IV q12–24h
		HD	250 mg–2 g IV q12–24h[b]
Ampicillin-sulbactam	1.5–3 g IV q6h	>30	No adjustment necessary
		15–30	1.5–3 g q12h
		<15	1.5–3 g q24h
		HD	1.5–3 g q24h[b]
Azithromycin	500 mg IV/PO q24h × 24–48 h, then 250–500 mg IV/PO q24h No renal adjustment necessary		
Aztreonam	500 mg–2 g IV q12–6 h	>30	No adjustment necessary
		10–30	Load with 1–2 g, then 500 mg–1 g IV q12–6 h
		<10	Load with 1–2 g, then 250–500 mg IV q12–6 h
		HD	Dose for CrCl<10<+supplemental dose 250–500 mg after HD
Cefazolin	500 mg–2 g IV q8h	>35	No adjustment necessary
		10–35	250 mg–1 g q12h
		<10	250 mg–1 g q24h
		HD	2 g after each HD
Cefepime	1–2 g IV q12h	>60	No adjustment necessary
		30–60	1–2 g q24h
		11–29	500 mg–1 g q24h
		<11	250–500 mg q24h
		HD	250–500 mg q24h[b]
	2 g IV q8h (neutropenic fever)	>60	No adjustment necessary
		30–60	2 g q12h
		11–29	2 g q24h
		<11	1 g q24h
		HD	1 g q24h[b]
Cefotaxime	1–2 g IV q6–8h	>50	No adjustment necessary
		10–50	1–2 g q8–12 h
		<10	1–2 g q24h
		HD	1–2 g q24h[b]

	USUAL DOSE	CrCl (mL/min)	DOSAGE ADJUSTMENT
Ceftazidime	1–2 g IV q8h	>50	No adjustment necessary
		30–50	1–2 g q12h
		10–30	1–2 g q24h
		<10	1–2 g q48–72 h
		HD	1–2 g after each HD
Ceftriaxone	1–2 g IV q24h	No adjustment necessary	
	2 g IV q12h (meningitis)	No adjustment necessary	
Ciprofloxacin	200–400 mg IV q12–8 h	>30	No adjustment necessary
		5–29	200–400 mg q18–24 h
		HD	200–400 mg q24h[b]
Colistin methane sulphonate (Colistimethate)	5 mg/kg/day in two to four divided doses	Scr <1.3	No adjustment necessary
		Scr 1.3–1.5	2.5–3.8 mg/kg/day in two divided doses
		Scr 1.6–2.5	2.5 mg/kg/day in one to two divided doses
		Scr >2.5	1.5 mg/kg q36h
		HD	1.5 mg/kg q24h[b,c]
Daptomycin	4 or 6 mg/kg IV q24h	≥30	No adjustment necessary
		<30	4 or 6 mg/kg IV q48h
		HD	4 or 6 mg/kg IV q48h
Doripenem	500 mg IV q8h	>50	No adjustment necessary
		30–50	250 mg q8h
		11–29	250 mg q12h
		HD	250 mg q12–24 h[b,c]
Imipenem-cilastatin	500 mg IV q6h	≥71	≥70 kg: 500 mg q6h 60–69 kg: 500 mg q8h 50–59 kg: 250 mg q6h 40–49 kg: 250 mg q6h 30–39 kg: 250 mg q8h
		41–70	≥70 kg: 500 mg q8h 60–69 kg: 250 mg q6h 50–59 kg: 250 mg q6h 40–49 kg: 250 mg q8h 30–39 kg: 125 mg q6h
		21–40	≥70 kg: 250 mg q6h 60–69 kg: 250 mg q8h 50–59 kg: 250 mg q8h 40–49 kg: 250 mg q12h 30–39 kg: 125 mg q8h
		6–20	≥70 kg: 250 mg q12h 60–69 kg: 250 mg q12h 50–59 kg: 250 mg q12h 40–49 kg: 250 mg q12h 30–39 kg: 125 mg q12h
	HD: 250 mg q12h[b]		
Levofloxacin	500–750 mg IV/PO q24h	≥50	No adjustment necessary
		20–49	500–750 mg q48h
		10–19	500–750 mg × 1, then 250–500 mg q48h
		HD	500–750 mg × 1, then 250–500 mg q48h[b]
Linezolid	600 mg IV/PO q12h	No adjustment necessary	
Meropenem	1 g IV q8h	>50	No adjustment necessary
		26–50	1 g q12h
		10–25	500 mg q12h
		<10	500 mg q24h
		HD	500 mg q24h[b]
	2 g IV q8h (meningitis)	>50	No adjustment necessary
		26–50	2 g q12h
		10–25	1 g q12h
		<10	1 g q24h
		HD	1 g q24h[b]

(*continued*)

	USUAL DOSE	CrCl (mL/min)	DOSAGE ADJUSTMENT
Metronidazole	500 mg IV/PO q8h	No adjustment necessary	
Moxifloxacin	400 mg IV/PO q24h	No adjustment necessary	
Nafcillin or oxacillin	2 g IV q4–6 h	No adjustment necessary	
Piperacillin-tazobactam	4.5 g IV q8h or 3.375 g IV q6h	>40 20–40 <20 HD	No adjustment necessary 2.25 g IV q6h 2.25 g IV q8h 2.25 g IV q12h, supplement 0.75 g after each HD
	Nosocomial pneumonia 4.5 g IV q6h	>40 20–40 <20 HD	No adjustment necessary 3.375 g IV q6h 2.25 g IV q6h 2.25 g IV q8h, supplement 0.75 g after each HD
Antifungals			
Amphotericin products			
Conventional	0.3–1 mg/kg IV q24h Maximum: 1.5 mg/kg/day	No adjustment necessary	
Liposomal	3–6 mg/kg IV q24h	No adjustment necessary	
Lipid complex	5 mg/kg IV q24h	No adjustment necessary	
Anidulafungin	200 mg × 1, then 100 mg IV q24h No renal adjustment necessary Esophageal candidiasis: 100 mg × 1, then 50 mg IV q24h No renal adjustment necessary		
Caspofungin[d]	70 mg × 1, then 50 mg IV q24h (No loading dose required for esophageal candidiasis) No renal adjustment necessary		
Fluconazole	200–800 mg IV/PO q24h	>50 ≤50 HD	No adjustment necessary 50% of normal dose q24h Normal dose after each HD
Itraconazole[d]	200–400 mg/day PO (divide doses in two if >200 mg)	No adjustment necessary	
Micafungin	100 mg IV q24h 150 mg IV q24h (esophageal candidiasis)	No adjustment necessary No adjustment necessary	
	50 mg IV q24h (antifungal prophylaxis in hematopoietic stem cell transplantation)	No adjustment necessary	
Voriconazole[d]			
IV	6 mg/kg q12h × 2, then 4 mg/kg q12h CrCl<50: no renal adjustment necessary. Cyclodextrin vehicle can accumulate. Use only when benefits outweigh risks		
PO	≥40 kg: 400 mg q12h × 2, then 200 mg q12h <40 kg: 200 mg q12h × 2, then 100 mg q12h No renal adjustment necessary		

