## 26.1 Introduction

---

Although rarely fatal, disorders of sinus node function and atrial arrhythmias are causes of much morbidity. They are the most common causes of clinical bradyarrhythmias and tachyarrhythmias, respectively. Sinus node dysfunction accounts for over half of permanent pacemaker implants worldwide [1], while atrial fibrillation occurs secondary to the progression of most cardiac conditions [2]. The sinus node and the atrium are closely related, both anatomically and functionally, and disorders of one interfere with the functioning of the other. This fact is of particular relevance to the electrocardiographic study of sinus and atrial activity.

The electrocardiographic diagnosis both of sinus disorders and atrial arrhythmias depends on the P wave as evidence of atrial activation, since sinus node activity itself is not recorded on the surface ECG. The presence or absence of P waves, their morphology and timing, including their relation to ventricular activation as manifest by the PR interval, provide sufficient information for the diagnosis of most sinus and atrial disturbances. While the application of invasive electrophysiological techniques to the assessment of sinus node function [3, 4] and atrial arrhythmias [5] has provided a wealth of information about their origins and the mechanisms underlying arrhythmias in general, it is now recognized that non-invasive studies, including electrocardiography and ambulatory monitoring, are sufficient for the investigation of the majority [6, 7]. Invasive electrophysiological study may be useful for cases in which there are diagnostic or management problems [8], and as a prelude to curative catheter ablation. With catheter ablation techniques playing an increasing role in the management of certain atrial arrhythmias, there has been renewed interest in P wave morphology on the surface ECG as a guide to the origin and mechanism of focal and reentrant atrial rhythm disturbances.

## 26.2 Normal Sinus Rhythm and Sinus Arrhythmias

---

### 26.2.1 Electrophysiology of the Sinus Node

---

Activation of the normal cardiac cycle originates in the sinus node, a small discrete mass of specialized pacemaker (P) cells situated at the junction of the high right atrium (HRA) and superior vena cava [9, 10]. Sinus nodal cells are characterized by a membrane potential of around  $-60$  mV at its most negative; that is, they are relatively depolarized compared to other non-nodal cardiac tissues which have a membrane potential of  $-80$  to  $-100$  mV [11]. At such a potential, fast sodium channels are largely inactivated and the action potential of the P cells is dependent on slower inward calcium currents [12, 13]. On repolarization after an action potential, slow spontaneous depolarization occurs during diastole until threshold is reached and another action potential occurs. This diastolic depolarization is often described as the pacemaker potential, or phase 4 of the action-potential cycle. Several ion currents have been implicated in the pacemaker potential, including potassium conductances, the hyperpolarization-activated cation current,  $I_f$  [14] and the sustained inward current,  $I_{st}$  [12, 15]. In addition, rhythmic release of calcium from intracellular stores, and its subsequent reuptake, may also play a role in generating the pacemaker potential [16]. Other cardiac tissues may also exhibit pacemaker potentials, notably atrioventricular (AV) nodal and Purkinje-fiber cells, but at a slower rate than in the sinus node. Thus, the rate of sinus firing determines the rate of the rest of the heart. In the absence of a sinus beat, however, these lower pacemakers may generate “escape” rhythms.

The activity originating in the sinus nodal cells is conducted out to the surrounding atrium through transitional (T) cells, which have electrophysiological properties intermediate between the pacemaker cells and the quiescent atrial tissue [17]. The site of the primary pacemaker may shift between groups of pacemaker cells within the sinus node, or into the T cells or even the atrium. Disorders of sinus function may result from a failure of impulse generation by the nodal (P) cells, or a failure of conduction of the impulse from sinus to atrial cells, via the T cells [4].

■ **Figure 26.1**

**Sinus rhythm: (a) normal sinus rhythm, 72 bpm; (b) sinus bradycardia, 36 bpm; (c) sinus tachycardia, 114 bpm; (d) sinus arrhythmia, rate 66 bpm on inspiration, 38 bpm on expiration. ECG leads shown on each strip recording.**

### 26.2.2 Normal Sequence of Atrial Activation and P Wave Morphology

The cardiac impulse in normal sinus rhythm originates in the sinus node, spreads directly to the right atrium and thence to the left atrium, before being conducted through the AV node and His-Purkinje system to the ventricles. This activation sequence is clearly seen in electrophysiological studies using multiple sites for intracardiac recordings. Atrial activation occurs first in the high right atrium, followed by the low right atrium at the AV junction, before it is seen in the proximal and finally the distal coronary sinus electrograms, the latter representing left atrial activation. Activation of the His bundle is then detected, followed by spread of excitation to the ventricles (see ▶ Fig. 24.2). The origin of the atrial activation in the HRA determines the P wave axis, the normal axis being from 0 to +90°. Thus, the P wave is usually upright in leads I, II and aVF, and inverted in aVR. In the horizontal plane, the activation from right to left produces upright P waves in the left-sided chest leads V<sub>3</sub>–V<sub>6</sub>. The P wave may also be upright in V<sub>1</sub>–V<sub>2</sub>, but is more commonly inverted or biphasic. Normal sinus rhythm has regular P waves, preceding the QRS complexes by a constant PR interval of 120–200 ms (▶ Fig. 26.1a). The P wave configuration should be constant in any given lead, other than minor changes in axis with respiration.

### 26.2.3 Autonomic Control of Sinus Rate

The sinus node has both sympathetic and parasympathetic innervations which control the rate of sinus firing by altering the rate of depolarization of the pacemaker potential. The parasympathetic vagal influence is dominant at rest, slowing the intrinsic rate, as shown by the increase in heart rate with atropine [18]. Sympathetic innervation and circulating catecholamines increase heart rate during exercise and stress. Autonomic tone has a major influence on sinus node function and an awareness of this fact is important in the assessment of sinus node dysfunction.

Variations of autonomic tone may also cause the location of the pacemaker to shift within the sinus node, or to an ectopic atrial focus. As vagal discharge slows the pacemaker cells, another region under less vagal control may take over pacing. The P wave configuration may change only slightly with “wandering sinus pacemaker,” but with “wandering atrial pacemaker” the P wave morphology and axis will change, as beats originate from ectopic atrial foci.

### 26.2.4 Normal Sinus Heart Rate

---

The normal heart rate in the adult is widely accepted as 60–100 beats per minute (bpm), lower than this being defined as bradycardia, and faster as tachycardia. However, not all physicians would agree with this stated range. A WHO/ISFC Task Force [19] thought that the inherent rate of the sinoatrial (SA) node had a “representative” range of 50–100 bpm. Spodick et al. measured the resting heart rate of 500 consecutive asymptomatic subjects, who were aged 50–80 years, and were free from cardiac medication. They found a range (2 standard deviations below and above the mean) of 46–93 bpm for men, and 51–95 bpm for women [20]. There was no association between age and the resting heart rate. Others have reported similar findings with ageing in healthy subjects, but in those with heart disease the resting heart rate falls with age (reviewed by Brignole [21]).

### 26.2.5 Sinus Bradycardia

---

A sinus rate of <60 bpm is defined as sinus bradycardia. Normal P waves precede each QRS complex with a constant PR interval (▶ Fig. 26.1b). Sinus bradycardia occurs in normal children [22] and adults [23, 24] during sleep, with heart rate commonly down to 30–40 bpm and also in athletes, owing to enhanced vagal tone [25]. Vagal overactivity may also be pathophysiological, producing profound sinus bradycardia during vasovagal episodes or acute inferior myocardial infarction [26]. Unexplained sinus bradycardia is the most common manifestation of sinus node dysfunction [21, 27, 28].

### 26.2.6 Sinus Tachycardia

---

The electrocardiographic features of sinus tachycardia are a heart rate of >100 bpm with a normal P wave morphology and axis and a normal PR interval (▶ Fig. 26.1c). Sinus tachycardia is normal in young children, while in adults it is seen in response to neural or hormonal influences. Physiological or pathological stresses, such as physical exercise, anxiety, fever, hypotension, heart failure or thyrotoxicosis all cause sinus tachycardia. The rate may be transiently slowed by carotid sinus massage. The rate of sinus tachycardia may be up to 200 bpm in young adults during maximal exercise. Maximal heart rate on exercise tends to decrease with age [29], an approximate guide being  $208 - (0.7 \times \text{age})$  bpm [30].

### 26.2.7 Sinus Arrhythmia

---

During normal sinus rhythm the P-P interval is relatively constant, but variations, termed sinus arrhythmia, may occur. This is a common arrhythmia, usually arising from physiological variations in autonomic tone [22, 23]. There is phasic variation in the P-P interval, the difference in sinus cycle length being  $\geq 120$  ms, with normal P waves and PR interval (▶ Fig. 26.1d). It is most commonly related to the respiratory cycle, with an increase in sinus rate during inspiration owing to reflex inhibition of vagal tone and a slowing of rate with expiration [31]. Non-respiratory sinus arrhythmia may also occur, secondary to heart disease, for example, acute myocardial infarction or digoxin toxicity.

A further form of variation in sinus rate, known as ventriculophasic sinus arrhythmia, is noted when there is prolongation of a sinus cycle which has no corresponding ventricular contraction. This is most commonly seen in complete AV block (▶ Fig. 26.2) [32]. The P-P interval of a cycle which includes a QRS complex is shorter than the following cycle which does not. A similar lengthening of P-P interval may be noted following a premature ventricular contraction with a compensatory pause. Proposed mechanisms for ventriculophasic sinus arrhythmia include mechanical and/or hemodynamic effects of ventricular systole on the sinus node and changes in baroreceptor-mediated vagal activity. In an interesting study, de Marchena et al. studied the phenomenon in patients who had received a cardiac transplant [33]. The P-P interval of the recipient's retained atrial tissue (which has preserved vagal innervation to its sinus node, but lacks flow in its sinus node artery) was found to be independent of the donor heart's ventricular activity. This lack of ventriculophasic effect suggests that hemodynamic rather than autonomic effects on the sinus node may be most important.

■ **Figure 26.2**

**Ventriculophasic sinus arrhythmia.** Cardiac monitor tracing in a patient with complete heart block and a narrow-complex escape rhythm, showing variations in the atrial rate in response to ventricular systole – the P-P intervals (indicated in ms) which contain a QRS complex are shorter than those which do not.

### 26.2.8 Inappropriate Sinus Tachycardia and Postural Orthostatic Tachycardia Syndrome

Inappropriate sinus tachycardia, also referred to as chronic nonparoxysmal sinus tachycardia, occurs in otherwise healthy people and is apparently a result of increased automaticity of the sinus node, due to defective autonomic control [34, 35]. The clinical features are of resting sinus tachycardia, and an exaggerated response to minimal activity, in the absence of other causes, such as hyperthyroidism, heart failure, anaemia, cardioactive drugs, or infection. The electrocardiogram shows P waves with an axis and morphology corresponding to those during sinus rhythm. Ambulatory monitoring or exercise testing shows a gradual onset and termination of the tachycardia. A related, and often overlapping, condition is the postural orthostatic tachycardia syndrome (POTS) which is characterised by an increase in the sinus rate by 30 bpm, or to greater than 120 bpm, when the patient stands up from a supine position. This increase in heart rate occurs in the absence of significant orthostatic hypotension [35]. These conditions may persist for months or years, and can cause troublesome symptoms but have a good prognosis. Treatments often include volume expansion, beta-blockers and other peripherally- or centrally-active agents to modify vascular tone. Studies of catheter-based modification of the sinus node have generally yielded disappointing long-term results [35].

### 26.2.9 Sinus Node Reentrant Tachycardia

Sinus node reentrant tachycardia accounts for around 5–15% of supraventricular tachycardias and is characterized by a modest increase in heart rate to 100–150 bpm, P waves which are similar, though not necessarily identical, to those during sinus rhythm and a RP/PR ratio of >1 [36–38]. As with other reentrant tachycardias, it can be initiated and terminated during electrophysiological study by premature atrial stimuli [39]. The atrial activation sequence is identical to that during sinus rhythm, originating in the HRA. It is not usually associated with sinus node dysfunction and is seen more commonly during electrophysiological study than as a spontaneous arrhythmia [40]. If treatment is required, sinus node reentrant tachycardia can be managed with drugs or by ablative therapy [38].

## 26.3 Sinus Node Dysfunction

Disturbance of sinus node function is a common cause of symptomatic arrhythmias and may be a result of a failure of sinus automaticity, or of a failure of propagation of the impulse from the sinus node to the atrium (SA block), or a combination of both. There are many etiological or associated conditions and the cause of sinus node dysfunction may be classified as intrinsic, related to pathological changes in sinus and atrial tissue, or extrinsic, with disturbance of sinus function being attributable to the influence of other factors, commonly autonomic overactivity, or cardioactive drugs [41]. Both intrinsic and extrinsic forms may be chronic, with slow progression, or acute, with sudden onset usually related to predisposing factors such as ischemia, inflammation, surgical trauma or drugs.

In view of the multifactorial etiology of sinus node dysfunction, it is not surprising that no single underlying histological abnormality has been identified, but rather a variety of findings have been reported. In most cases, the

node is of normal size with marked loss of nodal cells and replacement by fibrosis. With normal ageing, the sinus node undergoes striking loss of myocardial cells, with an increase in fibrous tissue [42]. In patients with sinus node dysfunction, there may be virtual total fibrosis of the node, with the proportion of nodal cells being as low as 5%. By contrast to these fibrotic nodes of normal size, the sinus node may be hypoplastic, presumably as a congenital abnormality [43]. Rarely, the node appears to be morphologically normal, with fibrosis or fatty infiltration around the nodal tissue [44]. Fibrotic involvement of atrium itself and AV nodal regions is commonly found in patients with sinus nodal fibrosis [42, 43], consistent with the common coexistence of AV conduction abnormalities [45, 46], or atrial tachyarrhythmias [47]. Acute sinus node dysfunction may result from inflammatory involvement of the node in pericarditis [48] or myocardial infarction, but only rarely is it a result of atheroma or thrombosis of the sinus node coronary artery branch itself [42, 43]. The sinus node can also be affected by systemic infiltrative conditions, such as amyloidosis [49] and hemochromatosis [50], leading to sinus node dysfunction, and a variety of arrhythmias.

In addition to abnormal autonomic influences as extrinsic causes of sinus dysfunction, it has been hypothesized that an abnormal response to the regulatory influence of adenosine, locally released by active myocardium, may underlie intrinsic sinus node disease [51]. Evidence to support an increased sensitivity to adenosine comes from the demonstration of marked bradycardia and sinus pauses produced by intravenous adenyly compounds [52], and the therapeutic response to theophylline, an adenosine antagonist, in some patients [53, 54]. Finally, the possibility of an autoimmune mechanism has been raised by the finding of autoantibodies against sinus node in over 25% of patients with sinus dysfunction or bradycardia [55].

### 26.3.1 Sick Sinus Syndrome

The term “sick sinus syndrome” was first coined in the 1960s by Lown [56], to describe acute sinus disturbance after cardioversion, and was subsequently applied by Ferrer [57] to patients with chronic SA dysfunction. Although, strictly, it should be confined to patients with intrinsic sinus node dysfunction, the term has been commonly applied to any patient with symptoms attributable to disorders of sinus node function [58, 59]. The clinical picture of sick sinus syndrome includes a variety of arrhythmias [21, 27] with multifactorial etiologies [59]. The sick sinus syndrome may be diagnosed in symptomatic patients with any of the following electrocardiographic findings:

- (a) Inappropriate sinus bradycardia,
- (b) Sinus arrest with or without an ectopic atrial or junctional escape rhythm,
- (c) Sinoatrial exit block,
- (d) Alternating bradycardia and atrial tachyarrhythmia (the “bradycardia-tachycardia syndrome”) [47, 60].

In addition, chronic atrial fibrillation with slow ventricular response in the absence of drug therapy usually indicates underlying sinoatrial dysfunction, and attempts at cardioversion typically produce a slow, unstable rhythm [56]. In patients with sinus node dysfunction there is commonly depression of the lower latent pacemakers and the failure of “escape” rhythms results in symptomatic bradycardia. Abnormalities of AV conduction are also found in over half of patients with sick sinus syndrome [45, 46], although more recent evidence suggests that in those with intact AV conduction, it remains stable with time, especially in those without concomitant bundle branch block [61]. Carotid sinus hypersensitivity may mimic, or unmask, sinus node dysfunction [62, 63].

The bradycardia-tachycardia syndrome comprises about half of the patients with sick sinus syndrome [59]. Symptoms may occur with the tachycardia, commonly atrial fibrillation or flutter, or especially with the bradycardia, as long pauses may result following spontaneous termination of the tachycardia (► Fig. 26.3). The tachycardia may simply be predisposed to by the bradycardia, occurring as an “escape” arrhythmia, and may be suppressed by atrial pacing [64]. In other cases, the finding of atrial histopathology [42] indicates that atrial arrhythmias may be the result of the general pathological process. It is probable that the development of atrial arrhythmias is the natural progression of the condition [65], but this progression occurs only very slowly [66].

■ Figure 26.3

Ambulatory monitor tracing, showing a pause of 4 s after spontaneous termination of atrial fibrillation in the bradycardia-tachycardia syndrome. The pause is followed by a junctional escape beat.

■ Figure 26.4

Sinus arrest, as seen on ambulatory monitor tracing. The lower trace is continuous with the upper trace. After two sinus beats there is a pause of 4.9 s, followed by an ectopic atrial escape beat (*arrowhead*). The first spontaneous sinus beat (\*) occurs after a total of 6.9 s. A further pause of 3.4 s occurs, followed by a junctional escape beat.

### 26.3.2 Sinus Arrest

Failure of impulse formation by the sinus node results in the absence of atrial activation and a pause is seen on the ECG (● Fig. 26.4). Sinus arrest may produce periods of ventricular asystole of variable duration, depending on the time taken for recovery of sinus automaticity, or appearance of an escape rhythm from a lower pacemaker. Since the regular sinus discharge has been interrupted, the duration of the pause has no arithmetical relation to the basic sinus cycle length.

### 26.3.3 Sinoatrial Block

Block of SA conduction may result in the failure of atrial depolarization, despite continuing sinus automaticity. Sinoatrial block may be classified as first degree, second degree or third degree, with delayed conduction, intermittent or complete block, analogous to AV block. Only second-degree SA block can be diagnosed from the ECG, although first-degree conduction delay may be assessed by electrophysiological study. Second-degree SA block can be further subclassified as type I (Wenckebach) or type II, which is again analogous to second-degree AV block. Type II SA block is the most frequently

■ **Figure 26.5**

**Sinoatrial block (type II). The sinus pause is twice the preceding sinus cycle length (P waves are indicated by filled arrowheads), owing to exit block of sinus activity preventing the expected P wave (open arrowhead).**

seen, with intermittent block occurring without preceding conduction delay. This is in contrast to AV block, where type I second-degree block is the more common. Sinoatrial block is diagnosed from the ECG by the intermittent absence of the P wave and subsequent QRS complex. The duration of the pause is an exact multiple of the preceding sinus cycle length, since sinus activity continues despite the failure of atrial activation (● Fig. 26.5). Type I (Wenckebach) SA block has increasing delay in SA conduction with successive beats until there is failure of atrial activation and an absent P wave. Since sinus activity is not apparent on the ECG, the diagnosis is established by a progressive decrease in P-P interval prior to the dropped beat, owing to the characteristic periodicity of the Wenckebach phenomenon, whereby, although conduction is progressively delayed, the beat-by-beat increment in delay decreases [67]. The pause with type I SA block will, therefore, be less than twice the preceding P-P interval.

### 26.3.4 Diagnosis of Sinus Node Dysfunction

The investigation of patients with suspected sick sinus syndrome must be directed to the demonstration of abnormalities of sinus function and the establishment of the correlation between the patient's symptoms and the arrhythmias. The rhythm abnormalities are often intermittent and the resting ECG may be normal. The likelihood of detecting arrhythmias is increased by longer periods of ECG recording, and ambulatory Holter monitoring reveals the diagnosis in many more patients [68, 69]. The development of implanted loop recorders has allowed more prolonged ECG monitoring (up to 3 years) and can increase the diagnostic yield in patients with normal baseline tests [70, 71]. The results of these tests, however, must be interpreted carefully since sinus bradycardia, sinus arrest and SA block may all be normal findings [24], particularly in young people [22, 23] or athletes [25]. Sinus pauses of >2 s are generally abnormal and indicate sinus node dysfunction [72, 73], but it is important to document the relationship of the patient's symptoms to an arrhythmia, as asymptomatic pauses do not require treatment [74].

Abnormal heart-rate responses to exercise [75], atropine [76, 77] or isoprenaline [77, 78] are common in the sick sinus syndrome, although these tests are of questionable clinical utility [21]. The combination of atropine (0.04 mg/kg) and propranolol (0.2 mg/kg) produces complete autonomic blockade and reveals the intrinsic heart rate (IHR), which has a well-defined normal range that decreases with age [79]. The IHR can be predicted from a linear regression equation:

$$\text{IHR} = 118.1 - (0.57 \times \text{age})$$

Patients with intrinsic sinus node dysfunction have an abnormally slow IHR, whereas it is normal in those with extrinsic vagally-induced dysfunction [80, 81]. The effects of carotid sinus pressure should also be determined (● Fig. 26.6). Carotid sinus hypersensitivity is present in around 33% of patients with sick sinus syndrome, although the two conditions appear to be pathophysiologically distinct [21].

In the majority of patients, noninvasive investigation is sufficient to establish the diagnosis of sick sinus syndrome [6, 7, 81]. Invasive testing is now seldom employed in this context, however in some circumstances it may help clarify the clinical diagnosis. For example, in patients with syncope thought to be due to sick sinus syndrome in whom ambulatory ECG monitoring has failed to record an event, the demonstration of markedly abnormal sinus node function in an invasive electrophysiology study may support the diagnosis and strengthen the case for implantation of a permanent pacemaker [4, 7]. The most commonly used tests involve atrial pacing to measure sinus automaticity (the sinus node recovery

■ Figure 26.6

Carotid sinus hypersensitivity. Traces are continuous. Carotid sinus pressure (CSP) results in sinus suppression, with a pause of 7.2 s.

■ Figure 26.7

Sinus node recovery time (SNRT). Following cessation of atrial pacing at a cycle length of 350 ms for 30 s, there is a pause of 6.9 s before the first spontaneous sinus beat (arrowed). The figure shows surface leads I, aVF and V1, and intracardiac recordings from the high right atrium (HRA) and His bundle electrogram (HBE). Time-bar (T) indicates seconds (large divisions).

time) and sinoatrial conduction (SA conduction time). Direct sinus node recordings [4, 82, 83] have added greatly to the understanding of the electrophysiological abnormalities in the sick sinus syndrome [84] but are not in routine clinical use [21]. The main invasive tests of sinus node function will be outlined below, but for more in depth reviews, the reader is directed elsewhere [4, 85–87].

## 26.3.5 Electrophysiological Assessment of Sinus Node Function

### 26.3.5.1 Sinus Node Recovery Time

Since the automaticity of cardiac pacemaker cells may be transiently suppressed by pacing at rates faster than their own firing rate [88], an assessment of sinus automaticity can be obtained by examining the time taken for recovery following a period of overdrive suppression by rapid atrial pacing [3]. The interval from the last paced P wave to the first spontaneous sinus P wave is the sinus node recovery time (SNRT). If sinus node dysfunction is present, the depression of automaticity is manifest by prolongation of the SNRT [3, 4, 89]. The resultant pause may be of several seconds duration in patients with sick sinus syndrome (► Fig. 26.7).

It is apparent that the duration of the pause following atrial pacing will also depend on the basic sinus cycle length (SCL): the slower the heart rate the longer the expected pause. The SNRT may be corrected for heart rate in a number of ways, the commonest being to subtract the mean SCL (corrected sinus node recovery time, CSNRT = SNRT – SCL) [90]. Different ranges of normal have been suggested by different investigators [85, 87], but a CSNRT > 550 ms is generally considered to be abnormal. Another commonly applied correction is the expression of the SNRT as a percentage of the SCL (normal SNRT/SCL × 100 < 150%) [85, 86].

In addition to the SNRT, further assessment of sinus function can be obtained by examining the atrial rhythm for several beats following pacing. While the first post-pacing pause is usually the longest, many patients with sinus dysfunction exhibit sudden prolongation of subsequent cycles [77]. Such “secondary pauses” are indicative of sinus node dysfunction and do not occur in normal individuals [91]. Pauses which are multiples of the basic SCL are a result of SA exit block. Secondary pauses may be the only manifestation of sinus dysfunction during electrophysiological study [77, 91]. The total recovery time (TRT) for the sinus cycle to return to stable prepacing values can also be taken as an indication of sinus function, and should be <5 s [77, 85].

### 26.3.5.2 Sinoatrial Conduction Time

An estimate of SA conduction may be obtained by examining the responses to atrial pacing, since a paced atrial activation must travel retrogradely into the sinus node and the subsequent sinus activity must then be conducted out to the atrium. Two methods of measuring the SA conduction time (SACT) are commonly used. The Strauss method [92] introduces atrial premature stimuli following successive runs of eight spontaneous sinus cycles (each impulse designated  $A_1$ ). If the paced atrial extrastimulus ( $A_2$ ) is introduced at an appropriate time in mid-diastole, it will penetrate the sinus node before it has fired spontaneously, and depolarize the pacemaker, which is then reset. The return cycle (the time from the paced atrial extrastimulus to the first spontaneous sinus beat,  $A_3$ ) will be the sum of the time taken for the beat to conduct into the node, the basic SCL following reset and the SA exit conduction time. Thus  $A_2A_3 = A_1A_1 + \text{SACT}$ , where SACT is the total conduction time into and out of the node.

The method of Narula [93] is simpler, employing an 8-beat train of atrial pacing ( $A_p$ ) at a slow rate (<10 bpm above the sinus rate). The return cycle to the first sinus beat ( $A$ ) is then measured, and the total SACT calculated as  $A_pA$ -post-pacing SCL. This method attempts to overcome one problem with the Strauss method – if there is any significant degree of sinus arrhythmia, then error will be introduced into the estimation of the SACT. The Narula method assumes that a short eight-beat train of slow atrial pacing effectively stabilizes the SCL, without significant suppression of automaticity.

The two methods for estimating SA conduction give similar, but not identical, values for SACT [83, 93, 94], and a fairly wide range of normal values for total SACT have been reported (from 200 to 344 ms, reviewed in [85]).

### 26.3.5.3 Sinus Node Refractoriness

Another technique which has been used for the assessment of sinus node function is the measurement of the retrograde sinus node effective refractory period (SNERP) [95]. Eight-beat trains of atrial pacing are followed by single extrastimuli of increasing prematurity and the return cycle  $A_2A_3$  is plotted against the coupling interval  $A_1A_2$ . The SNERP is taken as the longest coupling interval that is followed by an interpolated beat. There appears to be clear separation between values of SNERP in normal individuals and in patients with sinus dysfunction (325 as opposed to 522 ms) [95]. A limitation of this technique is that the SNERP could only be measured in 75% of patients in one study [87].

### 26.3.5.4 Direct Sinus Node Recording

The development of catheter techniques to record directly from the region of the sinus node in humans [4, 82, 84] has allowed the validation of the indirect assessments of sinus node function [4, 83, 84]. The technique involves the placement of a multipole catheter in the proximity of the sinus node and, with appropriate amplification and filtering, a sinus node electrogram (SNE) can be recorded. The direct SNE parallels the membrane potential changes seen in sinus pacemaker cells, with a slow diastolic depolarization (phase 4) prior to the upstroke (phase 0) of the sinus action potential, which precedes the rapid upstroke of atrial depolarization. The SACT is measured from the onset of sinus node depolarization to the onset of atrial activation, and is less than around 120 ms in normal individuals [83, 84, 96]. An additional measurement, the duration of sinus node depolarization ( $\text{SND}_d$ ), can be determined from direct sinus node recordings, and is usually <150 ms in normal subjects. A  $\text{SND}_d \geq 200$  ms can indicate the presence of significant sinus node dysfunction [4].

The role of the SNE in the investigation of sinus node dysfunction is doubtful as the placement of the catheter is relatively time-consuming, and recordings can be obtained in only 80% of patients and are seldom stable [86]. The technique, however, has provided some fascinating insights into the interpretation of results from indirect assessment of sinus function. For example, many patients with long pauses after rapid atrial pacing, who are considered to have a prolonged SNRT, have in fact been found to have continuing sinus activity, as shown by the SNE, the pauses arising from SA exit block preventing atrial activation [97, 98].

### 26.3.5.5 Clinical Role of Electrophysiological Testing

The main limitations of electrophysiological assessment of sinus node dysfunction are the low sensitivity of the tests and the variable clinical significance of abnormalities if found. Abnormalities of the measurement of SNRT and SACT have sensitivities of only about 50% or less in symptomatic patients with sinus node dysfunction [8, 85, 99]. The sensitivity is improved if both tests are combined, and the specificity of the tests is good, being of the order of 75–95% [6, 8]. Autonomic blockade may increase the sensitivity of the electrophysiological tests [87, 100, 101], and particularly aids in the identification of those patients with intrinsic sinus dysfunction [81]. Both sensitivity and specificity are best in symptomatic patients, especially those with syncope, but are less helpful in asymptomatic patients [102]. Thus, with respect to establishing a diagnosis, electrophysiological testing may support the clinical suspicion of sinus node dysfunction if abnormalities are found, but cannot be used to exclude sinus node disease, given the limited sensitivity of the tests. In addition, since the prognosis of patients with sinus node dysfunction is good [66, 102, 103] and does not appear to be altered by pacemaker implantation [74, 103], the finding of sinus node dysfunction in itself does not mandate therapeutic intervention [74, 104].

The correlation of arrhythmia with symptoms is most important, but is not always possible to achieve even with ambulatory monitoring [69]. Invasive investigation of patients with syncope of undetermined origin reveals sinus node disease in about 10% of cases [8] and other electrophysiological abnormalities may be detected in up to 75% [105]. A presumed diagnosis of sick sinus syndrome can be made if major abnormalities of sinus node function (e.g., a SNRT > 3 s) are demonstrated in an electrophysiology study and other causes for the patient's symptoms have been ruled out [7, 21]. Other supporting findings on non-invasive testing include: persistent daytime HR < 40 bpm, often with little variation in HR; second degree SA block; prolonged sinus pauses (which are not vagally-mediated); abnormal intrinsic HR; and severe chronotropic incompetence [21].

In patients with the bradycardia-tachycardia syndrome, in whom monitoring may have failed to demonstrate significant pauses, there is good correlation between pauses observed after atrial pacing and those occurring on spontaneous termination of tachycardia [106]. Other patients with documented bradycardia-tachycardia syndrome may be symptomatic from the tachyarrhythmia rather than the bradycardia and antiarrhythmic therapy may be more appropriate than pacing. Electrophysiological testing can indicate whether drug therapy may worsen sinus dysfunction, meriting prophylactic pacemaker implantation. Full electrophysiological study may also demonstrate inducible tachyarrhythmias, such as ventricular tachycardia, as the true cause of symptoms in some patients with suspected sinus disease [105].

Finally, assessment of AV conduction is important in patients with sick sinus syndrome for whom a single-chamber atrial (AAI) pacemaker is planned. This is usually assessed at the time of pacemaker implantation, rather than in a separate electrophysiology study, and if AV conduction is normal, with 1:1 AV conduction at atrial pacing rates of  $\geq 120$  bpm, then AAI pacing is generally appropriate. It should be noted that serial electrophysiological studies after single-chamber atrial pacemaker implantation have shown that AV conduction may subsequently deteriorate in patients requiring additional antiarrhythmic therapy [107].

## 26.4 Atrial Arrhythmias

Atrial arrhythmias are common and may occur in patients without heart disease as well as being a feature of most cardiovascular conditions. They are of major clinical importance, and can be associated with significant morbidity, but are only rarely fatal in themselves. The majority may be diagnosed without invasive investigation on the basis of the surface ECG

[108–110]. Satisfactory pharmacological management is often achieved, although there is an increasing role for curative catheter ablation for several types of atrial arrhythmias (see [Chap. 24](#), [108]).

### 26.4.1 Mechanisms of Atrial Arrhythmias

Tachyarrhythmias, in general, result from either abnormal impulse generation, such as abnormal automaticity and triggered activity, or abnormal impulse conduction, resulting in reentrant circuits [111].

Automatic atrial arrhythmias are a consequence of abnormal foci which have inherent pacemaker properties and thus generate arrhythmias spontaneously if their firing rate exceeds that of the sinus node. The pacemaker current,  $I_f$ , may contribute to this phenomenon in human atrial tissue [112]. Foci of abnormal automaticity can occur in a variety of sites, including within the vena cava and pulmonary veins [113, 114], and the arrhythmias they produce can be paroxysmal or incessant.

Triggered activity, by contrast, results from early or delayed afterdepolarizations which follow preceding action potentials [115]. These may reach threshold and result in further action potentials. Afterdepolarizations are a result of transient inward currents [116, 117] which are activated by oscillations of intracellular calcium in conditions of calcium overload, such as can be induced by cardiac glycosides or catecholamines. It is likely that triggered activity underlies arrhythmias caused by digoxin toxicity [118]. Intracellular calcium is also increased by repetitive stimulation which may induce afterdepolarizations.

Reentry is the commonest mechanism of cardiac arrhythmia generation, and can be dependent on a macro-reentrant circuit, such as in AV nodal reentrant tachycardia (AVNRT) and AV reciprocating tachycardia (AVRT), or on micro-reentrant circuits as in fibrillation (see [Chaps. 24](#) and [27](#)). Within the atria, structural or functional lines of block can exist which create the conditions necessary for macro-reentry [119]. The classic example is that of “typical” (cavo-tricuspid isthmus-dependent) flutter, as discussed in [Sect. 26.8](#).

The underlying mechanisms of tachycardias may be differentiated electrocardiographically to some extent, but more particularly by the responses to pacing and premature stimulation. Characteristically, reentrant tachycardias are reproducibly initiated and terminated by premature stimuli, whereas automatic tachycardias are not [120]. The latter may display suppression and reset of the automatic focus in response to premature stimuli, followed by a noncompensatory pause. Triggered activity is more difficult to differentiate as it may be initiated and terminated by pacing [118].

Based on these mechanistic considerations, most regular atrial arrhythmias can be classified into two broad groups – *Focal atrial tachycardia*, where activation spreads from a central point and is due to an automatic, triggered, or micro-reentrant mechanism; and *Macro-reentrant atrial tachycardia*, where conduction is occurring around a defined circuit [119]. *Atrial fibrillation* is distinct and characterized by relatively chaotic atrial activation, driven by complex mechanisms including multiple circuit reentry [218], and irregular ventricular activity (when AV conduction is intact).

### 26.4.2 General Electrocardiographic Features of Atrial Arrhythmias

Focal atrial arrhythmias may originate at any site in the atria, frequently remote from the sinus node. The morphology of atrial activation usually differs from the P wave observed in sinus rhythm, and depends on the site of origin [121]. The P wave vector and morphology can be used to predict the site of origin of an ectopic rhythm [122] (see [Sect. 26.6](#)), although some limitations exist [121, 123, 124] and accurate localization can only be obtained with certainty by intracardiac mapping [125].

Reentrant atrial tachycardias are generally initiated by spontaneous atrial premature beats, the initial P wave usually differing from subsequent P waves during the tachycardia. Unlike the junctional reentrant tachycardias (i.e., AVNRT and AVRT), initiation of atrial tachycardia is independent of AV nodal conduction and may be initiated by atrial beats which block proximal to the His bundle [123].

Atrial arrhythmias have often been defined with respect to the atrial rate, distinguishing between atrial tachycardia (100–250 bpm), flutter (250–350 bpm) or fibrillation (400–600 bpm). However, atrial rate alone cannot be considered a rigid diagnostic criterion as exceptions may occur. For example, the atrial rate in atrial flutter may be slower, particularly

in the presence of antiarrhythmic drugs, or faster, as rates of over 400 bpm have been documented [126]. Transition may occur between atrial arrhythmias, with atrial flutter or tachycardia converting to fibrillation [127, 128]. Intermediate forms may also be seen (termed “flutter fibrillation”) where organized atrial activity can be recorded from some areas of the atrium but not others [129].

Focal and reentrant atrial arrhythmias can be incessant, defined as being present for at least 90% of the monitored time. The rate may vary during the day, increasing on exercise and slowing during sleep [130]. Incessant tachycardias can occur in young people with otherwise normal hearts and may cause heart failure due to “tachycardiomyopathy” [131]. In such cases, successful ablation of the arrhythmia can be curative and lead to a sustained improvement in cardiac function [132–134].

## 26.5 Atrial Premature Complexes

### 26.5.1 Overview

The commonest atrial arrhythmia is the atrial premature complex (APC), also known as an atrial extrasystole or atrial ectopic beat. These atrial impulses are characterized by their prematurity, occurring before the next expected sinus beat, and abnormal P-wave morphology, owing to their ectopic origin (► Fig. 26.8). With respect to terminology, the terms

■ **Figure 26.8**

Atrial premature complexes (APCs, indicated by *arrowheads*). Part (a) shows an APC with a clearly abnormal P wave. Part (b) shows an APC superimposed on the preceding T wave, with aberrant conduction to the ventricles. In part (c), an APC occurs with a prolonged PR interval, and a less than compensatory pause. Parts (d) and (e) show APCs conducted with right bundle branch block, and left bundle branch block, respectively.

atrial “premature complex” and “extrasystole” clearly refer to an extra, premature beat, whereas atrial “ectopic” defines the site of origin but not the timing of the beat. An atrial ectopic, for example, may occur as an escape beat following a sinus pause, and so the term includes both premature and escape rhythms. It is, therefore, a less specific term and thus the others are to be preferred.

Atrial premature complexes are common and occur in normal individuals of all ages [22, 23, 135, 136]. Their frequency increases with age, being found in 13% of healthy boys [22], 56% of male medical students [23] and in 75–88% of adult males, although frequent APCs occur only rarely (2–6%) [135, 136]. They are more common in patients with cardiac disease; for example APCs can be found in 94% of patients with mitral stenosis [137]. They are exacerbated by fatigue, stress, caffeine, tobacco and alcohol [135]. They rarely cause symptoms requiring treatment although, occasionally, frequent early or blocked APCs may cause an effective bradycardia – the extrasystolic beat has a low stroke volume owing to inadequate ventricular filling and is followed by a postectopic pause, or has no associated ventricular systole. In atrial bigeminy, for instance, the pulse rate may effectively be halved (▶ Fig. 26.9). In sick sinus syndrome, an APC may be followed by symptomatic sinus pauses owing to sinus node suppression. The more important clinical relevance of APCs, however, is their role in triggering other arrhythmias. Most reentrant supraventricular tachycardias, including atrial flutter, are initiated by APCs (⊕ Fig. 26.10). Suppression of APCs may therefore be an important part of the prophylactic treatment of these arrhythmias, and can often be achieved with beta-blockers or calcium channel antagonists [108].

■ Figure 26.9

Ambulatory monitor tracing showing atrial bigeminy, with blocked atrial premature complexes (*arrowed* for first complex). This results in effective bradycardia, with a ventricular rate of 39 bpm.

■ Figure 26.10

Atrial premature complex initiating AV nodal reentrant tachycardia (AVNRT). The APC (*arrowhead*) is partly obscured by the preceding T wave and has a long PR interval due to conduction via the AV nodal slow pathway. Typical AVNRT occurs, with P waves almost coincident with the QRS complex. The presence of atrial activity can be inferred from the characteristic development of a “pseudo-R’ wave” (*arrowed*) in lead V1.

### 26.5.2 Electrocardiographic Features

The relationship of an APC to ventricular activation will depend on its site of origin, its prematurity and the refractoriness of the AV node. The PR interval may be normal, or even short if the ectopic atrial activity is close to the AV node [138]. However, when an APC occurs early in diastole, close to the refractory period of the AV node, conduction may be delayed with resultant prolongation of the PR interval (🔗 Fig. 26.8c). When the APC occurs even earlier, it may find that the AV node is refractory, preventing impulse conduction to the ventricles. Such a “blocked” atrial extrasystole may be obscured by the preceding T wave (🔗 Fig. 26.9), and the following postextrasystolic pause may be incorrectly diagnosed as owing to sinus arrest.

The pause which follows an APC is most commonly a consequence of sinus resetting, as the premature atrial activity depolarizes not only the atria but also the sinus node. As a result, the pause is less than compensatory, the sinus node having fired earlier than expected. Thus the P-P interval flanking the APC is less than twice the basic cycle length (🔗 Fig. 26.8a–c). This is in contrast to the pause following most ventricular premature complexes which do not interfere with sinus activity; the next sinus beat occurs as expected and the pause is fully compensatory, the P-P interval being equal to twice the basic cycle length. A compensatory pause can occasionally be seen after an APC when the atrial ectopic activity collides with the sinus impulse in the perinodal tissue, preventing the spread of the sinus beat to the atria but without resetting the pacemaker. Rarely, an APC may encounter SA entrance block in the perinodal tissue but the exit of the sinus beat is unaffected. The APC is thus interpolated between two consecutive sinus beats, although the sinus P-P interval is usually slightly prolonged.