[a]Please refer to the prescribing information for each drugs for details

[b]Dose after dialysis on dialysis days

[c]Limited dosing information available

[d]May require hepatic adjustment

KAZUMI MORITA

Antibiotic Dosing in Critically Ill Adult Patients Receiving Continuous Renal Replacement Therapy (CRRT)

	DOSAGE BY TYPE OF CRRT	
DRUG	**CVVH**	**CVVHD OR CVVHDF**
Amphotericin B formulation		
Deoxycholate	0.4–1 mg/kg q24h	0.4–1 mg/kg q24h
Lipid complex	3–5 mg/kg q24h	3–5 mg/kg q24h
Liposomal	3–5 mg/kg q24h	3–5 mg/kg q24h
Acyclovir	5–7.5 mg/kg q24h	5–7.5 mg/kg q24h
Ampicillin-sulbactam[a]	3 g q12h	3 g q8h
Aztreonam	1–2 g q12h	2 g q12h
Cefazolin	1–2 g q12h	2 g q12h
Cefepime	1–2 g q12h	2 g q12h
Cefotaxime	1–2 g q12h	2 g q12h
Ceftazidime	1–2 g q12h	2 g q12h
Ceftriaxone	2 g q12–24h	2 g q12–24h
Clindamycin	600–900 mg q8h	600–900 mg q8h
Ciprofloxacin[b]	200 mg q12h	200–400 mg q12h
Colistin	2.5 mg/kg q48h	2.5 mg/kg q48h
Daptomycin	4 or 6 mg/kg q48h	4 or 6 mg/kg q48h
Fluconazole[b]	200–400 mg q24h	400–800 mg q24h[c]
Imipenem-cilastatin[d]	250 mg q6h or 500 mg q8h	250 mg q6h, 500 mg q8h, or 500 mg q6h
Levofloxacin[b]	250 mg q24h[e]	250 mg q24h[e]
Linezolid[b]	600 mg q12h	600 mg q12h
Meropenem	1 g q12h	1 g q12h
Moxifloxacin	400 mg q24h	400 mg q24h
Nafcillin or oxacillin	2 g q4–6h	2g q4–6h
Piperacillin-tazobactam[f]	2.25 g q6h	2.25–3.375 g q6h
Ticarcillin-clavulanate[g]	2 g q6–8h	3.1 g q6h
Vancomycin	1 g q48h[e]	1 g q24h[e]
Voriconazole[h]	4 mg/kg p.o. q12h	4 mg/kg p.o. q12h

Note: all dosages are administered intravenously, unless otherwise indicated. The recommendations assume an ultrafiltration rate of 1 L/h, a dialysate flow rate of 1 L/h, and no residual renal function. *CAVHD* continuous arteriovenous hemodialysis; *CVVH* continuous venovenous hemofiltration; *CVVHD* continuous venovenous hemodialysis; *CVVHDF* continuous venovenous hemodiafiltration

Source: adapted from Trotman RL, Williamson JC, Shoemaker DM, Salzer WL. Antibiotic dosing in critically ill adult patients receiving continuous renal replacement therapy. *Clin Infect Dis*. 2005;41:1159-1166

[a]Available commercially in a fixed ratio of 2 mg of ampicillin to 1 mg of sulbactam

[b]The switch from intravenous to the oral formulation is possible when appropriate

[c]A dose of 800 mg is appropriate if the dialysate flow rate is 2 L/h and/ or if treating fungal species with relative azole resistance, such as *Candida glabrata*

[d]Available commercially in a fixed ratio of 1:1 mg

[e]Recommended loading dose is 15–20 mg/kg of vancomycin and 500 mg of levofloxacin

[f]Available commercially in a fixed ratio of 8 mg to 1 mg

[g]Available commercially in a fixed ratio of 30 mg to 1 mg

[h]The oral bioavailability of voriconazole is estimated to be 96%. Consider two loading doses of 6 mg/kg p.o. q12h. See referenced article for details on contraindications associated with the intravenous formulation in patients with renal failure

KAZUMI MORITA

Aminoglycoside Dosing and Monitoring in Adults

DOSING METHODS OF AMINOGLYCOSIDES

Multiple-daily ("traditional") dosing
The traditional dosing method recommended by the manufacturer
High-dose, extended interval (once-daily) dosing
This dosing method incorporates pharmacodynamic concepts (e.g., concentration-dependent killing and postantibiotic effect) of aminoglycosides
It is generally considered as efficacious as traditional dosing with possible less toxicity
Gram-positive synergy dosing (usually with gentamicin or streptomycin)
Used concomitantly with a cell wall–inhibiting agent (e.g., beta-lactams) to achieve synergistic effects for gram-positive infections

INITIAL DOSING FOR MULTIPLE-DAILY DOSING (INCLUDING GRAM-POSITIVE SYNERGY DOSIN(_,

Creatinine clearance (mL/min)	Gentamicin/tobramycin[a,b]		Amikacin[a,b]
	Gram-negative infection	Gram-positive synergy	Gram-negative infection
≥60	1.5–2 mg/kg q8h	1 mg/kg q8h	5–7.5 mg/kg q8h
40–60	1.5–2 mg/kg q12h	1 mg/kg q12h	5–7.5 mg/kg q12h
20–40	1.5–2 mg/kg q24h	1 mg/kg q24h	5–7.5 mg/kg q24h
<20 or hemodialysis[c]	1.5–2 mg/kg when level <2 mg/L	1 mg/kg when level <1 mg/L	5–7.5 mg/kg when level <2 mg/L

MONITORING FOR MULTIPLE-DAILY DOSING (INCLUDING GRAM-POSITIVE SYNERGY DOSING)

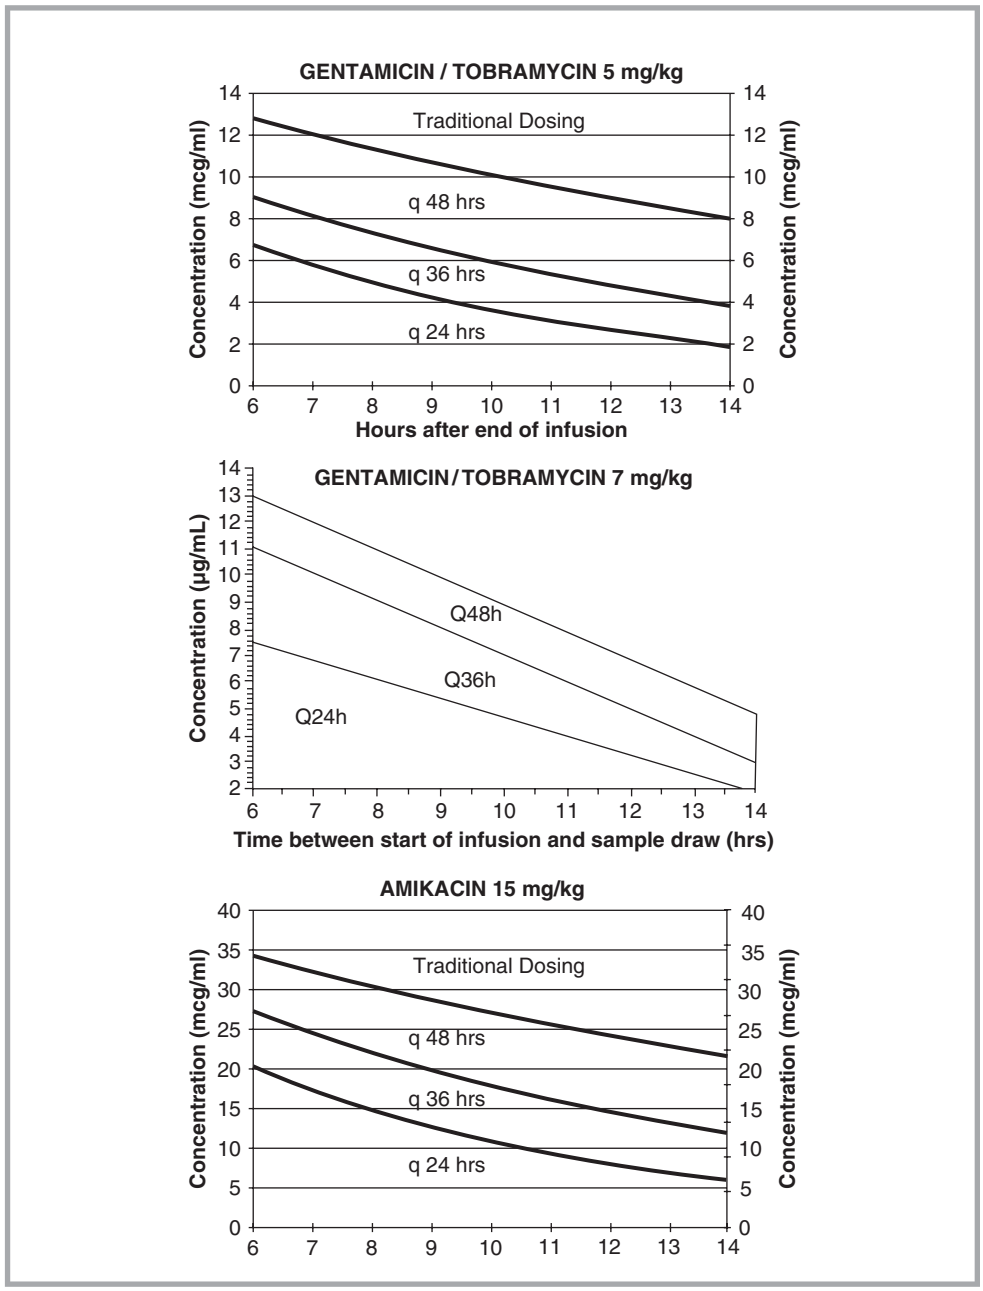
Timing of monitoring
- Draw "peak" and "trough" serum level around the third or fourth dose
  - Peak: 30-min after the 30-min infusion has been completed
  - Trough: immediately prior to the third or fourth dose
- Patient anticipated receiving therapy for ≥14 days should obtain a baseline audiometry to monitor for ototoxicity

Optimal concentration

	Gentamicin/tobramycin		Amikacin
	Gram-negative infection	Gram-positive synergy	Gram-negative infection
Peak	6–8 mg/L If life threatening: 8–10 mg/L	3–5 mg/L	6–8 mg/L If life threatening: 8–10 mg/L
Trough	<1–2 mg/L	<1 mg/L	<4–8 mg/L

Frequency of monitoring
- After therapeutic level is achieved, recheck trough levels every 5–7 days until therapy is discontinued
- Scr/BUN should be obtained at least 2 times a week to assess any changes in renal function
- Drug levels should be obtained whenever there is a change in renal function

(*continued*)



INITIAL DOSING FOR ONCE-DAILY DOSING[d]

Creatinine clearance (mL/min)	Tobramycin/gentamicin[a]	amikacin[a]
≥60	5 or 7 mg/kg q24h	15 or 20 mg/kg q24h
40–59	5 or 7 mg/kg q36h	15 or 20 mg/kg q36h
21–39	5 or 7 mg/kg q48h	15 or 20 mg/kg q48h
≤20 or dialysis	Not recommended. Use multiple-daily dosing	

MONITORING OF ONCE-DAILY DOSING

- Obtain a single random drug level at approximately 8–12 h after the initial dose, and then evaluate the interval based on the following nomograms. Repeat the drug level 1–2 times weekly
- If amikacin 20 mg/kg dose is used, multiply the reported drug level by 0.75 and plot the amikacin 15 mg/kg nomogram
- If 3–12 h level is undetectable and infection is not responding, consider traditional dosing

(Nomogram charts from Extended-interval aminoglycoside dosing (2008), Barnes-Jewish Hospital at Washington University Medical Center. Available from http://id2.wustl.edu/~casabar/downloads/antibioticstewardship08.pdf. Accessed April 2009. Reprinted with permission)

[a]Use of ideal body weight (IBW) for determining the mg/kg/dose appears to be more accurate than dosing on the basis of total body weight (TBW). In morbid obesity, dosage requirement may best be estimated using a dosing weight of IBW + 0.4 (TBW-IBW)

[b]Patients with serious infection or renal impairment may benefit from a loading dose

[c]Approximately 30% of aminoglycosides are removed by hemodialysis. Administer dose after dialysis and follow levels

Gentamicin/tobramycin: 2–2.5 mg/kg for gram-negative infection, 1.5–2 mg/kg for synergy dosing

Amikacin: 7.5–10 mg/kg

[d]This dosing is not recommended for the following patient populations: pregnancy, anasarca, dialysis, endocarditis, creatinine clearance <20 mL/min, cystic fibrosis, >20% body surface area burns, mycobacterial infections

KAZUMI MORITA

Vancomycin Dosing and Monitoring in Adults

INITIAL VANCOMYCIN DOSING

Creatinine clearance (mL/min)	Dose[a]	Dosing interval
>80	15 mg/kg	Q12h
65–80	Use actual body weight	Q12–18 h
50–64	Initial maximum dose: 2 g	Q24h
35–49		Q24–36 h
21–34		Q48h
Hemodialysis (HD)	Dosing interval varies based on the type of HD filter used, residual renal function etc Generally dosed based on levels. Redose with 15 mg/kg when level ≤15–20	