While an APC produces abnormal atrial activation, conduction below the AV node is usually normal with a resultant narrow QRS complex, in the absence of preexisting bundle branch block. Aberrant conduction may occur, however, as the impulse may reach the His Purkinje system while it is still relatively refractory from the preceding beat. Refractoriness of the conducting system is related directly to the preceding cycle length, a slower rate being associated with a longer refractory period. This is in contrast to AV nodal refractoriness, which increases with increasing rate. Aberrant conduction is therefore most likely to occur when a premature beat with a short coupling interval follows a longer interval, owing either to bradycardia or to a pause. This is termed the Ashman phenomenon [139]. For this reason, aberrant conduction may be seen with atrial bigeminy, where every extrasystolic cycle is preceded by a postextrasystolic pause. The refractory period of the right bundle branch is generally longer than that of the left and so right bundle branch block (RBBB) is the commonest configuration seen when an APC is aberrantly conducted (🔗 Fig. 26.8d). Less commonly, left bundle branch block (LBBB) may occur (🔗 Fig. 26.8e), particularly at faster rates, since at shorter cycle lengths the refractory period of the left bundle may exceed that of the right [140].

In an individual with frequent APCs there is usually a relatively constant interval between the APC and the preceding sinus beat. Such a constant coupling interval may indicate a reentrant mechanism underlying the premature impulse, such as intra-atrial or AV nodal echoes. This is in contrast to the rarely seen atrial parasystole [141, 142] when an automatic focus produces atrial beats independent of the sinus activity. Since the rate of atrial parasystole differs from that of sinus rhythm, the APCs have no fixed relation to the sinus beats. Atrial premature complexes commonly occur singly and sporadically, but may occur following every second or third sinus beat, producing bigeminy and trigeminy, respectively (see 🔗 Fig. 26.9). Multiple APCs may occur consecutively; the occurrence of six or more APCs is considered to be a burst of nonsustained atrial tachycardia (🔗 Fig. 26.11).

🔗 Figure 26.11

Ambulatory monitor tracing showing non-sustained atrial tachycardia.

## 26.6 Focal Atrial Tachycardia

### 26.6.1 Overview

Focal atrial tachycardia is usually non-sustained and asymptomatic and is often an incidental finding on ambulatory monitoring. It has a prevalence of 0.34% in the general population and is higher in those with a history of palpitations [143]. Symptomatic sustained atrial tachycardia accounts for up to 17% of patients undergoing electrophysiology (EP) study for supraventricular tachycardia (SVT), with no sex preponderance [144–146]. There appears to be a bimodal distribution with peaks in the pediatric age group and in the elderly. This probably reflects different mechanisms of arrhythmogenesis in these groups, with AT due to increased automaticity being prevalent in the young and micro-reentry being more common with increasing age [146–148]. Pharmacological treatment is often unsuccessful, and curative radiofrequency ablation should be considered at an early stage. Ablation is associated with success rates of between 69% and 100% [146, 149–151], with recurrence rates of 7% [148].

### 26.6.2 The Electrocardiogram in the Diagnosis of Focal Atrial Tachycardia

Focal AT produces a narrow-complex tachycardia (or wide-complex in the presence of fixed or rate-related bundle branch block). The surface electrocardiogram provides clues to the diagnosis and helps differentiate it from sinus tachycardia and other causes of SVT. Important features are the mode of onset and termination, the R-P relationship and the P wave vector.

Abrupt onset or a short 4–5 beat “warm-up” period helps distinguish AT from sinus tachycardia, AVNRT and AVRT. Similarly, termination is usually abrupt (unlike sinus tachycardia) or displays a short “cool down phase” (unlike AVNRT or AVRT). Termination with block in the AV node (ending on a P wave) effectively excludes AT [152].

AT usually has a long RP interval (defined as >50% of RR interval), distinguishing it from typical AVNRT and most forms of AVRT. This is a useful indicator, but it is important to remember that there are exceptions to this rule. For example, delay in AV nodal conduction during rapid AT may cause prolongation of the PR interval producing a short-RP tachycardia. Similarly, atypical AVNRT, and AVRT utilizing a decremental accessory pathway as the retrograde limb, may produce a long-RP tachycardia. Other features of the RP relationship may help distinguish AT from other forms of SVT. In AT, AV nodal and ventricular activation are passive and not necessary for tachycardia maintenance. As such, the relationship between atrial and ventricular activity is not fixed and variation in the RP interval supports the diagnosis of AT [152–154] although multiple or decremental accessory pathways may display a similar variation in RP relationship. Higher degrees of AV block can also occur, for example in digoxin toxicity [155, 156] where the resulting arrhythmia is commonly referred to as “paroxysmal atrial tachycardia (PAT) with block.”

Clues may also be gained from the P wave vector. A positive P wave in the inferior leads makes AT more likely, as a superiorly directed vector is characteristic in AVNRT and common in AVRT. However, a superior vector is seen in focal AT with origins from inferior structures such as the inferior annuli, CS os or low crista terminalis. All these features may aid in the diagnosis of AT, but ultimately, differentiation from other causes of supraventricular tachycardia may not be possible until the time of diagnostic EP study.

### 26.6.3 P Wave Morphology

P wave morphology is determined by point of origin and subsequent pattern of atrial activation. As such, analysis of the P wave provides information on the site of origin of focal AT, as activation spreads radially with the origin as the epicenter. However, the spatial resolution of the P wave is only 17 mm [124], and as such, P wave morphology can only be used to localize to a general region of interest. Fortunately, AT foci display characteristic anatomical distributions with clustering at several structures and therefore localizing to a general area is often sufficient to direct more detailed mapping at EP study. A useful algorithm has been developed to predict the site of origin of focal AT based on the P wave morphology, with a reported accuracy of 93% when compared to the anatomical site of successful ablation [157].

The P wave on the surface ECG is often obscured by fusion with the preceding T wave, in some cases giving the appearance of a junctional tachycardia [158]. Administration of adenosine or a short burst of ventricular pacing to induce

■ **Figure 26.12**

Assessment of P wave morphology in atrial tachycardia (AT). In part (a), intravenous adenosine has been administered. P wave morphology is clearly seen following transient AV block. The focus is right parahisian with a largely isoelectric P wave in lead V1 and positive P wave in the inferior leads. Part (b) illustrates the importance of assessing the initial P wave vector in determining the origin of an atrial tachycardia. The vertical line represents the onset of the P wave in the limb leads. The characteristic isoelectric component of V1 (arrowed) observed in AT from the os of the coronary sinus may have been missed if the P wave onset was not clearly defined. The ECG shows demonstrates the other features of AT from this site, with typical negative P wave in the inferior leads and a negative transition across the chest leads.

transient AV block may be necessary to remove T-P fusion (► Fig. 26.12a). It is important to limit analysis to clearly defined P waves and to include the initial vector which may be isoelectric and easily missed (► Fig. 26.12b). Increasing the sweep speed to 50 or 75 mm/s and the amplitude to 50 mm/mV better defines small changes in vector and is a useful tool when analyzing P wave morphology. Characteristic features of P wave morphology have been described for most common foci and are a function of the anatomic relationship of these foci and normal propagation away from the focus. As such, the utility of the P wave in localization is limited in those with structural heart disease or previous atrial surgery or extensive atrial ablation.

#### 26.6.4 Localizing Tachycardia Focus to the Left or Right Atrium

P wave morphology is useful in differentiating left from right atrial foci. This is a function of the anatomical relationship of the atria, with the left atrium being a more posterior and leftward structure than the right atrium. As such, leads V1 and aVL are useful discriminators [122]. Activation from right atrial foci spread leftwards, and a positive or biphasic P wave in aVL has a positive predictive accuracy of 83% and negative predictive value of 85%. In contrast, a positive P wave in V1 is a feature of left atrial foci as activation spreads anteriorly and rightward. It provides a sensitivity and specificity for a left atrial focus of 93% and 88% respectively [122]. Specificity is reduced by the virtue that foci arising from the high crista terminalis in the right atrium can display a positive P wave in this lead. Analysis of the sinus rhythm P wave can help in this situation. As the sinus node complex is located in the high crista [159], the tachycardia P wave morphology should be similar to the sinus P wave if site of origin is the high crista, but will be markedly different if tachycardia focus is of left atrial origin [122].

It is perhaps unsurprising that foci arising from septal structures provide exceptions to these rules, as activation wavefront progresses both left and rightward and a variety of P wave morphologies have been reported [160–163]. However, careful analysis of the initial vector may often help differentiate a right from left atrial origin. For example, tachycardias originating from the coronary sinus (CS) ostium [163] or right septal region [160, 161] often have an initial negative or

isoelectric vector in lead V1, which is in keeping with a right atrial origin (▶ Fig. 26.12b). Missing this initial component may lead to misclassification of the P wave as positive, localizing the focus to the wrong chamber. It is therefore essential that careful analysis of the entire P wave is performed.

Using this simple tool, it is possible to define the focus to the left or right atrium with a high degree of accuracy. However, further localization is possible as specific anatomical locations are associated with characteristic P wave morphologies, which are discussed below.

## 26.6.5 Right Atrium

### 26.6.5.1 Crista Terminalis

Up to 50% of right atrial tachycardias arise from the crista terminalis [149]. This structure extends the entire length of the right atrium inserting supero-medially into the inter-atrial septum near Bachmann's bundle and being contiguous with the Eustachian ridge inferiorly. It is therefore not surprising that there is some variation in P wave morphology along its length. Low cristal sites are usually associated with an negative P wave in lead V1 [149]. However, high and mid-cristal foci often display a biphasic P wave morphology in V1 with an initial positive vector followed by a negative component (▶ Fig. 26.13a), although, as discussed above, a completely positive morphology is sometimes present and in this situation one should consider the morphology of the sinus P wave [122, 149, 164]. Lead aVL displays marked variation in morphology, but lead I is positive and aVR negative in the majority of cases [164]. The inferior leads display different vectors depending on the position of the tachycardia focus along the length of the crista. P waves are positive inferiorly in high cristal foci and isoelectric or negative in more inferior cristal sites.

■ **Figure 26.13**

Surface electrocardiograms illustrating focal atrial tachycardias from different right atrial sites. Part (a) shows the characteristic P wave morphology of a high cristal focus being positive/negative biphasic in lead V1 (arrowed), negative in aVR and positive in lead I. A positive P wave vector in the inferior leads localizes the focus to the high crista terminalis. Part (b) illustrates an inferior tricuspid annulus (TA) focus. The P wave is negative in lead V1 (arrowed), and positive in lead I. P waves are isoelectric/negative inferiorly, localizing to the infero-anterior TA. Part (c) shows P wave morphology of a right atrial appendage focus, displaying a negative vector in lead V1, becoming increasingly positive across the precordial leads. P waves are positive in the inferior leads. Morphology from this site is similar to the superior TA, given its close anatomical proximity.

### 26.6.5.2 Tricuspid Annulus

The tricuspid annulus (TA) is a less common site for focal AT, comprising 13% of right atrial tachycardias in a series by Morton et al. [165]. The TA is an anterior and a relatively rightward structure, and as such, the P wave is characteristically negative in lead V1 and positive in leads I and aVL [164, 165], except for the rare cases of tachycardia arising from the septal TA, where the P wave will have an isoelectric component. The majority of foci arise from the infero-anterior TA and negative or iso-electric P waves are usual in the inferior leads (➤ Fig. 26.13b). Positive P waves inferiorly indicate a superior TA focus.

### 26.6.5.3 CS Ostium

Tachycardias arising from the CS os account for 7% of all focal atrial tachycardia [163] and display a characteristic P wave morphology similar to that of the flutter wave of typical counter-clockwise isthmus dependent flutter. This is a function of the close proximity to the usual exit site of flutter with both displaying an initial negative or isoelectric component in lead V1 which is characteristic of foci arising from the septum. This initial negative vector is followed by a positive deflection which may become more negative across the precordial leads (➤ Fig. 26.12b). The CS os is an inferior structure, and atrial activation is therefore in a superior direction with resultant negative P waves in the inferior leads [160, 163].

### 26.6.5.4 Right Atrial Appendage

The right atrial appendage is an uncommon site for focal AT. Insights into P wave morphology can be gained from a series of seven patients by Roberts-Thomson and colleagues [166]. P waves were negative in lead V1 in all patients, in keeping with the relative anterior and rightward position of the appendage. P wave vector became progressively more positive across the precordial leads and generally displayed an inferior axis (➤ Fig. 26.13c).

### 26.6.5.5 The Inter-atrial Septum

Focal AT has been described from several septal structures other than the CS os both on the right and left sides. These include the triangle of Koch, the right and left perinodal regions and the septal insertion of the crista terminalis [149, 160–162]. In general, P wave duration is relatively short, reflecting a short total atrial activation time due to simultaneous activation of both the right and left atria. Lead V1 displays an initial negative or isoelectric component (➤ Fig. 26.12a), followed by a positive deflection with right septal sites, and is usually completely positive in left septal foci. The inferior leads help further localize right septal sites, with anteroseptal sites displaying a positive P wave, and negative P waves being a feature of mid-septal sites.

## 26.6.6 Left Atrium

### 26.6.6.1 Pulmonary Veins

The pulmonary veins are a common site for focal AT, especially the superior veins [167, 168]. The veins are a posterior and leftward structure and the P wave is characteristically positive in V1 and across the other chest leads. Left-sided veins are further from the septum and total atrial activation time is longer than for foci originating in the right-sided veins. As a result, the P wave in left atrial foci display a longer P wave duration and are characteristically notched in the inferior leads (➤ Fig. 26.14a) [167]. Given the relative anatomical relationship of the veins, the lateral limb leads help distinguish right from left pulmonary venous foci. Lead I is usually positive in right-sided veins and isoelectric or negative in the left veins. In contrast, lead aVL is a poor discriminator. The P wave vector in the inferior limb leads help discriminate between the upper and lower veins, being more positive in superior venous foci.

**Figure 26.14**

Surface electrocardiograms illustrating focal atrial tachycardias from left atrial sites. Part (a) shows the characteristic P wave morphology from a left superior pulmonary vein focus (arrowed) between two sinus beats (\*). Lead V1 is positive and notched. Note the notched positive P waves in the inferior leads. Part (b) illustrates an atrial tachycardia arising from the aorto-mitral continuity. A burst of ventricular pacing has produced transient AV block which allows clear definition of the P wave (vertical line). Note the initial negative deflection in lead V1 (arrowed).

### 26.6.6.2 Mitral Annulus

Focal AT arising from the mitral annulus is well described, with the most common area being the supero-medial aspect at the aorto-mitral continuity [169, 170]. In keeping with its fairly midline anatomical position, this site typically displays a short P wave duration. The P wave in lead V1 is biphasic with an initial negative deflection followed by a positive vector, which becomes progressively more isoelectric across the precordial leads (Fig. 26.14b). P waves are usually negative in leads I and aVL and weakly positive in the inferior leads [169, 170].

### 26.6.6.3 Other Left Atrial Foci

P wave morphology of tachycardia arising from the left septum has already been discussed. Other uncommon sites of tachycardia reported in the literature are the left atrial appendage [122, 168] and the body of the coronary sinus [171–173]. Foci arising from the left atrial appendage display a similar P wave morphology to left sided pulmonary vein foci given their close anatomical proximity, with the exception of deeply negative P waves in leads I and aVL. Tachycardias originating from the CS musculature display a positive P wave in lead V1 and across the precordial leads.

## 26.7 Multifocal Atrial Tachycardia

### 26.7.1 Overview

Multifocal atrial tachycardia (MAT), or “chaotic atrial tachycardia,” is characterized by an atrial rate of greater than 100 bpm and discrete P waves of at least three different morphologies [174, 175]. The prevalence of MAT in hospitalized patients is 0.05–0.32%, and it characteristically occurs in severely ill elderly patients, in particular those with acute exacerbations of pulmonary disease [174–176]. Other associations include hypoxemia, pulmonary embolism, electrolyte

disturbance, and administration of theophylline or beta-agonist therapy [175, 177–179]. There is a high associated mortality, related to the underlying disease [174, 175, 180]. Multifocal atrial tachycardia may also be found uncommonly in children, where it may occur in the absence of underlying disease [175, 181]. In children, it is rarely associated with atrial fibrillation and is commonly self-limiting in nature.

The cornerstones of management are treatment of the underlying condition, correction of hypoxia and electrolyte abnormalities (in particular, hypokalemia), and discontinuation of medications thought to exacerbate the arrhythmia. The arrhythmia generally resolves as the patient's condition improves, but if pharmacological treatment is required, then the agents with the most evidence of efficacy are metoprolol [182] and intravenous magnesium [183]. Several other drug treatments have been reported, but generally in small trials, often without adequate control groups (reviewed by McCord and Borzak [175]). If MAT is refractory to medical treatment, then the ventricular rate can be controlled by catheter ablation of the AV junction combined with ventricular pacing [184], or catheter ablation to modify AV conduction [185].

MAT is thought to be due to triggered activity caused by delayed afterdepolarizations [118, 177, 186]. Although direct evidence for this is lacking, the fact that MAT is seen in conditions of calcium overload (e.g., high catecholamine states, and in the presence of phosphodiesterase inhibition), and can be suppressed by magnesium, supports triggered activity as the underlying mechanism. Magnesium is thought to have membrane-stabilizing effects, reducing afterdepolarizations. MAT is not a manifestation of digoxin toxicity [174, 176, 180].

## 26.7.2 The Electrocardiogram in MAT

---

By definition, at least three different P wave morphologies are seen on the surface ECG, separated by isoelectric intervals, and there is irregular variation in the P–P interval [174]. The multiple P-wave morphologies suggest a multifocal atrial origin, although a single focus with multiple exit pathways or intra-atrial conduction disturbances cannot be excluded. The irregular rhythm of MAT may mimic atrial fibrillation. There is a relation between MAT and other atrial arrhythmias, since in about half of patients it is either preceded by atrial flutter or fibrillation, or these arrhythmias subsequently develop [176, 180].

## 26.8 Macro-Reentrant Atrial Tachycardia

---

### 26.8.1 Overview

---

In contrast to the point source origin of focal AT with passive activation of the rest of the atrium, macro-reentrant AT is defined as a re-entrant circuit which can be entrained from at least two sites > 2 cm apart [119]. Entrainment is the transient increase in the rate of the tachycardia to match that of the overdrive paced rate (see ► Chap. 24) [187–190]. On termination of pacing, the tachycardia reverts to its basic cycle length. Entrainment provides evidence of a reentrant circuit which has an excitable gap that can be penetrated by the paced impulse. The paced beat repeatedly resets the tachycardia resulting in a decrease in the tachycardia cycle length to that of the paced drive cycle. The morphology of the atrial complexes changes during entrainment owing to fusion beats resulting from collision of the paced impulse with the preceding tachycardia wavefront. When pacing ceases, the last entrained beat does not manifest fusion since there is no impulse collision. At a critical paced rate, the pacing wavefront blocks in both directions and the reentrant tachycardia is interrupted [187–190].

Macro-reentrant circuits usually have a central barrier to conduction and an area of slow conduction, producing the excitable gap necessary for macro-reentry. Historically, the classification of atrial macro-reentry, also commonly referred to as atrial flutter, has been conflicting, and recent attempts have been made to standardize nomenclature [119, 191]. Scheinman et al. [191], propose a classification with three main divisions – right atrial cavo-tricuspid isthmus (CTI) dependent flutter, right atrial non-CTI dependent flutter and left atrial flutter. The former is commonly referred to as typical flutter, with the latter two often called atypical flutters.

Typical flutter (right atrial CTI-dependent) accounts for around 90% of macro-reentrant atrial tachycardia, with an increasing prevalence with advancing age to a peak incidence of 0.6% in those over 80 years [192, 193]. Atrial fibrillation and flutter often co-exist, and share the same risk factors, both being more prevalent in the elderly, in males and those with structural heart disease, hypertension, chronic pulmonary disease or an acute illness [192, 194]. It may also be associated with toxic or metabolic conditions, such as alcohol excess or thyrotoxicosis. Right atrial non-CTI dependent flutter or left atrial flutter, often grouped together as the atypical flutters, are less common and usually patients have a prior history of atrial surgery, catheter ablation procedures, valvular heart disease or congenital heart disease [119, 195, 196], although spontaneous scarring causing a flutter circuit in the right atrial free wall has recently been reported in the absence of traditional risk factors [197].

The clinical significance of atrial flutter depends on the ventricular rate and the severity of underlying heart disease. In the acute setting, cardioversion can be achieved by external DC shock, atrial overdrive pacing or pharmacological agents (reviewed by Blomstrom-Lundqvist et al. [108], Wellens [198], Lee et al. [193]). Satisfactory pharmacological control of the ventricular rate in atrial flutter by blocking AV nodal conduction is often more difficult to achieve than it is in atrial fibrillation. Chronic therapy with Class Ia, Ic or III antiarrhythmic agents in an attempt to maintain sinus rhythm is only moderately successful and can be associated with proarrhythmia, such as torsades de pointes (with Class III agents) or 1:1 AV conduction during flutter (Class Ia and Ic agents) [108, 198].

The recognition of the anatomical substrates for macro-reentry and advances in catheter ablation have revolutionized the management of atrial flutter in the last 10–15 years. Linear ablation to interrupt the macro-reentrant circuit can be curative, with a high success rate for typical (CTI-dependent) flutter and a low rate of recurrence, particularly if bidirectional isthmus conduction block is demonstrated [108, 193]. Ablation should be considered early in the management of recurrent or persistent typical flutter. Indeed, a randomized comparison of first-line radiofrequency ablation with antiarrhythmic drug therapy has shown better maintenance of sinus rhythm, fewer hospitalizations, and better quality of life in those who underwent ablation [199]. Ablation is also having an increasing role in the management of “atypical” flutters, facilitated by the development of new endocardial mapping technologies [200–203].

## 26.8.2 The Electrocardiogram in the Differentiation of Macro-Reentrant from Focal Atrial Tachycardia

The rate of tachycardia does not help differentiate a focal from macro-reentrant mechanism. Although focal AT is usually associated with lower rates than macro-reentry [146], cycle length is highly variable in focal AT and rates can be as high as 340 bpm [204]. Similarly, although macro-reentrant tachycardia usually displays high rates, marked delay in conduction may produce much slower tachycardia cycle lengths.

Careful examination of the flutter or P wave and analysis of the intervening P-P interval may be of value. They may be obscured by the QRS or T wave and maneuvers to cause transient AV block may be required to unmask the atrial activity (● Fig. 26.15). Atrial activation is largely passive in focal AT, but, by definition, there is atrial activation over the whole tachycardia cycle length in atrial macro-reentry. As such, continuous activity is often seen in the 12 lead ECG, with no isoelectric period between the flutter waves (“saw-tooth” waveform, ● Fig. 26.16). However, there may be no obvious discernible isoelectric period in short cycle length focal AT and it is not always present in flutter. Despite these limitations, a high atrial rate or lack of an isoelectric component should alert the physician to the possibility of a macro-reentrant mechanism.

### 26.8.2.1 Electrocardiographic Features of Typical (CTI-Dependent) Flutter

Typical flutter is a macro-reentrant circuit confined to the right atrium. It is bounded by the tricuspid annulus anteriorly and by the caval veins, the Eustachian ridge and the crista terminalis posteriorly. An obligate part of the circuit is the cavo-tricuspid isthmus [205, 206]. Linear ablation within this isthmus by radiofrequency ablation is curative with a high success rate. In 90% of patients with typical flutter, activation is counterclockwise around this circuit [119], with

■ **Figure 26.15**

Narrow-complex tachycardia (a), with a rate of 218 bpm. Intravenous adenosine (b) reveals flutter waves. After initial drug treatment, 2:1 AV conduction results, with a ventricular rate of 110 bpm (c).

■ **Figure 26.16**

Typical counterclockwise cavotricuspid isthmus-dependent atrial flutter with isoelectric/positive P wave in lead V1 (arrowed) and negative “saw tooth” flutter waves in the inferior leads.

**Figure 26.17**

Characteristic flutter wave morphology of clockwise cavotricuspid isthmus-dependent atrial flutter. Part (a) shows negative flutter waves in lead V1 and positive flutter waves in the inferior leads. Part (b) shows surface leads I, II, aVF and V1, and intracardiac recordings from electrode pairs (H1-2 to H19-20) of a 20-pole “Halo” catheter lying around the tricuspid annulus (see Fig. 24.1c), and the proximal poles of a catheter lying in the coronary sinus (CS9-10). Atrial activation travels in a clockwise direction from the distal poles of the Halo catheter (H1-2) to the proximal poles (H19-20).

the activation wavefront exiting the CTI medially near the CS os [207], activating the posterior and septal aspects of the right atrium in a superior direction, with later inferior activation of the lateral wall. This gives rise to a characteristic appearance on the ECG with negative saw-tooth flutter waves in the inferior leads (Fig. 26.16). Lead V1 displays a pattern similar to that seen in focal AT arising from the CS os [163], with an initial isoelectric component followed by a positive vector. The flutter waves become progressively more negative across the precordial leads. These features are highly specific for counterclockwise CTI-dependent flutter [119]. In 10% of patients with CTI-dependent flutter, activation is in the opposite direction (clockwise). Flutter wave morphology is reversed with positive saw tooth pattern in the inferior leads and lead V1 displaying a negative vector (Fig. 26.17), although other morphologies have been reported [208].

The atrial rate in typical flutter ranges from 240 to 340 bpm, which is often almost exactly 300 bpm. The AV node rarely conducts as rapidly and so AV block is usually seen, commonly with 2:1 AV conduction, giving a ventricular rate of 150 bpm. The diagnosis of atrial flutter with 2:1 block should always be considered when a regular tachycardia of 150 bpm is identified. Higher degrees of AV conduction block can also be seen, for example in the presence of nodal blocking agents, with a ratio of 4:1, or rarely 3:1 (Fig. 26.16). The preference for even multiples of conduction – 2:1 or 4:1 – may be due to two levels of block in the AV node [209]. Rarely, very rapid ventricular rates are found as a result of 1:1 AV conduction (Fig. 26.15). This may arise because of the presence of an accessory pathway with a short refractory period, but may also occur with enhanced AV nodal conduction [210, 211], or because of slowing of the flutter rate by medication.

### 26.8.2.2 Electrocardiographic Features of Atypical (Non-CTI-Dependent) Flutter

The 12 lead ECG is of less use in localizing other forms of atrial macro-reentry. Flutter wave amplitude is often low in atypical flutter, regardless of the site of the circuit. Analysis of flutter wave morphology in leads V1 and V2 may be of some use, as left atrial flutters tend to display a positive flutter waves in these leads [212].

## 26.9 Atrial Fibrillation

### 26.9.1 Overview

Atrial fibrillation has been called the “grandfather of atrial arrhythmias” [213]. It was first described as a distinct rhythm in humans in the 1900s [214], but irregularities of the pulse associated with valvular heart disease had been recognized centuries before [215]. It is the commonest sustained arrhythmia in adults, may occur in normal hearts or as a feature of all types of cardiovascular diseases, and is associated with significant morbidity and mortality. A number of schemes for classifying AF have been proposed (e.g., [216]), but were of limited clinical utility. Current international guidelines recommend a simple classification, with paroxysmal, persistent and permanent AF [217]. It recognizes “*first detected*” AF, which may present itself in a number of ways – from a clearly defined, symptomatic episode, to an incidental finding on a routine ECG. If the arrhythmia is recurrent and each episode spontaneously reverts to sinus rhythm within 7 days, it is termed “*paroxysmal*”. If it does not terminate spontaneously, AF is classed as “*persistent*” (usually lasting > 7 days). Persistent AF may respond to electrical or pharmacological cardioversion, or may go on to become “*permanent*” (e.g., lasting > 1 year) which is resistant to cardioversion. The classification also recognizes “*secondary*” AF, when the arrhythmia occurs as a consequence of another condition, for example acute myocardial infarction, pericarditis, cardiac surgery, or lower respiratory tract infection.

### 26.9.2 Mechanisms of Atrial Fibrillation

The electrophysiological mechanisms responsible for the initiation and maintenance of atrial fibrillation have been the subject of extensive experimental work [218]. Insights have been gained at single cell and whole tissue levels, as well as through computer modeling and clinical studies. Advancements in the understanding of the arrhythmia have led to novel therapeutic approaches that, in some cases, can offer the hope of a cure.

#### 26.9.2.1 Focal Triggers of AF

Recent work has demonstrated that paroxysms of AF are frequently triggered by foci of ectopic activity in the sleeves of muscular tissue which extend into the proximal portions of the pulmonary veins [114]. This tissue is in electrical continuity with the left atrium, and it is proposed that a rapidly firing source within the vein can lead to fibrillatory conduction in the atrium (“focal trigger”). In some cases, continued activity of the focus may be required to sustain the arrhythmia (“focal driver”), whilst in others the fibrillation is self-sustaining within the atria. The underlying mechanism of the focal ectopic activity is as yet unclear, with possibilities including increased automaticity, triggered activity and micro-reentry, and indeed these mechanisms may not be mutually exclusive. The recognition of these focal initiators has led to the development of catheter ablation techniques for the treatment of AF. These were initially directed at ablating the ectopic focus itself, but have now evolved to aim for electrical isolation of all four pulmonary veins, with or without other lesions in the atria [219, 220] (see [▶ Chap. 24](#)). Focal triggers have also been described in other venous structures, including the superior vena cava [113], the vein of Marshall [221] and the coronary sinus [172], and these may also be amenable to catheter ablation.

#### 26.9.2.2 Tissue Substrate for Sustained AF

The mechanisms responsible for sustained fibrillatory conduction within the atria have also been the subject of much research. It has been proposed on the basis of experimental work and computer modeling that fibrillation develops when a wavefront becomes fractionated and produces multiple random reentrant wavelets [222, 223]. These wavelets would generate disorganized, chaotic atrial activity on the surface ECG. This theory requires a critical mass of atrial tissue to sustain several reentrant waves, and has been supported by the demonstration of such multiple wavelets resulting from intra-atrial reentry of the leading-circle type [224]. Further support comes from the observation that a surgical procedure

to “compartmentalize” conduction in the left atrium (the Maze procedure) can cure chronic AF, presumably by preventing reentrant waves from being sustained [225]. However, more recent studies have proposed that in fact a single high frequency stably rotating spiral wave (“mother rotor”), usually in the left atrium, can lead to the activation pattern seen in AF (reviewed by Jalife et al. [226]).

### 26.9.2.3 Atrial Electrical Remodeling

It has been observed that the longer a patient has been in AF, the harder it is to restore and maintain sinus rhythm [227]. This observation has been confirmed in studies employing rapid atrial pacing in goats to induce AF – when AF was initially induced, it would self-terminate after a short time, but when repeatedly induced it would eventually lead to sustained fibrillation [228]. This has been encapsulated in the phrase “AF begets AF,” and the underlying process is referred to as electrical remodeling. Studies have shown that AF leads to a marked shortening of the atrial effective refractory period, along with dispersion of refractoriness, and both factors may facilitate reentry within the atria. The underlying ionic mechanisms for these phenomena have been investigated in animal models and changes in a number of ion channel conductances have been implicated (reviewed by Nattel et al. [229]).

### 26.9.2.4 Influence of the Autonomic Nervous System on AF

There is a complex relationship between sympathetic and parasympathetic activity and atrial electrophysiology. The autonomic nervous system has been implicated in the triggering and maintenance of AF, and, by altering AV nodal conduction, can also affect the ventricular rate. Vagal stimulation can reduce markedly the action potential duration and effective refractory period of atrial cells [230], and this can occur in a spatially heterogeneous fashion [231]. This leads to increased dispersion of refractoriness and conditions which could facilitate wavelet reentry. In animal experiments, intense vagal stimulation can promote induction of AF by atrial extrastimuli [231, 232]. Adrenergic stimulation and high catecholamine states can increase atrial ectopy, which may trigger episodes of AF (reviewed by Olshansky [233]). This mechanism may be of particular relevance in postoperative patients who develop AF.

Clinical observations of patients with paroxysmal AF (PAF) lead Coumel to propose that some have “vago-tonic” PAF, usually initiated during sleep or after meals; while some have “adrenergic” PAF, predominantly occurring after exercise or other high catecholamine states (e.g., see [234], reviewed by Olshansky [233]). Those classed as “vago-tonic” appear less likely to benefit from catheter-based pulmonary vein isolation as a treatment for PAF [235]. Other studies of catheter ablation for AF have shown that in around a third of patients, delivery of radiofrequency energy to some areas of the posterior left atrium results in intense vagal stimulation (e.g., causing sinus bradycardia, asystole or AV block) and elimination of such reflexes correlates with increased freedom from AF recurrence [236]. These sites may correspond to areas of vagal innervation via ganglia lying within fat pads behind the left atrium [233].

### 26.9.3 Epidemiology of AF

Both the prevalence and incidence of AF double with every decade beyond the age of 50 years [2]. The prevalence rises from 0.5% in the 6th decade of life to just under 9% in the 9th decade [237], and the lifetime risk of developing AF in those over the age of 40 years is 1 in 4 [238]. At any age, the arrhythmia is commoner in men than in women, and other significant risk factors include heart failure, hypertension, valvular heart disease, coronary artery disease, diabetes mellitus and hyperthyroidism [2, 239–241]. Atrial fibrillation occurs in about 10–20% of patients with acute myocardial infarction and is associated with more extensive infarction and higher mortality [217, 242]. Long-term moderate alcohol intake does not appear to lead to AF, but higher levels of consumption do significantly increase its incidence [243], and an alcoholic binge can precipitate an acute episode [244, 245]. In a minority of cases, no associated medical condition is identified and these patients are considered to have “lone” AF [246, 247].

A number of the conditions which predispose to AF may do so through the “final common pathway” of increased left atrial pressure and consequent dilatation of that chamber [248, 249]. Given the proposed mechanisms for AF, this step may be crucial in providing the necessary substrate to sustain the arrhythmia. Several other echocardiographic findings are commoner in patients with AF (e.g., increased left ventricular size, mitral annular calcification), although often they are “markers” for other predisposing conditions, rather than risk factors in themselves. However, after correcting for other risk factors, reduced fractional shortening and left ventricular hypertrophy, as well as increased left atrial size, do appear to be independent predictors of AF [250].

Non-rheumatic atrial fibrillation is associated with a two- to seven-fold increase in the risk of stroke, and in the presence of rheumatic heart disease, this risk is even higher (around 17 times the risk of age-matched controls) [2, 217, 237]. AF is also associated with an increased incidence of heart failure [251] and overall mortality is doubled, although some of this increased risk can be attributed to underlying heart disease [217].

#### 26.9.4 Electrocardiographic Features of Atrial Fibrillation

The atrial activity in atrial fibrillation is very rapid and irregular, and is seen on the surface ECG as chaotic fibrillatory (“f”) waves at rates of up to  $600 \text{ min}^{-1}$  (► Fig. 26.18). P waves are absent as no coordinated atrial activity occurs. The amplitude of the atrial fibrillatory waves may vary, being described as “coarse” or “fine” fibrillation. There is no correlation between the fibrillatory wave amplitude and atrial size on echocardiography or etiology of heart disease [252].

The ventricular rate is dependent on the conduction properties of the AV node and is usually rapid, unless there is preexisting, or drug-induced, AV nodal conduction delay (► Fig. 26.18). The ventricular rhythm is characteristically irregularly irregular, which reflects not only the irregularities of the atrial activity, but also the conduction through the AV node. Some atrial impulses may penetrate the node but are blocked at different levels without being conducted to the ventricles. The consequent refractoriness influences the conduction of subsequent atrial impulses through the AV node, the extent of the delay depending on the degree of penetration of the preceding impulse. The effect of such concealed conduction on ventricular rate is demonstrated by the fact that the ventricular rate during rapid atrial pacing may be greater than the rate once atrial fibrillation is initiated [253]. Clinically, regularization of the ventricular rhythm may be

■ **Figure 26.18**

Ventricular rate in atrial fibrillation. In part (a) there is a controlled rate (66 bpm) due to treatment with a beta blocker. Part (b) shows AF with a slow ventricular response (36 bpm) in a patient on no cardioactive medication (suggestive of sick sinus syndrome). A rapid ventricular response (102 bpm) is seen in part (c).

Figure 26.19

Aberrant conduction in atrial fibrillation due to rate-dependent refractoriness of the conducting system (the Ashmann phenomenon). An aberrantly conducted beat (*arrowhead*) occurs close to a beat which was preceded by a long interval.

Figure 26.20

Preexcited atrial fibrillation in the Wolff-Parkinson-White syndrome. The ventricular rate is rapid (282 bpm) and the complexes are broad and preexcited due to conduction down an accessory pathway.

observed with third-degree AV block and a junctional or ventricular escape rhythm or in digoxin toxicity, owing to the development of a junctional rhythm.

The QRS complex is normally narrow, unless aberrant conduction is present. Intermittent aberrancy (sometimes called “phasic aberrant ventricular conduction”) presents a particular diagnostic problem in atrial fibrillation since neither prematurity nor rate may distinguish between aberrancy and ventricular ectopics. Electrocardiographic criteria have been described to differentiate between aberrancy and ectopy based on QRS morphology and axis [254]. The aberrant morphology is usually RBBB, reflecting the relative refractory periods of the bundle, and it may exhibit the “Ashman phenomenon” (▶ Fig. 26.19, see ▶ Sect. 26.5.2). Less commonly, LBBB may occur, but at shorter cycles and independent of preceding cycle length [140]. A ventricular complex may be followed by a short “compensatory pause” even in atrial fibrillation, owing to retrograde penetration of the AV node inhibiting the next conducted beat [255].

An alternative, but less common, reason for broad complexes in atrial fibrillation is conduction via an accessory pathway in Wolff-Parkinson-White (WPW) syndrome (▶ Fig. 26.20). This diagnosis is important as the excessively rapid ventricular rate may lead to ventricular fibrillation, particularly if AV nodal blocking drugs are given which may enhance conduction down the bypass pathway [256]. Although reentrant tachycardia is the most common arrhythmia in such patients, there appears to be an increased incidence of atrial flutter and fibrillation [257]. Patients with WPW syndrome who exhibit preserved antegrade conduction via their accessory pathway at short cycle lengths (for example during exercise or rapid atrial pacing) are at particular risk of sudden death, and the treatment of choice is ablation of the pathway [217].

## 27.1 Atrioventricular Junctional Tachycardias

### 27.1.1 Definitions

*Junctional tachycardias* originate in the AV junction, i.e., the AV node and its approaches [1, 2]. Tachycardias originating in the AV junction can be classified into two types according to their underlying electrophysiological mechanism. The first type is caused by reentry movement in the region of the AV node and the adjacent perinodal tissue. It is therefore called atrioventricular nodal reentrant tachycardia (AVNRT). The second type comprises tachycardias that are caused by enhanced automaticity or triggered activity in the AV junction [1]. The term AV junction refers to a part of the atrioventricular specialized conducting system consisting of the transitional cell zone, the AV node and its extensions, and the penetrating part of the bundle of His [3–5]. Approximately one half of narrow QRS tachycardias are due to AV junctional reentry, and one third is due to reentry over accessory atrioventricular connections [1, 2]. In the absence of preexcitation during sinus rhythm, the most frequent cause of regular supraventricular tachycardia is reentry within the atrioventricular junction.

## 27.2 Atrioventricular Nodal Reentrant Tachycardia

### 27.2.1 Aetiology and Mechanism

Atrioventricular nodal reentrant tachycardia (AVNRT) is thought to result from reentry in the region of the AV junction. However, the precise anatomical site of the circuit and the pathways involved have not yet been established.

### 27.2.2 Conventional Concepts

The suggestion that circus movement in the atrioventricular node can be a mechanism for supraventricular tachycardia was made as early as 1913 [6]. The concept of dual AV nodal pathways dates from 1956 when Moe and colleagues [7] demonstrated evidence of a dual AV conduction system in dogs. They noted a sudden increase in the AV conduction time when a premature atrial impulse was delivered at a critical coupling interval after a regular extrastimuli series.

Denes et al. [8] in 1973 ascribed episodes of paroxysmal supraventricular tachycardia to AV node reentry due to the presence of dual atrioventricular nodal pathways. It was postulated that a dual conduction system was present, one having a faster conduction time and longer refractory period and the other having a slower conduction time and shorter refractory period (▶ Fig. 27.1). At a critical coupling interval, the premature impulse blocks in the faster pathway and conducts in the still excitable slow pathway, causing a sudden jump in the AV conduction time. Following this, the impulse returns to the atria, supposedly via the fast pathway, which has then recovered, and an atrial reciprocal response or “echo” beat or sustained tachycardia results (▶ Fig. 27.2) [8, 9]. Rosen et al. [10], using His bundle recordings and the atrial extrastimulus method, demonstrated sudden prolongation of the AH interval in a patient with dual atrioventricular nodal pathways. These discontinuities in AH conduction can be displayed by plotting  $A_2$ - $H_2$  conduction times or  $H_1$ - $H_2$  intervals against  $A_1$ - $A_2$  intervals giving the “antegrade conduction curve” (▶ Fig. 27.3) [11]. Normally, the AV node displays a gradual conduction time prolongation with atrial extrastimulation, thus resulting in smooth conduction curves with a progressive increment of the AH or HH intervals (▶ Fig. 27.4) [11]. A sudden increment of AV nodal conduction time results in a discontinuous curve. The portion of the curve to the right of the sudden increment was described as reflecting fast (or beta) pathway conduction time and that to the left as slow (or alpha) pathway conduction (▶ Fig. 27.3). An increase in  $H_1$ - $H_2$  of >50 ms for a decrease in  $A_1$ - $A_2$  of 10–20 ms was arbitrarily considered conduction “jump” reflecting the presence of dual AV nodal pathways [12–14].

Discontinuous refractory period curves, however, may not be present in all patients with AVNRT. Antegrade dual pathways are demonstrable in approximately 75% of patients with tachycardia [12, 14], and AVNRT may occur in the presence of continuous AV nodal conduction curves [15–17]. Conversely, antegrade dual pathways can be demonstrated in subjects without tachycardia [13, 18]. In children undergoing electrophysiological studies, up to 35% may have discontinuous curves [19, 20]. Similarly, people without tachycardia may exhibit discontinuous curves on antegrade or retrograde

■ **Figure 27.1**

**Theoretical depiction of the AV nodal reentrant circuit. During sinus rhythm (a) the impulse penetrates both the fast and the slow pathway. A premature beat results in conduction block of the fast pathway and propagation through the slow (b). An earlier impulse encounters more delay in the slow pathway in a way that the blocked fast pathway has recovered when the now retrograde impulse arrives and tachycardia begins (c).**

activation [21, 22]. It seems, therefore, that mere presence of AV nodal duality even in conjunction with AV echos is not enough to predispose to paroxysmal tachycardia.

In 5–10% of patients with AV nodal reentry, antegrade conduction is thought to proceed over the fast pathway and retrograde conduction over the slow pathway and may result in an incessant form of AVNRT [23, 24]. In these patients, antegrade conduction curves are not discontinuous. This pattern of conduction as well as the incessant nature can also be seen in the presence of concealed septal accessory pathways with decremental properties [25]. Depending on the orientation of the reentrant circuit, therefore, AVNRT has been traditionally classified into *slow-fast* or typical form and into *fast-slow* or atypical form.

### 27.2.3 Recent Developments

The concept of dual AV junctional pathways can provide explanations for many aspects of the electrophysiological behavior of these tachycardias, but several obscure points remain. These pathways have not been demonstrated histologically, and the exact circuit responsible for the reentrant tachycardia is unknown [26, 27]. Recently, exciting information from the ablation laboratory and the surgical theatre has appeared regarding the nature of the AVNRT circuit, although several questions still remain unsettled.

There has been considerable evidence that more than two pathways may be involved in the AVNRT circuit. Triple AV nodal pathways have been described [28, 29], and dual AV nodal conduction may persist in patients in whom AVNRT was abolished by catheter ablation [30]. Indeed, electrophysiologic demonstration of multiple discontinuities in the AV node conduction curve suggests the presence of multiple anterograde AV node pathways (▶ Fig. 27.5), although not all of them are involved in the initiation and maintenance of AVNRT [31]. In a series of 550 patients with AVNRT described by Tai et al., 36 patients had multiple anterograde and retrograde AV nodal pathways that constituted the substrates of multiple reentry circuits [32]. Hwang et al. [33] have also described 17 patients with the fast-slow or slow-slow forms of AVNRT in whom the slow-fast form was also inducible. This finding clearly suggests the potential existence of multiple slow pathways in certain patients in whom several different forms of AVNRT may coexist. There have also been reports of patients demonstrating evidence of multiple pathways following radiofrequency ablation of both the slow [33] and the fast pathway [34]. We have also reported on a patient with slow-fast AVNRT in whom, during radiofrequency ablation

**Figure 27.2**

Anterograde jump and initiation of slow-fast AVNRT with atrial extrastimuli. At ventricular pacing cycle length of 500 s, a ventricular extrastimulus is delivered at 260 ms (a) with resultant decremental conduction through the fast pathway (AH = 174 ms). At a coupling interval of 240 ms (b) there is a conduction jump with AH = 252 ms and tachycardia is induced. Note that atrial electrograms are superimposed on the ventricular ones, but on His bundle 3-4 electrogram, the atrial electrogram precedes the ventricular one. I: lead I of the surface ECG, HRA: high right atrium, His: His bundle, CS: coronary sinus.

■ **Figure 27.3**

**Anterograde conduction curves from a patient with “slow-fast” AVNRT. The sudden increase of AH (jump) indicates refractoriness of the fast (beta) pathway and conduction through the slow (alpha) pathway. Please see text for details. of his slow pathway, retrograde activation was continuously alternating from a fast to a slow pathway producing alternating tachycardia cycles during both the anterior and posterior (or slow-slow) (▶ Fig. 27.6) forms of tachycardia [35]. In another report, the initiation of fast-slow AVNRT was dependent on sudden A-H prolongation, indicating anterograde conduction over a slow pathway that shortened during the ensuing beats [36]. It seems therefore that, at least according to conventional definitions, a group of such pathways may be involved in the reentrant circuit [31, 32, 37].

There has also been a long debate whether the adjacent atrial tissue constitutes an obligate part of the reentrant circuit or an “upper common pathway” is present within subatrial nodal structures in the triangle of Koch. Early studies have demonstrated dissociation of the atrium during AVNRT and provided evidence in favor of the presence of a common pathway [38, 39], with decremental conduction properties [40], without any participation of the atrium. High-resolution mapping of the triangle of Koch in canine hearts has demonstrated that reentrant ventricular echo beats did not require the perinodal tissue [41] and AVNRT has been recorded in a patient during atrial fibrillation [42]. However, observations based on conventional electrophysiology studies have questioned the confinement of the AVNRT circuit to the AV node and suggested that the retrograde fast pathway may not involve normal AV nodal tissue. Schuger et al. [43] have shown that after concealed anterograde impulse penetration, the retrograde fast pathway in AVNRT exhibits an abrupt transition from full excitability to absolute refractoriness unlike AV nodal tissue. This “all or none” type of conduction had also been described in other studies [44–46]. Experimental and clinical studies presented evidence of perinodal involvement in the tachycardia circuit [47, 48], and slow pathway radiofrequency ablation in patients with AVNRT also

■ Figure 27.4

**Normal anterograde conduction curves.** Please note the gradual increase of AH intervals with shortening of the coupling intervals  $A_1A_2$ . resulted in persistent nondecremental retrograde conduction [49]. McGuire et al. [50] have demonstrated two types of presumed slow-fast AVNRT, corresponding to the A and B types previously described by the same group [51]. In the anterior type, the earliest atrial activity was recorded before ventricular activation and recorded near the His bundle, whereas in the posterior type, ventriculoatrial (VA) intervals were longer and the earliest atrial activity was recorded near the coronary sinus (CS) ostium. Although the different atrial activation sequences may be explained by intranodal circuits with different atrial exits, differences in ventriculoatrial intervals and tachycardia cycle lengths (TCLs) of the two tachycardias in each patient suggested different circuits for each tachycardia. This implies that a common pathway of AV nodal tissue is not present above the reentrant circuit and suggests that perinodal atrium forms part of the circuit. Recent observations have also documented that the majority of patients with AVNRT have multiple heterogeneous sites of early atrial activation during the arrhythmia rather than a focal breakthrough site, thus arguing against the concept of an anatomically discrete pathway [52]. It has been therefore postulated that the so-called “proximal common pathway” is probably a broad area allowing fast and slow pathways to have different retrograde exit sites [52, 53]. A recent study with direct recording of the AV nodal electrograms and correlation with histology has showed that the AV nodal reentry occurs in the complex network of nodal and transitional cells and in the rim of surrounding atrial cells [54].

**Figure 27.5**

Multiple conduction jumps (a) and decrement before tachycardia initiation (b), indicating the presence of more than one “slow” pathway. I: ECG lead, LRA: low right atrium, RHis: His bundle recorded from the right septum, LHis: His bundle recorded from the left septum, CS: coronary sinus.

Controversy also exists regarding the so-called lower common pathway, i.e., the tissue between the tachycardia circuit and the His bundle [40, 55, 56]. The conduction time over the lower common pathway has been usually estimated by subtracting the H-A interval during tachycardia from that during ventricular pacing at the same cycle length and considered a measurable interval in the majority of typical AVNRT cases [40]. Studies utilizing para-Hisian pacing, however, have failed to detect evidence of a lower common pathway in typical slow-fast AVNRT, as opposed to fast-slow or slow-slow AVNRT, and have actually used its presence to contribute toward the differential diagnosis between those forms of the tachycardia [55, 56].

Finally, the possibility of functional as opposed to anatomic reentry has also been raised. As already discussed, the demonstration of dual AV nodal characteristics is not a prerequisite for the induction of AVNRT, and successful ablation of the slow pathway does not necessitate changes in AV nodal duality characteristics and slow pathway electrophysiological parameters [57, 58]. The AV junction anatomical structure contains the conditions for the existence of functional pathways. A deep central portion is surrounded by successive layers of myocardium that gradually merge with atrial myocardium [59, 60]. In the region located anteriorly to the coronary sinus os, the terminal atrial tissue overlaps the AV node, showing a smooth rather than abrupt transition [61]. This area has the lowest velocity among cardiac tissues, including the node itself, demonstrates a high level of automaticity, and has characteristics of functional longitudinal

■ Figure 27.6

Anterior slow-fast AVNRT (a) and posterior slow-fast or slow-slow AVNRT (b) with alternating retrograde conduction intervals. This recording was obtained during slow pathway ablation and indicates AVNRT circuits alternatively using two different pathways in the retrograde direction. (From Katritsis et al. [35]. © John Wiley & Sons. Reproduced with permission.) dissociation [3, 61, 62]. Jalife [63] has shown that conduction jump and reentry can occur in a nonhomogeneous linear structure if conduction occurs electrotonically across an area of block and has demonstrated dual pathway responses in isolated Purkinje fibers. It seems that tissue anisotropy, because of fiber orientation heterogeneity and consequent anisotropic conduction or spatial inhomogeneity of refractoriness, may contribute to different electrophysiological characteristics [64, 65] as well as pharmacological responses of functional pathways that, given the right conditions, might constitute the antegrade and retrograde limbs of the circuit [66, 67].

#### 27.2.4 Proposed Models of the AVNRT Circuit

There is now evidence suggesting that AVNRT most probably results from reentry in various locations in the AV nodal and atrial perinodal area. The old model of the reentrant circuit comprised by two anatomically distinct limbs confined to the AV node is too oversimplified to represent reality. It is also debatable whether the two antegrade pathways seen in the majority of patients with AVNRT are the same two pathways used in the reentry circuit during tachycardia [68].

Wu and colleagues [69] have proposed that the slow pathway is the compact node and its posterior input of transitional cells, whereas the retrograde fast pathway is the anterior superficial group of transitional cells. Keim et al. [70] have proposed a more comprehensive model: the AV node, at least in patients with AVNRT, containing fibers capable of different conduction velocity. The fastest of the fast fibers and the slowest of the slow run at opposite edges of the AV node, superiorly and inferiorly, respectively, whereas the fibers between them are responsible for normal antegrade conduction without participation in the arrhythmia. Transitional nodal or atrial fibers constitute the upper connection of those two fiber sets. Patterson and Scherlag [68] have proposed a combined anatomic and functional model based on several hypotheses: transitional cells are the normal input for the fast pathway, AV Wenckebach behavior is due to another group of transitional cells (mid pathway), and fast pathway AV conduction during sinus rhythm and VA conduction during AVNRT are different. Spach and Josephson [71] have adopted a purely anisotropic model. The genesis of AVNRT is attributed to nonuniform anisotropy due to sparse side-to-side coupling between cells in the triangle of Koch. However, although anisotropic properties of the transitional cells do have a certain role in the genesis of this arrhythmia, anisotropic reentry as such cannot be accounted for the typical electrophysiologic characteristics of dual AV nodal conduction and AVNRT [72, 73].

### 27.2.5 The Role of Inferior Nodal Extensions

We have recently proposed a new model based on the description of the inferior nodal extensions [74, 75]. In 1906, Tawara described inferior extensions of the AV node in the human heart [76]. Later Becker and colleagues provided histological evidence of both rightward and leftward inferior extensions and speculated that they may be involved in slow pathway conduction [4, 77, 78]. The inferior nodal extensions are basically part of the AV node and facilitate atrial inputs that also contain transitional cells connecting atrial myocardium with the nodal extensions. Recent experimental studies in the rabbit heart have related the inferior (posterior) extension with slow pathway conduction properties [79–82], and histopathologic examination of the septum following successful ablation of the slow pathway in the human has demonstrated interruption of a long right inferior atrial extension [83]. We have shown that atrial inputs to the AV node can be studied in the human and have examined their electrophysiological properties in patients with and without discontinuous AV conduction curves [74, 75]. Fourteen patients without AVRT (atrioventricular reentrant tachycardia) or AV conduction jumps were studied by simultaneous recording of right- and left-sided His bundle electrograms during multisite atrial pacing. When atrial pacing resulted in conduction through the slow pathway, left inferoparaseptal pacing produced shorter stimulus to His intervals (St-H), as compared to low right atrial pacing. The difference between St-H at maximum decrement and St-H at constant pacing was significantly smaller during left inferoparaseptal than low right atrial pacing [74]. These findings are compatible with the observation that the leftward inferior extension is much shorter in length than the rightward inferior extension [78, 79], and suggest that the inferior atrial extensions are involved in “slow pathway” conduction. We have also studied ten patients with AV conduction jumps and inducible slow-fast AVNRT, before and after successful slow pathway ablation [75]. Simultaneous His bundle recordings from right and left sides of the septum were made during right and left inferoparaseptal pacing. Longer stimulus to His intervals was measured during right inferoparaseptal pacing compared to left inferoparaseptal pacing, at similar coupling intervals during AVNRT induction. Post-ablation, St-H intervals at maximum AV nodal conduction decrement were similar during right inferoparaseptal and left inferoparaseptal pacing, at similar coupling intervals. Pre-ablation, differences between St-H intervals at AVNRT induction or maximum AV conduction decrement (indicating slow pathway conduction) and constant cycle length pacing (indicating fast pathway conduction) for right His recordings with right inferoparaseptal pacing were significantly greater than differences measured with left His during left inferoparaseptal pacing. Post-ablation, these differences disappeared. Resetting of AVNRT with a left inferoparaseptal extrastimulus was achieved in seven of ten patients and indicated the presence of an atrio-nodal connection that is operating on the left side of the septum and allows the advancement of the next His bundle electrogram.

Thus, the electrophysiologic characteristics of the right and left inferior atrial inputs to the human AV node in patients with AVNRT and their response to slow-pathway ablation provide further evidence that the inferior nodal extensions represent the anatomic substrate of the slow pathway. Nodal decremental conduction might represent a fusion between a decrementally conducting AV node as well as activation through the inferior inputs. The demonstration of a jump indicates a shift of activation through the inferior extensions that now act as the “slow pathway.” Whether other superior extensions or the compact node itself [79, 80] might be responsible for the “fast pathway” is not known. Superior atrial inputs to the node have not been histologically demonstrated. However, the existence of multiple atrial inputs to the node is now established [84], and one might speculate that yet undefined superior extensions may also play a role in initial “fast pathway” conduction. There has been now considerable evidence that the right and left inferior extensions of the human AV node and the atrio-nodal inputs they facilitate may provide the anatomic substrate of the slow pathway, and a comprehensive model of the tachycardia circuit for all forms of atrioventricular nodal reentrant tachycardia based on the concept of atrio-nodal inputs has been proposed (▶ Fig. 27.7) [85].

### 27.3 The Electrocardiogram

Typically, AVNRT is a narrow, complex tachycardia, i.e., QRS duration is less than 120 ms (▶ Fig. 27.8), unless aberrant conduction, usually of the RBBB type, or a previous conduction defect exists. The QRS is normal in contour, but tachycardia-related ST depression may be seen during and after the event. The RR interval is regular, although some

■ **Figure 27.7**

(a) Proposed circuit of slow-fast AVNRT. Right- or left-sided circuits may occur with antegrade conduction through the inferior inputs (slow pathway conduction) and retrograde conduction through the superior inputs (fast pathway conduction). Theoretical possibilities are for a right-sided circuit, a left-sided circuit, simultaneous right and left circuits, and figure-of-eight reentry. Overlapping lines indicate possibilities of alternating operating circuits. The site of earliest retrograde atrial activation also depends on the relative length of left and right superior atrial inputs. (b) Proposed circuit of fast-slow AVNRT. Circuits may occur with antegrade conduction through the superior inputs (fast pathway conduction), and retrograde conduction through the inferior inputs (slow pathway conduction). Possibilities are as in slow-fast but in the opposite direction. The site of earliest retrograde atrial activation depends on the relative length of left and right inferior atrial inputs. (c) Proposed circuit of slow-slow AVNRT. The circuit travels antegradely through the right inferior input and retrogradely through the left inferior input, although theoretically the opposite might also occur (please see text for details). (Adapted with kind permission from Katritsis and Becker.[85]) RS: right superior input, LS: left superior input, RI: right inferior input, LI: left inferior input, CS: coronary sinus, TV: tricuspid valve, FO: foramen ovale.

■ **Figure 27.7 (Continued)**

variation due to changes in AV nodal conduction time (as mainly determined by the slow pathway conduction characteristics) may be seen.

Abnormal (retrograde)  $P'$  waves are constantly related to the QRS and, in the majority of cases, are indiscernible or very close to the QRS complex ( $RP'/RR < 0.5$ ). Thus  $P'$  waves are either masked by the QRS complex or seen as a small terminal  $P'$  wave that is not present during sinus rhythm (Figs. 27.8 and 27.9). In the atypical form of AVNRT (fast-slow),  $P'$  waves are clearly visible before the QRS, i.e.,  $RP'/P'R > 0.75$  (Fig. 27.10), denoting a “long RP tachycardia,” and are negative in leads II, III, aVF, and  $V_6$  but positive in  $V_1$ .  $P'$  waves are shallow in the inferior leads in the rare form of anterior fast-slow AVNRT [86]. Although AV dissociation is usually not seen, it can occur since neither the atria (or, more precisely, the majority of atrial tissue) nor the ventricles are necessary for the reentry circuit. If the tachycardia is initiated by atrial ectopic beats, the initial (ectopic)  $P'$  wave usually differs from the subsequent (retrograde)  $P'$  waves.

## 27.4 Electrophysiologic Study

### 27.4.1 Antegrade and Retrograde AV Conduction Curves

Discontinuous AV conduction curves ( $A_1$ - $A_2$ / $H_1$ - $H_2$  or  $A_1$ - $A_2$ / $A_2$ - $H_2$ ) are suggestive of the presence of antegrade dual AV junction pathway [12]. As previously discussed, discontinuous refractory period curves may not be necessarily demonstrated in all patients with AVNRT. In addition, the mere presence of AV nodal duality is not enough to predispose to paroxysmal tachycardia. Conventionally, an increase of at least 50 ms (conduction jump) in the AH interval for a decrease of 10 ms in the coupling interval ( $A_1$ - $A_2$ ) is considered to reflect dual AV nodal (or, more precisely, junctional) pathways. Failure to demonstrate dual pathways in patients with AVNRT may occur due to several factors as follows.

1. The functional refractory period of the atrium limits the prematurity with which extrastimuli can encounter the AV node [13], or the refractory periods of the slow and fast pathways are similar. Stimulation at faster rates or the introduction of multiple extrastimuli is required in these cases in order to decrease atrial refractoriness or merely dissociate the two pathways [16].

■ **Figure 27.8**

12-lead ECG during “slow-fast” AVNRT. Note that small P’ waves that are seen during tachycardia (arrows) are not present during sinus rhythm.

■ **Figure 27.9**

Slow-fast AVNRT from the same patient as in ▶ [Fig. 27.8](#). Small P’ waves at the end of QRS correspond to retrograde atrial conduction (arrows). I: ECG lead, II: lead II of the surface ECG, aVL: lead aVL of the surface ECG, HRA: high right atrium, His: His bundle, CS: coronary sinus.

2. The slow pathway has a longer antegrade refractory period than the fast one, thus preventing the demonstration of a jump, as happens with the fast-slow variety of AVNRT. Retrograde stimulation curves in these patients may demonstrate a jump if the retrograde refractory period of the fast pathway exceeds the retrograde refractory period of the slow one [23].

**Figure 27.10**

12-lead ECG during fast-slow AVNRT. Note the prolonged R-P' and the incessant nature of the tachycardia.

Ventricular extrastimulation frequently demonstrates continuous VA conduction curves with either fixed or minimal prolongation of the VA interval in patients with typical slow-fast AVNRT [87–89]. This has been traditionally accepted to reflect retrograde fast pathway conduction [90]. Decremental conduction or retrograde jumps may also occur. During retrograde stimulation curves, it is often difficult to obtain recordings of the retrograde His bundle potential. In the literature, retrograde conduction properties of the fast and slow pathways have been derived indirectly by analyzing the conduction curves ( $V_1$ - $V_2$ / $A_1$ - $A_2$ ). Thus, in case of discontinuous retrograde curves, the longest  $V_1$ - $V_2$  interval in which conduction fails in the fast pathway is assumed to be the retrograde effective refractory period of the fast pathway, and the shortest attainable  $A_1$ - $A_2$  interval on the fast pathway conduction curves (i.e., to the right of discontinuity) is assumed to be its functional refractory period. Similarly, the analysis of the curves on the left of discontinuity, which represent a slow pathway conduction, provides the refractory periods of the slow pathway [24, 53]. This method assumes that no other causes of discontinuities in VA conduction, such as intraventricular conduction delays, exist.

As a rule, at least two cycle lengths (usually 600 and 400 ms) should be studied both antegradely and retrogradely. On certain occasions, the application of two or three extrastimuli may be necessary to expose slow pathway conduction or to induce critical conduction delay required for the initiation of reentry.

### 27.4.2 Initiation of Tachycardia

The initiation of AVNRT in the electrophysiology laboratory can be accomplished by atrial or ventricular extrastimulation. These modes of induction have been explained according to the conventionally accepted mechanism, although, as previously discussed, this may not be the case.

### 27.4.2.1 Slow-Fast AVNRT

According to conventionally accepted mechanisms, the requirements for the induction of AVNRT are blocked in an antegrade fast pathway conduction with continued conduction in a slow pathway with critical AV nodal (AH) delay, followed by retrograde conduction over the fast pathway [91]. A critical AV node conduction is necessary in order to allow the antegradely blocked fast pathway to recover and resume retrograde conduction, leading to the occurrence of an atrial echo beat. Depending, therefore, on both critical antegrade delay and retrograde conduction properties, the echo zones may not coincide with the entire slow pathway conduction curves. Sustained reentry requires the ability for repetitive antegrade slow pathway and repetitive retrograde fast pathway conduction.

A *single atrial extrastimulus* can initiate the slow-fast form of tachycardia by producing antegrade block in the fast pathway while conducting through the slow one (➔ Fig. 27.2). If the tachycardia is induced during the conduction of antegrade AV conduction curves, usually a typical decrement (jump) precedes the initiation of tachycardia, but this is not always seen. If the atrial pacing length has already reached antegrade fast pathway refractoriness, with resultant antegrade AV conduction exclusively over the slow pathway, tachycardia initiation is associated by smooth rather than discontinuous AV node conduction curves. *Double or triple atrial extrastimuli* or *incremental atrial pacing* may occasionally be required for tachycardia induction [16]. At critical atrial pacing rates, either a jump or an atypical Wenckebach periodicity or even both can be seen [92]. At faster pacing cycle lengths, the conduction time of one pathway may be prolonged with simultaneous lengthening of the refractoriness of the other pathway. Consequently, the resultant atrial echo zone is widened, and self-initiation (i.e., without an atrial extrastimulus) of sustained reentry may become possible at shorter pacing lengths. Rarely, atrial extrastimuli or even sinus beats may produce simultaneous fast and slow pathway conduction, resulting in double ventricular responses [93]. Repetition of such a phenomenon produces a paroxysmal form of non-reentrant tachycardia [94, 95].

*Ventricular extrastimuli* or *incremental ventricular pacing* may also initiate slow-fast reentry, but much less commonly than atrial stimulation. In one third of patients, tachycardia can be initiated by ventricular extrastimuli [90]. This mode of tachycardia initiation requires that the slow pathway has a retrograde refractory period longer than that of the fast pathway. Consequently, the ventricular extrastimulus blocks in the slow pathway and is conducted over the fast one, thus preventing the demonstration of any retrograde jump. Retrograde refractoriness of the His–Purkinje system appears to be an important limiting factor with respect to initiation by ventricular pacing.

### 27.4.2.2 Fast-Slow AVNRT

*Ventricular extrastimuli* may cause initiation of tachycardia after blocking the fast pathway and conducted retrogradely over the slow pathway. After the attainment of a critical VA conduction delay ( $H_2-A_2$ ), the impulse is conducted through the fast pathway in the antegrade direction and produces a ventricular echo. The ventricular echo zone may or may not coincide with the entire retrograde slow pathway conduction curves since the ventricular or the His–Purkinje tissue may exhibit conduction delay in response to ventricular extrastimulation, thereby precluding maintenance of critical  $H_2-A_2$  delay. When tachycardia is induced during retrograde curves, its initiation is usually preceded by a sudden jump in ventriculoatrial conduction times. If, however, the ventricular pacing length has already reached retrograde fast pathway refractoriness with resultant retrograde VA conduction exclusively over the slow pathway, tachycardia initiation is associated by smooth rather than discontinuous VA conduction curves. *Incremental ventricular pacing* can also induce tachycardia of this form with a mechanism analogous to the one described previously for the slow-fast form.

*Atrial extrastimuli* can initiate tachycardia of this form only if the slow pathway has an antegrade refractory period longer than that of the fast pathway being incapable of antegrade conduction. Sudden increment of AV conduction, therefore, is not noted in this case. The critical AV node conduction delay required for the initiation of an atrial echo or sustained reentry is minimal, since the  $A_1-H_2$  interval is within the range of antegrade fast pathway conduction times. When the slow pathway has markedly prolonged antegrade refractoriness relative to that of the fast pathway (wide window), late atrial premature beats or spontaneous acceleration of the sinus rate can easily induce AV node reentry of the fast-slow form. This may explain the incessant nature of this tachycardia.

The initiation of an AV junctional reentry tachycardia of any form is therefore dependent on several factors such as the effective refractory periods of the two pathways, the functional refractory periods of the atrium or the ventricle, and the number of the delivered extrastimuli or the cycle length of the basic pacing drive. Both atrial and ventricular incremental pacing may facilitate initiation of AV node reentry tachycardia of either form [12]. In certain occasions, isoprenaline infusion or atropine may be necessary to modulate the autonomic tone and allow the induction and sustenance of tachycardia [96].

### 27.4.3 Effect of Stimulation During Tachycardia

A late single atrial extrastimulus may fail to depolarize the entire atria or, if the atria are depolarized, may fail to penetrate the reentrant circuit causing a compensatory pause without affecting the cycle length of the tachycardia. Earlier extrastimuli may penetrate the reentrant circuit, resulting in premature depolarization of the atria and termination of the tachycardia. Resetting of the tachycardia may also occur, although rarely, because atrial refractoriness usually does not allow adequately early extrastimuli. The latter usually happens in AVNRTs with cycle lengths more than 300 ms, unless the stimulation is carried out very close to the AV node (▶ Fig. 27.11). Faster AVNRTs usually require two extrastimuli or rapid atrial pacing to stop.

Ventricular extrastimuli behave in a similar manner. A very important point typical of AVNRTs is the inability of His-synchronous ventricular extrastimuli to capture the atrium and advance or delay the subsequent atrial activation or reset the whole tachycardia cycle. Ventricular extrastimulation is very important for the differential diagnosis, as will be discussed later.

■ Figure 27.11

Resetting of slow-fast AVNRT. The tachycardia cycle length is 365 ms. An atrial extrastimuli is delivered from the left inferoparaseptal area very close to the His area, 350 ms following the His bundle activation, and results in resetting of the next His bundle electrogram. I: ECG lead, HRA: high right atrium, His: His bundle, CS: coronary sinus, LIPS: left inferoparaseptal pacing.

## 27.5 Electrophysiologic Forms of AVNRT

According to the conventional description of a dual AV junctional pathway, AVNRT has been traditionally classified as slow-fast or typical AVNRT, and fast-slow or atypical AVNRT. The fast pathway of the reentry circuit runs superiorly and anteriorly in the triangle of Koch, whereas the slow pathway runs inferiorly and posteriorly close to the coronary sinus ostium [70]. Indeed, detailed endocardial mapping in patients with AVNRT has demonstrated that in the majority of slow-fast cases of AVNRT, the site of earliest atrial activation is close to the apex of Koch's triangle, near the AV node–His bundle junction, i.e., anterior to the node [44, 97]. Thus, the earliest retrograde A, whenever atrial electrograms are separated from ventricular ones, occurs in the His bundle electrogram, followed by the ostium of the coronary sinus, distal coronary sinus, and high right atrium [14, 97]. Depolarization of the distal coronary sinus may also be simultaneous or slightly later than in the high right atrium. However, the recognition of the fact that all forms of AVNRT may present with atypical retrograde atrial activation has made classification attempts more complicated, and a universally accepted scheme does not exist. Most authors, however, would accept the following classification:

1. In *typical or slow-fast form* of AVNRT, the onset of atrial activation appears prior, at the onset, or just after the QRS complex, thus maintaining an atrial-His/His-atrial ratio  $A-H/H-A > 1$  (▶ Fig. 27.2). In particular, the following criteria are considered as diagnostic for the slow-fast form of AVNRT: an A-H/H-A ratio  $> 3$  [44], a VA interval measured from the onset of ventricular activation on the surface ECG to the earliest deflection of the atrial activation in the His bundle electrogram  $< 60$  ms, or a VA interval measured at the high right atrium  $< 95$  ms [98]. Although, typically, the earliest retrograde atrial activation is being recorded at the His bundle electrogram, cases of posterior retrograde fast pathways, i.e., with posterior earliest retrograde atrial activation at the CS [99] have been described.
2. In *atypical or fast-slow form* of AVNRT (approximately 5–10% of all AVNRT cases), retrograde atrial electrograms begin well after ventricular activation with an A-H/H-A ratio  $< 1$ , indicating that retrograde conduction is slower than antegrade conduction [24]. The VA interval measured from the onset of ventricular activation on surface ECG to the earliest deflection of the atrial activation in the His bundle electrogram is  $> 60$  ms, and in the high right atrium  $> 100$  [100]. In the majority of fast-slow cases, the site of earliest atrial activation is posterior to the AV node near the orifice of the coronary sinus [49, 101]. However, anterior and mid-forms of fast-slow AVNRT have also been described [33, 86].
3. In the *slow-slow form*, the A-H/H-A ratio is  $> 1$  but the VA interval is  $> 60$  ms, suggesting that two slow pathways are utilized for both anterograde and retrograde activation [33, 102]. Usually, but not always, earliest atrial activation is at the posterior septum (coronary sinus ostium) [33, 102]. The so-called *posterior or type B* AVNRT can be demonstrated in approximately 2% of patients with the anterior form of slow-fast AVNRT [50]. In posterior tachycardia, the VA times (as measured from the onset of ventricular activity to the onset of atrial activity by whichever electrode recorded the earliest interval) may be prolonged, ranging from 76 to 168 ms [50]. The atrial-His/His-atrial ratio, however, remains more than one. Some cases of posterior slow-fast AVNRT may actually represent the slow-slow form [26, 99]. Since conduction times are sensitive to autonomic changes, attempts to classify the AVNRT forms according to retrograde atrial activation sequence and the possibility of demonstrating a lower common pathway, have appeared [56]. We know now that all forms of AVNRT (slow-fast, fast-slow, and slow-slow) may display anterior, posterior, and middle retrograde activation patterns [86]. Heterogeneity of both fast and slow conduction patterns has been well described, and in certain patients all forms of AVNRT may be inducible [33, 86].

## 27.6 Differential Diagnosis

### 27.6.1 Narrow-QRS Tachycardia

In the presence of a narrow QRS tachycardia, AVNRT should be differentiated from atrial tachycardia or orthodromic atrioventricular reentrant tachycardia (AVRT) due to an accessory pathway, i.e., tachycardia using the AV node for antegrade conduction and the accessory pathway for retrograde conduction.

### 27.6.1.1 AVNRT versus Atrial Tachycardia

Simple pacing maneuvers can be utilized in order to exclude reentrant or triggered atrial tachycardias. If there is demonstration of change in (1) AA interval when a ventricular extrastimulus is delivered during tachycardia, (2) tachycardia termination by a ventricular extrastimulus that did not conduct to the atrium, (3) constant His-atrial interval of the return cycle after the introduction of a premature atrial impulse with a wide range of coupling intervals during tachycardia, and (4) ventricle to atrium to His sequence during retrograde initiation of tachycardia, then the aetiology is other than atrial tachycardia [103–105]. In particular, the atrial response upon cessation of ventricular pacing associated with 1:1 ventriculoatrial conduction during tachycardia can distinguish between atrial tachycardia and AVNRT or AVRT. Atrial tachycardia is associated with an A-A-V response, whereas AVNRT or AVRT produce an A-V response [104]. The difference in the AH interval between atrial pacing and the tachycardia may also allow differentiation of AVNRT from atrial tachycardia. A  $\Delta$  A-H >40 ms indicates AVNRT, whereas in atrial tachycardia this difference is <10 msec [105]. This concept is discussed later under the differential diagnosis of AVNRT vs. AVRT.

### 27.6.1.2 AVNRT versus AVRT due to Accessory Pathways

The eccentric retrograde atrial activation during ventricular stimulation or tachycardia and the demonstration of continuous AV or VA conduction curves usually characterizing nonseptal concealed accessory pathways, differentiate this form of atrioventricular reentry from AVNRT. Care is needed, however, since AVNRT is now known to occur with eccentric atrial activation and, in addition, decremental septal pathways may mimic AVNRT especially of the fast-slow or slow-slow forms (▶ Fig. 27.12). Septal pathways may have the property of decremental conduction [106, 107] and normal atrial retrograde activation during tachycardia. These tachycardias tend to be incessant [108, 109]. The documentation of pre-excited beats as well as AV dissociation and the induction of bundle branch block (BBB) during tachycardia may assist the differential diagnosis. The demonstration of AV block or AV dissociation during tachycardia is characteristic of AVNRT excluding the presence of an accessory pathway [110, 111]. Similarly, the development of bundle branch block either spontaneously or after the introduction of ventricular extrastimuli during AVNRT does not change the AA or HH intervals. Although the first VV interval may be prolonged for one cycle due to HV prolongation associated with the development of BBB, the subsequent cycles of tachycardia are identical to the basic tachycardia cycle length. A significant change in the VA interval with the development of bundle branch block is diagnostic of orthodromic AVRT and localizes the pathway to the same side as the block [112].

In general, septal ventriculoatrial interval < 70 ms is diagnostic of slow-fast AVNRT provided that atrial tachycardia has been excluded [113, 114]. In the case of relatively delayed retrograde conduction that allows the identification of retrograde P waves, ECG criteria can be applied for diagnosis. The presence of a pseudo r' wave in lead V<sub>1</sub> or a pseudo S wave in leads II, III, and aVF was indicative of anterior AVNRT with an accuracy of 100%. A difference of RP' intervals in lead V<sub>1</sub> and III > 20 ms was indicative of posterior AVNRT rather than AVRT due to a posteroseptal pathway [115].

In septal decremental pathways, ventricular extrastimuli introduced while the His bundle is refractory during tachycardia may advance or delay subsequent atrial activation (extranodal capture), whereas in slow-fast AVNRT, either anterior or posterior, atrial activity is not perturbed. Atrial capture at a time when the His bundle is refractory implies the presence of an accessory pathway (▶ Fig. 27.13) [116]. In practice, the extrastimulus has to be delivered coincident with the His potential or up to 50 ms before this [117]. Failure to reset the atria (▶ Fig. 27.14) suggests, but does not prove, that an accessory pathway is not present or that it is relatively far from the site of premature stimulation (e.g., right ventricular stimulation in the presence of a left free wall pathway) [118]. Theoretically, it is possible that resetting of the atrium might be a result of an increase in conduction time over such a pathway of a magnitude equal to the interval by which the extrastimulus preceded atrial activation, but such a coincidence is rare. In addition, at the time of His bundle activation, the accessory pathway may be refractory and resetting by ventricular extrastimuli may not be seen. Failure to demonstrate resetting, therefore, does not exclude an anomalous septal pathway with decremental properties. Thus,

■ Figure 27.12

12-lead ECG during atrioventricular reentrant tachycardia due to a posteroseptal accessory pathway.

resetting or termination of the tachycardia with His-refractory ventricular extrastimuli is a specific but not highly sensitive criterion for differential diagnosis. Additional criteria have therefore been suggested. Using ventricular-induced atrial preexcitation, Miles et al. [119] devised a preexcitation index for the differentiation of AVNRT and AVRT using an accessory pathway. Progressively premature right ventricular extrastimuli ( $V_2$ ) were introduced during tachycardia, and the difference between the tachycardia cycle length and the longest  $V_1V_2$  at which atrial preexcitation occurred defined the preexcitation index. Atrial preexcitation occurred in 10% of 22 patients with AVNRT compared with 89% of 55 patients with AVRT. A preexcitation index of 100 ms or greater characterized AVNRT, whereas an index less than 45 ms characterized AVRT using a septal pathway. Left free wall pathways had indices of 75 ms or greater. In another report of 16 patients with AVNRT and 23 patients with AVRT studied at St. George's Hospital in London, the ratio between the minimum ventriculoatrial interval during tachycardia and ventricular pacing was 0.32–0.27 in AVNRT, 0.48–0.71 in AVRT using a left free wall pathway, 0.91–1.08 in posteroseptal pathways, 0.94–1.29 in anteroseptal pathways, and 1.53–1.68 in right free wall pathways [114]. A difference in the VA interval during tachycardia and right apical ventricular pacing > 90 ms has also been reported to differentiate patients with AVNRT from those with AVRT [120]. The difference between the ventriculoatrial interval obtained during apical pacing and that obtained during posterobasal pacing (ventriculoatrial index) can also discriminate between patients with posteroseptal pathways (> 10 ms) and patients with nodal retrograde conduction (< 5 ms) [121].

Miller et al. [122] found the His to atria (HA) intervals to offer more precise discrimination. Their criterion is the difference between His to atrial intervals during pacing and during tachycardia ( $\Delta$ HA). In 84 patients, a retrograde His was present in 93% of them and the  $\Delta$ HA was > 0 ms in AVNRT and < -27 ms in orthodromic AVRT incorporating a septal accessory pathway. Thus, an intermediate value of  $\Delta$ HA = -10 ms had 100% sensitivity, specificity, and predictive accuracy in differentiating the two forms of tachycardia. Parahisian pacing and the change in timing and sequence of retrograde atrial activation between His and proximal right bundle branch capture and noncapture has also been

■ Figure 27.13

Resetting of atrioventricular reentrant tachycardia due to a left posteroseptal accessory pathway. The tachycardia cycle length is 292 ms. At 270 ms, a ventricular extrastimulus is delivered at a time when the His bundle is expected to be refractory and resets the next atrial electrogram (from 292 to 282 ms). I, II: ECG leads, HRA: high right atrium, RHis: His bundle recorded from the right septum, LHis: His bundle recorded from the left septum, CS: coronary sinus.

■ Figure 27.14

No resetting of AVNRT. Absence of resetting with para-Hisian pacing from the right septum. I, II, aVL: ECG leads, HRA: high right atrium, RHis: His bundle recorded from the right septum, LHis: His bundle recorded from the left septum, CS: coronary sinus, RIPS: right inferoparaseptal area.

used for differentiation between AV nodal and septal pathway retrograde conduction [123]. The response is considered extranodal when the retrograde atrial activation during His bundle capture is the same as during ventricular capture without His bundle capture. These techniques, however, require recording of both antegrade and retrograde His bundle activation.

The difference in the AH interval between atrial pacing and the tachycardia may also allow differentiation of atypical AVNRT from other types of long RP tachycardias. A  $\Delta A-H > 40$  ms indicates AVNRT, whereas in atrial tachycardia, this difference is  $< 10$  msec [105].