MONITORING

Timing of monitoring	Trough concentration (just prior to the next dose) approximately after the fourth dose (steady state) Monitoring of peak concentration is unnecessary
Optimal concentration	10–20 mg/L Minimum serum trough concentrations should always be maintained above 10 mg/L to avoid development of resistance For complicated infections such as bacteremia, endocarditis, osteomyelitis, meningitis, and hospital-acquired pneumonia caused by *Staphylococcus aureus,* serum trough concentrations of 15–20 mg/L are recommended
Frequency of monitoring	Frequent monitoring (more than one trough) for short course or lower intensity dosing (goal trough <15 mg/L) is not recommended For goal trough 15–20 mg/L, once-weekly monitoring is recommended for hemodynamically stable patients. More frequent or daily trough monitoring is advisable in patients who are hemodynamically unstable

[a]Patients with serious infection may benefit from a loading dose of 20–25 mg/kg (maximum dose 2 g)

APPENDIX J

ANNA M. WODLINGER JACKSON

Intravenous Antihypertensive Medications

MEDICATION	MECHANISM OF ACTION/ONSET/DURATION	DOSE/TITRATION RECOMMENDATIONS	ADVERSE EFFECTS	ADDITIONAL NOTES
Clevidipine	Dihydropyridine calcium channel blocker Onset: 2–4 min Duration: 5–15 min	Begin 1–2 mg/h Double in short intervals (90 s) initially As BP approaches goal, increase in smaller increments of dose and larger increments in time (5–10 min) Usual effective dose 4–6 mg/h (maximum 16–32 mg/h)	Avoid in patients with soy or egg allergies	Cost – more expensive than older agents Formulation is an emulsion (0.2 g lipid per mL) Doses >21 mg/h should not be infused for >24 h Minimal experience with infusions of any rate beyond 72 h
Enalaprilat	Angiotensin-converting enzyme inhibitor Onset: 15 min (may take up to 4 h with initial dose) Duration: 6 h	IV push over 5 min Initial dose: 0.625 mg (if Clcr <30 mL/min) Usual dose 1.25–2.5 mg Q6H Can repeat after 6 h Maximum: 5 mg (per dose)	Hyperkalemia Renal dysfunction Cough Angioedema	Not recommended as first-line therapy for HTN urgency or emergency
Esmolol	β1 (and β2 at higher doses) blockade Onset: 2–10 min Duration: 10–30 min	Starting: 50 μg/kg/min Titrate up by 50 μg/kg/min every 5 min Maximum: 300 μg/kg/min	Bradycardia	Recommended for use in patients experiencing myocardial infarction, aortic dissection Use with caution in patients with pheochromocytoma (without concomitant alpha blockade)
Fenoldopam	Selective postsynaptic dopamine receptor (D_1) agonist Onset: minutes (steady state in 15 min) Duration: 5–10 min	Starting: 0.1–0.3 μg/kg/min Titrate up by 0.05 μg/kg/min every 15 min Maximum: 1.6 μg/kg/min	Contains sodium metabisulfite which may cause allergic-type reactions Reflex tachycardia	Cost – more expensive than older agents Only indicated for short-term (up to 48 h) management Use with caution in patients with glaucoma or intraocular HTN
Hydralazine	Direct arteriolar vasodilator Onset: 5–20 min Duration: 1–4 h (varies depending on the acetylator status of the patient)	Can be given intermittent IV push Initial dose: 10 mg Can repeat after 2–4 h Up to: 50 mg/dose	Reflex tachycardia SLE (at higher doses)	Can be used for eclampsia
Labetalol	Nonselective β (1 and 2)- and α-blockade Onset: 2–5 min Duration: 3–6 h	Initial: 20 mg *slow* IV push Can repeat injection (up to 40–80 mg) after 10 min (up to 300 mg *total*) Continuous infusion: initial rate 0.5 mg/min (6 mg/min)	Bradycardia	No consensus on recommendations for prolonged infusions (>24 h) of high doses (6 mg/min)
Metoprolol	β1 (and β2 at higher doses) blockade Onset: minutes Duration: 3–6 h	5 mg IV push Can be repeated Q10 minutes ×3 during AMI Scheduled Q6H in patients unable to take oral	Bradycardia	Recommended for use in patients experiencing myocardial infarction Use with caution in patients with pheochromocytoma (without concomitant alpha blockade)

Nicardipine	Dihydropyridine calcium channel blocker Onset: 5–10 min Duration: 15–30 min (up to 3 h)	Initial: 5 mg/h Titrate up by 2.5 mg/h every 15 min Maximum: 15 mg/h		Cost – more expensive than older agents Change infusion site every 12 h to minimize the risk of peripheral venous irritation
Nitroglycerin	Relaxation of vascular smooth muscle (venous>>arteriole) Onset: 2–5 min Duration: 3–5 min	Starting: 5 μg/min Titrate up every few minutes Maximum: 200 μg/min	Headache	Tolerance may develop if infusion is continued for >24 h (may require dose titration) Use with caution in patients who recently took phosphodiesterase-5 inhibitors (sildenafil, tadalafil, vardenafil)
Nitroprusside	Peripheral vasodilation of venous and arteriolar smooth muscle Onset: immediate Duration: 1–2 min	Starting: 0.3 μg/kg/min Titrate up by 0.1 μg/kg/min every few minutes Maximum: 10 μg/kg/min	Cyanide toxicity (liver dysfunction) Thiocyanate toxicity (renal dysfunction)	Toxicity associated with prolonged use (>48 h), high dose (>4 μg/kg/min) and/or organ dysfunction (renal/liver)