Right apical stimulation is relatively close to the insertion of a septal accessory pathway as opposed to the AV junction. Thus, ventricular fusion during resetting or entrainment of tachycardia has been reported to occur in patients with AVRT due to septal pathways but not with AVNRT [124]. Michaud et al. [100] have proposed two additional criteria for differential diagnosis. The ventriculoatrial (VA) interval and tachycardia cycle length (TCL) were measured during tachycardia, and entrainment of the tachycardia was accomplished with right apical ventricular pacing. The intervals between the last ventricular pacing stimulus and the last entrained atrial depolarization during tachycardia (SA) as well as the post-pacing interval were considered. All patients with AVNRT had SA-VA intervals  $> 85$  ms and PPI-TCL intervals  $> 114$  ms [100]. Conventional entrainment techniques do not take into account pacing induced incremental AV nodal conduction (ie in the post-pacing A-H) that may alter the PPI. Thus, Gonzalez-Torrecilla et al [126], “corrected” the PPI-TCL difference by subtracting from it the difference: postpacing AH interval minus basic AH interval. The presence of a corrected PPI-TCL  $< 110$  msec indicated AVRT. Entrainment through basal RV pacing away from the septum may produce prolonged PPI-TCL intervals in the absence of a septal pathway due to the distance of the RV base from the AV node (activation occurs retrogradely through the distal His-Purkinje system) and has been found superior to apical entrainment for diagnostic purposes [127]. A differential (between base and apex) corrected PPI-TCL  $> 30$  msec or a differential VA interval  $> 20$  msec has been reported to predict AVNRT very reliably [128]. The main advantage of this technique is that the differential VA interval could be calculated from the last paced beat in case the tachycardia was terminated after transient entrainment.

It should be noted that in clinical practice, pacing or other maneuvers cannot be applied to all cases and multiple criteria have to be used for the differential diagnosis of narrow complex tachycardias with atypical characteristics [113].

## 27.6.2 Wide-WRS Tachycardia

In the presence of wide-QRS tachycardia, when ventricular tachycardia is excluded, antidromic atrioventricular reentrant tachycardia should be differentiated from AVNRT with a bystander accessory pathway, and the possibilities of AVNRT or atrial tachycardia with aberrant conduction due to bundle branch block should also be considered.

### 27.6.2.1 AVNRT with a bystander Accessory Pathway versus Antidromic AVRT

Antidromic AVRT, i.e., tachycardia utilizing the accessory pathway for antegrade conduction and the AV node for retrograde conduction, may be induced in approximately 6% of the patients with accessory pathways located in the left or right free wall, or the anterior septum at an adequate distance from the AV node [125]. In some cases, atrioventricular junctional reentry may be the underlying mechanism of the preexcited tachycardia and the possibility of AVNRT conducting over a bystander accessory pathway should be considered in the presence of transition from narrow to wide complex tachycardia of a similar cycle length and without disturbing the HH intervals [129]. In this case, atrial extrastimuli fail to induce advancement of the following preexcited QRS complex, the next retrograde His bundle deflection where apparent, and the subsequent atrial deflection, as may happen in the presence of a macroreentrant loop [130].

■ Figure 27.15

Junctional tachycardia initiated with atrial pacing. Although there is a prolonged AH interval during tachycardia, the first tachycardia beat conducts without AH delay. (Reproduced from Hamdan et al. [136] with kind permission.) I, aVF, V<sub>1</sub>: ECG leads, ABL: ablation catheter, His: His bundle, CS: coronary sinus, RV: right ventricle, Stim: stimulation channel.

## 27.7 Non-Reentrant AV Junctional Tachycardias

### 27.7.1 Non-Paroxysmal Junctional Tachycardias

The term *non-paroxysmal junctional tachycardia* was initially used to denote junctional rhythms of gradual onset and termination with a rate between 70 and 130 beats/min [131]. This tachycardia was frequently diagnosed in the past, and considered to be a typical example of a digitalis-induced arrhythmia [132]. Non-paroxysmal junctional tachycardia usually occurs in patients with underlying heart disease, such as myocardial infarction, or after open-heart surgery, although it can occur rarely in apparently normal persons [133, 134].

Most cases of non-paroxysmal junctional tachycardia, especially the digitalis-induced, are caused by delayed after-depolarizations and triggered activity in the AV node [135]. In these patients, tachycardia can be induced by atrial ectopics or atrial pacing. Enhanced automaticity can also occur however, as suggested by the ability of this tachycardia in some patients to accelerate with enhanced sympathetic tone.

### 27.8 Focal Junctional Tachycardia

Focal junctional tachycardias have been also called automatic junctional tachycardias since the dominant (but not the only) mechanism is enhanced automaticity [136].

### 27.8.1 Pediatric Population

These tachycardias were first described in the pediatric population as junctional ectopic tachycardias [137] or His bundle tachycardias [138]. They may occur as a congenital arrhythmia [138–140] or early after infant open-heart surgery [141, 142]. The focus of the tachycardia seems to be localized in the lower part of the AV junction or, most probably, within the His bundle. They are dangerous forms of arrhythmia refractory to medical therapy, overdrive pacing, and DC cardioversion. Diagnosis is made on the ECG, which shows a narrow QRS tachycardia with slower and dissociated P waves. In electrophysiology study, there is a normal HV interval and normal AV conduction curves [139, 143].

### 27.8.2 Adults

In adult patients, the tachycardia is associated with a structurally normal heart and the prognosis is usually benign [144, 145].

The usual electrocardiographic finding is a narrow QRS tachycardia with AV dissociation. Occasionally, the tachycardia might be irregular, thus resembling atrial fibrillation. In the electrophysiology laboratory, the arrhythmia is not inducible by programmed electrical stimulation, thus making reentry an unlikely mechanism. It is, however, sensitive to isoproterenol administration, and in some cases, rapid atrial or ventricular pacing may result in tachycardia induction, suggesting abnormal automaticity or triggered activity as the other possible mechanism. During tachycardia, there is a normal or increased HV interval with atrioventricular dissociation that is interrupted by frequent episodes of ventriculoatrial conduction with earliest atrial activation in the posteroseptal, anteroseptal, or midseptal regions. At times, the mode of tachycardia induction resembles a double AV nodal response that is characteristic of AVNRT (● Fig. 27.15) [136].

## 28.1 Introduction

### 28.1.1 Definitions

The atrioventricular (AV) conduction system has the property of anterograde AV conduction in case of supraventricular activation of the heart, and in many instances of retrograde VA conduction, in case the heart is dominated by ventricular activation. AV dissociation is the phenomenon of independent activation of the atria and the ventricles. Different mechanisms for its occurrence exist, but the common denominator is the absence of the usual anterograde AV relation or retrograde VA relation. AV dissociation can be (1) complete or incomplete, (2) continuous or intermittent, and (3) structural or functional. When AV dissociation is incomplete, occasional AV or VA conducted beat is termed a capture beat (▶ Fig. 28.1). AV dissociation is not synonymous to AV block, the latter being just one of the mechanisms for AV dissociation [1].

### 28.1.2 Types

Three types of AV dissociation can be differentiated.

- AV dissociation may be found in the presence of a slow sinus or atrial rhythm, where the atrial rate is below the AV junctional or ventricular escape rhythm in combination with second-degree or incomplete block in the anterograde and retrograde direction. If the AV dissociation is incomplete, this could be the result of intermittent anterograde capture of sinus (or atrial) impulses or of intermittent capture of retrogradely conducted ventricular (▶ Fig. 28.2) or AV junctional escape beats. Complete AV dissociation is diagnosed when complete block in both directions is present.
- The second type is found in the presence of an AV junctional or ventricular rhythm with rate above the sinus (or atrial) rate in combination with second (▶ Fig. 28.3) or third (▶ Fig. 28.4) degree block in the retrograde direction.

■ Figure 28.1

The ladder diagrams illustrate incomplete AV dissociation during ventricular tachycardia. Part (a) demonstrates occasional atrial capture of the ventricle (arrow), while part (b) shows occasional ventricular capture of the atrium (arrow). In (a), there is retrograde block of the atrioventricular conduction system (AV) during ventricular tachycardia (cycle length 500 ms). The second atrial impulse from the left is able to capture the ventricle, because at that time there is no retrograde invasion of the AV conduction system. Part (b) shows the opposite. Anterograde conduction of atrial impulses is not possible during the existing ventricular tachycardia. However, a retrograde capture (fourth ventricular impulse) can arise if concealed anterograde penetration of the atrial impulse is absent. In this illustration, it can be seen that this impulse gives an echo beat back to the ventricle due to a dual AV nodal pathway.

■ **Figure 28.2**

The ladder diagrams illustrate intermittent capture (arrows) during sinus bradycardia: (a), anterograde capture and (b), retrograde capture. In (a), the ventricular escape rhythm is not able to conduct in the retrograde direction. Because of the feasibility of anterograde conduction, the second beat from the left of the slow atrial rhythm captures the ventricle. In (b), anterograde conduction of the slow atrial rhythm is not possible. No retrograde conduction is present in the third and sixth ventricular escape beats. The fifth and eighth ventricular beats from the left are able to capture the atrium (arrows) because at that time anterograde concealed penetration from the atrium is absent. No echo beat is seen, because there is no dual AV nodal pathway as was present in [Fig. 28.1](#).

■ **Figure 28.3**

Simultaneously recorded five-channel ECG and a right-atrial endocavitory recording illustrating a rather rare example of 5:4 retrograde VA conduction in a patient with ventricular tachycardia. As can be seen in this case, leads II and V<sub>1</sub> are often helpful in detecting P waves on the surface ECG (RA: right atrium, a: atrial endocavitory signal).

■ Figure 28.4

This five-channel ECG shows a tachycardia with a rate of  $150 \text{ beats min}^{-1}$  (bpm). The endocavitary atrial recording (HRA) indicates complete AV dissociation with a ventricular rate higher than the atrial rate. The P waves are also clearly visible in lead II. The finding of complete AV dissociation is extremely suggestive of the presence of ventricular tachycardia.

In the presence of normal anterograde conduction, capture beats can frequently be seen at lower rates of the accelerated ventricular (or AV junctional) rhythm (► Fig. 28.5). Higher ventricular (or AV junctional) rates usually do not allow anterograde conduction (complete AV dissociation). This form of AV dissociation is clinically important in tachycardias with a wide QRS complex. It helps to differentiate a supraventricular tachycardia with aberrant conduction from a ventricular tachycardia [1]. AV dissociation in wide QRS tachycardias is diagnostic of ventricular tachycardia. Approximately 50% of ventricular tachycardias have complete AV dissociation. In the other 50%, 1:1, 2:1, or Wenckebach type, VA conduction is present [2–5]. Capture or fusion beats are also of help in differentiating supraventricular tachycardia with aberrant conduction from ventricular tachycardia. However, their occurrence is rare (6%) [2].

- (c) The third and most important type of AV dissociation is AV block. Block describes delay or failure of impulse propagation. Varying degrees of block exist. AV block is usually classified as first-, second-, or third-degree block according to the severity of the conduction disturbance [6]. AV block will be discussed in detail, because it is the most frequent cause of AV dissociation and its presence has important clinical implications.

## 28.2 History of Atrioventricular Block

In 1827, Robert Adams [7] opposed Morgagni's hypothesis [8] that the brain was the cause of seizures in patients with bradycardia. He stated that perhaps the heart was the cause of the bradycardia and the neurological symptoms were the subsequent result. Many disagreed with Adams, but William Stokes [9] concluded in 1846 that Adams' concept was correct. The term heart block was introduced by Gaskell [10, 11] in 1882. Einthoven [12] demonstrated the first case of AV block on an electrocardiogram. Wenckebach [13], Hay [14], and Mobitz [15] described and classified several types of AV

■ **Figure 28.5**

Recording of a ventricular tachycardia with a rate of approximately 135 bpm. The HH intervals are 460 ms. The fifth beat from the left is a little earlier than expected with an HH interval of 400 ms. The QRS configuration is also different. The intracardiac recordings indicate that this premature beat is a fusion between an anterogradely conducted (capture) beat and impulse formation in the ventricle (HRA, high right atrium; CS<sub>d</sub>, distal coronary sinus; HIS, His bundle; CS<sub>p</sub>, proximal coronary sinus).

block. In the following years, many other clinical and experimental studies were published [16–19]. The introduction of intracardiac recordings [20] made possible more precise determination of location of block in humans.

## 28.3 Classification of Atrioventricular Block

### 28.3.1 First-Degree AV Block

This represents a prolongation of the AV conduction time (PR interval) beyond 0.2 s. However, every atrial impulse is conducted to the ventricle. Therefore the term block should be avoided. These criteria can be applied only in the presence of a regular sinus or atrial rhythm. The normal PR interval is age-dependent. In younger patients, the PR interval is shorter due to sympathetic tone. The PR interval is also shortened during exercise.

### 28.3.2 Second-Degree AV Block

This is diagnosed when some of the atrial impulses are not conducted to the ventricle. Second-degree block can be subdivided into the following categories.

#### 28.3.2.1 Mobitz Type I (Wenckebach) Block

In this form of second-degree AV block, the PR interval in several successive beats becomes progressively prolonged, resulting in the dropping on one ventricular depolarization due to failure of conduction. The subsequent PR interval is shortened (▶ Fig. 28.6) [13, 15, 21].

■ **Figure 28.6**

Six-channel ECG recording illustrating a Mobitz type I AV block in the AV node or His bundle (narrow QRS complex). Statistically, there is an 8:1 chance that the block is situated in the AV node.

### 28.3.2.2 Mobitz Type II Block

In this type of second-degree AV block, there is a sudden failure of one or more atrial impulses to be conducted during maintenance of a constant PR interval (▶ Fig. 28.7) [15–21].

### 28.3.2.3 Higher Degree AV Block

In 2:1 AV block, every second atrial impulse is not propagated to the ventricle (▶ Fig. 28.8). High-degree or advanced AV block, such as 3:1 or 4:1 block, or occasional conducted impulses can exist [22].

### 28.3.2.4 Third-Degree (Complete) AV Block

In third-degree (complete) AV block, no atrial impulses are propagated to the ventricle (▶ Fig. 28.9).

## 28.4 Methodology for Determining the Site of a Block

The conduction defect can be present in the AV node, His bundle, bundle branches, or at multiple sites. Determination of the location of the type of block has important consequences in terms of prognosis and treatment.

■ **Figure 28.7**

Twelve-lead ECG of a patient with Mobitz II block in acute anteroseptal infarction. The third P wave in the left panel and the second P wave in the right panel are suddenly blocked. The QRS width is narrow, suggesting a conduction problem within the His bundle.

■ **Figure 28.8**

In this recording, leads III, V<sub>1</sub>, high rate atrium (HRA), and His-bundle lead (HIS) are shown. On the left side of the figure, sinus tachycardia at a rate of 105 bpm with 1:1 conduction is present. First-degree AV block is seen with an AH interval of 120 ms (normal 50–120 ms) and an HV interval of 260 ms (normal 35–55 ms). The sudden change from 1:1 to 2:1 AV block develops without further prolongation of the preceding HV interval. The His recording proves that AV block is located distal to His, because every atrial activation is followed by a His signal. The presence of block in the bundle branches is suggested by the QRS width ( $\pm 220$  ms) in the surface ECG. The configuration in lead V<sub>1</sub> indicates the presence of a right bundle branch block and the negative QRS complex in lead III is in favor of a left anterior fascicular block.

**Figure 28.9**

This ECG shows an extensive acute infero posterior wall myocardial infarction with third-degree block situated in the AV node and an AV nodal escape rhythm (narrow QRS complexes) of 38 bpm. In acute inferior myocardial infarction, AV block can occur due to vagal stimulation. Usually, the sinus rate is then also low. In this illustration, the sinus rate is approximately 100 bpm, which makes it unlikely that the AV conduction disturbance is caused by vagal influences.

## 28.4.1 The Value of the Electrocardiogram

### 28.4.1.1 PR Interval

The PR interval is the time between the beginning of the P wave and the beginning of the QRS complex, and as such, gives an indication of AV conduction.

AV conduction delay or block can be present in the atrium, AV node, His bundle, bundle branches or Purkinje fibers, but the actual site cannot be determined from the surface ECG. PR prolongation of more than 0.3 s is very suggestive of conduction delay in the AV node, but a PR interval between 0.2 and 0.3 s has no indicative value as to the site of block. Block can also be simultaneously present at different levels of the conduction system.

### 28.4.1.2 QRS Complex

Puech et al. [23], Narula [24], and Schuilenburg [25] found in their studies that the width of the conducted QRS complex gives an indication of the site of block.

### 28.4.1.3 Conducted Beats: Narrow QRS Complexes

QRS complexes of less than 0.12 s usually signify that the block is located in the AV node or His bundle (Fig. 28.10). A rare exception of a narrow, conducted QRS complex in the presence of trifascicular disease is the coincidence of identical conduction delay in both bundle branches, resulting in PR prolongation and a narrow QRS complex.

**Figure 28.10**

Leads I, II, III, V<sub>1</sub>, and V<sub>6</sub> are shown in combination with the intracardiac recordings from high right atrium (HRA) and His bundle (HIS). Paper speed is 100 mm/s. First-degree AV block is present. Because of the prolonged AH time of 210 ms, the conduction delay is located in the AV node. This might have been expected from the surface ECG because of the narrow QRS complexes (0.09 s).

#### 28.4.1.4 Conducted Beats: Widened QRS Complexes

QRS complexes  $\geq 0.12$  s do not allow any conclusions to be drawn as to the site of block. A significant group of patients has a combination of AV nodal or intra-Hisian block associated with an intraventricular conduction defect (▶ Fig. 28.11), while others have block in the bundle branches (▶ Fig. 28.8). However, AV block with widened QRS complexes in the setting of an extensive anterior wall infarction is frequently associated with bilateral bundle branch block (▶ Fig. 28.12) [26–28].

#### 28.4.1.5 Escape Rhythm

In patients with third-degree block situated in the AV node, 65% have an escape rhythm with a narrow QRS complex, while 35% have a wide QRS complex [29–31]. All patients with trifascicular block have a wide QRS escape rhythm.

Although Adams–Stokes attacks cannot be predicted on the ECG, patients having wide QRS complexes with a slow escape rate are most prone to syncopal attacks, because distal block has a slow (25–45 bpm) and unreliable escape rhythm with long periods of asystole (▶ Fig. 28.13) [32]. The escape rate in the AV node is usually higher and reliable (40–60 bpm). Sometimes the escape rhythm is faster than expected (▶ Fig. 28.14). These accelerated idioventricular rhythms (AIVR) have rates between 60 and 125 bpm, and are commonly seen in the reperfusion phase of an acute myocardial infarction. AIVR is a very specific reperfusion arrhythmia with a specificity of more than 80% and a positive predictive value of more than 90% [33–35]. AIVR is probably caused by reperfusion damage. It is a transient, self-terminating arrhythmia that does not need treatment. It usually has no major hemodynamic consequences, and it is not a precursor of more malignant

**Figure 28.11**

Five surface and four intracardiac recordings illustrating that the first-degree AV block arises from conduction delay at two levels. The AH interval is slightly prolonged (130 ms). The most important delay is present in the distal conduction system (HV interval = 100 ms). This last finding is an indication for pacemaker implantation.

arrhythmias. Engelen et al. [36] showed a relation between the number and duration of AIVR's and the recovery of left ventricular function following reperfusion. In that study, it was also found that after percutaneous coronary intervention, AIVR was less frequent than after reperfusion due to fibrinolytic treatment.

## 28.4.2 The Value of Diagnostic Interventions

### 28.4.2.1 Noninvasive Methods

Noninvasive interventions can be useful for detecting the location of block. These interventions include the following.

#### Atropine

Atropine, when given intravenously in a dosage of 0.5–1 mg, has an accelerating effect on the sinus rate, which can produce further deterioration of AV conduction. On the other hand, the drug improves impulse conduction through the AV node [24]. Because of the delicate balance of these two effects, it is not surprising that the outcome of atropine administration is not completely predictable, since it depends on the variable responses of impulse formation and conduction (▶ Fig. 28.15). When given to patients with AV nodal conduction problems, atropine can shorten the PR interval or diminish the degree of block. In patients with a conduction problem below the AV node, no effect on conduction is seen although sometimes a more severe degree of block is provoked by the increase of the sinus rate.

#### Ajmaline

A latent conduction defect, present in the bundle branches, can be uncovered by ajmaline (50 mg intravenously) because this drug depresses conduction below the AV node [37–39].

This test is dangerous, however, because it can result in ventricular asystole (for explanation see ▶ Sect. 28.4.1.5). Ajmaline should be given only after introducing an external ventricular pacemaker. The second rare, but more serious,

■ **Figure 28.12**

Twelve-lead ECG of a patient with an extensive anteroseptal myocardial infarction and trifascicular conduction problems which were acquired during the infarction. Lead V<sub>1</sub> shows a QR pattern typical of septal involvement of the infarct in combination with a complete right bundle branch block. Right axis deviation suggests block in the posterior fascicle of the left bundle, while the PR prolongation (0.26 s) is most likely caused by additional block in the third bundle – the anterior fascicle of the left bundle. Intracardiac recordings showed a normal AH interval and a prolonged HV interval indicating that conduction delay indeed was located below the His bundle. Mortality is extremely high (86%) due to the extensive muscle damage, which can be indirectly derived from the above-mentioned conduction defects.

■ **Figure 28.13**

ECG recording demonstrating third-degree AV block in a patient with Lev's disease. The external pacemaker rate was gradually turned down and switched off. After the last paced beat, long periods of ventricular asystole can be seen.

Figure 28.14

Left panel. Twelve-lead ECG of a patient with an acute anteroseptal infarction. Right panel. Accelerated idioventricular rhythm (AIVR) with a configuration suggesting an origin in the basal septal part of the left ventricle, that is, the infarcted area. Typically, AIVR in this setting starts with a long coupling interval and has regular R-R intervals.

Figure 28.15

Six surface ECG leads of a patient with distal AV conduction disturbance. In (a) third-degree block is present. Because of the narrow QRS escape rhythm, the conduction problem is located in the AV node or the His bundle. P-P interval is 720 ms and R-R interval 1500 ms. In (b) carotid sinus massage (CSM) is performed. In proximal AV block, further depression of AV nodal conduction would therefore be expected. However, the significant slowing of the sinus rate allows the AV node to propagate every P wave to the ventricle and to restore normal conduction. In (c) atropine was given. In proximal AV block, atropine improves AV nodal conduction. In this case, the important decrease in P-P interval (440 ms) prevents normal conduction. The two opposite effects result in second-degree AV block. It can be deduced that the second beat from the left is conducted because it comes earlier than expected and its configuration is identical to that in the conducted beats in (b) and different from the escape beats in (a). The rate of the escape rhythm has increased slightly with the R-R interval shortening from 1500 to 1300 ms.

**Figure 28.16**

Twelve-lead ECG showing a complex arrhythmia due to distal conduction disease in a patient after aortic valve replacement. Advanced AV block present with the first 2 QRS complexes show incomplete right bundle branch block and left axis deviation (anterior fascicular block). The 3<sup>d</sup> QRS complex is conducted with a prolonged PR interval and shows left bundle branch block. A fourth beat with the initial configuration is seen, followed, due to carotid sinus massage (CSM)–induced mild slowing of the sinus rate, by 1:1 conduction with prolonged PR intervals and left bundle branch block.

complication that has been described is ventricular fibrillation. Therefore, sound advice is to restrict this test to special cases only.

#### Vagal maneuvers

Vagal maneuvers, such as carotid sinus massage, have the opposite effect to atropine and produce further prolongation of the PR interval or provoke second-degree block in the AV node, whereas no effect is seen in distal block [24]. However, the vagal maneuver can give concomitant AV nodal conduction delay in those patients having conduction problems in the His–Purkinje system [40]. Furthermore, conduction may be restored in both types of block because of slowing of the sinus rate (► Figs. 28.15 and ► 28.16). Therefore, vagal maneuvers are of less value for differentiation among various sites of block.

Vagal maneuvers can depress, and atropine or exercise can accelerate, the escape rhythm in the AV node during third-degree block. They do not usually have much influence on escape rhythm below the AV node.

#### Exercise

Exercise has an adrenergic effect on the heart, which is comparable to atropine. During exercise, sinus rate increases and AV nodal conduction improves. In patients with conduction problems in the His bundle or bundle branches, exercise may enhance the degree of block due to increase of the sinus rate (► Fig. 28.17). Occasionally, in patients with bridging of one of the coronary arteries, block can also develop during exercise [41].

### 28.4.2.2 Invasive Methods

#### Atrial pacing

Atrial pacing will produce further prolongation of the PR interval, and can result in a higher degree of AV nodal block in patients with AV nodal disease. In contrast to this, the effect of atrial pacing on infranodal block is

■ **Figure 28.17**

Six-lead ECG of a 54-year-old male, who exercised on a treadmill. A sudden change from 1:1 to 2:1 AV conduction was found at sinus rates more than 65 bpm, as well as a change to 3:1 AV conduction at sinus rates above 145 bpm. In this patient, the His bundle is the most likely location of block, because the PR interval of the (probably) conducted P wave remained constant (0.15 s) and the QRS complex was narrow (0.09 s).

minor. Patients with first-degree block in the His–Purkinje system will usually maintain 1:1 conduction at high atrial rates [24].

The escape rhythm can be suppressed by ventricular stimulation in patients with third-degree AV block in or distal to the His bundle (► Fig. 28.13). The escape rhythm in AV nodal block is not so easily suppressed by ventricular pacing.

There is no difference in respect of the reaction to atropine, exercise, and artificial pacing of the atrium in a normal heart [42–44]. The same holds also for the diseased heart. This is true for first-degree as well as for second-degree block [45–48].

### The His-bundle ECG

The most appropriate method for determining the site of block is His-bundle recording [20, 25, 49–58]. Using this approach, the intra-atrial (PA) conduction time can be measured. This is the time between the onset of the P wave on the surface ECG (or the intracavitary high right-atrial ECG) and the first rapid deflection of the atrial wave in the His-bundle recording (see ► Fig. 28.5). AV nodal conduction is measured as the AH time (the time between the atrial wave and the beginning of the His-bundle spike on the His-bundle recording). The HV time is the time from the beginning of the His-bundle spike to the earliest onset of activation of the ventricle. PA time varies between 25 and 45 ms, AH time between 50 and 120 ms and HV time between 35 and 55 ms. The width of the His-bundle potential is 15–20 ms [46, 54, 55, 59–65]. A full discussion on His-bundle ECG recording is presented in ► Chap. 24.

Electrophysiological investigations are of great help in the presence of AV block and widened QRS complexes. Such recordings allow us to find the exact location of block (► Figs. 28.11 and ► 28.18), to predict the likelihood of asystole, and to determine the reliability of the escape rhythm. His-bundle recordings may be required to identify those patients at risk of developing complete block, because in patients with bifascicular block, abnormal conduction of the remaining fascicle may also be present. It has been shown that AV conduction delays may exist in the absence of PR prolongation or other electrocardiographic abnormalities [46].

A His-bundle recording is, however, not a routine procedure because it is a time-consuming and invasive investigation [66]. The level of the conduction defect can roughly be estimated by studying the PR interval, QRS duration, and AV relationship on the surface ECG in the majority of cases [67–69].

■ **Figure 28.18**

This recording is taken from a patient with Adams–Stokes attacks due to paroxysmal complete AV block. It shows five surface leads and five intracardiac recordings. The His-bundle electrogram shows that every atrial signal is followed by a His deflection, indicating that block is located distal to His. The rate of the ventricular escape rhythm is only 26 bpm. The second escape beat is retrogradely conducted to the His bundle. The next atrial event is blocked proximal to the His bundle because of retrograde concealed penetration of the AV node (HRA, high right atrium; RV, right ventricle; HIS, His bundle; CS; coronary sinus; LRA, low right atrium; interval given in milliseconds).

For the clinician, a knowledge of whether the site of the block is above or below the His bundle is probably sufficient. Invasive and noninvasive methods for determining the site of block will be discussed in detail for all three types of conduction disturbances.

## 28.5 Incomplete Block

### 28.5.1 First-Degree AV Conduction Delay

In the following discussion, the term first-degree AV “block” will be avoided, as there is no block but rather delay in conduction.

In first-degree AV conduction delay, the site of the delay is most frequently located in the AV node, but can also be found infranodally (▶ [Table 28.1](#)). Some patients have PR prolongation due to intra-atrial conduction delay. The P wave will then be widened and markedly diminished in voltage [70]. In these cases there may be no impaired conduction in the AV nodal or His–Purkinje system. However, intra-atrial conduction delay is often related to atrial arrhythmia [70].

PR prolongation greater than 0.2 s has no value as far as locating the site of block is concerned. However, a PR interval greater than 0.3 s is very suggestive of a delay within the AV node. Narula et al. [24] stated that in 79% of all cases with prolonged PR interval, the conduction delays were located at more than one site, although the AV node was the dominant site of delay (83%). Delay at a single site was noted in the atrium in 3%, in 11% in the AV node, and in the His–Purkinje system in 7%. Puech et al. [29] reported conduction disturbances at multiple sites in only 20% of their cases.

A narrow QRS complex suggests that block is located in the AV node (▶ [Fig. 28.10](#)). First-degree AV conduction delay in combination with a wide QRS complex is most commonly associated with a conduction defect in the bundle

Table 28.1

Incidence of the location of block in first degree AV-block [29]

	AV node	Intra-Hisian	Bundle branches
Narrow WRS complex (< 0.12 s)	87%	13%	
Wide QRS complex ( $\geq$ 0.12 s)	22%	12%	66%

branches (Figs. 28.8 and 28.11). However, frequently (66%) block is present at two levels, especially in those with left bundle branch block [29, 30, 68, 69, 71, 72]. When PR prolongation and left bundle branch block are found together, block is predominantly located in the common bundle (Fig. 28.7) [29, 71, 72]. Complete right bundle branch block with first-degree AV conduction delay, without extreme right or left axis deviation, is associated with conduction delay in the left bundle branch in only 40% of the cases. All other patients have additional conduction problems in the AV node or His bundle. The combination of first-degree AV conduction delay and bifascicular block (right bundle branch block and left anterior or posterior fascicular block) is commonly a result of a conduction delay in the third bundle branch (Fig. 28.12), although in rare cases the conduction delay can be located in the AV node [71, 72].

In patients where the ECG shows a PR prolongation and a wide QRS complex, His-bundle studies should be performed. HV intervals of more than 75 ms are an indication for pacemaker implantation [73, 74], because in patients with these findings, total AV block and syncope will probably shortly appear due to progressive disease of the conduction system. In contrast to this, first-degree AV nodal delay carries a good prognosis. In such cases, pacing is not indicated.

It has to be realized that occasional prolongation of PR time is found in apparently normal subjects [43, 75, 76]. PR intervals up to 0.28 s were found in 1.6% of 19,000 healthy aviators [3, 77]. A 10-year follow-up study showed that none of these people had progression of their first-degree AV block [78].

Interventions such as atropine (Fig. 28.15) and exercise will decrease PR interval in patients with AV nodal conduction delay. On the other hand, carotid sinus massage produces further prolongation of the PR interval, or can give second-degree block when the conduction delay is present in the AV node. Carotid sinus massage, when performed in patients with first-degree block in the His–Purkinje system, does not generate second-degree block. In patients with AV nodal disease, atrial pacing at rates above 130 bpm will either produce further prolongation of the PR interval or second-degree block. In the presence of HV prolongation, atrial pacing at rapid rates usually maintains 1:1 AV conduction without further prolongation of the HV interval. Only occasionally does second-degree infranodal block develop.

## 28.5.2 Second-Degree AV Block

Table 28.2 presents the incidence of second-degree block at the various sites.

### 28.5.2.1 Mobitz Type I (Wenckebach) Block

The classic type I second-degree block is characterized by a progressive lengthening of the PR interval until a P wave is blocked. The PR interval is longest in the beat preceding the blocked P wave and the shortest after the dropped beat. The maximum PR increment occurs between the first and second conducted beat. In the following conducted cycles, the increment of PR interval gradually diminishes, resulting in a lessening of the PR interval increment (Figs. 28.6 and 28.18).

The explanation for this type of conduction defect is probably that the progressive delay is caused by increasing fatigue of the AV node or distal conduction system until a block occurs. Presumably, each impulse arrives earlier in the relative refractory phase of the conduction system (see Chap. 3). Therefore, the impulse is conducted more slowly, until it reaches the absolute refractory phase. After the dropped beat, the conduction system has partially recovered, resulting in a shorter PR interval. The Wenckebach phenomenon can be observed in any portion of depressed conduction system [13, 67, 79–82]. However, this classic pattern of Wenckebach block is seen infrequently (14%) [83, 84]; it is seen more often in patients with higher conduction ratios such as 4:3 or 5:4. Conduction ratios such as 7:6 are normally associated

■ **Table 28.2**

**Incidence of the location in second-degree AV block [29]**

	AV node	Intra-Hisian	Bundle branches
Mobitz type I (Wenckebach)	72%	9%	19%
Mobitz type II		20%	80%
2:1 block	27%	23%	50%

■ **Figure 28.19**

Part (a) represents a typical 5:4 Wenckebach sequence. Progressive lengthening of the AV interval is present. The increment of the AV interval becomes smaller from beat to beat, decreasing from 120 to 30 ms over the first four cycles. This results in shortening of the R-R intervals. Part (b) also shows a Wenckebach sequence. The behavior of this block is atypical. In other words, although there is a gradual prolongation, the AV interval changes unpredictably from beat to beat. The atypical behavior of the Wenckebach sequence is in this case caused by the change in atrial rate.

with an atypical behavior. They show progressive PR prolongation with unpredictable changes in increment. This is called atypical Wenckebach (► Fig. 28.19).

The explanations for the atypical Wenckebach behavior have been described by Langendorf and others [83–93], and are as follows.

- Changes in sinoatrial rate which influence the PR interval. This is probably the most important explanation. The change in sinoatrial rate could be caused by a change in cardiac output caused by the Wenckebach sequence.
- Interpolated atrial premature contractions causing changes in AV conduction [89].
- Reentry or premature impulses giving rise to concealed premature depolarization of conduction tissue [86–88, 90–93]. Concealed conduction may lead to an unanticipated prolongation of PR interval or blocked P waves after a Wenckebach pause, because partial penetration of an impulse into the conduction system influences the subsequent impulse conduction. The degree of penetration of a blocked impulse can sometimes be inferred from its effect on subsequent events. Atypical Mobitz type I block is seen intranodally as frequently as infranodally [94].

Location of type I block is rather unpredictable and requires His-bundle studies, especially when the conduction disturbance is associated with wide QRS complexes [94, 95]. Minimal increment in the PR interval suggests distal block, but it is not diagnostic.

Significant prolongation of the PR interval during the Wenckebach cycles suggests AV nodal block. Second-degree block located in the AV node has a relatively benign course in patients without organic heart disease and does not produce syncope [96, 97]. In contrast to this, distal second-degree block requires pacemaker implantation [98].

First-degree and second-degree type I block can be present in normal subjects especially during sleep [75, 99–104]. A 6% incidence of spontaneous Wenckebach periods during sleep has been reported in healthy students without apparent heart disease. In none of these subjects were symptoms or progression of block observed in a 6-year follow-up period [101]. The same was found in athletes, where there was a 9% incidence of Wenckebach periods [76, 100–103, 105]. However, the

benign prognosis of this type of block is not confirmed in all studies. During prospective analysis of 16 infants with second-degree type I AV block, seven of them had progression to third-degree block, and one of these seven experienced syncopal attacks [102].

Intervention procedures are not helpful for the differential diagnosis between normal and diseased subjects [45–48].

### 28.5.2.2 Mobitz Type II Block

Mobitz type II second-degree AV block is characterized by a sudden failure of a P wave to be conducted to the ventricle without PR prolongation in the preceding beats (Figs. 28.7 and 28.20). This type of block is always located below the AV node (Table 28.1). The nonconducted P wave will be followed by a His-bundle signal. Sometimes a “split” His can be seen in the His-bundle recording in the presence of His-bundle disease. In the rare case of a proximal His-bundle defect, the His signal will not be seen after the P wave, but preceding every QRS complex thereby fallaciously simulating AV nodal block [46, 106, 107]. In patients having disease of the bundle branches, widened QRS complexes are present [24], while the PR interval is usually normal or slightly prolonged [79]. One-third of the cases of chronic second-degree block have the typical behavior of Mobitz type II AV block. A finding of Mobitz type II block is always an indication for pacemaker implantation, because it is usually permanent and often progresses to complete AV block [108].

With respect to interventions during second-degree Mobitz type I or II AV block, atropine and exercise can enhance AV conduction and restore 1:1 conduction. Such a finding is suggestive of AV nodal block. If distal block is present, sometimes the reverse effect can be seen and progression of block will appear because of an increase in sinus rate without improvement of conduction of the His–Purkinje system [40]. The opposite is seen after carotid sinus massage.

In AV nodal block, atrial pacing will produce further progression of AV block, while in His–Purkinje system block, minor changes are seen in PR and HV intervals.

Figure 28.20

Twelve-lead surface ECG combined with intracavitary recordings from the same patient, as in Fig. 28.7, shows the location of the block distal from the His bundle.

Differentiation between type I and II is important with respect to management, because type II block is always indicative of distal disease. Distinction between types of block can be difficult if there is only a minimal increment in PR interval before and after a dropped beat or in the presence of 2:1 block. In these patients, exercise or atropine may clarify the situation by provoking Wenckebach periods due to higher sinus rates. Vagal maneuvers may produce a higher degree of block and indicate which is the underlying type of block.

### 28.5.2.3 2:1 or Higher Degree AV Block

Several terms are used for this type of block such as advanced AV block [22] and severe or high-degree block [109]. In 2:1 block, every second P wave is conducted to the ventricle (▶ Fig. 28.8). These cases cannot be distinguished as type I or type II unless two consecutively conducted beats are seen, such as during temporary 3:2 block or 1:1 conduction (▶ Fig. 28.8) [96]. Changes in conduction can be secondary to slight alterations of the vagal tone [30].

With respect to interventions in this group, carotid sinus massage, if applied with caution, may be clinically useful in indicating the site of block. Increase of block in the AV node is suggestive of an AV nodal conduction problem, while decrease of block indicates distal block because of slowing of the sinus rate. In rare cases with bradycardia-dependent distal block (phase 4 block – see ▶ Chap. 23), carotid sinus massage aggravates block [56, 110]. Atropine and exercise have the opposite effect to vagal stimulation [30, 47, 48, 111].

The interesting phenomenon of ventriculophasic arrhythmias in digitalis intoxication should be mentioned. Excess of digitalis can produce all three types of block in the AV node [112, 113]. Second-degree AV block as a manifestation of digitalis intoxication most commonly shows the Wenckebach type of block or a constant type of 2:1, 3:1, or 4:1 block. During 2:1 AV conduction, the P–P interval embracing the QRS complex [114] differs from the P–P interval without a QRS complex [114]. This is possibly the result of a change in autonomic tone during the cardiac cycle [115, 116].

## 28.6 Complete Block (Third-Degree AV Block)

In complete block, no atrial impulses are propagated to the ventricle. Third-degree or complete AV block can be located at all three sites of the conduction system [61, 72, 117]. (▶ Table 28.3). The location of block cannot be predicted from the escape rhythm. However, during the acute phase of a myocardial infarction the site of infarction provides indirect information as to the site of block. Myocardial infarction located in the inferior wall can give AV nodal block (▶ Fig. 28.9), while damage located in the anteroseptal wall indicates that the conduction disorders are in the bundle branches (▶ Fig. 28.12) [26, 28, 118]. If the rate of the escape rhythm is more or less the same as the atrial rate, it can be difficult to distinguish this “isorhythmic dissociation” from sinus rhythm with 1:1 conduction to the ventricle. An example of such a problem is given in ▶ Fig. 28.21.

Interventions can be performed in patients where the origin of block is unclear. In contrast to findings during distal block, exercise and atropine [47, 48] can increase rate in the AV node significantly or can restore first- or second-degree AV block [30, 32, 60, 118–120]. Atrial pacing does not help in further differentiation between sites of block. Ventricular pacing has to be carried out with caution because subsidiary pacemakers are readily suppressed by ventricular stimulation and can produce long episodes of asystole. Such a finding is suggestive of distal block. Carotid sinus massage may slow the AV nodal escape rhythm, but can produce second-degree block instead of third-degree block in distal conduction disturbances due to slowing of the sinus rate with late arrival of the impulses at the distal conduction system, giving them more time to recover [121, 122].