APPENDIX K

ANNA M. WODLINGER JACKSON

Antiarrhythmia Medications – Overview

CLASS	DRUG	USE	DOSE	DOSE ADJUSTMENTS	COMMON ADRS, DRUG INTERACTIONS AND OTHER NOTES
Ia	Disopyramide (Norpace)	*AF-CV* (class IIb) *AF-M* (class IIb)	PO <50 kg: 100 mg q6h or 200 mg q12h (CR) >50 kg: 150 mg q6h or 300 mg q12h (CR) Maximum: 400 mg q6h	*Renal impairment* 100 mg given at interval of CrCl 30–40: q8h, CrCl 15–30: q12h, CrCl <15: q24h Or alter doses: CrCl 30–40: ↓ dose 50%, CrCl 15–30: ↓ dose 75% *Hepatic impairment* 100 mg q6h or 200 mg q12h (CR)	ADR Anticholinergic effects (urinary retention, dry mouth, glaucoma, constipation), TdP, hypotension, CHF, depress LV contractility. DI QT prolonging drugs Major CYP 3A4 substrate *Avoid in CAD, CHF, AV block (apply to all Ia, Ic antiarrhythmics)*
	Procainamide (Procanbid)	*AF-CV* (class IIb) *AF-M* (class IIb) (no longer recommend) *Vent. Arrh* (class IIa)	IV LD: 15–18 mg/kg over 25–30 min IV MD: 1–4 mg/min cont. inf. PO: 50 mg/kg/24 h in divided daily doses (depending on dosage formulation used) (maximum 5 g/24 h) Conversion of IV: PO ≈1:1	*Severe renal or cardiac impairment* IV: LD 12 mg/kg PO: CrCl 10–50: q6–12 h, CrCl <10: q8–24 h *Hepatic impairment:* reduce dose by 50%	ADR: hypotension, drug induced SLE (+ ANA in 50% patients), N/V, TdP, blood dyscrasias, agranulocytosis DI: QT prolonging drugs Therapeutic range: procain. 4–10 μg/mL NAPA 15–25 μg/mL
	Quinidine	*AF-CV* (class IIb) (with rate-control drugs. Use with caution) *AF-M* (less effective)	Test dose PO or IM 200 mg given several hours before full dosage PO: sulfate 100 mg–600 mg/dose q4–6 h (maximum daily dose 3–4 g) Gluconate: 324–972 mg q8–12 h Quinidine gluconate 267 mg>quinidine sulfate 200 mg	*Renal impairment* CrCl<10: administer 75% of dose *Hepatic impairment* May administer larger LD and reduce MD dose by 50%	ADR: TdP, hypotension, N/D, hepatic dysfunction, thrombocytopenia, hemolytic anemia, cinchonism (tinnitus, hearing loss,, headache, nausea, dizziness) DI: Digoxin; QT prolonging drugs Major CYP 3A4 substrate
Ib	Lidocaine (Xylocaine)	*Vent. Arrh* (class IIb) (preferred if AMI)	Initial: 1–1.5 mg/kg may repeat 0.5–0.75 mg/kg bolus every 5 min for a maximum of three doses or 3 mg/kg Maintenance: 1–4 mg/min IV cont. inf.	Decrease dose in patients with CHF, shock, or hepatic disease Toxic metabolite accumulates in renal dysfunction	ADR: neurotoxic effect: drowsiness, dizziness, confusion, slurred speech, paresthesias, visual disturbance, seizures Therapeutic range: 1.5–5 mg/L
	Mexiletine (Mexitil)	*Vent. Arrh (LQT3/TdP)* (class IIb)	Initial 200 mg q8h PO, may adjust dose every 2–3 days; Usual dose 200–300 mg q8h Maximum: 1.2 g/day	*Hepatic impairment:* reduce to 25–30 % of usual dose	ADR: lightheaded, dizziness, incoordination, tremor, ataxia, GI distress, N/V, hepatotoxic
Ic	Flecainide (Tambocor)	*AF-CV* (class I for <7 days, class IIb for >7 days) *AF-M*: IIa Life-threatening vent arrh.	AF: 50 mg q12; maximum: 300 mg/day Vent Arrh: 100 mg q12; increase by 50–100 mg/day q4 days to a maximum of 400 mg/day	*Renal*: GFR <35 mL/min – initial dose 50 mg q12 *Hepatic*: monitor	ADRs: visual disturbances, dizziness, dyspnea DI: major substrate 2D6 Notes: avoid use in patients with structural heart disease

	Propafenone (Rythmol)	*AF-CV* (class I)*AF-M* (class IIa)	IR: 150 mg q8; increase at 3–4 day intervals (maximum 300 mg q8h) ER: 225 mg q12; maximum 325–425 mg q12; increase at 5 day intervals	*Hepatic*: dose reduce; no guidelines Dose reduce for patients with widened QRS or second or third degree AV block	ADRs: dizziness, N, V DI: reduce digoxin by 25% Notes: avoid use in patients with structural heart disease
III	Amiodarone (Cordarone)	*AF-CV* (class IIa) *AF-M* (I) *Vent Arrh* (class IIa)	[a]Must load before maintenance (goal LD: 3–6 g IV or 6–10 g PO total given over several days) PO: 800–1,600 mg/day in 1–2 doses × 1–3 weeks, when adequate control is reached, decrease to maintenance: 400 mg /day for ventricular (200 mg/day for atrial) IV: bolus 300 mg (pulseless VT/VF) or 150 mg (stable VT/SVT) (can repeat bolus prn) then 1 mg/min × 6 h then 0.5 mg/min. Can continue infusion up to 4 weeks or convert to PO ASAP		ADRs: photosensitivity/blue–gray skin discoloration, pulmonary toxicity, GI upset (esp. w/ doses >400 mg p.o.), bradycardia, hypotension (esp. w/ IV bolus), hepatotoxicity, hyper/hypothyroidism, corneal microdeposits (in 90% of patients, does not cause visual changes). Rarely causes TdP DI: warfarin, digoxin (reduce dose by 50%) Note: preferred agent in patients with structural heart disease
	Dofetilide (Tikosyn)	*AF-CV* (class I) *AF-M*	Starting dose: 500 μg BID Measure QTc 2–3 h after initial dose and for two to five doses, adjust dose accordingly or D/C if QTc >500 ms	Adjusted starting doses ClCr 40–60 mL/min – 250 μg BID ClCr 20–39 mL/min – 125 μg BID ClCr <20 mL/min – CI	ADRs: TdP, HA, dizziness DI: CYP3A4 inhibitors, use of drugs that prolong QT interval, many others *Notes: special program–restricted use*
	Ibutilide (Corvert)	*AF-CV*: (class I) *AF-M*: not rec	<60 kg: 0.01 mg/kg over 10 min >60 kg: 1 mg over 10 min May repeat ×1 after 10 min	Contraindicated if QTc >440 ms	ADRs: TdP DI: do not use with class Ia or other drugs that prolong QT interval
	Sotalol (Betapace)	*AF-CV* (class III-NR) *AF-M* (class IIa) *Vent Arrh* (class IIa) for life-threatening VT	Initial 80 mg BID; increase dose at 3 day intervals Maximum dose AF: 240–320 mg/day Vent arrh: up to 480–640 mg/day	AF ClCr >60: q12 40–60: q24 <40: CI Vent arrh ClCr >60 mL/min: q12 30–60: q24 10–30: q36–48	ADRs: bradycardia, fatigue, dizziness, dyspnea, weakness, dizziness, N/V DI: other QT prolonging drugs, CCB, antacids, other beta-blockers Notes: do not substitute betapace for betapace AF. Initiate dosing in hospital setting. Can use in structural heart disease, but not HF

AF atrial fibrillation; *CV* for cardioversion; *M* for maintenance of NSR; Class=recommendations based on ACC/AHA guidelines; *ADR* = adverse drug reaction; *DI* = drug interactions; *TdP* = Torsades de Pointes; *CR* = controlled Release; *IR* = Immediate Release; *ER* = Extended Release; *GFR*=glomerular filtration rate

[a]First line therapy

ANNA M. WODLINGER JACKSON,
AND COURTNEY D. VINCENT

Indications and Dosing for Heparin

Contraindications
Absolute

- Known active or history of heparin-induced thrombocytopenia (HIT)
- Active bleeding or significant risk of bleeding

Relative

- Thrombocytopenia (platelets <50,000)

Monitoring

- Activated partial thromboplastin time (aPTT) – at baseline, as appropriate during titration and daily once stable
- Hemoglobin (Hgb), hematocrit (Hct) and Platelets – at baseline and at least every other day (clinical evidence of HIT)
- Signs/symptoms of bleeding
- Signs/symptoms of thrombosis (clinical evidence of HIT)

Indications and Dosing for Treatment
Dosing calculations should be based on *total body weight.*

INITIAL DOSING

INDICATIONS	INITIAL BOLUS	INITIAL INFUSION
	ROUND TO THE NEAREST 100 UNITS	ROUND TO THE NEAREST 10 UNITS/H
Venous thrombosis Pulmonary embolism (no alteplase (tPA)) Atrial fibrillation (with thrombus) Acute arterial emboli/thrombosis	80 Units/kg Maximum: 10,000 Units	18 Units/kg/h Maximum 2,000 Units/h
Pulmonary embolism or extensive proximal deep venous thrombosis (DVT) with tPA administration	Do not administer following tPA infusion	18 Units/kg/h Hold during tPA infusion and restart following end of infusion
Mechanical heart valve – new Bioprosthetic valve (mitral) – new	None	12 Units/kg/h Maximum 1,000 Units/h

INDICATIONS	INITIAL BOLUS	INITIAL INFUSION
	ROUND TO THE NEAREST 100 UNITS	ROUND TO THE NEAREST 10 UNITS/H
Mechanical heart valve – old	80 Units/kg Maximum: 10,000 Units None if INR >2.0	18 Units/kg/h
Acute coronary syndromes Atrial fibrillation (no thrombus)	60 Units/kg Maximum: 4,000 Units	12 Units/kg/h Maximum 1,000 Units/h

Please refer to your hospital anticoagulation guidelines for dosing adjustments

Indications and Dosing For Prophylaxis

RECOMMENDATIONS BASED ON CLINICAL GROUP AND LEVEL OF VTE RISK

INDICATION	HEPARIN DOSE
Surgical/laparoscopic procedures *Moderate risk* – benign GYN, major GU, or venous thromboembolism (VTE) risk factor *High risk* – major surgery, GYN or GU malignancy, or multiple VTE risk factors	*Moderate risk* – 5,000 Units SQ every 8 or 12 h *High risk* – 5,000 Units SQ every 8 h
Hip fracture surgery	5,000 Units SQ every 8 or 12 h
Elective spine surgery with VTE risk factor(s) – advanced age, malignancy, neurologic deficit, previous VTE, anterior surgical approach	5,000 Units SQ every 8 or 12 h
Acute spinal cord injury (when primary hemostasis is evident)	5,000 Units SQ every 8 h combined with intermittent pneumatic compression (IPC)
Burns with VTE risk factor(s) – advanced age, morbid obesity, extensive or lower extremity burns, lower extremity trauma, femoral venous catheter, prolonged immobility	5,000 Units SQ every 8 or 12 h
Acutely ill medical patients – CHF, severe respiratory disease, or confined to bed with one or more additional VTE risk factors	5,000 Units SQ every 8 or 12 h
Critical care patients with moderate VTE risk (i.e., medically ill or postoperative general surgery)	5,000 Units SQ every 8 or 12 h
Neurosurgery	*Major neurosurgery* – 5,000 Units SQ every 8 or 12 h may be used as alternative to IPC *Major neurosurgery with high thrombosis risk* – 5,000 Units SQ every 8 or 12 h combined with graduated compression stockings (GCS) and/or IPC

RISK FACTORS FOR VTE

Surgery	Trauma (major trauma or lower extremity injury)
Immobility, lower extremity paresis	Cancer
Cancer therapy (hormonal, chemotherapy, radiotherapy, angiogenesis inhibitors)	Venous compression (tumor, hematoma, arterial abnormality)
Previous VTE	Increasing age
Pregnancy and postpartum period	Estrogen containing oral contraceptives or hormone replacement therapy
Selective estrogen receptor modulators (i.e., raloxifene)	Erythropoiesis stimulating agents
Acute medical illness	Inflammatory bowel disease
Nephrotic syndrome	Myeloproliferative disorders
Paroxysmal nocturnal hemoglobinuria	Obesity
Central venous catheterization	Inherited or acquired thrombophilia

COURTNEY D. VINCENT

Common Respiratory Agents Used in the Intensive Care Unit for Adults

AGENT	INDICATION	DOSE
Albuterol (Ventolin HFA®, Proventil HFA®, ProAir HFA®, AccuNeb®)	Treatment or prevention of bronchospasm in patients with reversible obstructive airway disease	*Solution for nebulization* Bronchospasm: 2.5 mg every 4–8 h as needed Quick relief: 1.25–5 mg every 4–8 h as needed Patients may require higher doses and more frequent administration of nebs including continuous nebulization *Metered-dose inhaler in mechanical ventilation* Bronchospasm: four to six puffs every 3–6 h Higher doses may be required for patients with acute bronchoconstriction
Levalbuterol (Xopenex®)	Treatment or prevention of bronchospasm in patients with reversible obstructive airway disease	*Solution for nebulization* Bronchospasm, quick relief: 0.63–1.25 mg every 6–8 h as needed Exacerbation of asthma (acute, severe) 1.25–2.5 mg every 20 min for three doses, then 1.25–5 mg every 1–4 h as needed
Ipratropium: (Atrovent HFA®,Atrovent®)	Bronchospasm associated with COPD, bronchitis, and emphysema	*Solution for nebulization* 0.5 mg 3–4 times/day with doses 6–8 h apart *Metered-dose inhaler in mechanical ventilation* Bronchospasm: four to six puffs every 3–6 h Higher doses may be required for patients with acute bronchoconstriction

(*continued*)

AGENT	INDICATION	DOSE
Combination of Ipratropium and Albuterol (DuoNeb®, Combivent®)	Treatment of COPD in patients who are currently on a regular bronchodilator who continue to have bronchospasm and require a second bronchodilator	*Solution for nebulization* Initial: 3 mL every 6 h (maximum: 3 mL every 4 h) *Metered-dose inhaler in mechanical ventilation* Bronchospasm: four to six puffs every 3–6 h Higher doses may be required for patients with acute bronchoconstriction
Budesonide (Pulmicort Respules®)	Maintenance and prophylactic treatment of asthma and COPD	*Solution for nebulization* 0.25 mg–2 mg/day as a single dose or divided twice daily Doses can be given up to every 6 h in patients with severe disease
Acetylcysteine (Mucomyst®)	Adjunctive mucolytic therapy in patients with respiratory diseases who have abnormal or viscous secretions	*Solution for nebulization:* 3–5 mL of 20% solution nebulized 3–4 times/day Patients should receive albuterol with administration
Dornase alfa (Pulmozyme®)	Management of patients to reduce viscosity and presence of large amounts of secretions	*Solution for nebulization*: 2.5 mg nebulized 1–2 times daily

COURTNEY D. VINCENT

Contrast Media Prophylaxis in Adults

Premedication is indicated for patients at a higher risk of developing an acute allergic reaction and require contrast media. The following regimens have been used to reduce the frequency and or severity of adverse reactions to contrast media.