■ **Table 28.3**

**Incidence and location of block in third-degree AV block [29]**

Escape rhythm	AV node	Intra-Hisian	Bundle branches
Narrow QRS complex (<0.12 s)	48%	52%	
Wide QRS complex (≥0.12 s)	11%	5%	84%

■ Figure 28.21

The rhythm in this tracing is either sinus rhythm with first-degree AV block or “isorhythmic dissociation,” that is, a situation where, in the presence of complete block, rates at atrial and ventricular level are more or less identical. In this registration, careful measurement will show that the PR intervals of the first two beats are longer than the other PR intervals, which could fit with an isorhythmic dissociation. However, the sinus rate of the first two beats is higher, causing further lengthening of PR interval. The key for making the correct diagnosis is that the R–R interval of the first beats is also shorter. Therefore, a relation between atrium and ventricle must be present. If complete block were present, the ventricular rate would not have been influenced. This proves that sinus rhythm with first-degree AV block is the correct diagnosis.

## 28.7 Etiology of Atrioventricular Block

Multiple pathological processes can affect the conduction system. The common causes of AV block are the following.

### 28.7.1 Fibrosis

The most frequent cause of AV block (40–50%)[123] is fibrosis of the specialized conduction system due to progressive sclerosis of the ventricular septum and the surrounding tissues [16, 123–126]. This is also called Lenègre and Lev disease. It is a typical disease of the elderly. These patients can have normal coronary arteries [127–131].

### 28.7.2 Ischemic Heart Disease

The second important cause of AV block (40%) is ischemic heart disease. Two out of five occurrences are chronic [130] and three out of five can be found in the setting of an acute myocardial infarction (🔗 Figs. 28.9 and 🔗 28.13) [132–135]. In approximately 19% of patients having an acute myocardial infarction, AV block develops (8% first degree, 5% second degree and 6% third degree) [136–138]. Only a few patients have exercise-related ischemic AV block.

### 28.7.3 Drugs

Digitalis [112, 114, 139–141] can create different degrees of AV nodal block, especially when given in a toxic dosage (🔗 Fig. 28.22). Other drugs which can create AV nodal block are verapamil, amiodarone, diphenylhydantoin [142], and beta-blocking agents [143]. Quinidine and other class I drug [144] can produce block in the His–Purkinje system.

### 28.7.4 Vagal Influences

Not uncommonly, vagal reactions, for example, due to pain (🔗 Fig. 28.9) or during carotid sinus massage, can produce complete AV block, sometimes with longer ventricular asystole [145–148]. In elderly patients, the presence of hypersensitive carotid sinus syndrome can produce profound fall in arterial pressure and marked slowing in heart rate either by slowing of the sinus rate and/or the development of second-degree or third-degree AV block [147, 149, 150]. This may or may not be combined with a vagal vasodilatory effect.

**Figure 28.22**

Atrial tachycardia with 2:1 AV conduction in digitalis intoxication. After dissipation of the digitalis compound from the blood, sinus rhythm with normalization of the AV conduction and the ST segments reoccurred.

### 28.7.5 Valvular Disease

Disease of the aortic or mitral valve with a calcified valve ring (rheumatic, congenital bicuspid, or other) can give rise to block in the His bundle. This is frequently seen in aortic stenosis. When the aortic valve is severely calcified, the deposits can extend down into the ventricular septum and advanced or complete block may develop (▶ Fig. 28.16) [125, 130, 151].

### 28.7.6 Postsurgery

Replacement of a calcified aortic or mitral valve [5], closure of a ventricular septal defect, or other surgical traumas can result in AV block [19, 134, 152–156].

### 28.7.7 Congenital Disease

Complete AV block may also be congenital occurring as an isolated finding or, in half of the patients, in association with congenital malformations of the heart [152, 154, 157–167]. Most patients with congenital block have their conduction disturbance in the AV node and some of them in the His bundle [72, 153, 159, 168]. Microscopic studies suggest that there is a failure of the atrial myocardium to contact the AV region or a congenital separation between the AV node and the His–Purkinje system caused by an alteration in the development of the AV node [19, 120, 125, 130, 153, 169–175].

### 28.7.8 Cardiomyopathy

Any type of block can coexist with any type of cardiomyopathy as in amyloidosis, sarcoidosis (▶ Fig. 28.23) [176], and hypertrophic obstructive cardiomyopathy [125, 130, 177–179].

■ **Figure 28.23**

Twelve-lead ECG of a male with documented cardiac sarcoidosis, involving the distal conduction system. Sinus rhythm is present with complete AV block and a slow escape rhythm suggesting an origin in the inferior part of the right ventricle.

### 28.7.9 Myocarditis

Myocarditis can be bacterial, like acute rheumatic fever, diphtheria or Lyme disease, or viral [180–192]. AV block developing in this setting is a sign of a poor prognosis in the evolution of the disease [125, 130].

### 28.7.10 Potassium

High potassium levels [193, 194] can create AV block at plasma levels above  $6.5 \text{ mEq l}^{-1}$ .

### 28.7.11 Others

An association of AV block with muscular and neuromuscular hereditary degenerative syndromes is known [124, 125, 195–197]. In myotonic muscular dystrophy, Kearns–Sayre syndrome [198], Erb's dystrophy (limb-girdle), and peroneal muscular atrophy with or without symptoms of pacemaker implantation should be considered because there may be unpredictable progression of AV conduction disease [199, 200]. Cardiac tumors, primary [201] or metastatic [202], after chemotherapy [203] and radiation [204], cysts [125, 205], myocardial bridging [41], and traumas [125, 206] have been described as rare causes of AV block. Also in the congenital long QT syndrome the conduction system may be involved and functional 2:1 block and bundle branch block was described [207].

## 28.8 Age and Sex

Campbell [208] found in patients with chronic third-degree AV block that age varied between 50 and 70 years and that males predominated in a ratio of 4:1. In Ide's series [209], peak incidence occurred between 70 and 80 years of age and the ratio of males to females was 5:2. Elderly women are predilected to distal lesions due to degenerative calcified infiltrations in that area. They are three times more likely to have block in that region compared to men [210, 211].

## 28.9 Clinical Features

Clinical features are dependent on ventricular rate during the presence of AV block. First-degree and most types of second-degree AV block do not produce symptoms. An exception is the Mobitz type II second-degree AV block, where

sudden longer episodes of ventricular asystole can produce syncope. Higher degrees of second-degree block (3:1 or 4:1 AV block) with lower ventricular rates may give symptoms similar to those of third-degree block. These patients can develop dizziness or syncopal attacks (Adams–Stokes attacks). Syncope is usually caused by transient ventricular asystole, but ventricular tachycardia or fibrillation can also be the etiology of the complaints [29, 52, 56, 212–215]. Fatigue, dyspnea or cardiac asthma, and angina can be present in patients with marginal myocardial reserve or coronary circulation at rates of 40–50 bpm or lower [71, 72, 216–218]. Generally, in contrast to the patients with chronic and stable third-degree block, those with paroxysmal episodes of third-degree block have most complaints.

## 28.10 Therapy

---

Only in those patients who are symptomatic, or who will have a high chance of becoming symptomatic, is therapy needed. This can be atropine, isoproterenol, or artificial pacing. Atropine and isoproterenol are useful for short-term treatment. Atropine can be given to patients having a severe vagal reaction which, for example, is not uncommon in the acute stage of an inferior wall infarction (▶ Fig. 28.9). In the other patients, a temporary or permanently implanted pacemaker may be indicated. When drugs play a role in the presence of the AV block, the drug should be discontinued, or at least the dosage should be lowered or a pacemaker implanted if it is important to continue the use of the drug. Isoproterenol is sometimes helpful as an acute temporary treatment prior to insertion of a temporary pacemaker in patients having block in the His–Purkinje system.

AV block located below the AV node, that is, in the His bundle or bundle branches, is associated with a high incidence of sudden asystole [219–223]. Most investigators agree that patients with bifascicular block with HV prolongation and neurological symptoms should be paced [224–226]. If the HV interval exceeds 75 ms, pacing is indicated even without the presence of neurological complaints [227].

Each patient should be evaluated individually. If any doubt exists, other possible causes of syncope must be excluded prior to pacemaker implantation [215]. In patients with syncopal attacks due to AV conduction problems, long term ambulatory rhythm monitoring is very useful to confirm the diagnosis (see ▶ Chap. 39)

Approaches to treatment of patients with chronic AV conduction disturbances can be summarized as follows [228].

### 28.10.1 Normal PR Interval

---

The HV interval can be prolonged in patients with a normal PR interval. The HV interval should be measured in symptomatic patients with bifascicular block. If the HV interval is prolonged, pacemaker implantation should be considered. The incidental finding at electrophysiological study of a markedly prolonged HV interval (greater than or equal to 100 ms) in asymptomatic patients is a class IIa indication for pacemaker implantation.

### 28.10.2 First-Degree AV Delay

---

Asymptomatic first-degree AV delay is treated conservatively. Even asymptomatic conduction delay with bifascicular block is considered a class III indication for pacemaker insertion. First-degree AV delay with symptoms suggestive of pacemaker syndrome and documented alleviation of symptoms with temporary AV pacing is a class IIa indication for pacemaker treatment [229, 230].

### 28.10.3 Second-Degree AV Block

---

No pacemaker is indicated in asymptomatic type I second-degree AV block at the supra-Hisian (AV nodal) level not known to be intra or infra-Hisian. Type II second-degree AV block is a pacemaker indication. Also the non-physiological induction of distal AV block at electrophysiological study is a class IIa indication. After the acute phase of myocardial infarction, transient advanced second-degree AV block and associated bundle branch block should be treated with a

pacemaker. If the site of block is uncertain, an electrophysiological study may be necessary. Persistent second-degree block at the AV nodal level is considered a class IIb indication for a pacemaker.

#### 28.10.4 Third-Degree AV Block

A pacemaker must be used in case of intermittent or permanent third-degree AV block and also in alternating bundle branch block. Also, after the acute phase of myocardial infarction, distal AV block is a pacemaker indication.

### 28.11 Prognosis

The prognosis of heart block depends on the causative factor. Before the existence of artificial pacemakers, the average life expectancy following discovery of complete chronic heart block varied between 2.5 and 7 years [136, 138, 208]. Since restoration of the heartbeat by artificial pacing was made possible, the prognosis of patients having chronic AV block is much better [231]. At the present time, pulse generators last well beyond 5–10 years. The prognosis of patients with serious underlying cardiac or other diseases is therefore related to this disease [135, 232–236] while the pacemaker patient without serious underlying disease has the same mortality rate as the general population [232].

In patients with ischemic heart disease, inferior wall infarction is the most frequent cause of AV block; less often it can be found in extensive anterior wall infarctions. In patients with an inferior infarct, block is located in the AV node [118, 237]. When third-degree AV nodal block develops, the patients usually have a reliable escape rhythm and are not threatened by asystole. In nearly all cases, the conduction disturbance disappears within 1–2 weeks. In the prereperfusion era the in-hospital mortality of patients with inferior wall infarction in combination with second- or third-degree AV block was 22% compared to 9% in patients with an inferior infarct and normal AV conduction or first-degree AV block [26, 238–245]. This difference in mortality is probably a result of larger infarct size.

Patients with an extensive anterior wall infarction have a conduction problem in the bundle branches. This is associated with a poor prognosis. Block can be fatal, because of long periods of asystole due to an unreliable escape rhythm arising in the ventricle when third-degree block is present [18, 133, 238, 246]. However, the major cause of death is the extent of the myocardial damage [26, 238, 243, 245]. Cardiac pacing will, therefore, not change the mortality but it can prevent Adams–Stokes attacks [133, 241]. In the prereperfusion era development of right bundle branch block in setting of such an infarct had an in-hospital mortality of 67%, right bundle branch block in combination with left anterior fascicular block 72%, and in combination with left posterior fascicular block 86% (► Fig. 28.12). Ninety-five percent of the patients with trifascicular block died [241]. The incidence rates of complete heart block resulting from AMI have not changed over time [247, 248]. Early reperfusion either by thrombolytic therapy or percutaneous coronary intervention can reverse ischemia related conduction disturbances, but they remain an indicator of higher risk [247–254].

In the general population, asymptomatic subjects with bifascicular block statistically carry little risk of developing total block and dying. Conduction studies are not necessary [255, 256]. In the selected group of hospital inpatients with this phenomenon, however, prognosis is compromised. This is probably related to the prognosis of the underlying disease. In a retrospective study, McNulty et al. [257] found a 5-year mortality of 55%. Narula [258] and Gupta [259] also stated in their prospective studies that there was a positive correlation with both mortality and complete block inpatients with bifascicular block.

In another prospective study, Kulbertus recorded in 32% progression to complete block in 5 years [260]. He found that although bifascicular block is related to a high incidence of death, it is not related to the conduction disturbance itself, but to other (e.g., cardiac) causes.

## 29.1 Introduction

---

Ventricular arrhythmias are an important topic in cardiology and are frequently observed in clinical practice. They present in different forms ranging from benign ventricular extrasystoles to ventricular tachycardia and fibrillation which may lead to sudden death.

The latter group has been the focus of major interest in recent years. Such arrhythmias are usually observed as a complication of coronary artery disease and are responsible for about 500,000 deaths a year in North America. Autopsy findings often show minimal lesions or chronic scars, which suggest that some of these deaths are entirely the result of an arrhythmia and that the treatment of these severe ventricular arrhythmias should be one of the major objectives of modern electrophysiology. This is especially true now that significant advances have been made in the following areas:

- The synthesis of new antiarrhythmic drugs
- The effectiveness of implantable defibrillators
- The benefit of catheter ablation techniques

This chapter on ventricular arrhythmias has been arbitrarily divided into two parts: the first deals with ventricular extrasystoles and the second, with ventricular tachycardia and fibrillation. This is, of course, an artificial distinction and the same pathological situations may be discussed according to whether they present clinically as a form of isolated ventricular extrasystoles or ventricular tachycardia. This latter form is not necessarily a sign of disease's progression, as patients may show one or the other arrhythmia from the beginning.

It might be necessary to consider first the electrophysiological mechanisms of these arrhythmias. It should be emphasized that there are probably significant differences between those observed in an electrophysiological bath with microelectrodes in normal animal tissues placed in artificial electrophysiological conditions, and those which are the substrate of human pathology. Although the relationship between these two approaches remains uncertain, both the cellular electrophysiological and clinical aspects will be discussed.

### 29.1.1 Cellular Electrophysiological Mechanisms of Arrhythmias

---

The electrophysiological mechanisms of cardiac arrhythmias at cellular level can be divided into three main groups; namely, increased automaticity, triggered activity, and reentry.

#### 29.1.2 Increased automaticity

---

Increased automaticity corresponds with an increase in the normal phenomena of automaticity, and is the result of a slow diastolic depolarization in phase 4 of the action potential [1]. The activation of the adjacent nonspecific myocardium is the result of an electrotonic effect occurring when the resting potential of the automatic cells reaches its threshold. In abnormal automaticity, the resting potential is less negative ( $-60$  mV) than in normal His-Purkinje fibers ( $-90$  mV). In pathological conditions, every ventricular myocardial fiber [2] may exhibit this abnormal rapid automaticity. At these low potentials, which correspond to partial depolarization, the rapid sodium channel is inactivated. The ionic mechanism on which this abnormal activity is most dependent may be influenced by a number of factors. In particular, myocardial ischemia, which increases the extracellular potassium concentration, may lead to this type of abnormal automaticity when a certain level of myocardial depolarization is reached.

In addition, the partial depolarization which inactivates the rapid sodium channel can cause a conduction defect which suppresses the physiological inhibition of automatic activity by a more rapid rhythm arising from the sinus node. This is the case in complete atrioventricular block [1].

### 29.1.3 Triggered activity

Triggered activity is the term used to describe a possible mechanism whereby, a cardiac arrhythmia does not occur spontaneously in resting fibers, but arises only after electrical stimulation [3]. It is immediately apparent that this cellular electrophysiological phenomenon, which is distinct from re-entry, may pose a diagnostic problem in clinical electrophysiology where the same property of triggering and termination is considered to be a criterion of re-entry.

Two types of triggered activity have been described [4, 5] and have been restudied and developed in cellular electrophysiology [6, 7]. One is the result of early after-depolarization occurring on the plateau phase of the action potential, or in phase 3, corresponding to the T wave of the surface ECG [6, 8]. The other is owing to delayed after-depolarization occurring at the end of phase 3 or the beginning of phase 4 of the action potential, corresponding to the end of the T wave, or the remaining part of the diastolic period. The latter has been particularly well studied in atrial tissues [9].

Early after-depolarization has also been observed in myocardial ischemia as a result of hypoxia or increase in the partial pressure of carbon dioxide. It is characterised by an abrupt “hump” in the action potential at the end of phase 2, which may trigger another action potential. This action potential therefore may occur at a low or at a high membrane potential level although the initial potential of the first stimulated beat had a normal resting potential ( $-75$  to  $-80$  mV). Early after-depolarization is, however, considered as being “triggered” because it is only observed if a stimulated potential which initiates the sequence is present. This phenomenon is facilitated by slow pacing while fast pacing can abolish it. After the triggered action potential at a low resting membrane potential, repetitive activity, known as oscillatory after-depolarization becomes possible [6].

Low level early after-depolarization occurs at low membrane potentials suggesting intervention of the calcium window current underlie by L-type  $\text{Ca}^{2+}$  channel, triggering slowly conducted action potential. High level early after-depolarization occurring at high membrane potentials are triggered by an increase of the window sodium current often giving rise to bursts of fast conducted re-excitations [10, 11]. Following the formation of thrombus in cardiac cavities or coronaries, the serine protease thrombin is formed and can reach the myocardial tissue by the active process of extravasation. It was recently shown that thrombin markedly increases the window sodium current, and thus may induce high level EAD that underlies Torsades de pointes [12].

Sodium channel mutations (E1295K and  $\Delta$ KPQ) responsible for a familial form of long QT syndrome (LQTS-3) result in notable increase in window sodium current [13]. Activity arising from low level early after-depolarisations is generally short-lived as the fibers return to a normal potential after a few oscillations.

Delayed after-depolarization is observed at the end of repolarization of the stimulated potentials in fibers placed under special electrophysiological conditions in which the presence of steroid or glucocorticoids seem to play an important role (Fig. 29.1). The stimulated action potential is first followed by depolarization, but it then returns to an even more negative value of resting potential than the basal resting membrane potential (hyperpolarization). This is followed by a wave which comprises the delayed after-potential or several oscillatory potentials and which has a less-negative value that may return to the value of the fiber's resting potential if its amplitude is small. If the amplitude is large enough, the peak of the wave created by the delayed after-depolarization will reach the threshold level and an action potential will be initiated. Depending on local conditions, these potentials may fade away, after having initiated a new depolarization and another delayed after-depolarization which is unable to reach the threshold of depolarization. However, if the threshold of depolarization is reached, a second action potential will be triggered and so on. Once triggered, this repetitive activity can continue for a long period of time (several hours). A warming-up phenomenon is often observed with an acceleration of the rate of depolarization. It is the activity related to this delayed after-depolarization which can cause diagnostic difficulties with tachycardia resulting from re-entry.

There are different means by which a delayed after-depolarization may reach threshold level. It may result from the rate of stimulation; that is, if the first stimulus induces an after-depolarization which does not attain the threshold value, there will be no propagation. However, the following stimulation, if sufficiently early in the cycle, will produce an increase in the amplitude of its after-depolarization which may or may not reach the threshold value. The next stimulus will again increase the amplitude of its after-depolarization, until eventually it reaches the threshold value, thereby generating a propagated action potential. That is to say that acceleration of the pacing rate will increase the amplitude of the delayed after-depolarization and the number of the propagated triggered action potentials, and will decrease their coupling interval: the faster the pacing rate, the faster the rate of the triggered rhythm.

■ **Figure 29.1**

**Delayed after-depolarization occurring in sheep Purkinje fibers following hypokalemia ( $2.7 \mu\text{mol l}^{-1}$ ) and the addition of a toxic amount of ouabain. The first oscillation is subthreshold, the second one reaches threshold and is followed by the beginning of triggered action potentials (Courtesy of Dr F. Fillette).**

The same sequence of events may be observed after a premature stimulation during an artificially driven rhythm. The amplitude of the delayed depolarization and its prematurity both increase when the stimulus is delivered earlier in the cycle. This is a notable feature and will be referred to later in the discussion on the mechanism of arrhythmias in clinical electrophysiology. It explains the warming-up phenomenon; its action potential gives rise to a new delayed after-depolarization earlier in the cycle and of greater amplitude, which then plays the same role as an extrastimulus for the following potential.

At the cellular level, delayed-after-depolarizations are favoured by high intracellular calcium load and are due to the activation of calcium-dependent transient inward current (Iti). Various ionic conductances can underlie Iti [14, 15]. It can be a calcium-activated nonselective cationic channel [16], or calcium-dependent chloride current [17] but in most cases it is the Na-Ca exchanger when it removes calcium from the cytosol that generated Iti [18, 19]. The molecular nature of Iti takes into account that both the occurrence and amplitude of delayed-after-depolarization increase in conditions characterized by an enhanced intracellular calcium load such as rapid stimulation rate or beta-adrenergic stimulation. In failing myocardium, the altered excitation-contraction coupling process results in an abnormal intracellular calcium homeostasis that can favour delayed-after-depolarization [20].

### 29.1.4 Re-entry

The third fundamental mechanism of arrhythmias is the re-entry phenomenon [21]. Well known in clinical studies of the Wolff-Parkinson-White (WPW) syndrome, it has been extended to the field of ventricular tachycardia, as the myocardium behaves in a similar way during programmed pacing [22]. There are three essential conditions for the initiation of re-entry, as follows:

- The presence of two separate conduction pathways with different functional electrophysiological properties.
- Unidirectional block (usually induced by the preceding beat and located at the junction between healthy and pathological myocardium).
- A conduction delay hindering the activation front from encountering excitable myocardium beyond the site of the block.

Reentry phenomena have different clinical expressions, depending on whether they have microreentry (between Purkinje fibers and healthy myocardium), or macroreentry circuits (involving the bundle branches in case of dilated cardiomyopathy and/or a larger amount of myocardium) [23–25].

At that time, it was difficult to accept that conduction could be sufficiently delayed for the propagation time of the activation front to exceed the duration of the refractory period of the tissues located distal to the block. This was because calculations showed that it required delays about 100 times the normal value for this phenomenon to be possible [26]. In fact, this was only demonstrated partially by the recording of delayed potentials occurring in the diastolic period 250 ms after the onset of QRS complexes in experimental acute ischemic tissue [27]. These delayed potentials were observed in the animal and later in humans in diverse pathological conditions, and their behavior during premature stimulation showed unusual phenomena commonly observed in the nodo-Hisian conduction system [28, 29]. These time-dependent properties support the explanation of the mechanism of ventricular tachycardia initiation; that is, the prematurity of the extrastimulus increases the conduction time in abnormally slow conducting fibers, so allowing the most delayed potentials to transmit the activation to adjacent myocardium in the same way that stimulation of fibers in a zone of markedly delayed conduction enables reactivation of the adjacent myocardium [30–33]. Experimental studies have demonstrated the phenomenon of reentry by mapping the first cycles of an ischemic ventricular tachycardia [34, 35].

These mechanisms are important in clinical arrhythmias because ventricular tachycardia can be initiated and terminated by programmed pacing, or by bursts of rapid pacing. However, the demonstration of triggered activity unrelated to reentry has raised the problem of distinguishing between these two mechanisms.

It has also been demonstrated that programmed pacing is able to initiate ventricular arrhythmias in only a small number of cases in the acute phase of myocardial infarction, a situation in which it was thought that both increased automaticity and reentry could play a role.

On the other hand, intraventricular reentry is probably the only operative mechanism in sustained chronic ventricular tachycardia in the chronic phase after myocardial infarction. In clinical practice, the phenomena of extrasystoles, and even ventricular tachycardia can be triggered by pacing methods in severe digitalis overdose. However, pacing methods are often used to prevent bradycardias or atrioventricular blocks induced by digitalis [36].

Finally, focal reexcitation phenomena may be observed when the repolarization of adjacent fibers is asynchronous, a condition favored by beta-adrenergic stimulation or acute ischemia [35].

A delayed activation of normal myocardium after pacing in a zone where late potentials were recorded was reported in 1978 by Fontaine et al [31]. This again reinforced the concept of reentrant phenomenon in heart muscle and definitely excluded the mechanism of triggered activity. In patients at the chronic phase of myocardial infarction, De Bakker demonstrated the presence of a “zig-zag” slow conduction pattern, in which wave fronts could travel perpendicular to the fiber direction ensheathed by collagenous septa [37].

### 29.1.5 Criteria for Discriminating Between Cellular Electrophysiological and Clinical Mechanisms of Tachycardia

The main difficulty concerning the respective mechanisms of reentry and phenomena of triggered activity is the paucity of discriminating methods which can be used both in cellular and clinical electrophysiology. It was noted above that the induction and termination of tachycardia by programmed stimulation may be observed in both situations, but there is one way of differentiating the two mechanisms. In tachycardias triggered by delayed after-depolarization, the coupling interval of the first propagated potential decreases with increasing prematurity of the initiating extrasystole. Indeed, the moment at which delayed after-depolarization reaches the threshold becomes more premature as the coupling interval of the extrastimulus decreases. Conversely, in reentry, the coupling interval of the first propagated potential which initiates the tachycardia increases as the prematurity of the extrastimulus increases. This is owing to the conduction-time increase in the zone of delayed conduction.

Using these criteria, a retrospective study of 425 patients investigated in the authors' clinical electrophysiological laboratory in which tachycardia could be initiated and terminated by programmed pacing, showed that in 33 patients tachycardia originated in the atrium, whilst in 79 patients the point of origin was ventricular. Seven patients with atrial

tachycardia and only one with ventricular tachycardia had positive evidence in favor of a mechanism of triggered activation. In addition, in five of the patients with atrial tachycardia and in the patient with ventricular tachycardia, the administration of intravenous verapamil terminated the tachycardia and prevented its reinitiation.

These results suggest that the role played by a triggered activity in the clinical situation is quite modest especially as far as the ventricular arrhythmias are concerned [38].

## 29.2 Ventricular Extrasystoles

Ventricular extrasystoles (VES) result from premature depolarization of the myocardium distal to the atrioventricular junction; that is, below the bifurcation of the His bundle. They may, therefore, arise from either of the two ventricles or from the interventricular septum. Recently, triggers of VES and of ventricular fibrillation (VF) were found in various locations within the Purkinje network in patients presenting with recurrent VF without underlying cardiac disease and were successfully treated by radiofrequency catheter ablation [39].

### 29.2.1 Clinical features

From the clinical standpoint it is useful to distinguish between asymptomatic VES detected during clinical examination and confirmed by ECG, and symptomatic VES which are not necessarily the most dangerous, but which can have important effects on the quality of life.

Ventricular extrasystoles may be totally asymptomatic, but often they cause symptoms such as palpitations, a sensation of a missed beat, of cardiac arrest or of strong beats. Less commonly, when VES are frequent or in salvos, the patient may experience dizziness, angina, hypotension and finally tachyarrhythmia cardiomyopathy.

It is important to inquire about the patient's general health and lifestyle, in order to assess as accurately as possible the functional disturbance and the frequency of symptoms, as well as to detect any predisposing factors such as exercise, anxiety, stimulants (tobacco, alcohol, coffee, and so on), sleep disturbances, hypoxia, physical stress, drug administration, and so forth.

On examination, VES cause an irregular heart beat and changes in the intensity of the heart sounds. A systolic murmur may be detected. Organic aortic systolic murmurs decrease in intensity during the extra systolic beat but are accentuated during the following systole (contraction produced by the strong normal beat following the compensatory pause).

The hemodynamic effects of VES include the following [40]:

- Reduction in left ventricular systolic pressures (prematurity dependent)
- Increase in the length of diastole (postextrasystolic compensatory pause) resulting in an increase of stroke volume of the following systole (▶ Fig. 29.2)
- Abnormal valve motion (premature closure, mitral valve prolapse, decreased valve opening, and so on) clearly demonstrated by echocardiography

#### 29.2.1.1 Relationship to the P wave

Diagnosis and study of VES depend on the analysis of the ECG. Ventricular extrasystoles are premature, wide QRS complexes (usually > 120 ms) followed by a T wave with an axis opposite to that of the QRS. Characteristically, VES are not preceded by P waves. As the P wave is not easily detected in some leads, simultaneous multichannel recordings are useful in distinguishing VES from atrial and junctional extrasystoles with aberrant conduction. As a rule, VES are completely dissociated from the preceding atrial activity but they may be followed by a retrograde P wave (▶ Fig. 29.3).

A bipolar sternal lead recording with the “right arm” electrode on the manubrium and “left arm” electrode on the xiphoid process may help to show the P waves. Another more sensitive method of recording the atrial activity is to use an esophageal or an endocardial lead (▶ Fig. 29.2).

■ **Figure 29.2**

Left ventricular extrasystole recorded during an endocardial study: CS, coronary sinus showing the atrial and the ventricular component of the ECG; RV 1–2, RV 3–4, Quadripolar catheter positioned in the infundibular area; LV, left ventricle showing that the activation commences first in this ventricle; RVa, apex of the right ventricle; AP, arterial pressure recorded on the radial artery. The second arrow indicates the drop of end-diastolic blood pressure.

### 29.2.1.2 Morphology

It is often difficult to distinguish VES from supraventricular or junctional extrasystoles with ventricular aberration resulting from a decrease in conduction in the intraventricular conduction system. Conversely, VES arising just above the division of the His bundle will give rise to narrow QRS complexes, suggesting supraventricular activity [41]. In addition, an extrasystole occurring at the appropriate time may lead to a narrow QRS complex in the case of fusion with a normal ventricular activation, but showing bundle branch block ipsilateral to the site of origin of the extrasystole.

The morphology of VESs may generally indicate their site of origin. Appearances of right bundle branch block are observed in left ventricular extrasystoles. The arrhythmia arises within the right ventricle or septum when left bundle branch block appearances are recorded, the site being apical when the QRS is negative in leads I, II and III, and basal when positive in these leads [42]. Right-sided VES always give rise to appearances of left-sided delay whilst left-sided VES (base of interventricular septum) could show appearances of right- or left-sided delay [43].

The morphology of VES may be unchanged from one extrasystole to the next (▶ Fig. 29.3), or they may vary (● Fig. 29.4), in an unpredictable manner (polymorphic extrasystoles). Polymorphism must be distinguished from possible fusion between very late VES and normal depolarization (QRS complex preceded by a normal P wave with shortened PR interval and an intermediate QRS morphology).

### 29.2.1.3 Chronology

Ventricular extrasystoles may be divided into two types according to their relationship to the preceding QRS complex; namely, those with a short coupling interval occurring near to or on the peak of the T wave (R-on-T phenomenon) and late VES with long coupling intervals (▶ Fig. 29.5). These intervals may be fixed (varying less than 80 ms) suggesting parasystole (▶ Fig. 29.6) [41, 44]; that is, the interectopic interval is approximately a multiple (>1) of a fixed interval.

The following types of VES may be distinguished from the analysis of their relationship to the sinus beats.

■ Figure 29.3

Bigeminy is visible at the beginning of the tracing. Tracing A represents the endocardial atrial electrogram. In this case, atrial activity is not modified by the extrasystoles which are therefore followed by a full compensatory pause. On the right, there is atrial pacing (St A) at a period longer than the coupling interval of extrasystoles, resulting in complete disappearance of extrasystoles. A fusion beat F is observed at the beginning of atrial pacing.

■ Figure 29.4

Polymorphic ventricular extrasystoles recorded during open chest surgery. Note the existence of multiple fragmented potentials on the epicardial leads E<sub>1</sub>-E<sub>3</sub> preceding runs of extrasystoles which end with highly fragmented complexes (stars). RV is the potential recorded from the epicardium of the right ventricle. Note the major asynchrony between the two ventricles. RA is the atrial endocardial lead. Each atrial activity is preceded by the stimulation artifact.

- VES with a compensatory pause (▶ Fig. 29.3) is the most common type. The interval between the sinus beat preceding the extrasystole, and the VES itself added to that following the VES, corresponds to two normal periods (retrograde conduction to the atrium and normal anterograde depolarization are blocked).
- In VES with retrograde conduction which recycles the sinus node, the pause following the VES is equal to the normal sinus period (▶ Fig. 29.7 (b)).
- Interpolated VES do not affect the normal period. These VES are not conducted to the atrium and the normal sinus depolarization which follows is not blocked in refractory, junctional tissues (▶ Fig. 29.7 (a)).

■ Figure 29.5

The top panel illustrates an extrasystole with a relatively short coupling interval. The bottom panel shows an extrasystole with a relatively long coupling interval initiating a run of sustained ventricular tachycardia.

■ Figure 29.6

Parasystolic focus interfering with sinus rhythm. The interval measurements demonstrate that this focus is not completely protected from the supraventricular beats. The strips are continuous running from top to bottom. The arrows indicate fusion beats.

Other ECG appearances may also be observed [41]:

- The VES may be followed by AV junctional escape (🔗 Fig. 29.7 (c)).
- The VES may have a visible retrograde conduction. In this case, a  $P'$  wave, usually negative in lead II, is situated in the ST segment or T wave.
- The VES may have a ventricular echo. Here, the abnormal activation is conducted retrogradely to the atrium and then returns to the ventricle without the intervention of sinus node activity. Ventricular extrasystoles are followed by either a normal or widened (aberration) ventricular complex with a fixed coupling interval which may be preceded by a  $P'$  wave and is often followed by a compensatory pause.

**Figure 29.7**

Part (a) illustrates an interpolated extrasystole; part (b) shows an extrasystole with an atrial retrograde conduction (arrow) and part (c) shows an extrasystole followed by a junctional escape.

Finally, when VES are repeated with a fixed coupling interval, it is possible to record the following:

- Ventricular bigeminy when one ventricular extrasystole follows each normal complex (▶ Fig. 29.3).
- Ventricular trigeminy when one ventricular extrasystole occurs following every two normal beats (in fact, trigeminy literally corresponds to one normal complex following every two VES).
- A salvo defined as three or more successive VES (▶ Fig. 29.2).
- When more than three successive VES are recorded, it is sometimes called ventricular tachycardia (VT), or a burst of VT (▶ Fig. 29.8).

### 29.2.2 Endocavitary studies

Electrophysiological investigations (▶ Chap. 24) are rarely indicated for the study of VES in themselves, but the latter could be undertaken during electrophysiological studies indicated for other reasons. Ventricular extrasystoles always precede the H potential on His-bundle recordings. In case of ventriculoatrial conduction, they are followed by a retrograde atrial electrogram.

However, it could be important to study the behavior of VES during atrial pacing. In some, cases, the VES are suppressed beyond a critical pacing rate. This rate is not stable with time, but an appropriate level could be found in certain patients and this could be used to prevent VES in the long-term, using an atrial pacemaker system (▶ Fig. 29.3).

Pace mapping [45] is a technique of endocavitary pacing, which may be carried out in sinus rhythm (and sometimes during tachycardia). Its object is to duplicate the configuration of VT and so define its site of origin. However, this technique also has its limitations [46].

### 29.2.3 Management

Management is the major problem of VES. The prognosis is closely related to the presence of underlying cardiac disease, especially ischemic cardiomyopathy. Although the vast majority of VES are benign, even in cases with underlying cardiac

**Figure 29.8**

Difficulties in the definition of ventricular tachycardia are exemplified in these ECGs. There are salvos of three (a) or four (b) ectopic ventricular beats; a burst of extrasystoles, alternatively regarded as a short run of ventricular tachycardia is seen in (c) and the beginning of a sustained episode of ventricular tachycardia in (d).

disease, others are markers of potentially dangerous arrhythmias and indicate a high risk of sudden death. Investigation and treatment must take these two facts into consideration.

Some investigations provide information about the arrhythmia itself, whilst other, mainly noninvasive, techniques (echocardiography, angiography, exercise-stress testing, Holter monitoring and scintigraphy) may provide clues to the underlying cause of the arrhythmia. As a general rule, only cases of potentially lethal arrhythmias, or patients with history of cardiac arrest or “resuscitated sudden deaths” are referred for electrophysiological investigation and coronary angiography for evaluation of the risks of ventricular tachycardia or ventricular fibrillation (VF).

#### 29.2.4 VES in normal subjects with apparently healthy hearts

Ventricular extrasystoles in “normal” persons are often called “idiopathic.” The widespread use of Holter monitoring (Chap. 33) has shown that this arrhythmia is very common and may be observed in nearly all cases when the period of observation is long enough (73% in 48 h monitoring) [47–51]. The frequency of VES increases with age and other factors which must be considered when assessing the prognosis.

A number of workers, including Rosenbaum [42] have described the following characteristic features of “benign” VES: vertical axis, left bundle branch block pattern, large R waves in leads II and III, fixed, long coupling intervals, secondary ST-T wave changes (sloping ST depression and T wave of opposite polarity to the QRS), isolated and infrequent VES.

Electrophysiological studies and epicardial mapping have shown that these VES arise in the upper part of the right side of the interventricular septum (Fig. 29.9), also called right ventricular outflow tract VES. They usually disappear on exercise and are only recorded on Holter monitoring when the spontaneous rhythm slows [47, 52].

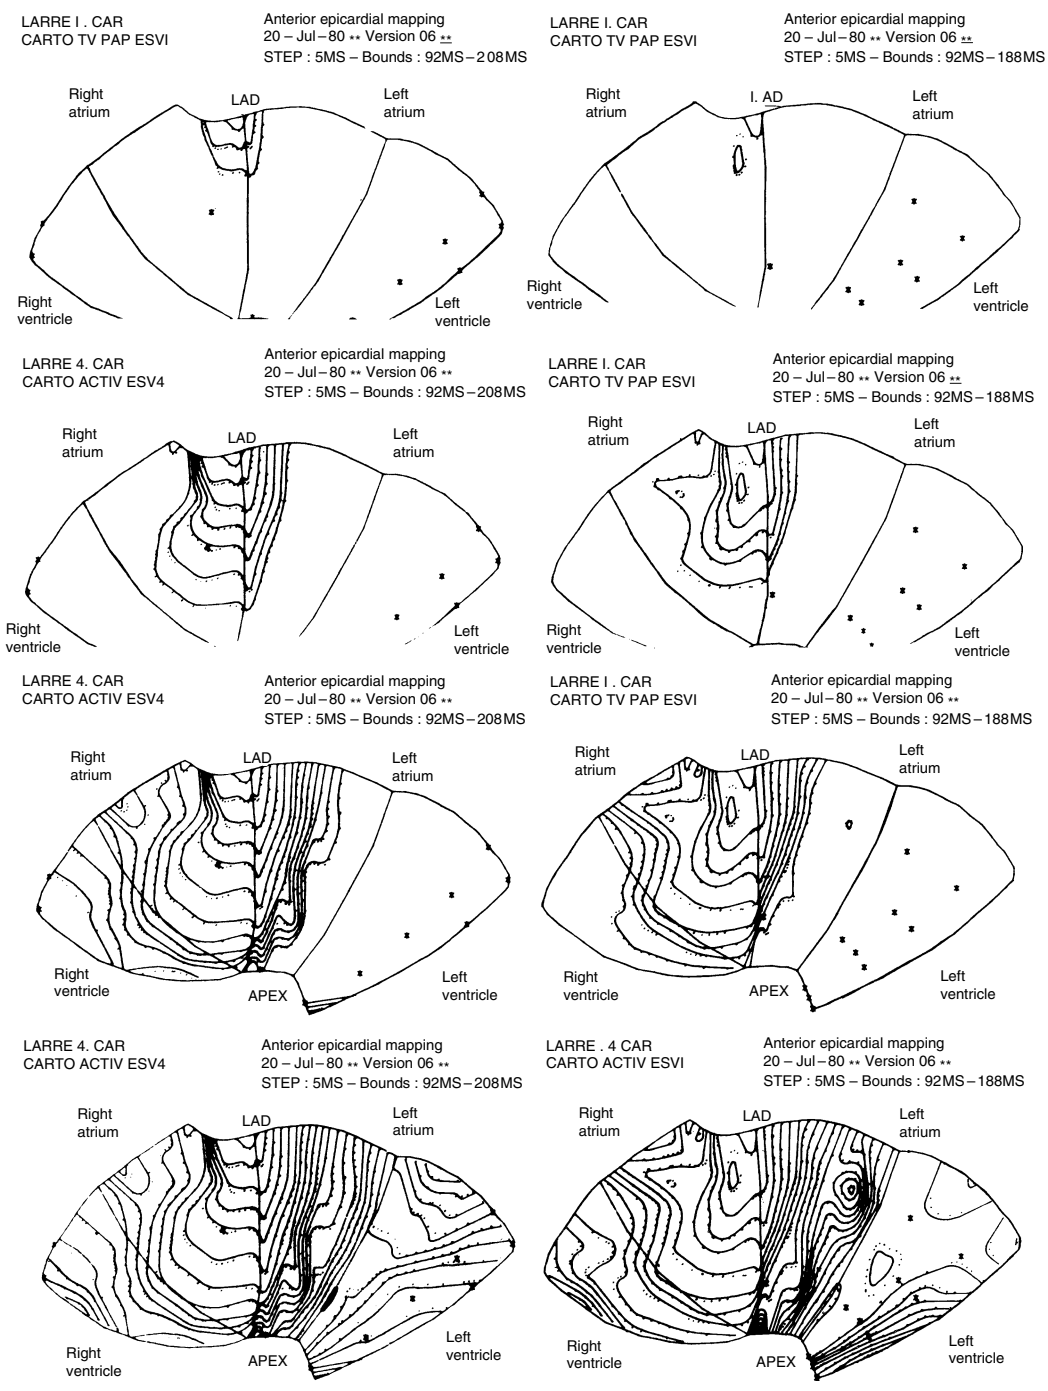

Figure 29.9

Spread of activation is shown on epicardial maps during normal sinus rhythm on the right, and on the left during an extrasystole arising from the upper part of the septum. The latter could lead to paroxysmal episodes of extrasystoles or runs of ventricular tachycardia, which could in some very rare cases be treated by a surgical approach if antiarrhythmic therapy had failed. In sinus rhythm, epicardial activation is first seen in the free wall of the right ventricle in the anteroparaseptal area. On the left, the earliest epicardial activation is noted at the origin of the left anterior descending (LAD) coronary artery. In all maps, the time interval between isochrones is 5 ms.

This concept of “benign” VES must be interpreted with caution but it remains useful when the arrhythmia is totally asymptomatic in patients without apparent cardiac disease. Treatment is unnecessary [53] in most cases but therapy may be required for psychological reasons in some patients. These VES are particularly common in women and may be poorly tolerated. To complicate matters, most classic antiarrhythmic drugs are ineffective. This explains the use of drugs aimed more at relieving symptoms than at treating the arrhythmia; formerly, patients were prescribed sedatives, or usually, as second-line therapy, relatively weak antiarrhythmic agents such as beta blockers or verapamil. Nowadays, the use of radiofrequency ablation [54] or powerful antiarrhythmic drugs (class I, like flecainide) which are easy to use in healthy hearts, has completely transformed the lives of these patients.

Identical VES have been reported to come more rarely from the left ventricular outflow tract, the aortic sinus of Valsalva or the trunk of the pulmonary artery [55]. The VES morphology in precordial leads, especially the presence of a transition complex, is a good first approximation regarding the location of the successful ablation site [56].

Ventricular extrasystoles observed during the period of awakening, or during or immediately after exercise in apparently normal patients, are also very common. The autonomic nervous system is thought to play a major role in their initiation [57–59]. The frequency of this type of VES varies with age [57]. They are observed on Holter recording when the patient awakes, and tend to become more frequent on exercise but disappear during sleep. This arrhythmia does not seem to be a marker for a latent coronary artery disease and is not associated with an increased risk of sudden death [52, 57, 59, 60].

Treatment is based on the underlying physiopathogenic mechanism of the arrhythmia and so beta blockers are considered appropriate first-line drugs. As most patients require long-term therapy, beta blocker with a 24 h duration of action, some of which also have weak class I antiarrhythmic effects, are to be preferred.

Even in patients with “normal” hearts, short coupling intervals [61], changing morphologies, complex interaction (bigeminy, ventricular tachycardia) and predisposing factors (sleep, exercise, postexercise) may be observed without higher risk of potentially lethal arrhythmia or sudden death [62], especially when the VES are infrequent and the patients are young [47–49, 52, 63].

Nevertheless, frequent (over 5/h or 10/1000 sinus beats) and/or polymorphic VES, aggravated by exercise in patients over 40 years old are suggestive of coronary artery disease, even in the absence of cardiovascular risk factors. They appear to be associated with a higher risk of sudden death and coronary events [49, 50, 58, 63–65] although this premise is not universally accepted [60, 66].

The presence of cardiovascular risk factors increases the predictive value of these VES especially that of complex VES [58–60, 63–67].

## 29.2.5 VES and coronary artery disease

It is useful to distinguish VES occurring in the acute phase of myocardial infarction (the first 10 days) from those observed in chronic coronary insufficiency (with or without previous infarction).

### 29.2.5.1 Acute phase of myocardial infarction (Lown’s classification)

Electrocardiogram monitoring in the coronary care unit has shown that VES are very common and are nearly always present [68–70]. Different classifications have been proposed for assessing the prognosis but the best known is that of Lown [53, 71], as shown in [Table 29.1](#).

This classification distinguishes dangerous arrhythmias (grade 2 and over) from apparently benign arrhythmias. Although some points are debatable, especially the significance of grade 5, this classification is still used [68, 72, 73].

High-grade VES (that is, frequent and repetitive VES) do not seem to be related to the site of infarction but are related to its size [74, 75]. These VES (especially grade 5) seem to increase the risk of VT [68], but effective treatment of them has not been shown to prevent VT or VF as these particular arrhythmias seem to have different triggering factors.

No significant correlation has been found between ventricular arrhythmias (VES, VT and VF) observed in the acute phase and those observed after hospital discharge (after 3 weeks) [76], probably because they have different mechanisms;

■ **Table 29.1**

**Lown's classification of ventricular extra-systoles (VES) [53, 71]**

Grade	Type of VES
0	no VES
1a	isolated, rare VES (>1 mn-1 or >30 h)
1b	infrequent VES (>1 mn-1 but <30 h)
2	frequent monomorphic VES (>30 h)
3	frequent polymorphic VES
4a	Couplets
4b	triplets or salvos > 3
5	R-on-T phenomenon

namely, reentry in the chronic phase and increased automaticity in the acute phase [77]. However, the more serious repetitive VES observed in the acute phase are also probably as a result of reentry [74].

The treatment in the acute phase is now well established. When the arrhythmia exceeds grade 1 (1 b for some authors) treatment with intravenous (IV) lidocaine is recommended [71, 78]. This drug is effective and has only a slightly depressive effect on contractility and conduction. In addition, its time of action is short. Therefore, this drug is easier to handle in the case of negative inotropic effects. On the other hand, IV administration with an electric pump is mandatory in order to have a constant infusion rate.

In the rare cases of complete or relative inefficacy or major side effects (usually owing to overdosage), drugs with the least-negative inotropic effects are to be preferred. In the authors' experience IV amiodarone is very useful as it has both an antianginal and powerful antiarrhythmic action without depression of the activation process or myocardial contractility. It may be administered intravenously by continuous infusion (2 g in 24 h). Bolus injection is dangerous because of the hypotensive effect of the excipient. Oral administration with high loading doses (1.2 g per day for the first 4 days) is also well tolerated and reduces the delay of onset of action [79].

Other antiarrhythmic agents, especially the class I drugs were used in the 80s but their negative inotropic effects must not be overlooked. They are best administered by slow IV infusion, preferably with an electric syringe, again to ensure a constant infusion rate.

### 29.2.5.2 The chronic phase

The problem of management of VES is more difficult at the chronic phase of myocardial infarction.

There is a need to determine the following:

- The best means of detecting the VES and assessing their severity;
- The most appropriate moment after infarction at which to perform the study;
- The prognosis of the arrhythmia detected and the risks of sudden death or progression of the coronary artery disease;
- The best treatment and effective prophylaxis against more serious arrhythmias.

Some of these questions have now been answered. Most workers agree that all patients at risk should undergo at least one 24 h Holter ECG before hospital discharge, sometimes associated with an exercise test. If repeated or performed after the third week postinfarction, the test does not seem to provide any additional information [80] despite the fact that the frequency and complexity of VES may increase up to the sixth month [81].

It is more difficult to assess the severity and prognosis. Lown's classification remains useful: grade 2 or more complex arrhythmias must be carefully managed while complex VES are associated with a higher risk of sudden death [53] [82–85] or cardiac death [63, 86, 87].

Holter monitoring seems to be more useful than exercise-stress testing in the evaluation of these arrhythmias but the two methods are complementary [80, 88]. Exercise testing may show an increase in the number of VES as well as changes in the ST segment.

In order to assess the prognosis, the arrhythmias must be interpreted in a wider context, taking into account a number of other factors. First, factors related to the cardiac rhythm must be considered. These are as follows.

- Low ejection fraction and raised left ventricular end diastolic pressure [53, 89–94];
- The frequency of VES appears to be proportional to the mean sinus rate [47, 95];
- Aggravation during exercise has been known to be a poor prognostic factor for a long time [47] but is not a constant finding in uncomplicated myocardial infarction without global left ventricular dysfunction [80];
- Second, cardiac factors should be considered: the severity of coronary artery disease is difficult to dissociate from ventricular arrhythmias. The following factors play a role;
- Previous myocardial infarction;
- ST changes on exercise-stress testing have been shown to be more sensitive than Holter monitoring [80, 95, 96];
- Segmental abnormalities of wall motion [84, 92, 93, 97];
- The number of diseased vessels [92], although this factor is not universally accepted [84, 93].

On the other hand, the site of infarction does not seem to be important [51] although some workers do not agree [53]. Finally, the clinical context and the patient's mental condition have to be taken into consideration. The roles of the autonomic nervous system and of certain hormonal and humoral factors, though not fully understood, are certainly not completely divorced from the mechanism of some arrhythmias [53].

The presence of complex and frequent VES after myocardial infarction seems to be associated with higher mortality, especially as a result of sudden arrhythmic death, and also appears to be independent of other factors [83, 86, 87, 90, 93, 94, 98]. The risk is maximal during the first six months and then gradually decreases [81, 99].

A cooperative study on a group of 804 cases [100] studied by Holter monitoring was able to indicate, after univariate analysis, that it was possible to classify these patients into three groups at risk of sudden death over a two-year period. Two electrocardiographic markers are considered: number of VES per hour and the presence or absence of runs (i.e., three or more VES in a row). In the first grade, defined as patients having less than three VES per hour and no runs, the two-year mortality rate is 8%; in the second, which consisted of patients having more than three VES per hour, or having runs, the mortality rate increases to 16%; in the third group, composed of patients having more than three VES per hour and runs, the mortality rate increases to 37%.

Other investigators have proposed electrophysiological studies shortly after the acute phase of myocardial infarction for these high-risk patients. The recording of repetitive ventricular responses to a single extrastimulus may help identify the subgroup with a high risk of sudden arrhythmic death [91].

About 90% of complex VES can now be effectively controlled by antiarrhythmic drugs, the number of which is continually increasing [94]. However, the role of VES in the induction of more severe arrhythmias is still not clear, and the suppression of VES has not been shown to protect patients from sudden death [53, 70, 94, 97]. Some drugs suppress VES without reducing the risk of sudden arrhythmic death. Other drugs seem to reduce the risk with only a partial but perhaps adequate, effect on the VES [41, 51, 53, 82]. Beta blockers belong to this latter group.

It is, nevertheless, rational to treat patients with complex, frequent, repetitive VES at rest or at exercise, irrespective of whether they are associated with other bad prognostic factors such as previous infarction and poor ventricular function [51, 86, 89, 90]. The benefits of treatment are less obvious in patients who have suffered small, uncomplicated infarcts and who have rare, monomorphic VES [47, 53, 89].

Patients in whom an effective antiarrhythmic treatment is most useful are included in the subgroup with salvos or short coupled VES [101]. In a study of 140 patients including two thirds with coronary artery disease, the suppression of salvos and most of the isolated extrasystoles led to a marked decrease in the annual rate of sudden arrhythmic death from 40 to 2.8%. This result was even more impressive in the subgroup of patients with a reduced ejection fraction in which

■ **Figure 29.10**

Computerized bedside monitoring report showing premature ventricular contraction ( $\text{VES min}^{-1}$ ), in a patient with ventricular extrasystoles after myocardial infarction. The vertical arrows indicate that during the awakening period (7.40 a.m.), the basic cardiac rate (lower curve) increases, to be followed by a concomitant increase in the frequency of premature ventricular contractions. (V.Fib, ventricular fibrillation.)

the control of ventricular arrhythmias led to a decrease in the annual risk of sudden arrhythmic death from 80 to less than 5%.

Several methods of evaluating the efficacy of treatment have been proposed, all based to a certain degree on repeated bedside or Holter monitoring and/or exercise-stress testing (► Fig. 29.10). These investigations are used to determine the most effective drug with least side effects. Beta blockers in combination with amiodarone have the advantage of associating an antianginal and an antiarrhythmic effect (► Fig. 29.11) [79].

### 29.2.6 Chronic coronary insufficiency without infarction

Spontaneous or exercise-induced VES are generally recognized as having an important predictive value in patients with coronary artery disease. VES induced or aggravated by exercise are usually associated with more severe, multivessel disease [78, 96, 102] often associated with abnormalities of regional-wall function [59]. The risk of sudden death or of further ischemic events is higher. A reduction in the frequency of VES on exercise also seems to have the same significance [58]. It is, therefore, logical to treat these arrhythmias especially when they are complex and associated with ST changes on exercise-stress testing. Infrequent monomorphic VES, on the other hand, require only regular follow-up.

### 29.2.7 Other cardiac diseases

Most cardiac diseases are associated with a higher risk of ventricular arrhythmias and sudden death. The relationship between these two factors has often been studied and the efficacy of antiarrhythmic therapy evaluated. Three main types of cardiac disease may be distinguished: cardiomyopathies, mitral valve prolapse, and aortic valve disease.

■ **Figure 29.11**

A study of the effect of two opposite antiarrhythmic methods in the treatment of premature ventricular contraction (VES  $\text{min}^{-1}$ ) in two patients in the chronic phase of myocardial infarction. In (a), ventricular extrasystoles are suppressed by increasing the patients cardiac rate from 55 to 70  $\text{min}^{-1}$  by a temporary pacemaker. In (b), sinus tachycardia related extrasystoles (on the left) are suppressed after administration of acebutolol which produces a decrease in the cardiac rate from 120 to 65  $\text{min}^{-1}$ , with complete disappearance of the premature ventricular contractions.

### 29.2.7.1 VES and cardiomyopathies

The study of ventricular arrhythmias in cardiomyopathy is difficult because of the poor definition of the frontiers of this condition. Cardiomyopathy may, however, be broadly divided into three subgroups: hypertrophic cardiomyopathy (HCM), dilated cardiomyopathy (DCM), and restrictive cardiomyopathy (RCM).

Hypertrophic cardiomyopathy has been studied in more depth than the other forms. The incidence and prognosis of arrhythmias seem to be the same, whether the hypertrophy is diffuse or localized to the interventricular septum (asymmetric septal hypertrophy), with or without obstruction (HOCM). Ventricular extrasystoles are common, especially on Holter monitoring, and the incidence varies from 80 to 90% [103–105]. The arrhythmia is severe (frequent and/or polymorphic, grade 2 or more in Lown's classification) in about half the patients [104–106]. There is little correlation between symptoms and the severity of the arrhythmia. Ventricular arrhythmias are commonly asymptomatic and often occur at night [103–105]. Holter monitoring is the investigation of choice for detecting these arrhythmias, the presence of which,

in the experience of most workers increases the risk of sudden death [103, 104, 107, 108]. A family history of sudden death, especially in young patients, and asymptomatic VT on Holter monitoring are two factors which help identify a subgroup of patients at high risk [103, 106, 109] requiring antiarrhythmic therapy or a prophylactic implantation of an ICD [110]. The classical treatment of HCM is beta-blocker therapy but it is not 100% effective in preventing sudden death [106, 111]. Of note, verapamil is the gold standard treatment of atrial fibrillation in hypertrophic cardiomyopathy [112].

Ventricular extrasystoles are also more frequent and complex in DCM and RCM than in so-called “normal” hearts. They become more severe as the disease progresses in association with the increased risk of sudden death. However, the presence of ventricular arrhythmias does not appear to be an independent prognostic criterion [113–115], and its treatment remains subject to caution. Numerous mutations have been reported, encoding for sarcomeric protein genes, some conveying either favorable or adverse prognosis [116].

### 29.2.7.2 Mitral valve prolapse

Mitral valve prolapse is the most common form of valvular disease (5 to 15% of the general population) and is easily diagnosed by echocardiography. Ventricular arrhythmias are commonly observed in association (60 to 70% of cases) and they may be complex. In the majority of subjects this is an obviously benign condition, but a small number are at high risk from severe arrhythmias. Holter monitoring is a more sensitive means of identifying these patients than the standard ECG [117, 118]. There is no correlation between the severity of the arrhythmia and the clinical symptoms or the valvular lesions [117–119]. High-risk patients may show ST-T wave changes in the posterior and/or lateral leads [119, 120] and frequent VES (over 400 per 24 h) [117]. The clinical context seems to play an important role.

The arrhythmias often seem to be influenced by the sympathetic nervous system, with a reduction of the number of VES during the night and an increase on exercise [119]. Considering the high incidence of mitral valve prolapse, it is probable that a number of cases of sudden death in young asymptomatic patients are the result of high-grade ventricular arrhythmias, especially VF [121], but this hypothesis has never been clearly demonstrated [122] and no consistent predictor of sudden cardiac death (SCD) has been found. However, the presence of a myocardial dysfunction or a severe mitral regurgitation is correlated with a poor outcome.

Antiarrhythmic treatment is logical in high-risk patients. Beta-blockers are indicated in obvious adrenergic-induced arrhythmias.

### 29.2.7.3 Aortic valve disease

The frequency and complexity of VES in aortic stenosis or regurgitation without associated coronary artery disease are comparable with those in HCM. Ventricular extrasystoles are usually asymptomatic [123], and unrelated to the transvalvular pressure gradient in aortic stenosis, or to the severity of the leak in aortic regurgitation [124]. Arrhythmias seem to be more common in dilated ventricles [125] when the ejection fraction is low and the peak systolic stress increases [73, 126]. The frequency of these VES seems to paradoxically increase after valve replacement. This behavior is not related to any preoperative feature of the disease.

Myocardial dysfunction is thought to be an important causal factor [73], but the treatment of these arrhythmias remains controversial. Some authors believe antiarrhythmic therapy to be mandatory [126] while others question its efficacy in this type of pathology [73].

In conclusion, the management of VES is clearly dependent on the type and severity of the underlying cardiac disease. An accurate assessment of the risk of “degeneration” of the arrhythmia is essential in each condition and each patient. This remains difficult and further study of the mechanisms involved in the initiation of life-threatening arrhythmias, the cause of most sudden deaths, is required.

## 29.3 Ventricular Tachycardias

Ventricular tachycardia is defined as a tachycardia originating below the bifurcation of the His bundle and consisting of at least three successive complexes, occurring with a frequency between 100 and 250 per minute (➤ Fig. 29.8) [127, 128].

### 29.3.1 Diagnosis

The diagnosis of ventricular tachycardia is generally established by study of the ECG recording. In most cases, this diagnosis is relatively simple. However, at times, it can be extremely difficult or misleading even for experts. The most common problem is distinguishing ventricular tachycardia from supraventricular tachycardia with aberration or more complex situations like the involvement of an accessory pathway. As the consequences of these alternative diagnoses may be very different from a therapeutic point of view, it may sometimes be necessary to confirm the diagnosis by esophageal recordings, or by endocavitary investigation [128–131] without delaying the DC shock in case of poorly tolerated arrhythmia.

#### 29.3.1.1 Electrocardiographic features

The characteristic features of VT are the following:

- Regular tachycardia with a rate usually between 100 and 200 beats/min,
- Wide deformed monomorphic ventricular complexes (QRS > 0.12 s), and
- Anterograde atrioventricular dissociation.

#### Atrial activity

The atrial rhythm depends on the sinus node and is usually slower than rapid rhythm of the VT (➤ Fig. 29.12). However, retrograde ventriculoatrial conduction is often observed with the ventricular activation conducted 1:1 to the atrium, or with retrograde block of different degrees.

In order to confirm VT, the P waves capable of capture or fusion must be carefully identified. This may be difficult using classical surface recordings and a bisternal lead or an esophageal recording may help in the diagnosis. This occurrence of fusion indicates that a ventricular focus has been modified by an external influence, usually supraventricular, but which may also be of ventricular origin. Capture of the ventricle by the supraventricular rhythm with a normal QRS complex implies an atrial origin of the activation. However, extrasystoles arising from the contralateral site of origin of the VT can also normalize the QRS width.

There are exceptions to the above. Atrial rhythm is not always slower and dissociated from the ventricular rhythm. This may be the case in two situations:

- There may be retrograde conduction. Therefore, ventricular tachycardia should be differentiated from atrial or junctional tachycardia with 1:1 conduction with either functional bundle branch block or preexcitation.
- The atrial activity may be atrial fibrillation or an isorhythmic atrial tachycardia.

Conversely atrial activation at a slower rate dissociated during tachycardia with wide QRS complexes, is not always a ventricular tachycardia. A tachycardia originating in the His bundle associated with bundle branch block and retrograde block may also give the same appearances.

■ **Figure 29.12**

An episode of sustained ventricular tachycardia recorded during epicardial mapping. E<sub>1</sub>, E<sub>2</sub>, E<sub>3</sub> are the epicardial leads. The atrial rhythm (A) is completely dissociated from the ventricular rhythm (V) recorded on the anterior aspect of the right ventricle. In this patient with arrhythmogenic right ventricular dysplasia, the moving epicardial probe (E) records a phenomenon of 2:1 Mobitz II block in the ventricle. The delayed potential stressed by the upward directed arrows appears on one of the other beats, and follows a normal synchronous beat indicated by the downward oriented arrow. U is the unipolar recording from the bipolar roving probe.

■ **Figure 29.13**

Accelerated idioventricular rhythm with a fusion beat owing to simultaneous activation between the supraventricular activity and the ventricular rhythm. The strips are recorded continuously, beginning with the top panel.

### Ventricular activity

The ventricular rhythm may be as follows:

- Irregular (ventricular tachyarrhythmia), posing the difficult differential diagnosis of a Kent bundle with a short refractory period in atrial fibrillation (pseudoventricular tachycardia);
- Slower (< 100 beats/min), in cases of accelerated idioventricular rhythm (▶ Fig. 29.13) or on account of treatment; or
- Faster (> 200 beats/min), with a regular large-amplitude sinusoidal wave called “ventricular flutter.”

### 29.3.1.2 Electrocardiographic discrimination between VT and SVT

In the case of a wide complex tachycardia (WCT), a SVT may simulate a VT because of:

- A rate dependent bundle branch block aberration
- An accessory pathway with fast atrioventricular conduction
- Some electrolyte disorders (i.e. hyperkalemia) or antiarrhythmic drugs widening the QRS complex (especially class I).

Many algorithms based on ECG features have been published in the last two decades [140, 141] to improve the differential diagnosis between SVT and VT when major criteria like capture and fusion phenomenon or atrioventricular dissociation are missing or dubious. Before using these complex algorithms, the first step of clinical evaluation is to look for the presence of the following abnormalities on previously recorded ECGs (in sinus rhythm) if available:

- LBBB or RBBB
- Ventricular preexcitation
- VES with the same morphology as the WCT.

Other criteria like QRS axis and QRS duration generally provide a small contribution to the diagnosis. However, a QRS axis rotation between  $-90^\circ$  and  $-180^\circ$  is considered as very specific of a ventricular origin, whereas other deviations can be achieved by both VT and SVT. Concerning QRS duration, a value above 140ms was found to have a very high specificity for VT, even if antiarrhythmic drug administration (class Ia and Ic especially) during SVT or conduction through an accessory pathway may widen the ventricular complex up to 140–160ms. Conversely, VT arising from the ventricular septum or from the His-Purkinje system in patients without structural heart disease is known to give relatively “narrow” WCT. These data suggest that there is no reliable measure able to discriminate SVT from VT, even if a QRS duration of more than 140 ms has a high specificity in the absence of antiarrhythmic drugs or Wolff-Parkinson-White syndrome.

The main step in the differential diagnosis is ultimately based on the analysis of QRS morphology during WCT, which can be divided into LBBB or RBBB pattern according to the polarity of QRS in lead  $V_1$ :

- When  $V_1$  has a RBBB morphology, monophasic R wave or biphasic qR and Rs patterns are very suggestive of VT whereas a triphasic ventricular complex like rSr', rsr', rSR' or rsR' is more consistent with an aberration in conduction. At the same time, an R/S ratio < 1 in  $V_6$  is expected during a WCT related to SVT. Classical patterns for VT in  $V_6$  are rS, QS or an R exclusive wave (▶ Fig. 29.14).
- When  $V_1$  has an LBBB morphology, the discrimination criteria are mainly based on the beginning of the QRS complex. When the depolarization is transmitted from the atrium to the ventricle through the His-Purkinje network, the QRS complex keeps a sharp onset even in the presence of aberrant conduction. Conversely, the ventricular depolarization of a VT through undifferentiated or scar tissue is supposed to give a slow rising or descending wave at the onset of the QRS complex. Criteria like R wave duration longer than 30 ms or an interval between the onset of the QRS to the S wave nadir of at least 60 ms in  $V_1$ , are highly correlated with a ventricular origin [142]. In  $V_6$ , the common pattern encountered during SVT is R exclusive or RR', with the lack of an initial q wave. In the case of VT, the usual morphologies are QR or QS (▶ Fig. 29.15).

■ **Figure 29.14**

Classical morphologies of QRS in  $V_1$  and  $V_6$  encountered in case of SVT (left patterns) and VT (right patterns) with a RBBB pattern.

■ **Figure 29.15**

Classical morphologies of QRS in  $V_1$  and  $V_6$  encountered in case of SVT (left patterns) and VT (right patterns) with a LBBB pattern. R duration above 30 ms and interval between the onset of the QRS to the S wave nadir of at least 60 ms in  $V_1$  suggest VT.

This analysis of QRS morphology during WCT may seem so difficult to carry out that some authors have suggested to look for more simple features like:

- lack of RS complex in precordial leads, highly suggestive of a VT according to Brugada [140], especially in the presence of a long interval between the onset of the QRS to the S wave nadir of at least 60 ms in  $V_1$  (specificity = 100%);
- negative or positive concordance from  $V_1$  to  $V_6$  (all precordial leads predominantly positive or negative) is very uncommon in SVT except in the presence of an accessory pathway.

In case of an uncertain diagnosis, especially during administration of antiarrhythmic drugs (given the risk of false positive criteria for VT), the ultimate step for WCT discrimination is the use of vagal maneuvers (carotid sinus massage or valsalva maneuver for instance) or parasympathomimetic drugs.

### 29.3.1.3 Results of endocavitary investigations during VT

Endocavitary electrophysiological investigations can be of diagnostic and therapeutic value when the VT is well tolerated and does not require immediate cardioversion. Electrophysiological studies usually confirm the diagnosis of VT, and in addition define the atrial rhythm (sinus, retrograde, ectopic).

In the His-bundle recording in VT, the His potential H' is dissociated from P waves and related to the QRS complex. The timing of H' with respect to the QRS is variable, but it is usually situated within or just after the QRS complex. This is an argument in favor of VT. However, a WPW syndrome with reciprocating tachycardia involving Mahaim fibers in the retrograde direction may pose a difficult differential diagnosis with VT.

A programmable stimulator is used to deliver 2 ms pulse duration stimuli at twice the diastolic threshold (around 2 mA), this amplitude being sometimes increased up to five times the threshold value. The stimuli can be directed to any of the three catheters through a remote-controlled switch box. Two stimulators should be available, one preset for tachycardia interruption and the other for programmed pacing during the investigation.

Ventricular tachycardia may be initiated by either atrial or ventricular pacing. In the former, the maneuvers involve introducing two or three atrial extrastimuli with increasing prematurity into a basal sinus cycle. When this is ineffective, coupled extrastimuli at increasing prematurity are introduced on a fixed atrial paced rhythm. Finally, overdrive pacing up to the Wenckebach point can be used. Ventricular pacing, includes the following:

- Asynchronous ventricular pacing at an increasing rate, from 70 to 200 beats/min;
- Coupled ventricular stimulation, then paired ventricular extrastimuli during sinus rhythm at increasing prematurity until the effective refractory period (erp) is reached and eventually three to five premature stimulations up to the erps (► Fig. 29.16);
- Paired ventricular stimulation which is repeated at fixed basic ventricular rate at 100, 130 and 150 beats/min;
- Bursts of rapid ventricular pacing with each stimulus eliciting a ventricular response for a period of 3–7 s;
- Pharmacological injection of isoproterenol [143].

In fact, protocols and definitions of VT vary from group to group. Selected protocols have been summarized in ► Table 29.2. Some groups use different intensities of stimulation or different sites of stimulation [144, 145]. However, these protocols are very controversial [146, 147] especially as some groups use them to test the effectiveness of treatment.

Different sorts of response may be elicited by the above pacing maneuvers. These include the following:

- Simple repetitive ventricular responses with an identical configuration to the paced beat. This type of response is physiological and corresponds to re-entry from branch to branch and has no pathological significance [148].
- Initiation of sustained ( $\geq 30$  s) or nonsustained ( $< 30$  s) VT that comprises at least three successive complexes. The frequency, configuration and electrical axis enable VT to be classified as “clinical” when identical to the spontaneous recorded VT, or “nonclinical” when otherwise. However, nonclinical VT may in fact correspond to a clinical VT which has not been recorded.
- Rapid and poorly tolerated VT or ventricular fibrillation must be defibrillated when the patient has lost consciousness.

### 29.3.2 Etiologies

The cause of VT may be deduced from clinical examination of the patient and from the results of different complementary investigations. In patients without clinically obvious cardiac disease, investigations may be limited to standard electrocardiography, stress testing, echocardiography, and eventually myocardial scintigraphy. In patients with obvious underlying cardiac disease, it may be necessary to perform right and left ventriculography, as well as coronary arteriography. The most common pathologies are outlined in the following subsections.

**Figure 29.16**

Induction of sustained ventricular tachycardia by three premature stimuli  $S_1$ ,  $S_2$ ,  $S_3$  during sinus rhythm, in a patient in the chronic phase of myocardial infarction.  $RV_1$ ,  $RV_2$ ,  $RV_3$  are recorded from the right ventricle.  $LV$  indicates the endocardial bipolar lead in an abnormal zone of the left ventricle showing fragmentation, both during sinus rhythm and during programmed pacing. When ventricular tachycardia is elicited, note the fragmentation of delayed potential bridging diastole (stars).

### 29.3.2.1 Coronary artery disease

Coronary artery disease occurs in about 80% of cases. Acute myocardial infarction is often complicated by polymorphic ventricular arrhythmias which explained the high mortality previously associated with acute myocardial infarction [149]. Ventricular arrhythmias may also be observed after a delay of 10 to 15 years following the initial infarct and may be the only clinical sign of a ventricular aneurysm [150, 151]. In this group of patients, the association with cardiac failure is a poor prognostic factor.

During the last decade, several major studies have clearly demonstrated the benefit of the ICD in the secondary [152–154] and primary prevention [155–157] of sudden cardiac death compared with an optimal treatment including ACE and beta-blockers, sometimes completed with an antiarrhythmic drug strategy guided by an electrophysiologic testing. A major challenge in the management of patients with CAD remains the definition of subgroups at high risk of SCD. Major criteria in this risk stratification strategy are, a previous history of SCD or spontaneous sustained VT, and left ventricular ejection fraction of 30% or less one month after an acute coronary syndrome. Conversely, prevention of ventricular arrhythmias by ICD or drugs in patients with preserved systolic function still remains unclear.

During the early phase after myocardial infarction (40 days), ICD shows no benefit in terms of survival among high risk patients with reduced left ventricular ejection fraction of 35% or less and depressed heart-rate variability.

According to these trials, indications for ICD implantation [110] in patients with a coronary heart disease are:

- Spontaneous sustained VT with impaired left ventricular ejection fraction,
- Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiological study when drug therapy is ineffective, not tolerated, or not preferred (bad compliance on long term),
- Coronary disease, prior myocardial infarction, left ventricular dysfunction, and inducible VF or sustained VT at electrophysiological study that is not controlled by a Class I antiarrhythmic drug,
- Spontaneous sustained VT that is not amenable to other treatments,

■ **Table 29.2**

**Protocols of programmed pacing and definition of ventricular tachycardia (VT)**

Study	Programmed pacing	Definition of VT
Mason and Winkle [134]	A1 atrial stimulation V1 ventricular stimulation extrastimulus V2, V2-V3, V2-V3-V4, V2-V3-V4-V5 V1,V2,V3 stimulation burst of VT RV1 + LV2 isoproterenol	Sustained for > 15 s Nonsustained: 6–15 complexes.
Mann et al [135]	ventricular stimulation (apex + septum) extrastimulus V2, V2-V3, V2-V3-V4, V2-V3-V4-V5 stimulation (500 ms) + extrastimulus burst of VT.	sustained for > 1 min or necessitating intervention for termination (poor hemodynamic tolerance) nonsustained > 6 beats, spontaneous termination within one minute.
Doherty and Josephson [136]	atrial A1, A1-A2, A1-A2-A3, stimulation extrastimulus V2, V2-V3, V2-V3-V4 ventricular pacing V2, V2-V3 other site isoproterenol	
Ruskin et al [137]	atrial A1, A1-A2, stimulation V1 ventricular stimulation extrastimulus V2, V2-V3 burst (RV) of VT	sustained VT: 100 narrow nonspontaneous complexes nonsustained VT > 5 complexes and < 100 complexes repetitive ventricular response, 3 or 4 extrasystoles.
Vandepol et al [138]	V2, V1-V2, V1-V2-V3 during sinus rhythm burst (multiple site) of VT	sustained VT > 1 min, nonspontaneous termination nonsustained VT > 3 complexes < 1 min, spontaneous termination
Perrot et al [131]	A1-A2, A1-A2, -A3 atrial stimulation ventricular stimulation with V1-V2, V1-V2-V3 extrastimuli pacing from 70 to 100 min <sup>-1</sup> .	nonsustained VT > 5 complexes at a rate of > 100 min <sup>-1</sup> for < 1 min, spontaneous termination, sustained VT > 1 min, frequency > 100 min <sup>-1</sup> .
Livelli et al [139]	A1-V2, A1-V2-V3 atrial stimulation V1-V2, V1-V2-V3 during sinus rhythm burst (apex, infundibulum RV) of VT.	sustained VT: nonspontaneous termination (necessitate intervention) nonsustained VT > 3 complexes, but spontaneous termination.
Fisher [132]	A1-A2, A1-A2-A3 atrial stimulation + V1-V2-V3, V1-V2-V3-V4 burst of VT isoproterenol	VT > 3 ventricular complexes with a frequency > 100 min <sup>-1</sup> .
Josephson et al [2]	A1-A2, V1-V2-V3 during sinus rhythm and pacing (multiple sites, sometimes right sided, sometimes left sided).	sustained VT > 30 s or termination by extrastimuli or shock (when poorly tolerated) nonsustained VT: spontaneous termination before 10 complexes.
Breithardt et al [215]	V1-V2, V1-V2-V3 during sinus rhythm and ventricular pacing (120, 140, 160, 180 min <sup>-1</sup> ) burst of VT from 10 to 20 s (180 to 220 min <sup>-1</sup> ).	sustained VT > 30 s or necessitating intervention for termination nonsustained VT: spontaneous termination within 30 s.

- Patients with left ventricular ejection fraction  $\leq 30\%$ , at least one month post myocardial infarction and three months post coronary artery revascularization surgery.

### 29.3.2.2 Dilated cardiomyopathy

Dilated cardiomyopathy (4% of cases) is generally associated with normal coronary arteriography [158]. Ventricular arrhythmias, especially VT and ventricular fibrillation, are some of the lethal complications of this condition. These

arrhythmias may be very varied, usually polymorphic, and have a poor prognosis. Sudden death is commonly observed an average of three years after the clinical onset of the arrhythmias, unless the natural outcome is shortened by other complications of this condition such as embolism and chronic heart failure. However, some cases of dilated cardiomyopathy (DCM) progress very slowly, with some patients surviving more than ten years. Some of these cases of dilated cardiomyopathy may be of viral origin [159]. In patients with DCM, primary prevention of SCD is more and more based on ICD, often combined with a resynchronization device [160, 161]. Indications are comparable with those concerning CAD.

### 29.3.2.3 Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is generally diagnosed in young and apparently healthy subjects, some of whom may practice sport at a high level, which may explain some of the sudden deaths in this group [162]. Some investigators [106] reported an incidence of 66% of severe ventricular arrhythmias and 19% of sustained VT in a series of 99 patients with hypertrophic cardiomyopathy. During a three-year follow-up period, six cases of cardiac arrest were observed, two of which were the result of ventricular fibrillation. The annual mortality of patients with VT was 8.6% compared to only 1% in patients without this arrhythmia. Arrhythmias were more commonly observed at night time, perhaps because of nocturnal sinus bradycardia. Another form of hypertrophic cardiomyopathy has been described [163] involving only the apex of the ventricle, characterized by deeply inverted T waves in the left precordial leads (see [▶ Chap. 20](#)). The diagnosis is confirmed by angiography which shows characteristic obliteration of the apex of the left ventricle. Although ventricular arrhythmias were reported for a long time in patients with HCM, the magnitude of ventricular arrhythmias and their relation with SCD have become more fully understood following a larger use of ICDs [164].

Current indications from both the American College of Cardiology and the European Society of Cardiology [110] for ICD implantation are listed below:

- Cardiac arrest
- Spontaneous sustained VT
- Family history of SCD and HCM
- Unexplained syncope
- Extreme LV hypertrophy with septal wall thickness  $\geq 30$  mm
- Hypotensive blood pressure response to exercise
- Nonsustained VT (Holter).

The significance of LV outflow tract obstruction has been demonstrated after many small studies had previously reported conflicting results. In 2003, Maron et al published a large study of 1101 patients followed for a mean of  $6.3 \pm 6.2$  years [165]. Patients with obstruction (defined as a basal gradient of at least 30 mm Hg) have an increased risk of SCD (RR = 1.9;  $p = 0.01$ ), but the low annual rate of death (1.5% vs 0.9%) gives a poor predictive value to this criterion beside risk stratification and is not sufficient alone to justify an ICD implantation.

Management of HCM may also change in the next few years in terms of risk stratification with the contribution of genetics and in terms of treatment due to a more widespread use of percutaneous alcohol septal ablation. However, the impact of this recent technique on the general course of the disease is unknown.

### 29.3.2.4 Mitral valve prolapse

Mitral valve prolapse (Barlow syndrome) is commonly complicated by ventricular arrhythmias. Ventricular extrasystoles are observed in almost 50% of cases [117]. Salvos of extrasystoles and sustained VT may also be recorded. However, although mitral valve prolapse is a relatively common condition, ventricular arrhythmias leading to VT are rare. Nevertheless, 25 cases of sudden death were reported in one review in 1979 [166]. The typical presentation is a woman of about 40 years of age with polymorphic VES and VT with a right bundle branch block configuration. The ECG shows characteristic ST-segment changes with inversion of the T wave in the left precordial leads. These forms of mitral valve prolapse are usually associated with mitral regurgitation.

No clinical or electrocardiographic criterion appears to be valuable in determining patients with a high-risk of SCD. The only indication for an ICD implantation is in secondary prevention [167].

### 29.3.2.5 Arrhythmogenic right ventricular dysplasia

Arrhythmogenic right ventricular dysplasia [168–170] arises from an abnormality in the development of a part of the right ventricular myocardium. There is a progressive alteration of the subendocardial and mediomural fibers leading to fibroadipose degeneration. The general structure of the myocardium is usually preserved but the adipose cells seem, progressively, to replace the myocardial fibers. The disease progresses very slowly in most cases with preservation of strands of healthy or partially degenerated myocardial fibers within the adipose tissue, interconnecting with some strands in the subendocardial layers. The network of fibers may be the site of delayed conduction and the origin of delayed potentials favoring the initiation of VT by reentry (▶ Fig. 29.17). Major complications are ventricular arrhythmias, mainly VT, with the risk of sudden cardiac death, and congestive heart failure. This appears when right ventricular enlargement impairs left ventricle filling or when left ventricle itself is directly affected by the disease, masquerading as a dilated cardiomyopathy. Factors defining the prognosis have been clearly described by Hulot [171]: 130 patients were followed during  $8.1 \pm 7.8$  years - 24 deaths occurred of which 21 were of a cardiovascular origin (progressive heart failure for 14 patients, sudden death for the remaining 7 patients). Multivariate analysis showed that right ventricular failure, left ventricular dysfunction and ventricular tachycardia identified high-risk subjects. Treatment strategy remains unclear in the absence of large prospective studies and a combined therapy is generally required, based on anti-arrhythmic drugs and catheter ablation [172], sometimes coupled with an ICD. Indications for defibrillator implantation are still debated except in cases of secondary prevention [167]. Two retrospective, non randomized studies have recently been published which demonstrated a better outcome in high risk patients implanted with an ICD [173, 174]. In case of frequent episodes of VT requiring external or post ICD implantation defibrillation shocks, radiofrequency catheter ablation or DC ablation remains the therapy of choice [172]. At the time of symptomatic congestive heart failure, heart transplantation or right ventricular cardiomyoplasty [175] has to be planned.