Prednisone 50 mg by mouth 13, 7, and 2 h prior to contrast media
PLUS Diphenhydramine 50 mg by mouth, intravenously or intramuscularly 1 h prior to contrast media

or

Methylprednisolone 32 mg by mouth 12 and 2 h prior to contrast media.
Diphenhydramine 50 mg by mouth, intravenously or intramuscularly 1 h prior to contrast media can also be added to this regimen.

CHRISTINA RUGGIA-CHECK

Treatment of Anaphylaxis and Allergic Reactions in Adults

DRUG	DOSE	COMMENTS
Epinephrine	*IV single dose*: 0.1 mg over 5–10 min; 1:100,000 dilution given as 0.1 mg in 10 mL at 1 mL/min	IM dosing provides higher, more consistent, and more rapid peak blood levels than SQ administration
	IV infusion: 1–4 mcg/min	Use caution in patient taking beta-blocker since severe hypertension may occur due to unopposed alpha-adrenergic stimulation
	IM: 0.3–0.5 mg (0.3–0.5 mL of 1:1,000 dilution)	
IV fluids: normal saline or lactated ringers	1–2 L bolus concurrently with epinephrine infusion	
Diphenhydramine	25–50 mg q6h IV, IM, or orally	
Ranitidine	50 mg IV over 5 min	Histamine-2 blockers are effective in shock refractory to epinephrine, fluids, steroids, and histamine-1 blockers
Corticosteroids	*Hydrocortisone*: 250–500 mg IV	Highly recommended for patients with anaphylaxis
	Methylprednisolone: 125 mg IV	Methylprednisolone may be preferred for fluid restricted patients (i.e., cardiac or renal impairment) due to less fluid retention
Albuterol	*Single treatment*: 2.5–5 mg nebulized	Treatment of allergic bronchospasm
	Continuous nebulization: 5–10 mg/h	
Ipratropium bromide	*Single treatment*: 0.25–0.5 mg nebulized	May be added to albuterol for severe acute or severe refractory bronchospasm
Magnesium sulfate	2 g IV over 20 min	May be added to albuterol for severe refractory bronchospasm
Glucagon	1 mg IV every 5 min until hypotension resolves, followed by 5–15 mcg/min infusion	May be used in patients taking beta-blockers with hypotension refractory to fluids and epinephrine
Prednisone	40–60 mg/day (for outpatients: 3–5 days without taper)

CHRISTINA RUGGIA-CHECK

Management of Toxic Syndromes or Drug Toxicities in Adults[a]

TOXIC SYNDROME OR DRUG	TREATMENT OR ANTIDOTE
Acetaminophen	*Acetylcysteine*: oral dose: 140 mg/kg followed in 4 h by 70 mg/kg every 4 h for 17 doses IV dose: 150 mg/kg over 1 h followed by 50 mg/kg over 4 h then 100 mg/kg over 16 h
Alpha 2-Adrenergic Agonists (i.e., clonidine, tizanidine)	Dopamine and norepinephrine for hypotension. Atropine for symptomatic bradycardia
Antipsychotics (i.e., chlorpromazine, clozapine, haloperidol, risperidone)	Hypotension refractory to fluid resuscitation may be treated with direct alpha-adrenergic agonist (i.e., norepinephrine, phenylephrine). After correction of electrolyte abnormalities, sodium bicarbonate and lidocaine for ventricular tachydysrhythmias associated with QRS prolongation. Magnesium, isoproterenol, and overdrive pacing for torsades de pointes. Avoid class IA, IC, and III antiarrhythmics
Benzodiazepines (i.e., alprazolam, clonazepam, lorazepam)	*Flumazenil*: 0.2 mg IV over 30 s. If the desired level of consciousness is not attained, 0.3 mg IV over 30 s can be given. Repeat doses of 0.5 mg IV over 30 s may be given at 1 min intervals up to a cumulative dose of 3 mg. Patients with a partial response at 3 mg may require additional titration up to a maximum cumulative dose of 5 mg. If resedation occurs, may repeat doses at 20 min intervals with a maximum of 1 mg/dose or 3 mg/h
Beta-adrenergic blockers (i.e., atenolol, metoprolol)	Glucagon and calcium for hypotension and symptomatic bradycardia. *Glucagon dose*: 1–10 mg IV over 1 min followed by an infusion of 1–10 mg/h with dose reductions based on patient response. *Calcium Chloride dose*: 1 g IV bolus via central line. Atropine, isoproterenol, dopamine, dobutamine, epinephrine, and norepinephrine may sometimes be effective
Calcium channel blockers (i.e., diltiazem, nifedipine, verapamil)	Glucagon and calcium for hypotension and symptomatic bradycardia *Glucagon dose*: 1–10 mg IV over 1 min followed by an infusion of 3–6 mg/h with dose reductions based on patient response. Dopamine, epinephrine, norepinephrine, atropine, and isoproterenol may be used adjunctively
Cyclic antidepressants	Hypotension refractory to fluid resuscitation may be treated with direct alpha-adrenergic agonist (i.e., norepinephrine, phenylephrine). After correction of electrolyte abnormalities, sodium bicarbonate and lidocaine for ventricular tachydysrhythmias associated with QRS prolongation. Avoid class IA, IC, and III antiarrhythmics