### 29.3.2.6 Uhl's anomaly

Uhl's anomaly [176] is an anatomically similar condition to arrhythmogenic right ventricular dysplasia, but is associated with severe dilatation of the right heart and characteristic thinning of certain zones of the free wall of the right ventricle. The latter occurs to such a degree that, in some cases, no myocardium is observed between the epicardial and endocardial layers. Severe forms of this condition have been described as “parchment heart” and are associated with a very poor prognosis, with death intervening in the first days or weeks of life. However, there are some rare adult forms which may, like arrhythmogenic right ventricular dysplasia, lead to attacks of VT and sudden death.

### 29.3.2.7 Brugada syndrome

Brugada syndrome, recently described in 1992, is characterized by a “coved” ST segment elevation in right precordial leads in generally young patients with structurally normal hearts. It is correlated with a high incidence of sudden arrhythmic deaths related to ventricular fibrillation [177]. This specific ECG pattern is the consequence of a mutation on a gene encoding for the sodium channel, leading to an imbalance between the outward potassium current and the inward sodium channel generating an electric gradient between epicardial and endocardial layers during ventricular repolarization. Sudden cardiac death risk is predicted by personal and familial presentation and by the onset of ventricular fibrillation during programmed ventricular stimulation. Screening parents and siblings is mandatory due to the autosomal dominant transmission of mutations described. In high-risk patients and in secondary prevention, an ICD implantation is required [177].

■ Figure 29.17

Epicardial map showing the activation pattern in a patient with arrhythmogenic right ventricular dysplasia. The first activated area (1) is situated on the posterodiaphragmatic aspect of the left ventricle. The second area (2) of excitation appears also abnormally on the anterior aspect of the left ventricle. The right ventricle shows major delay of conduction as indicated by tightly packed isochrones. The latest activated area is located near the AV groove in the area indicated by the minus sign. This place was also the area where the VT originated. LAD indicates the left anterior descending artery.

### 29.3.2.8 Idiopathic VT

Idiopathic VT is observed in clinically normal hearts and is generally the only symptom present. The arrhythmia starts as VES which become progressively more frequent, leading to sustained VT of the same configuration. These VES and VT mainly arise from:

- the right ventricular outflow tract (RVOT), giving a pattern of LBBB with a normal QRS axis [178] and less frequently from the left ventricular outflow tract (LVOT) or the aortic root with a RBBB pattern [56]. These are the most common type of VES or VT, occurring generally in young patients in the absence of overt cardiac disease, especially after having excluded an arrhythmogenic right ventricular cardiomyopathy which gives VES with the same morphology. Long term prognosis is generally good, except for the risk of developing a tachyarrhythmia cardiomyopathy, but medical treatment including class I or class II anti-arrhythmic drugs is required in symptomatic patients or in case of repetitive VES. These forms of VT are frequently very difficult to initiate and impossible to terminate by programmed pacing but are sensitive to isoprenaline infusion. Radiofrequency catheter ablation is performed when drugs are ineffective or badly tolerated, with a high level of success [179].
- the left Purkinje network system, also called “fascicular VT”, usually seen in young patients with clinically normal hearts experiencing episodes of VT with a particular ECG pattern showing right bundle branch block with left axis deviation. This arrhythmia is frequently misleading suggesting at first sight a supraventricular tachycardia with functional aberration. Electrophysiological studies, however, demonstrate a typical VT. This arrhythmia could in many cases be triggered by ventricular or even atrial pacing. Endocardial mapping shows that the origin of the VT is located in the left inferior paraseptal area, with a presystolic potential recorded on the Purkinje system [180]. It is surprising that this arrhythmia can be reproducibly stopped by an IV verapamil (10 mg) injection. Radiofrequency catheter ablation is required in case of drug refractory VT.

### 29.3.2.9 Cardiac tumors

Cardiac tumors [181] may present with recurrent VT. They are rare in adults but should be suspected in cases of childhood VT. The tumors are more commonly primary than secondary. They usually give rise to polymorphic forms of VT, the clinical characteristics of which depend on the site of the lesion. Prognosis is usually very poor except in rhabdomyoma in which some cases of spontaneous regression have been reported. Cardiac fibromas are basically benign tumors but local extension of the lesion may lead to death. Surgery may be possible in some cases, but it may be very difficult or impossible to resect the tumor from the interventricular septum.

### 29.3.2.10 Catecholamine-induced polymorphic VT

Catecholamine-induced polymorphic ventricular tachycardia is usually seen in childhood [182]. This is a rare form of VT which occurs in clinically normal hearts, almost exclusively on effort, despite a normal QT interval. These arrhythmias always occur in identical conditions after acceleration of the sinus rhythm owing to exercise or emotion. Sinus tachycardia leads to a junctional tachycardia and then VES or bigeminy which trigger polymorphic and often bidirectional VT. This finally degenerates to rapid polymorphic VT at a rate of about 300 beats/min accompanied by syncope. The arrhythmia may be reproduced during an exercise-stress test or isoproterenol infusion, and can cause sudden death. The treatment of choice seems to be beta blockade and amiodarone. Nevertheless, further studies are required to assess long-term results of this treatment.

■ Figure 29.18

Two episodes of Torsades de pointes recorded at a very slow speed which shows the crescendo type of ventricular arrhythmias. First, in (a), there are two single extrasystoles, and then two extrasystoles following each sinus beat. Thereafter, the typical features of Torsades de pointes, which ends spontaneously, can be seen. Note the giant T wave on the last three beats before the re-establishment of the basic rhythm. The same pattern is also observed on tracing (b) recorded in the same patient. Tracing (c) is from a different patient. Note the huge deformation of the last part of the T wave, denoted by an asterisk, sometimes leading to an extrasystole. These giant waves are the harbingers of Torsades de pointes.

### 29.3.2.11 Torsade de pointes (TdP)

The term Torsade de pointes (TdP), chosen by Dessertenne, corresponds with a continuously changing morphology of the QRS (🔗 Fig. 29.18) during a VT run, with a cyclic decrease in the amplitude of the ventriculograms with a periodic rotation of QRS axis [183]. Such a polymorphic VT occurs in patients with long QT syndromes, induced by drugs or genetically inherited, with the risk of syncope during the episode and the possibility of conversion into ventricular fibrillation. Endocardial recordings show fragmented potential during QRS complexes initiating TdP, then followed by twisting electrograms with a pattern of double spikes at the time of QRS axis rotation [184]. The first hypothesis reported was the presence of two foci of activation firing simultaneously with varying degrees of fusion, but subsequently the spiral wave activity theory was confirmed following the *in vitro* experiments led by Davidenko [185]. Using high resolution optical mapping, he demonstrated that the core position of the arrhythmia was moving at every beat in a single direction, giving a pattern of TdP, or in various directions, leading to VF. Good results have been reported with IV injection of magnesium sulphate to prevent recurrence. It appears to be as effective as isoproterenol but without the undesirable side effects of the latter [186]. “Quinidine-like” (class I) antiarrhythmics are contraindicated in torsades de pointes with long QT intervals. Similarly, defibrillation is indicated only when torsades de pointes degenerates into VF.

### 29.3.2.12 Congenital long-QT syndrome

The congenital long-QT syndrome is a rare condition which may lead to attacks of polymorphic VT described as torsade de pointes, preceded by a very abnormal lengthening of the corrected QT (QTc) interval (calculated from Bazett's formula), associated with a U wave leading to a dimpled appearance at the end of the T wave.

Two subgroups have been defined:

- The Lange-Nielsen syndrome, described in 1957, which associates ventricular arrhythmias and ST changes with deafness, transmitted in the autosomal recessive mode; and
- The Romano-Ward syndrome, in which deafness is absent and which is transmitted in the autosomal dominant mode.

These congenital long QT syndromes correspond with mutations involving sodium or potassium channels and are classified into seven types from LQT1 to LQT7 [187]. However, sporadic cases do occur without a familial context. Syncope occurs during exercise or emotion. The QT interval is prolonged during the appearance of VES at the end of the repolarization associated with alternating changes in amplitude of the ST segment. This leads to very rapid bursts of tachycardia with cardiovascular collapse and loss of consciousness. Electrophysiological studies show prolongation of the refractory period with a large variation in its value from one point to another in the ventricle. The prognosis, conditioned by the symptoms, the QTc duration and the mutation identified, varies from less than 5% of major cardiac event at 5 years under treatment to more than 50% in high risk patients [188]. Treatment strategy is based on beta-blocker therapy for every patient with a long QT syndrome, avoiding QT prolonging drugs and sports. ICD implantation is required in secondary prevention or in case of bad observance or poor efficacy of beta-blockers [167]. Permanent cardiac pacing has limited indications, and is mostly used for rate support in cases of symptomatic bradycardia under treatment. Parents and siblings should be screened by ECG and genotypic analysis is mandatory.

### 29.3.2.13 Bouveret VT

“Bouveret ventricular tachycardia” (Parkinson-Papp) affects young patients without obvious myocardial disease [189]. It comprises runs of monomorphic VT, suggesting a point of origin in the upper part of the interventricular septum, as has been shown by epicardial mapping performed in a few cases. This diagnosis can only be retained after a complete cardiological checkup to exclude any other cardiac disease, remembering that sometimes VT may be the only presenting symptom of a cardiac disease for many years.

The classification of some idiopathic right ventricular tachycardias with left bundle branch block configuration and a normal or right axis, is imprecise. The prognosis is usually good [178]. However, some patients may be very disabled by these episodes of tachycardia.

### 29.3.3 Treatment of ventricular tachycardia

All forms of VT should be treated to restore sinus rhythm. The clinical tolerance of VT depends, above all, on the underlying myocardial condition, a factor which partially determines the urgency of treatment and therapeutic choice.

#### 29.3.3.1 Termination methods

##### Pharmacodynamic methods

The most widely used intravenous antiarrhythmic agents (▶ Tables 29.3 and ▶ 29.4) are beta blockers, procainamide, disopyramide and amiodarone (if VT is well tolerated). Lidocaine and mexiletine are mainly used to prevent VT in the acute phase of myocardial infarction, suppressing, or at least decreasing, the frequency of VES.

##### Endocavitary pacing

Ventricular tachycardia may rarely be terminated by atrial extrastimuli but one, two or three right ventricular extrastimuli are usually more effective. This is an elegant method of terminating VT and has the advantage that it can be used to predict the efficacy of antiarrhythmic therapy (no negative inotropic effect).

##### Defibrillation and cardioversion

External DC shock is normally used when the patient has lost consciousness or after a short-lasting general anaesthetic. The electrical energy delivered ranges from 80 to 300 J [190]. When VT has a tendency to recur, during transport or in the operating theatre, adhesive defibrillation electrodes may be used which reduce the discomfort and increase the margin of safety. Repetitive shocks must be used with caution in patients with a low ejection fraction, especially in dilated cardiomyopathy and acute myocardial infarction. In all cases, the lowest amount of electrical energy possible should be used, to avoid local changes in ionic concentration and cellular damage.

#### 29.3.3.2 Termination strategy

The strategy used to terminate attacks of VT depends mainly on the condition of the patient on admission to hospital. If VT is very rapid, and poorly tolerated with cardiovascular collapse and syncope, immediate direct current shock is required, with or without anaesthetic, depending on whether or not the patient is conscious.

When VT is better tolerated, with the risk of cardiac failure in the short term, an antiarrhythmic agent with a rapid onset of action has to be used, despite the possibility of a negative inotropic effect and the need for cardiovascular resuscitation.

When VT is well tolerated, the drug of choice is amiodarone which has the great advantage of having no negative inotropic effects, providing that it is injected over a 5–10 min period at a dose of 300–400 mg. However, if VT is well tolerated and an electrophysiological laboratory is available, electrical stimulation techniques are to be preferred to drug therapy. Endocavitary catheters can be used to confirm the diagnosis of VT and then terminate the majority of attacks by programmed pacing techniques. A catheter left at the apex of the ventricle allows better control if VT occurs.

#### 29.3.3.3 Prevention of recurrence

Once an attack has been terminated, measures must be taken to prevent a recurrence and to assess the effectiveness of antiarrhythmic therapy. A distinction should be drawn between VT in the acute phase of myocardial infarction

Table 29.3  
Properties of administration of the most widely used intravenous antiarrhythmic agents

Class	Antiarrhythmic Effects	Properties	Drug	Effect On MI <sup>b</sup>		Side effects	Dosage <sup>c</sup>		Interval Between Successive doses (h)	Antiarrhythmic effectiveness
				Ch	In		iv	PO per 24 h (mg)

Table 29.5

Classification of antiarrhythmic drugs [191]

Class	Mechanism	Example
Ia	Sodium channel blockade	quinidine, ajmaline, procainamide
Ib	Sodium channel blockade	lidocaine, mexiletine, tocainide
Ic	Sodium channel blockade	flecainide, propafenone
II	Beta blockade	propranolol, metoprolol
III		amiodarone, sotalol
IV	Calcium channel blockade	verapamil, diltiazem

and chronic VT which occurs usually after the first week following infarction, but which may also be observed in cardiomyopathy, ventricular dysplasia, idiopathic aneurysm, mitral valve prolapse, tumors of the heart, and so forth.

#### Palliative methods

Cellular electrophysiological techniques have been used to classify the different antiarrhythmic drugs into four main groups [191], as shown in Table 29.5. A full discussion on the drug therapy for the treatment of VT is beyond the scope of this book. However, commonly used drugs are outlined below and further references to the advantages and disadvantages (side effects) of each are provided.

Amiodarone is widely used [192] having some advantages, such as a long half-life, but with commonly occurring side effects [193–204].

Although beta blockers do not have a direct antiarrhythmic effect, apart from sotalol, they may prevent extrasystoles induced by the autonomic nervous system by decreasing the heart rate; for example, VES occurring on waking or during exercise have a reduced frequency when treated with beta-blocking agents [205].

Verapamil [206] is a calcium antagonist which has no effect on VT except in the special case described above where VT occurs in young patients with right bundle branch block and left axis deviation.

### 29.3.3.4 Strategy for the use of palliative methods for the treatment of chronic recurrent VT

Ventricular tachycardia is a potentially dangerous arrhythmia which has to be controlled by antiarrhythmic therapy. Patients may be divided into two groups. The first group are those considered as low-risk cases, in whom the arrhythmia is perceived, is not too rapid, is infrequent and monomorphic. In these moderately symptomatic cases, amiodarone may be given at a moderate dose from 400–600 mg daily, before reducing to the maintenance dosage. The common class I antiarrhythmic drugs are selected by successive therapeutic trials. Treatment is prescribed orally and its effectiveness confirmed by Holter monitoring.

When VT is life-threatening, that is, there are frequent attacks of rapid polymorphic VT, degenerating to VF and associated with syncope or functional angina, the patient should not be discharged from hospital until the arrhythmia is well controlled. As the frequency of attacks may be greatly variable, it is not practical to wait for spontaneous recurrence of the arrhythmia and, therefore, provocative methods are used to trigger an attack, essentially by programmed pacing maneuvers.

Electrophysiological provocation tests are performed under the same conditions as those in which VT could be induced initially [49, 131, 136, 206–210], bearing in mind that these are not the usual conditions in which the patient lives. The choice of the most effective drug is made on the results of repeated provocative-pacing tests during drug therapy, which implies that VT can be inducible. Different criteria are used by different groups of workers which makes comparison of results difficult. First of all, there is no agreed definition in a recurrent tachycardia of its sustained or nonsustained character. Different protocols for electrical stimulation are used, stimulating different zones and cardiac chambers (► Fig. 29.19).

Nevertheless, in the subgroup of patients at high risk, programmed pacing methods seem to have made an important contribution to their treatment. However, the pacing protocol must be performed under clearly defined conditions. Some groups have based their results on studies performed in the electrophysiological laboratory with antiarrhythmic drugs administered parenterally. A judicious selection of these drugs allows assessment of two or three of them at each investigation. However, the eventual effectiveness of the same drug administered orally may be different. Therefore, it may be preferable to test antiarrhythmic drugs given only orally, which implies retesting the patient after each therapeutic trial, when the concentration of the drug has reached therapeutic levels. This is time consuming and expensive.

■ Figure 29.19

Part (a) shows the induction of nonsustained ventricular tachycardia by two premature stimuli S<sub>2</sub> and S<sub>3</sub>, following a regular driven cycle. The tachycardia stops after 3 s. On tracing (b), recorded in the same patient, the same protocol induces a sustained episode of ventricular tachycardia. This suggests that each procedure has to be repeated several times, taking into consideration only the highest-grade arrhythmia obtained.

In addition to electrophysiological investigation, the authors' policy is to perform exercise-stress testing. This allows an evaluation of the antiarrhythmic effect on remaining VES and, above all, aims to confirm the absence of VT during exercise.

The absence of VT on repeated 24-hour Holter recordings during antiarrhythmic therapy seems to be a reliable prognostic factor [211]. This is an important investigation as the patient is assessed under everyday living conditions [212].

Whatever the results with the different antiarrhythmic drugs used, there seem to be two major factors which influence the risk of sudden or cardiac death as follows:

- Myocardial function, which may be assessed by the New York Heart Association functional classification – patients in stage IV have a higher risk of sudden and cardiac death [213, 214];
- The ability to trigger VT despite antiarrhythmic therapy [207, 215].

However, several points must be remembered. First, all antiarrhythmic drugs may aggravate or even provoke ventricular arrhythmias. This has been reported with quinidine, procainamide [216], amiodarone [217], disopyramide, propranolol, pendolol, mexiletine, tocainide, aprindine, propafenone [218, 219], encainide [220] and flecainide [221, 222]. Secondly, most antiarrhythmic agents have potentially dangerous hemodynamic effects, especially in severe cardiac disease. The risk is even higher when several antiarrhythmics are used in association [223]. Finally, any exacerbation of a stable arrhythmia should alert the physician to an aggravation of myocardial function.

#### Inefficacy of antiarrhythmic therapy

A number of precautions must be observed before confirming that an antiarrhythmic drug is inefficient. Sufficient time must be allowed for the plasma concentrations to reach therapeutic levels. When drug dosage is not readily available, this interval is estimated to be about five times the drug's half-life. In the case of amiodarone, which has a very long half-life compared to other antiarrhythmic drugs, the delay would be unacceptably long and so measures are taken to shorten it by using loading doses (up to 1200 mg of amiodarone per day). When an antiarrhythmic agent is judged to be ineffective, drugs of a different group should be tried if necessary in association with drugs of another group or subgroup (e.g., quinidine, mexiletine or beta blocker, flecainide, etc.) [224].

#### The implantable defibrillator

The implantable defibrillator is a considerable technological achievement. It was originally designed to prevent sudden death due to ventricular fibrillation, but it is now often used to treat rapid resistant VT [226, 227]. This device is capable of storing energy of 25–30 J in a capacitor which charges when the arrhythmia occurs. An internal electric shock is delivered after an interval of less than 30 s following the onset of the arrhythmia. The theoretical total capacity is 100 shocks. Several improvements have been made to the original design. Defibrillation was initially performed using a spring electrode positioned in the superior vena cava and another patch-shaped metallic electrode positioned at the apex of the left ventricle. This design has been replaced by two epicardial patches, and since 1991, by an intracardiac coil-shaped electrode, including bipolar sensing and pacing distal electrodes for tachycardia interruption and bradycardia prevention. A microcomputer stores the number of shocks delivered, the electrograms of each arrhythmia detected, and the amount of energy remaining. The use of this device is indicated for patients with ventricular arrhythmias which start as VF, and for VT interruption.

When the patients cannot be treated by antiarrhythmic drugs, surgical ablation of the arrhythmogenic substrate, the first radical treatment, is seldom used nowadays, due to its risks of complications. It has been superseded by transcatheter ablation techniques [228, 229].

#### 29.3.3.5 Radical treatment

There are two radical methods of treating VT: surgery and by definitive medical treatment, namely, catheter ablation using radiofrequency methods, or sometimes fulguration.

■ **Figure 29.20**

**Endocardial mapping during ventricular tachycardia using a bipolar catheter located inside the left ventricle. Fragmented activity is seen on this lead (LV). A large potential is observed 100 ms before the onset of the surface QRS complex. Note also that fragmented activity is also obtained 210 ms before QRS complexes. The right ventricle is activated later, confirming that the tachycardia originates on the left side of the heart. RV 1-2 and RV 3-4 are two bipolar tracings from a bipolar right ventricular lead.**

### Surgery

The surgical treatment of VT is reviewed by Fontaine et al. [230]. The classical treatment of VT complicating coronary artery disease involved two main techniques: aneurysmectomy based on the perioperative findings and myocardial revascularization by coronary bypass grafting (saphenous vein or mammary artery). However, these two methods were not always effective as VT recurred in 30 to 40% of operated patients. New surgical techniques have been developed in the late seventies, based on the result of preoperative endocardial and perioperative epicardial mapping (simple ventriculotomy, encircling endocardial ventriculotomy, subendocardial excision, cryosurgery, and perioperative laser).

The site of origin of VT is determined either preoperatively or perioperatively. The former uses an endocardial recording catheter. The results depend on the thorough manipulation of the catheter within the left ventricle, usually around a myocardial scar. This method involves the following processes:

- the recording of fragmented low-amplitude diastolic potentials usually detected in the zone of the aneurysm [129, 231] which indicate areas of abnormal conduction but which do not actually determine the site of origin,
- the recording of the earliest potential during induced VT (▶ Fig. 29.20), and
- the reproduction of the morphology of the documented VT by stimulation at different points within the ventricle.

The perioperative method involves endocardial mapping and, above all, endocavitary recording during induced VT to determine the earliest potential during the arrhythmia (▶ Fig. 29.9) (during normothermia). The point of breakthrough of VT can thereby be determined with more accuracy in order to guide the surgical action (▶ Figs. 29.4 and ▶ 29.12).

The use of techniques based on electrophysiology should be adapted to the type of anatomopathological lesion. An important case is the ventricular aneurysm [232]. After opening the aneurysm, endocavitary mapping is performed. This may be followed by various alternatives as follows:

- Encircling endocardial ventriculotomy [233, 234] with the aim of interrupting the reentrant phenomenon without too much damage to the healthy myocardium;

- Subendocardial resection;
- Cryosurgery aimed at destroying or excluding the zone of abnormal conduction by freezing; and later,
- The use of preoperative laser treatment with the same objective as cryosurgery, but whose action is more rapid and less traumatic;
- Cardiomyoplasty.

These techniques may be associated with excision of the fibrous wall of the ventricular aneurysm, which gives an improved ventricular ejection fraction by remodelling the left ventricle. In addition, myocardial revascularization may be indicated [235, 236].

Other pathologies [237] and their treatments include the following:

- Arrhythmogenic right ventricular dysplasia which can be treated by simple ventriculotomy or resection of the dysplastic zones if not too extensive [238–240];
- Dilated cardiomyopathy with ventricular arrhythmias which can be treated by simple ventriculotomy when the patient's condition permits;
- Ventricular arrhythmias complicating cardiac tumors which can sometimes be cured when the tumor is resectable, although benign primary cardiac tumors are rare in adults; and
- Idiopathic VT, which can be treated by simple ventriculotomy or subendocardial excision;
- Catheter ablation.

After localizing the point of origin of VT by endocardial mapping with a mapping catheter, the arrhythmia may then be treated by applying a destructive energy at the distal electrode of the same catheter. Fulguration was the first to be applied, using the energy of an external cardiac defibrillator. It has been substituted by the thermal energy of radiofrequency ablation in the early 90's for safety reasons and for improved accuracy. The acute efficacy of this technique is tested by using the usual protocols of provocative pacing to try to reinitiate clinical VT immediately after the ablation and then ten days later. This later investigation seems to have a better predictive value.

The fulguration technique proved to be a very successful method in an evaluation of a series of 38 consecutive cases [241, 242]. It has the advantage of being applicable to patients for whom surgery has been refused because of their poor general condition and the extent of myocardial damage [243]. Owing to its excellent results, this technique has been extended to less critical cases. However, the method is long and difficult, and several sessions are necessary in half of the cases. It is also necessary to use antiarrhythmic drugs in 50% of the patients. Nevertheless, improvements should be possible in order to produce optimal results.

In practice, radical forms of treatment of VT are indicated in the following situations [244]: cases of VT with proven resistance to different antiarrhythmic agents and documented spontaneous recurrences, and cases of VT treated effectively by antiarrhythmic drugs but in which there is a surgical indication for myocardial revascularization. Ventriculotomy, plication of an aneurysm, or cryosurgery may be the associated methods in the latter situation.

## 30.1 Introduction

---

Atrial tachycardias comprise a minority of all supraventricular tachycardias in pediatric patients. Mechanistically, these tachycardias present a multiple of different types of tachycardias that originate and sustain in the atria and often express themselves as tachycardias in association with a rapid ventricular response in the younger patient. Atrial tachycardias can be categorized into three basic mechanistic universes: those that are automatic in nature, those that are triggered in nature, and those that are reentrant in nature.

Differentiation of the three different types of atrial tachycardias is important and can sometimes be difficult. In general, abnormalities of impulse formation, that is, atrial automatic tachycardia and/or atrial triggered tachycardia, tend to express beat-to-beat variability and have been associated with a “warm-up, cool-down phenomenon.” In contrast, abnormalities of impulse propagation include atrial tachycardias that are reentrant in nature and tend to have a fixed atrial rate with either a fixed or variable ventricular response. These individuals usually present with an inappropriately fast heart rate with little heart rate variability.

In contrast to atrial tachycardias that are associated with abnormalities of impulse formation, abnormalities of impulse propagation, as stated above, use a reentrant circuit within the atrium as their primary mechanism. This tachycardia usually occurs in patients with congenital heart disease, especially those who have had surgery for either repair or palliation of the underlying heart defect. The tachycardia responds transiently to atrial pacing and cardioversion and can sometimes be suppressed with antiarrhythmic medications. In most recent years, this tachycardia has proven to be responsive to ablative therapies and has been the subject of much study.

The first part of this chapter will focus on the clinical evaluation and treatment of automatic atrial tachycardia, while the second part dwells on atrial reentrant tachycardias. Representative electrophysiologic tracings and maps are interspersed.

### 30.1.1 Automatic/Triggered Atrial Tachycardias

---

Automatic or ectopic atrial tachycardias are caused by abnormal impulse formation where one or a few closely associated cells generate an atrial impulse faster than that of the sinus node. The arrhythmia has unique clinical features in that it usually occurs in a structurally normal heart. It classically expresses some degree of heart rate variability, and is often incessant. Because of its persistent nature, this tachycardia can be associated with a cardiomyopathy [1–3]. Automatic tachycardias are also difficult to treat, because they are often resistant to medications and/or chemical or electrical cardioversion.

Automatic atrial tachycardias are thought to be focal in nature, depolarizing the atrium in a spreading fashion originating from the rapidly firing, abnormal focus. The exact underlying pathophysiology of automatic activity is not well understood. It is thought that the cells express abnormally rapid depolarization resulting in a faster pacemaker rate than that of the sinus node. This tachycardia comprises approximately 15% of newly diagnosed supraventricular tachycardias in the pediatric population and comprises only 5% of all supraventricular tachycardias in the adult age group. Because the atrial rate is variable and sometimes only marginally above the sinus tachycardia rate, patients with this type of tachycardia may go undiagnosed for several years until they present with ventricular dysfunction associated with cardiomyopathy. Cardiomyopathy is more likely to occur in patients with higher heart rates (150–176 beats per minute), but may occasionally occur in patients with lower heart rates (90–136 beats per minute) [4]. When this happens, it is possible that the tachycardia is misdiagnosed as sinus tachycardia before a final diagnosis can be made. Myocardial dysfunction is noted to be present in about 50% of patients with ectopic atrial tachycardia. Automatic activity tends to be associated with either spontaneous diastolic Phase IV depolarization or abnormalities in repolarization of Phase III of the action potential. The location of the focus can be discerned by critical evaluation of the P-wave morphology suggesting direction of depolarization. Ectopic atrial tachycardias arising from the right atrium or the right atrial appendage are directed to the left and, usually, inferior, so that there are positive P-waves in leads I, II, III, and aVF, very similar to those in sinus rhythm. However, the P-wave morphology is usually distinctly different from that in sinus rhythm, although the non-electrophysiology physician may call it “sinus like.” In contrast, ectopic atrial tachycardias from the left-sided atrium express a P-wave morphology very different from those seen in sinus rhythm. The P-wave is directed to the right and

**Figure 30.1**

**Eight-year-old male referred for evaluation of an irregular heartbeat. Note that the ECG shows episodic salvos of a triggered atrial tachycardia arising from the right atrium as evidenced by P-waves that are positive in I, II, III, and aVF.**

inferior so that the P-waves of ectopic atrial tachycardia arising from the left atrium express negative P-waves in I and aVL and usually positive P-waves in II, III, and aVF.

Electrocardiographic and monitored rhythm recordings characteristic of automatic atrial tachycardia are highly variable. Heart rates range from just above the sinus rate to as fast as 300 beats per minute. In addition, this tachycardia exhibits multiple varied behaviors including the classic warm-up and cool-down behavior; expressed salvos of beats anywhere from three beats to several seconds in duration; as well as variable atrioventricular relationships with transmission of conduction to the ventricles varying from one to one conduction to first-degree, second-degree, and “apparent” third-degree atrioventricular block or multilevel block through the atrioventricular node. Atrial tachycardia rates associated with automatic atrial tachycardia vary highly; in addition, the tachycardia heart rate, as stated above, can vary in association with the degree of atrioventricular node transmission to the ventricle (▶ Fig. 30.2). There may also be a wide complex QRS owing to aberrant ventricular conduction. As these tachycardias, typically, have “a mind of their own,” they tend to express themselves with variable rates in a persistent fashion. Higher levels of atrioventricular conduction block can usually be seen while the patient is sleeping and, therefore, a Holter monitor of the heptum of such patients might be helpful in elucidating the diagnostic expression and behavior of the automatic atrial tachycardia (▶ Fig. 30.2). Adenosine can be used as a tool to diagnose automatic atrial tachycardia, as it causes transient atrioventricular node block. In the majority of cases, the tachycardia itself is not sensitive to adenosine and, therefore, P-waves can be dissociated from the ventricles unmasking the atrial tachycardia during transient atrioventricular node block with P-waves, lone-standing. A minority of automatic atrial tachycardias are sensitive and responsive to adenosine and will terminate, usually inscribing a QRS complex as the last expressed electrogram before they resume their activities a few seconds later. Electrical or chemical cardioversion may be transiently effective, but the tachycardia usually resumes. Automatic tachycardias tend to be variably initiated and are not responsive to extra-stimulation techniques or overdrive pacing in regards to initiation or termination of the tachycardia. Triggered activity is thought to be associated with delayed afterdepolarization; these tachycardias express their own behavior independent of pacing maneuvers and are difficult to induce and/or terminate with traditional electrophysiologically mediated pacing techniques.

As stated above, ectopic atrial tachycardia may arise either from the right or the left atrium. Although the origin of ectopic atrial tachycardia appears to be widely distributed throughout both atria, there is some suggestion that automaticity or increased triggered activity may have a propensity to arise near atrial appendages, or in and around atrial extensions into pulmonary veins. The reasons for this distribution are unclear, but there appears to be some association with the expression of HNK-1 antigen, which has become known as a marker for specialized conduction tissues during cardiac development [5, 6]. In a study by Blom-Gitinberger, investigators demonstrated an association between the

**Figure 30.2**

Newborn infant with a virtually incessant atrial tachycardia that showed multilevel block on the 24 h Holter recordings.

HNK-1 antigen expression and a propensity to develop automaticity [6]. However, the stimulus for automaticity expression and, therefore, tachycardia expression remains poorly understood.

Electrophysiologic testing can be performed to confirm the diagnosis of a suspected ectopic atrial tachycardia and can be especially meaningful if the patient has an associated myopathy, as it offers a potential cure if a successful ablation can be achieved [6, 7]. Activation sequence mapping can be done with newer mapping technologies, which delineate detailed localization of the automatic focus so that ablation can be successful (► Fig. 30.4). Should a successful ablation occur, echocardiography can then be used to follow ventricular function, which will often return to normal. Both systolic and diastolic dysfunction improve over time if successful ablation is achieved. As stated above, usually cardiomyopathy is observed in patients with higher heart rates as compared to those with lower heart rates [4].

Pharmacologic management of patients with atrial ectopic tachycardias is often quite challenging. An initial approach with rate control should be tried to maximize optimal hemodynamics. Though desirable, rhythm control is difficult and often fraught with challenging side effects from antiarrhythmic medications. Since medications, that provide rate control,

■ **Figure 30.3**

Eleven-year-old male with incessant atrial tachycardia mapped to the posterolateral left atrium and successfully ablated; bright red color denotes areas of earliest atrial activation as noted by the color bar; gray denotes absent atrial signals consistent with the orifice of the left atrial appendage; note that centric activation of the left atrium away from the mapped dominant tachycardia pacemaker.

Successful radiofrequency energy application in an 11-year-old male with incessant atrial tachycardia, mapped in the left atrium.

including beta-blockers and digoxin, seem to be well tolerated in the pediatric population, these drugs are chosen as a first-line option. In addition to rate control, by suppressing automaticity, beta blockers appear to control ectopic atrial tachycardia in about 20% of cases. Ultimately, successful suppression of tachycardia occurs in about 50% of cases, often utilizing multiple medications. Class IC (Flecainide and/or Propafenone) and/or Class III (Sotalol) agents are favorably used for atrial ectopic tachycardias that present a challenge in regards to control. Verapamil has been commonly cited for rate control in the adult literature, but is less commonly used in pediatrics. This drug is thought to suppress triggered activity. Thus, verapamil may offer both rate control and rhythm control. However, calcium channel blockers are contraindicated in the infant, as they are associated with asystole, probably related to the infant's poorly differentiated endoplasmic reticulum and therefore, inability to benefit from the drug's actions.

The natural history of ectopic atrial tachycardia is variable. When it occurs in younger neonates and infants, the tachycardia seems to regress spontaneously in about 50% of cases. However, when the patients are older and present with cardiomyopathy, the tachycardia tends to be more persistent and requires more aggressive intervention.

Though surgical techniques were employed effectively for drug-resistant ectopic atrial tachycardia throughout the 1980s, the advent of radiofrequency energy application changed the outcomes. The earliest attempts to ablate ectopic atrial tachycardia using transvenous methods occurred in 1984 using direct DC energy. Further developments in technology introduced the application of radiofrequency energy as an intervention. When used appropriately, this intervention tends to underscore the relatively benign course and good outcomes in association with high success rates for ablation of this type of tachycardia. The success rate with currently available technology for the ablation of ectopic atrial tachycardia is now greater than 90% with a relatively low complication rate. Nowadays, patients who present with ventricular failure due to an atrial tachycardia are promptly managed with electrophysiologic study and catheter ablation using either radiofrequency or cryoablative energy. This otherwise malignant arrhythmia can now, be often-cured (▶ Figs. 30.3 and ▶ 30.4).

Multifocal atrial tachycardia, also known as chaotic atrial tachycardia, is a rare form of automatic atrial tachycardia, where there is more than one focus firing rapidly [8]. Multifocal atrial tachycardia is mostly a condition seen in adults, particularly with cor pulmonale or chronic obstructive pulmonary disease [10]. Multifocal atrial tachycardia is frequently idiopathic in nature, although it has been associated, in rare cases, with Macrocephaly-Cutis Marmorata Telangiectatica Congenita [9] and other rare diseases. When it occurs in the postoperative period, it is often very difficult to control and may require aggressive therapy including early consideration of radiofrequency ablation of the atrioventricular node for rate control. Classic ECG (electrocardiogram) findings include P-waves that are irregularly inscribed at heart rates greater than 100 beats per minute. There may be three or more different P-wave morphologies. The ventricular response to such a tachycardia can be quite varied. Rate-related bundle branch block can be seen after short–long or after long–short ventricular responses due to variable ventricular transmission of the rapid impulses in the atrium.

The clinical course of multifocal atrial tachycardia in children includes spontaneous resolution of the tachycardia in 50–80% of the cases by 12–18 months of age. Rarely, during the time in which the multifocal atrial tachycardia is expressed, there may be progressive cardiomyopathy and sudden cardiac death, presumably associated with rapid ventricular conduction [11, 12]. Multifocal atrial tachycardia tends to be quite resistant to medical management, even aggressive pharmacologic therapy. Traditionally, beta-blockers or digoxin can be used for rate control and, sometimes, can suppress atrial and ventricular irritability. However, rhythm control is usually quite difficult in these patients. Combinations of medications have been used with limited success, including amiodarone [13]. As a last resort, ablation of the atrioventricular node can be performed to control the rate in patients who are severely symptomatic. In this case, careful consideration of the aggressive approach to the hemodynamic compromise should be weighed as the patient will most likely require a pacemaker for the rest of his/her life. Most telling is that once the tachycardia has resolved, the recurrence risk is quite low as the tachycardia does not reoccur during later life.

Regardless, short of ablation therapy, medical management of both rhythm control and rate control appears to be challenging in patients with a triggered and/or automatic atrial tachycardia. With the advent of radiofrequency energy application and/or (now) cryo-ablation, the cure rate for atrial tachycardia remains high and especially hopeful for those patients suffering from associated myocardial dysfunction.

### 30.1.2 Reentrant Atrial Tachycardias

As stated above, in contrast to atrial tachycardias associated with abnormalities of impulse formation, abnormalities of impulse propagation use a reentrant circuit within the atrium as their primary mechanism. The history related to the development of understanding of atrial reentrant tachycardias is of particular interest. The traditional term for atrial reentrant tachycardia is atrial flutter. The term “flutter” originates from the Anglo-Saxon word “floterian,” meaning to move or flap wings rapidly without flying or to move with quick vibrations or undulations. This descriptive term was first used by a British physiologist, MacWilliams, in 1887 while looking at a dog atrium [14]. In 1905, there was a first recording of atrial flutter by William Richie using an ink-polygraph recorder in a patient with complete atrioventricular block [15], which was followed in 1910 by a first-time recording of atrial flutter in the same patient using an electrocardiograph [16]. Einthoven in 1906 had reported a similar phenomenon in his laboratory from a patient 1.5 km away [17]. The most

clear electrocardiographic recordings of atrial flutter were made in 1913 by Sir Thomas Lewis who described a classic saw-toothed pattern with negative deflections in leads II and III [18]. Once this arrhythmia was acknowledged, many investigators began to hypothesize and study its mechanism with two basic schools of thought predominating: Is the primary mechanism one of automaticity (abnormal impulse formation, as believed by Lewis) or reentry (abnormal impulse propagation)? Works by Mayer with the *Scyphomedusae* (1906), Mines (1913), and Garrey (1914) suggested reentry as a primary mechanism. In 1921, after a series of canine experiments, Lewis changed his mind and supported the notion that atrial flutter was supported by reentry [19]. Since mapping techniques were crude at the time, controversy continued to exist. Clinically, different ECG patterns of flutter were noted raising further questions in regards to the underlying mechanism. Telling work by Cabrera and Sodi-Pallares in 1947 showed that atrial flutter was a result of consecutive regular activation fronts oriented in the sagittal plane using data obtained from ECG and VCG recordings [20]. Despite these experiments, several clinical observations suggested that atrial flutter may be arising from a single focus firing rapidly. In a classic paper by Puech et al. in 1970, the authors identified two types of flutter: the common type, where P-waves were negative in II, III, and aVF; and the “rare” type, where flutter waves were best expressed in leads I and aVL [21]. Even though these studies showed that activation of the right atrium during common flutter preceded cranially along the interatrial septum and then caudally along the free wall of the right atrium, with the left atrium being activated at the same time as during septal activation, the question of reentry versus automaticity was not clearly answered from these studies. Finally, several ongoing studies by Waldo et al. in 1977 both in the canine sterile pericarditis model and in postoperative patients demonstrated that the mechanism for atrial flutter was reentrant and, thus, an abnormality of impulse propagation. These investigators used entrainment techniques to support the notion of reentry as opposed to automaticity as the underlying mechanism for flutter. Using epicardial electrode recordings, four electrophysiological criteria were identified with each of them sufficient to demonstrate circuit movement tachycardia incorporating an excitable gap [22–32]. Waldo also made a distinction between the two types of atrial flutter: Type 1, easily influenced by programmed pacing, and Type 2, which was infrequently seen, faster, and not easily influenced by rapid atrial pacing. In 1978, Wyndham was the first to report that atrial flutter could be interrupted using a self-activated radiofrequency generator [33]. Once identified as reentrant in mechanism, the quest to understand a more detailed mechanism continued. Pastelin et al. were able to identify that cutting the medial and posterior bundles in the atrium interrupted atrial flutter [34]. The role of anatomic and functional barriers was investigated including the proposed role of an area of slow conduction [35, 36]. Other investigators looked at the type of atrial reentry demonstrating that it was macroreentrant [37] and dependent on myocyte interconnections [38]. Another experimental model suggested that atrial reentry was possible without an area of slow conduction [39]. In the same year (1986), Guy Fontaine used radiofrequency energy in two patients to treat atrial flutter [40]. Further work demonstrated that the expression of atrial flutter was related to the time course of postoperative pericarditis. At the same time, the role of double potentials and fractionated atrial signals was interrogated by Cosio et al. suggesting that these signals were associated with areas of slow conduction [41] and that they provided an opportunity to study the reentrant mechanism further. Finally, after electrical fulguration was shown to be effective in the late 1980s [42], Feld et al. showed that atrial flutter was amenable to radiofrequency ablation in 1992 [43], targeting areas of slow conduction. As the quest to understand more complex types of atrial reentrant tachycardia continues, technology supports and parallels better understanding of the underlying mechanisms that can, therefore, support better outcomes in patients.