TOXIC SYNDROME OR DRUG	TREATMENT OR ANTIDOTE
Digoxin	Digoxin immune Fab is the treatment of choice for ventricular arrhythmias and hyperkalemia. Bradycardia or high degree AV block unresponsive to atropine or presence of hemodynamic instability may be treated with digoxin immune Fab. Monitor renal failure patients for prolonged period of reintoxication due to rerelease of bound digoxin into blood
Ethylene glycol	Sodium bicarbonate to correct acidemia (pH<7.3). Thiamine, magnesium, and high-dose pyridoxine may be used to facilitate metabolism. Ethanol or fomepizole for anion-gap metabolic acidosis crystalluia or renal dysfunction, ethylene glycol level >3 mmol/L (20 mg/dL), and for ethanol-like intoxication or increased osmolal gap if the level is not readily obtainable. *Fomepizole dose* – IV: 15 mg/kg loading dose followed by 10 mg /kg every 12 h for four doses then 15 mg/kg every 12 h until ethylene glycol level <20 mg/dL and patient is asymptomatic with normal pH. Administer each dose over 30 min. Dose adjustment is required in renal impairment
Extrapyramidal reactions	Oral or parenteral anticholinergic agents such as benztropine or diphenhydramine
Heparin	Protamine dose depends on the duration of time since heparin was administered. If time elapsed is immediate, 1–1.5 mg of protamine to neutralize each 100 U of heparin. If 30–60 min elapsed, 0.5–0.75 mg of protamine to neutralize each 100 U of heparin. If more than 2 h elapsed, 0.25–0.375 mg of protamine to neutralize each 100 U of heparin
Low-molecular weight heparin	Enoxaparin – 1 mg of protamine for each mg of enoxaparin. If PTT prolonged 2–4 h after first protamine dose, may consider an additional dose of 0.5 mg for each mg of enoxaparin Dalteparin or Tinzaparin – 1 mg of protamine for each 100 anti-Xa int. units of dalteparin or tinzaparin. If PTT prolonged 2–4 h after first protamine dose, may consider an additional dose of 0.5 mg for each 100 anti-Xa int. units
Monoamine oxidase inhibitors (i.e., phenelzine, selegiline)	Short-acting agents such as nitroprusside or esmolol for severe hypertension and tachycardia. Epinephrine or norepinephrine for hypotension and bradycardia
Methemoglobinemia (i.e., dapsone, nitrates, nitrites, primaquine-type antimalarials, sulfonamides)	Intravenous methylene blue for methemoglobin fraction >30%, symptomatic hypoxia, or ischemia. Use with caution in patients with G6PD deficiency; use may not be efficacious and may cause hemolytic anemia and/or methemoglobinemia. Dose: 1–2 mg/kg IV over 3–5 min; may be repeated in 30–60 min if necessary; maximum dose 7 mg/kg. High doses may cause paradoxical methemoglobinemia
Neuroleptic Malignant Syndrome	*Bromocriptine*: 5 mg orally three times/day; in case of inadequate response, increase dose to a maximum of 20 mg 4 times/day. *Dantrolene*: 1 mg/kg rapid IV push; may repeat every 1–3 min until muscle relaxation or total dose of 10 mg/kg
Opioids (i.e., codeine, morphine, oxycodone)	*Naloxone:* 0.4–2 mg IV; may need to repeat doses every 2–3 min; after reversal, may need to readminister dose(s) at later interval depending on the type/duration of opioid *Naloxone continuous infusion:* use 2/3 of initial effective bolus dose on an hourly basis (usually 0.25–6.25 mg/h); 1/2 of initial bolus dose should be readministered 15 min after starting continuous infusion to prevent drop in naloxone levels; adjust infusion rate as needed for adequate ventilation and prevention of withdrawal symptoms Opioid-dependent patients may require lower doses (0.1 mg) titrated incrementally to avoid precipitation of acute withdrawal. Use caution in patients with cardiovascular disease or history of seizures

TOXIC SYNDROME OR DRUG	TREATMENT OR ANTIDOTE
Serotonin syndrome	Benzodiazepine is helpful in treatment of agitation, hyperthermia, muscle rigidity, seizures, and possibly autonomic instability. Moderate to severe serotonin syndrome or persistent symptoms despite treatment with benzodiazepines may be treated with cyproheptadine 12 mg orally or via nasogastric tube followed by 2 mg every 2 h as needed; maintenance dose is 8 mg every 6 h
Warfarin	*Phytonadione (vitamin K):* For INR ≥5 and <9 with risk factors for bleeding, may administer 1–2.5 mg orally. If INR ≥9 with no bleeding administer 2.5–5 mg orally. If there is serious bleeding at any INR elevation administer 10 mg by slow IV infusion and supplement with fresh frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa depending on the urgency of the situation; may repeat phytonadione 10 mg IV every 12 h

[a]It is highly recommended that treatment decisions be made in consultation with a poison control center or clinical toxicologist

NEELA BHAJANDAS

Commonly Used Drugs Which Prolong the QT Interval and Have a Risk of Torsades De Pointes

GENERIC NAME	BRAND NAME	DRUG CLASS
Amiodarone	Cordarone®, Parcerone	Antiarrhythmic
Amitriptyline	Elavil®	Antidepressant
Atazanavir	Reyataz®	Antiretroviral agent
Clarithromycin	Biaxin®	Antibiotic
Desipramine	Norpramin®	Antidepressant
Disopyramide	Norpace®	Antiarrhythmic
Dofetilide	Tikosyn®	Antiarrhythmic
Dolasetron	Anzemet®	Antiemetic
Doxepin	Sinequan®	Antidepressant
Droperidol	Inapsine®	Antiemetic
Erythromycin	Erythrocin®, E.E.S®	Antibiotic
Flecainide	Tambocor®	Antiarrhythmic
Fluoxetine	Prozac®, Sarafem	Antidepressant
Fosphenytoin	Cerebyx®	Anticonvulsant
Gatifloxacin	Tequin®	Antibiotic
Granisetron	Kytril®	Antiemetic
Ibutilide	Corvert®	Antiarrhythmic
Imipramine	Tofranil®	Antidepressant
Isradipine	Dynacirc®	Cardiovascular agent
Itraconazole	Sporanox®	Antifungal
Ketoconazole	Nizoral®	Antifungal
Levofloxacin	Levaquin®	Antibiotic
Lithium	Lithobid®, Eskalith®	Antimania
Methadone	Dolophine®, Methadose®	Analgesic
Moxifloxacin	Avelox®	Antibiotic
Ondansetron	Zofran®	Antiemetic
Paroxetine	Paxil®	Antidepression
Pentamidine	Pentam®	Antibiotic
Posaconazole	Noxafil®	Antifungal
Procainamide	Procan®, Pronestyl®	Antiarrhythmic
Quetiapine	Seroquel®	Antipsychotic
Quinidine	Cardioquin®, Quinaglute®	Antiarrhythmic
Ranolazine	Ranexa®	Cardiovascular agent
Risperidone	Risperdal®	Antipsychotic
Sertraline	Zoloft®	Antidepressant
Sotalol	Betapace®	Antiarrhythmic
Tizanidine	Zanaflex®	Skeletal muscle relaxant

GENERIC NAME	BRAND NAME	DRUG CLASS
Trimethoprim-sulfamethoxazole	Bactrim®	Antibiotic
Venlafaxine	Effexor®	Antidepressant
Voriconazole	Vfend®	Antifungal
Zisprasidone	Geodon®	Antipsychotic

[a]This is not an all inclusive list. The following information may not reflect all the information available on this topic The absence of any drug on the list is not a safety endorsement for it. Always double-check with the drug products package insert