The observation that atrial tachycardias are more common in the postoperative patient with congenital heart disease has resulted in several investigators focusing on the role of surgical incisions in the expression of atrial reentrant tachycardia. It was thought that atrial reentry in these patients was also subeustachian isthmus dependent, although subsequently this observation has been scrutinized further to show that there are a variety of complex reentrant rhythms present in the patient with postoperative congenital heart disease.

### 30.1.3 Atrial Anatomy: Lessons from Atrial Flutter in Animal Models and Adult Patients with Heart Disease

Anatomic studies evaluated the role of the crista terminalis of the right atrium, which is located in the sulcus terminalis located in the right atrium inferior to the superior caval vein. The sinus node rests within the crista terminalis and supports the initiation of the sinus impulse. The origination of the impulse that initiates atrial flutter was thought to be the sinus node [35], but it is now accepted that any premature beat originating anywhere in the myocardium can serve as the

initiator of atrial reentry as long as a supportive substrate is present. There is also a school of thought that atrial flutter is a later manifestation of atrial fibrillation once given the opportunity to organize. In general, right atrial pacemaker activity is thought to originate from along the sulcus terminalis, whereas premature atrial beats from the left atrium are thought to originate from the pulmonary veins. The right atrium is largely smooth-walled and derived from the embryologic sinus venosus. In contrast, the left atrium is formed from the anlage of the pulmonary veins. There is a fold between the right pulmonary veins and the superior vena cava known as the “Waterston groove.” The orifice of the inferior vena cava (IVC) and coronary sinus have fibrous continuity with only variable amounts of myocardial tissue bridging the right and the left atrium superficially [44]. Posteriorly, the right and the left atrium are separated by a groove that is filled with fibro-fatty tissue; only anteriorly, there is a distinct band of muscle that passes from the anteromedial aspect of the right atrium and superior vena cava to the left atrium, known as Bachman’s bundle [45]. In the right atrium, the pectinate muscles run obliquely toward the right atrial appendage. In contrast, in the left atrium, myocardial fibers encircle the pulmonary veins and to some degree the mitral valve annulus. Several natural orifices exist in the right atrium including the superior vena cava, inferior vena cava, atrial septum, tricuspid valve, coronary sinus, and right atrial appendage orifice. This geometry plays a crucial role during activation sequences involved while atrial reentry occurs, like posing selective lines of block or activating conduction pathways during expression of atrial reentrant tachycardias.

Atrial reentrant tachycardias, classically referred to as atrial flutter, have now been accepted to involve abnormalities of impulse propagation that occur within either atria. Although primarily thought to be associated with right atrial disease, atrial reentrant arrhythmias can occur involving the right, the left, or both atria. Even though atrial flutter/atrial reentrant tachycardia is a common arrhythmia seen in the adult population, this arrhythmia is much more rare in the pediatric population and usually occurs in patients with underlying cardiac abnormalities, especially those who have undergone surgery for correction or palliation of congenital heart disease. In patients with underlying cardiac abnormalities, this arrhythmia, though rare, poses a challenge with regards to diagnosis, management, and therapy. In addition, this arrhythmia is often associated with significant morbidity and mortality in young patients with structural or functional heart disease.

Improved understanding of atrial reentrant tachycardias has allowed for differentiation of different types of atrial reentry in most recent years. Both clinical and experimental studies and observations over the last 10–15 years have been able to delineate the electrophysiologic circuit(s) that support macroreentry in atrial reentrant tachycardias. It has been shown that atrial reentry most commonly occurs in the right atrium. It is a self-sustaining circuit, and usually occurs in patients with either structural or functional heart disease. Continued study of atrial reentry defined the role of the crista terminalis as an anisotropic barrier to conduction during the common forms of atrial flutter. It has also been shown that the tricuspid valve annulus serves as an anterior anatomic barrier, supporting this “classic” reentrant loop. Finally, abnormal automaticity of the crista terminalis, the remnants of the cardinal veins, the sinus venosus and pulmonary veins have been shown to serve as triggers to express premature electrical activity that subsequently serves as the initiating factor for the expression of atrial reentry. Further research has demonstrated that intrinsic anisotropic properties of the right atrial wall related to the trabeculations of the right atrium and the number and distribution of gap junctions or connexin proteins support expression of atrial reentry. There is no doubt that the expression of atrial reentry is multifactorial, but the tachycardia seems to be more present in the right atrium, especially in patients who have either functional or congenital abnormalities of the right atrium.

The debate in regards to the underlying mechanism of atrial flutter continued for several decades until a variety of experimental animal models of atrial reentrant tachycardia were developed and demonstrated that, indeed, atrial flutter and/or atrial reentrant tachycardia is an abnormality of impulse propagation supporting reentry inside the atria (mostly the right atrium). In addition to delineating the underlying mechanism for atrial reentry tachycardia, these models supported a better understanding of the exact reentrant loop and conduction behavior during atrial tachycardia. Evaluation of a variety of anatomic structures in association with the expression of the atrial reentrant tachycardia became the next subject of intensive study. Most recently, with the advent of catheter-based mapping and ablation techniques, atrial reentrant tachycardias have been further characterized and studied in regards to distribution, expression, reentrant loop and insight into the roles of specific anatomic structures and/or surgical incisions.

In 1947, Rosenbluth and Garcia-Ramos developed a model of intercaval crush injury to study atrial flutter [46]. This model served to support the notion that nonconductive barriers were necessary for the induction and sustenance of intra-atrial reentrant tachycardias. The observation that the extension of the injury to the tricuspid valve annulus terminated the arrhythmia was essential to understanding that this particular arrhythmia was reentrant in nature and

required an isthmus. A second surgical model developed by Frame et al. [39] used a posterior intercaval incision that was y-shaped and demonstrated that the reentry was around the tricuspid ring sustaining flutter. In this model, it was demonstrated that the tricuspid valve annulus forced activation in a circular manner around the tricuspid valve annulus. A model of acetylcholine-induced tachycardia developed by Alessie et al. described the refractoriness of atrial tissue and its role in the support of atrial reentry in the right atrium [37]. It was thought that functional refractoriness played a critical role in determining propagation of reentrant wavefronts in the right atrium. Secondly, the sterile pericarditis model of atrial flutter assessed and proved the relative importance of anatomic boundaries, functional refractoriness, and the role of anatomic barriers in the expression of atrial reentry [22, 28, 30–32]. It appeared that in several of these models, nonconductive barriers were crucial for the expression of reentry and that some of these barriers were functional in nature. Several other models then undiscovered the importance of endocardial structures, both anatomically and functionally.

Finally, in a canine model, Boineau [35] demonstrated that the crista terminalis was crucial in regards to expression of the common type of atrial flutter in adults. This model demonstrated the interaction between anisotropic conduction and the complex geometry of the right atrium with regards to common atrial flutter expression. In addition, this model was extended by several investigators who further elucidated the role of anisotropy and conduction velocity change along the crista terminalis. It was, therefore, thought that the cellular basis for observed directional preferences for longitudinal conduction in the crista terminalis may very well be associated with the role of gap junctions and cell-to-cell interactions favoring conduction in one direction and, therefore, suggesting that anisotropy plays a critical role in the expression of atrial reentry [47–54].

### 30.1.4 Intra-Atrial Reentry in the Postoperative Patient with Congenital Heart Disease

Intra-atrial tachycardia has carried many names in the past, including the traditional name of atrial flutter [49, 50]. Reentrant in nature, this tachycardia uses a variety of reentrant loops, in contrast to common atrial flutter, which uses the subeustachian isthmus as a critical component of its reentrant loop. Common atrial flutter usually depicts a tachycardia cycle length of around 200 ms and inscribes P-waves that are negative in II, III, and aVF. In contrast, intra-atrial tachycardia, which typically occurs in the post-operative patient, expresses a broad range of tachycardia cycle lengths and P-wave morphologies [55]. This tachycardia has been denoted as such because the reentrant tachycardia may use reentrant circuits that are not similar to that found in common atrial flutter. Even though the tricuspid valve subeustachian isthmus can be involved in the expression of postoperative intra-atrial reentrant tachycardia in the patient with congenital heart disease, there appear to be other reentrant pathways or loops, sometimes involving the atriotomy, or other anatomic boundaries. About one third to one fourth of patients with congenital heart disease, especially those who have had either surgery or palliation for congenital heart disease, will develop or have a propensity to develop sustained atrial tachycardia that can be demonstrated using programmed stimulation [56–58]. Only about 8% of patients who develop atrial reentrant tachycardias have anatomically and functionally normal hearts, with over 80% having associated repaired or unrepaired congenital heart disease [56] (► Table 30.1).

In regards to intra-atrial reentry tachycardia in the postoperative patient, two key surgical models have served to improve our understanding of the atrial reentrant tachycardia in the postoperative patient with pediatric heart disease.

■ Figure 30.5

The Kaplan–Meier curve depicts probability of experiencing no atrial tachycardias after Fontan operation with respect to time and type of Fontan operation performed.

The first of these models was one developed by Cronin et al. [59, 60], which involved a sham Mustard operation. Rodefeld et al. [61–65] also developed a sham model of a lateral tunnel variety of the Fontan procedure (► Fig. 30.5). In both of these models, it was felt that a common pathway for most of the observed tachycardias was in the free wall of the right atrium and that the tachycardia resolved when connecting the atriotomy to either the tricuspid valve annulus or the superior vena cava. These studies also found that the inclusion of the crista terminalis in the suture line aggravated the propensity of atrial tachycardia expression.

## 30.2 Epidemiology

In general, intra-atrial reentrant tachycardia in patients with congenital heart disease occurs in patients who have had significant manipulation or alterations of the right atrium, most often associated with surgery for heart disease [56]. Most of these surgeries include surgery for either atrial septal defect or ventricular septal defect repair, Mustard or Senning operations for the transposition of the great arteries (TGA), and those surgeries involving palliative procedures for single-ventricle physiology. In addition, there is a significant incidence of atrial tachycardia in association with lesions such as Tetralogy of Fallot and/or Ebstein's Anomaly. Of particular challenge is atrial tachycardia in the postoperative patient after a Fontan operation. Because of single-ventricle physiology and an often underlying myopathy, atrial tachycardia in these patients is hemodynamically poorly tolerated. Gelatt showed that 14–29% of patients after Fontan operation had atrial tachycardia at a mean follow-up of 4 years [57, 58]. One of the primary predictors of atrial tachycardia expression was the presence of atrial tachycardia in the immediate postoperative period. Another study showed that 16% of patients had atrial tachycardia at 5-year follow-up and appeared to correlate the expression of atrial tachycardia to the presence of extensive atrial baffling, and co-related the type of repair with arrhythmia expression [66]. Finally, a study from the Mayo Clinic demonstrated a prevalence of 17% at a 5-year follow-up with associated risk factors including perioperative arrhythmia, age at operation, and atrioventricular valve dysfunction [67]. It appears that about 40% of Fontan survivors have atrial tachycardia at a 10-year follow-up (► Fig. 30.5). Although the overall prevalence of atrial tachycardia is lower in those patients undergoing total cavopulmonary connection, these patients are not completely free of the atrial arrhythmias. The incidence of atrial arrhythmias seems higher in patients with complex heart disease, there is a documented incidence of 14% in patients undergoing atrial septal defect repair. In addition, atrial arrhythmias may be associated with sinus node dysfunction as a cofactor [68–70]. The Mustard procedure has been quoted to have an incidence of 43% of atrial tachycardia with 16% having recurrent atrial arrhythmias. Patients who have undergone the Mustard procedure have an increased risk of atrial tachycardia with an incidence of 27% at 20 years, and have an increased risk of sudden death of 6.5% at a mean follow-up period of 11.6 years [57, 58]. It appears that atrial tachycardia may be associated with concordant

sinus node dysfunction, as shown by a study of patients with atrial flutter after Tetralogy of Fallot [71] or atrial septal defect repair [69], superimposed on a genetic propensity.

### 30.3 Clinical Symptoms

---

Symptoms associated with intra-atrial reentry tachycardia in patients with postoperative heart disease are quite varied, ranging from no symptoms, to palpitations, to hemodynamic collapse, to sudden cardiac death thought to be associated with concomitant rapid conduction and ventricular dysfunction. From clinical observations, it is obvious that the presence of atrial tachycardia adds significant morbidity and mortality to postoperative patients. Especially in patients with single-ventricle physiology, the added burden of atrial arrhythmias is significant. In these patients, early postoperative arrhythmias were poorly tolerated, particularly atrial fibrillation and junctional ectopic tachycardia. Peters et al. observed that more than half of all patients who died in the perioperative period had atrial tachycardias [72].

Late postoperative arrhythmias are associated with higher right atrial pressures measured both early and late after the operation and worse ventricular function. Late arrhythmias may be the first manifestation of anatomic obstruction, which should be investigated promptly. In these patients with atrial arrhythmias, atrial thrombi can also be frequently noted, requiring aggressive anticoagulation.

### 30.4 Treatment of Atrial Tachycardia

---

The treatment of atrial tachycardias is challenging in patients with postoperative congenital heart disease [71, 73–80]. The acute treatment of atrial tachycardias depends on the clinical symptoms and associated cardiac defect(s). Once suspected, the patient should undergo full evaluation including documentation and definition of the arrhythmia with a 12-lead electrocardiogram and interrogation of intracardiac structures for thrombus formation and cardiac function [81]. Depending on the clinical arrhythmia, patients will often have associated cardiomyopathy. Patients with underlying complex congenital heart disease have an increased risk of intracardiac thrombus formation, especially during expression of the atrial tachycardia. Careful evaluation of intracardiac stasis or thrombus is essential prior to proceeding with plans for either chemical or electrical cardioversion to normal sinus rhythm. Acute conversion of an atrial tachycardia can be achieved in most cases where the mechanism of the tachycardia is supported by reentry. In these cases, either chemical cardioversion with Ibutilide (0.01 mg/kg/dose repeated 2 times after 5–10 min) can be tried. In these patients, it is of prime importance that the patient's electrolytes are evaluated for hypomagnesemia or hypokalemia. A defibrillator should be available with experienced staff, since Ibutilide can cause Torsades de Pointe in association with QTc prolongation, which can be exacerbated in the presence of hypokalemia or hypomagnesemia and/or concomitant myopathy.

Chronic treatment of atrial tachycardias can be achieved with Class IA, IIC, or III antiarrhythmic agents, antitachycardia pacing devices, or with a more promising and more permanent approach of electrophysiologic study with ablation. Medical management of these arrhythmias is additionally hampered, because most antiarrhythmic medications affect myocardial function, which is often depressed in patients after cardiac surgery. It appears that Sotalol may have a beneficial effect on both acute and chronic tachycardia control [82, 83]. Antitachycardia pacing has also proven to be promising, though not always successful. Often patients exhibit multiple tachycardias or are unresponsive to pacing maneuvers perhaps due to the relative small excitable gap of the reentrant loop [78, 84–86]. Antitachycardia pacing has been reported to be associated with lethal pro-arrhythmias in selected patients, so that patient selection is critical. If there is significant myopathy and a normal atrioventricular node, rapid conduction with cardiovascular compromise is more likely [85, 87–89].

Ablation procedures offer the potential for cure for patients with postoperative atrial tachycardias. Initial evaluation and outcome of electrophysiologic study with ablation was less than optimal because traditional mapping techniques were hampered by poor definition of the underlying anatomic defect(s), associated postoperative distortions and scars that are not visualized with current fluoroscopic techniques, and poor understanding of the tachycardia mechanism. In addition, traditional techniques are limited in their inability to outline and display impulse propagation. These limitations hindered the clinician's understanding of the complexity of the tachycardia mechanism and the identification of critical areas

■ Figure 30.6

for successful ablative therapy [76, 80, 90–97]. Newer mapping techniques (▶ Fig. 30.6) supported by better understanding of the tachycardia mechanism and improved electrophysiologic techniques, including entrainment mapping promise improved outcomes. Therefore, newer approaches offer hope for cure of these reentrant tachycardias [98, 99].

### 30.4.1 Mechanisms of Postoperative Atrial Reentrant Tachycardias

In a small cohort of 21 consecutive patients with congenital heart disease, who were admitted to the University of California between 6/97 and 12/98 and to Rainbow Babies and Children's Hospital at Case Western Reserve University between 6/99 and 12/2000, a total of 33 atrial tachycardias were studied in the electrophysiology laboratory using advanced mapping techniques. All patients had documented clinical atrial tachycardia in association with postoperative congenital heart disease. Patients underwent electrophysiologic study under sedation, and in addition to the traditional electrophysiologic approach, patients underwent mapping of the clinical tachycardia using the non-fluoroscopic electroanatomic mapping (EAM) system (using CARTO) [98, 99]. Atrial tachycardia was induced using atrial overdrive pacing, atrial extrastimulation techniques, and/or isoproterenol infusion, when needed. The electroanatomic map was carefully interrogated for (1) activation sequences; (2) areas of low voltage ( $<0.03$  mV), to identify areas that could be associated with diseased tissue and/or scar, supporting a barrier(s) for intra-atrial reentry tachycardia; (3) double potentials, which may reflect areas of slow conduction or functional and/or structural lines of conduction block. Entrainment techniques were used to define the mechanism and to identify a critical tachycardia isthmus.

Traditional electrophysiologic catheters were used to perform fluoroscopic mapping followed by electroanatomic mapping. The superior vena cava to (systemic venous) atrial junction and the inferior vena cava (IVC) to (systemic venous) atrial junction were mapped and marked with a three-dimensional ring or a tag. When possible, the His position was also tagged. In five of six patients with D-transposition of the great arteries (TGA) status post atrial switch operation, the pulmonary venous atrium was mapped from the arterial side as well. When present, double potentials and areas of scar were tagged during mapping and data acquisition.

Entrainment mapping was used to characterize each tachycardia circuit. After consistent capture was ensured, the intracardiac electrograms and the surface 12-lead ECG (electrocardiogram) were carefully interrogated to evaluate activation sequences compared to the native tachycardia. If the post-pacing interval (PPI) equaled the tachycardia cycle length and was associated with changes in either intracardiac activation sequences or surface P-wave morphology, the paced location was considered to demonstrate fusion and, therefore, labeled as manifest entrainment. These areas were considered less optimal for ablation. Concealed entrainment was present when (a) the post-pacing interval, defined as the stimulus

artifact to the onset of the next atrial electrogram recorded from the pacing bipoles, was  $\leq 30$  ms of the tachycardia cycle length, (b) the intracardiac activation sequences were identical during pacing as compared to those during spontaneous tachycardia, and (c) the surface P-wave morphology was identical to the paced P-wave morphology. Areas of manifest and concealed entrainment were marked on the constructed three-dimensional image created by the EAM. Only areas with concealed entrainment were targeted for the radiofrequency energy application. Patients were subdivided into two cohorts: those with simple atriotomies (such as those seen after ASD [atrial septal defect], VSD [ventricular septal defect], AVSD [atrioventricular septal defect], or TOF [tetralogy of fallot] repair) and those with more complex atriotomies, as found in patients after Mustard or Senning operation and/or surgery for single-ventricle physiology.

### 30.4.2 Intra-Atrial Tachycardias Associated with a Simple Atriotomy

In patients with simple atriotomies ( $N = 12$ ), one underwent correction of an atrial septal defect(s) (ASD), five underwent correction of an ASD and ventricular septal defect(s) (VSD), and one underwent complete atrioventricular septal defect (AVSD) repair. Five of these had a single tachycardia that was mapped and ablated. The sixth patient (with an ASD and VSD) had two separate tachycardias, of which both were mapped and ablated. Of these seven tachycardias, four had tachycardias involving the cavotricuspid isthmus and all were successfully ablated in the subeustachian isthmus. The other three tachycardias were successfully ablated by creating lesions from either anterior double potentials to the IVC ( $N = 2$ ), where the tachycardia was revolving around an anterior barrier, or from the posterolateral right atrial wall double potentials to the IVC, where the tachycardia was found to revolve around a posterolateral barrier (► Fig. 30.7).

There were three patients with Tetralogy of Fallot. Two of these three patients had a single tachycardia. These tachycardias were successfully ablated by creating lesions from anterior double potentials to the IVC in one and from the posterolateral right atrial wall to the IVC in another, which recurred 18 months later. Repeat mapping of the same tachycardia revealed a “Figure-of-8” (previously missed) and was successfully ablated between a suspected atriotomy (mapped double potentials) and the posterolateral wall, and the posterolateral wall and the IVC. The third patient had three different tachycardias, all of which were successfully ablated; ablative lesions were successful in the subeustachian isthmus for a subeustachian-dependent tachycardia, between anterior double potentials and the IVC for an incisional tachycardia and between the posterolateral wall and the IVC for a free wall atrial tachycardia.

The remaining three patients had simple atriotomies for Ebstein’s anomaly of the tricuspid valve, Marfan’s syndrome, and L-TGA with a VSD; all patients had a single atrial tachycardia. Two of these tachycardias were successfully ablated in the subeustachian isthmus. The patient with Ebstein’s anomaly received multiple ablative lesions in the subeustachian isthmus, which did not result in tachycardia termination. Retrospective evaluation revealed a “Figure-of-8” tachycardia with a common isthmus between an anterior atriotomy and posterolateral double potentials. This complex mechanism was not recognized at the time of the study (► Fig. 30.8).

In those patients where the posterolateral right atrial free wall provided a pivot area for the tachycardia (5 of 16 tachycardias), the EAM revealed a reentrant circuit that was distinctly different from classic clockwise or counterclockwise flutter around the tricuspid valve. Impulse propagation occurred around the valve, but these activation sequences were driven by a circuit that was primarily located laterally and posteriorly and almost perpendicular to the frontal plane. In these patients, entrainment from the subeustachian isthmus exhibited manifest entrainment, confirming that the subeustachian isthmus was not critical to the reentrant loop. Successful ablation of these tachycardias was achieved by ablation of an area that bridged the posterolateral right atrial free wall (behind the crista terminalis) to the IVC in all five patients (► Fig. 30.7).

Three other tachycardias were noted to propagate around an anterior barrier. In one patient, the tachycardia was thought to be isthmus dependent, but unsuccessful ablation of the subeustachian isthmus was thought to be due to the inability to achieve a transmural lesion or due to poor understanding of the underlying mechanism. Only a traditional ablation catheter was used.

In summary, patients with a simple atriotomy demonstrated four different tachycardia mechanisms: subeustachian isthmus dependent (7/16 or 44%), reentry around posterolateral double potentials (4/16 or 25%), reentry around anterior double potentials (3/16 or 19%), and “Figure-of-8” tachycardia (2/16 or 12%) with a common isthmus located between mapped double potentials either laterally or anteriorly and another anatomic barrier such as the tricuspid valve.

■ Figure 30.7

These activation maps of the right atrium in a 37-year-old male after atrial septal defect repair confirm non-isthmus-dependent atrial tachycardia. Shown are PA (posteroanterior) and RAO (right anterior oblique) projections displaying that the atrial tachycardia was mapped to revolve around a lateral scar within the right atrium in a counterclockwise fashion.

■ Figure 30.8

Figure-of-8 loop atrial tachycardia in a patient after simple atriotomy for tricuspid valve surgery for Ebstein's anomaly.

### 30.4.3 Intra-Atrial Tachycardias Associated with Complex Atriotomies

#### 30.4.3.1 Patients after Atrial Switch Operation

Thirteen of the 17 tachycardias were mapped in six patients after an atrial switch operation. Two of these patients had a single tachycardia that was successfully ablated in the subeustachian isthmus on the pulmonary venous side. This tachycardia traversed the isthmus arising posteroseptally on the pulmonary venous side, inscribing a clockwise propagation pattern moving anteriorly and superiorly, and then descending to the posteroseptal area. The systemic venous atrial side was passively activated by the reentrant wavefront as it traversed the upper and mid-septal portions (▶ Fig. 30.9). A third patient had two tachycardias. One of these tachycardias appeared to be focal in nature. The EAM of this tachycardia revealed passive activation of the systemic venous atrium from the posteroseptal area, where the post-pacing interval was identical to the tachycardia cycle length. Because of patient size (5 years old), the pulmonary venous atrium was not accessed. However, the patient had recurrent tachycardia with a different cycle length and surface ECG morphology

**Figure 30.9**

These activation maps of the systemic and pulmonary venous atrium of a 26-year-old female with transposition after atrial switch operation confirm that the atrial reentrant tachycardia is primarily confined to the pulmonary venous atrium (earliest activation is in red) with passive activation of the systemic venous atrium. Some areas of the atria could not be mapped due to technical difficulties.

about 8 months later. This tachycardia was then successfully ablated with lesions in the posteroseptal area of the anatomic right atrium on the pulmonary venous side; there has been no recurrence in over 4 years.

The remaining three patients had multiple tachycardias (one patient each had two, three, and four different atrial tachycardias, respectively). The subeustachian isthmus served as the successful ablation site in only one of these tachycardias. Of the remaining tachycardias ( $N = 8$ ), six were successfully ablated either in the systemic venous atrium ( $N = 4$ ), or the posterolateral wall of the pulmonary venous atrium ( $N = 1$ ), or between the posterolateral systemic venous atrial free wall and the IVC ( $N = 1$ ). Two tachycardias were not ablated due to procedure length and/or poor understanding of the mechanism of tachycardia.

### 30.4.3.2 Patients After Fontan Operation

Four of 17 tachycardias were mapped in three patients' status after a Fontan operation. All of these patients had an atrio-pulmonary connection ("classic" Fontan connection for tricuspid atresia,  $N = 2$ , and for double inlet left ventricle,  $N = 1$ ). In two patients, a single intra-atrial reentry tachycardia was addressed. Successful ablation occurred in the area between a suspected atriotomy and an atrial septal defect patch in one patient and in the area between posterolateral double potentials and the IVC in the other. The third patient had at least two tachycardias; neither could be successfully ablated.

### 30.4.4 "Figure-of-8" Intra-Atrial Tachycardias

"Figure-of-8" tachycardias were noted to occur more often (25%) in patients with complex atriotomies. "Figure-of-8" tachycardia with a common isthmus in the systemic venous atrium (▶ Fig. 30.10) involved clockwise propagation around a scar and/or double potentials in the right lateral free wall and counterclockwise propagation around anterior atrial

■ Figure 30.10

Figure-of-8 loop atrial tachycardia in a 13-year-old male patient after complex atriotomy for transposition of the great arteries and atrial switch operation (Mustard operation at 2 years of age).

■ Figure 30.11

Figure-of-8 loop atrial tachycardia in an 18-year-old male patient after complex atriotomy for transposition of the great arteries and atrial switch operation (Mustard operation at 2 years of age). Shown is the electroanatomic map of both atria.

incisions (lower pant leg). A long ablative lesion bridging the superior and inferior pant leg resulted in successful ablation with no recurrence in more than 4 years.

“Figure-of-8” tachycardia in the pulmonary venous side involved counterclockwise propagation around the mitral valve annulus and clockwise around double potentials recorded on the lateral right free wall of the pulmonary venous atrium. Successful ablation was achieved from the posterolateral right free wall of the pulmonary venous atrium to the mitral valve (▶ Fig. 30.11).

Another two “Figure-of-8” tachycardias were noted in patients after the Fontan operation. One of these demonstrated a common isthmus between an anterior atriotomy and an ASD patch and was successfully ablated. The second “Figure-of-8” tachycardia could not be ablated presumably because a transmural lesion could not be achieved. Ablative lesions from the right atrial posterolateral wall to both the IVC and the tricuspid valve dimple did not result in successful ablation of the tachycardia. This patient has had no clinical recurrence, however, after 8 months of follow-up.

**Figure 30.12**

**Summary of locations of successful ablation of atrial reentrant tachycardias in patients after a simple atriotomy. Atriotomies included those for ASD repair, VSD repair, TOF repair, AVSD repair, Ebstein's anomaly, and ventricular inversion. Note that the subeustachian isthmus was critical in supporting reentry in 44% of atrial tachycardias.**

### 30.4.5 Role of the Subeustachian Area (Classic Flutter Isthmus)

In patients with postoperative atrial tachycardia, only 33% of reentry tachycardias involved the subeustachian isthmus as a critical part of the reentrant loop (▶ Fig. 30.12). These findings are in contrast to those of Chan et al. [52]. This discrepancy in observation can be explained by several factors. Our patient population included patients with complex atrial surgery; the Chan study included patients with a simple atriotomy only. We used EAM in our study, allowing for more precise evaluation of the reentrant circuit. Our findings also differ somewhat from those of Collins et al. [100] and Love et al. [99], who noted that the subeustachian isthmus was critical to 57% of patients after atrial switch operation, whereas we noted that only 24% of these tachycardias involved the subeustachian isthmus. Regardless, our study confirms that intra-atrial reentry tachycardia in postoperative patients more often involves other crucial areas, such as the posterolateral right atrial wall [7, 9, 18]. We believe that the observed differences are due to the inclusion of a wider spectrum of congenital heart diseases and perhaps, more intensive evaluation of the tachycardia.

Another isthmus frequently mapped and successfully targeted for ablation was between posterolateral double potentials and the IVC. This isthmus is also recognized in adult patients with unusual types of atrial reentry tachycardia. Our study demonstrates that this reentrant atrial tachycardia is fairly common in patients after repair for congenital heart disease, involving an atriotomy that supports this unique reentrant substrate. Finally, a less common isthmus was between an anterior atriotomy and the IVC, and is in congruence with other studies. The implications of these findings for mapping and ablation suggest that subeustachian ablation may be more successful in patients after simple, rather than complex, atriotomy for congenital heart disease, and that other isthmuses could be crucially involved in postoperative reentry tachycardia and may even coexist.

The type and complexity of the reentry tachycardia varied with the type and complexity of the surgical repair. For simple atriotomies, multiple circuit tachycardias were less common than in patients with complex atriotomies (▶ Figs. 30.12 and ▶ 30.13).

## 30.5 Long-Term Follow-Up of Patients with Atrial Tachycardia

Even with the use of advanced imaging techniques, the long-term success rate for our patients is 71% at a mean follow-up of  $29 \pm 17$  months and at least 25% of patients (5/21) required repeat procedures. Failures may be due to inability to create transmural lesions (especially in patients after the Fontan operation), limited ability to reach critical areas (i.e., pulmonary venous atrium), or other limiting factors (i.e., procedure time and patient tolerance).

■ Figure 30.13

**Summary of locations of successful ablation of atrial reentrant tachycardias in patients after a complex atriotomy. Atriotomies included those for Senning operation, Mustard operation, Bidirectional Glenn operation, and Fontan surgery. Note that the subeustachian isthmus was critical in supporting reentry in 24% of atrial tachycardias.**

In summary, there are variety of different mechanisms of tachycardias in postoperative patients, some inscribing complicated reentrant loops such as “Figure-of-8” atrial reentry tachycardia. Because patients with congenital heart disease encompass a heterogeneous population and because surgical techniques are variable and the anatomy of the expressed disease so complicated, we found the use of multiple complementary approaches to be of great benefit to successful treatment of these postoperative tachycardias.

## 31.1 Introduction – History and Technology

---

Body surface potential mapping is an extension of conventional electrocardiography that acknowledges the fact that cardiac electrical fields – the voltage distributions and current flow patterns arising from cardiac currents – exist everywhere within and on the body surface. Waller, Einthoven, Wilson, and many of the early electrocardiographers recognized that the electrocardiogram could be measured from any body surface site and that the measured signals were different at each site, but because of limitations in recording technology, they could measure only one or at best a few sites at a time. The evolution of electronic amplifiers and the advent and access of laboratory computers during the late 1960s made possible the recording of many ECGs at a time, thus allowing the *mapping* of spatial distributions of potential. The sequence of these distributions defines what has come to be known as the body surface potential map. Unlike *scalar* electrocardiography which relies on interpretation of waveform features including amplitudes, durations, and morphologies of the different electrocardiographic waves, body surface potential mapping focuses on the magnitude, location, and migration of potential extrema as well as the shape and dynamics of isopotential contours throughout the cardiac cycle.

Body surface potential mapping (BSPM) is a subset of the more general field of cardiac mapping that includes the *direct* study of cardiac fields measured in the intracavitary space, intramurally within the myocardium, and on epicardial and endocardial surfaces. While body surface mapping is completely noninvasive and makes use of passive or active electrodes placed on the body surface, direct cardiac mapping techniques are invasive and require insertion of catheter mounted arrays (balloons, baskets) in the cavities, multipolar catheters placed in the coronary veins, multipolar needles inserted directly into the myocardium, or “sock” or patch mounted arrays of electrodes for use on the epicardium at the time of open chest surgery. In all cases, the objective is to assess the 2D and 3D distributions of potential or current on and within the myocardium, thus the more the recording sites, the greater the resolution and ability to characterize the underlying cardiac electrical sources. In this chapter, we shall focus exclusively on BSPM.

The original rationale for BSPM was that the ability to visualize the dynamic patterns of cardiac generated potentials was hypothesized to provide a more complete picture of the underlying electrical sources of the heart than that provided by the limited view of six “unipolar” precordial leads and the six limb/augmented leads of which only two are independent. This, in turn, would provide better means to detect and characterize the underlying disease, namely infarction, ischemia, abnormalities of conduction, hypertrophy, and cardiomyopathy. A secondary, more powerful rationale was that the rapidly developing methodology of inverse electrocardiography offered an opportunity for body surface map data to be used to calculate, estimate, characterize, or localize the electrical sources within the heart. In fact, the work of Ramanathan et al. and others in recent years has shown the feasibility of generating reliable estimates of cardiac electrograms and extracted information such as depolarization (activation) sequence and repolarization (recovery) sequence derived from measured body surface maps and measured torso and organ geometries and resistivities [1].

In point of fact, largely because of the expense of custom recording equipment and the consideration that computing power needed for processing and display was available only as expensive, laboratory computing systems, the early mapping efforts in the 1970s and early 1980s were relegated almost exclusively to the laboratory. Additionally, the rapid evolution of ultrasonic imaging of the heart began to provide inexpensive, noninvasive means of detecting cardiac abnormalities, including wall motion abnormalities (infarction and ischemia), valve dysfunction, wall thickness (hypertrophy), and conduction defects (bundle branch block). This new technology siphoned energy and rationale for body surface mapping, leaving electrophysiology and arrhythmias as the major remaining areas of study. Nevertheless, BSPM continues to be used, particularly as a means to better characterize heart disease and, more recently, as a means to facilitate localization key circuits in arrhythmias.

## 31.2 Recording Techniques

---

Body surface mapping systems include an electrode array, electronics for amplification, and recording of the ECG data, computing resources for preprocessing the recorded ECGs, displaying them in a variety of formats, and for analyzing the signals for purposes of detection, classification, or monitoring changes in cardiac electrophysiological state.

### 31.2.1 Electrode Arrays

Most early mapping was done using regular arrays (fixed numbers of columns and rows) of passive metal electrodes, typically chlorided silver, attached to individual strips of nylon, rubber, or other substrate material. Conventional electrode paste was routinely used to enhance electrical contact with the skin and double-sided adhesive strips or “doughnuts” were used to hold the electrodes in place. At least one group used polished insect pins attached to individual wires to record signals and another group devised a vest embedded with active dry electrodes – electrodes that have preamplifiers mounted directly on the metal. The objective of these designs was to obtain high quality and low noise signals while minimizing the time needed to apply the electrode arrays.

In the early days of mapping, little was known about redundancy of electrocardiographic information in the sense of correlation between sites, and hence mappers used large numbers of electrodes (242, 192, 128, 64, etc.). As body surface potential map databases grew and as experience and understanding of distributions demonstrated that there was considerable redundancy in these signals, several groups focused on “limited” or “reduced” lead systems to maximize capture of information while reducing the costs associated with large numbers of leads and the associated electronics and computing needed to manage the data. This topic will be addressed later in this chapter.

Several techniques have been developed to facilitate and speed up the process of applying the electrodes to patients. These include the use of strips of electrodes with double sided adhesive, inflatable vests in which electrodes are embedded on the inner surfaces, arrays of electrodes supported by a mechanical shell and adjustable to fit each torso, and strips of electrodes attached to the patient via suction. Most electrode systems use and require use of electrode gel for purposes of ensuring good electrode–skin contact, but others have reported success using active dry electrodes that eliminate the need for electrode gel.

### 31.2.2 Electronics

Mapping systems require the need for amplification of the small (~2 mV magnitude) signals, analog-to-digital (A/D) converters to convert the amplified voltages into numerical representation for later processing, and a means to store these samples from each of the electrodes. The basis of all electrocardiographic recording is the electronic amplifier tailored for bioelectric signals having maximum amplitudes of 2 mV. During the late 1960s and early 1970s, such amplifiers were readily available, but not configured in size and cost to permit assemblies of the hundreds needed for the “simultaneous” recording, essential for mapping. Several groups developed their own custom amplifier systems using low noise, high performance integrated circuits that allowed packaging of tens of individual amplifiers on each circuit board. The addition of individual *sample and hold* circuits made possible the “simultaneous” sampling of data from all amplifiers, important for maintaining temporal integrity of the data. Another important contribution to the technology was the use of analog *multiplexers*, integrated circuits that allowed signals from multiple amplifiers to be switched into one data stream that could then be fed to one A/D converter. This innovation drastically reduced the system cost by eliminating the need for expensive A/D converters for each channel. The stream of digital samples was then stored in computer memory or directly to disk using double buffering techniques and finally to digital tape. Early systems were limited to short recording times, typically just a few seconds, a consequence of the limits of available computing technologies and storage media. Present systems, both custom laboratory systems and the few commercially available, can record continuously to memory or disk for long periods of time.

### 31.2.3 Computer Processing and Display

The advent of laboratory computers and later, the availability of personal computers, made possible the extensive processing, analysis, and display of body surface potential map data. For each multichannel recording, individual signals had to be calibrated, adjusted for baseline drift, filtered if there were excessive noise, or estimated or interpolated from other signals if the signal were excessively noisy or “missing”, often a problem when hundreds of leads and connectors were considered. The signature presentation of body surface potential data is the isopotential contour map, in which potentials for each sample time are displayed as contour maps on geometric representations of the torso. Data in [Fig. 31.1](#) show

■ Figure 31.1

Examples of isopotential contour map displays from the early QRS of a normal subject. On the upper left panel is a stylized 2D contour plot showing an array of 12 rows by 16 columns (192 sites) that represent a torso surface. The *top* and *bottom* edges of the rectangle correspond to the levels of the sternal notch and umbilicus, respectively. The *vertical midline* of the array corresponds to the vertical anterior thoracic midline and the *left* and *right* edges of the display correspond to the spine. On the upper right panel is the same data as displayed in the left panel except with vertical modulation of the potential, thus showing positive and negative extrema as “mountain peaks” and “valleys”. The bottom panel shows the same data now presented on a 3D torso model. Contours are colored from blue (*negative*) to red (*positive*).

the same “frame” (sample) early in the QRS of a normal subject using a flat 2D array (upper left) as well as a 3D torso array (bottom). A third presentation of the same data (upper right), the orthographic projection, shows the potential distributions as “mountains and valleys” and is useful in enhancing magnitude differences and changes at the expense of extrema localization. An example of early, mid, and late “frames” within the sequence of QRS maps of a normal subject is shown in ► Fig. 31.2. The features of these maps used to describe them include the location and movement of the positive and negative extrema (trajectories) and the shape, steepness (gradient), and levels of isopotential contours. A variety of scaling techniques is used including *linear*, in which contours are spaced at fixed intervals, *normalized* in which a fixed number of contours is drawn for each map and which is useful for displaying data having low amplitude or widely varying amplitude, and *logarithmic* spacing for widely varying amplitudes. Additionally, since positive and negative potentials may be quite disparate in magnitude, it is often helpful to use *separate scaling* for positive and negative potentials. Such scaling options offer flexibility in assessing pattern and/or amplitude differences or changes.

### 31.3 Lead Systems for Recording and Estimating Body Surface Potential Maps

Since the objectives of electrocardiographic body surface potential mapping are measurement, analysis, and the use of **distributions**, measurement explicitly requires extensive spatial sampling. In contrast to the conventional 12 lead ECG and VCG techniques, which were developed from empirical considerations as well as representations of the electrical activity of the heart as a simple dipole, mapping lead systems were designed to measure “all” available ECG information.

Lead systems have been characterized as “complete” or “limited” (also referred to as “reduced lead systems”), the former implying the actual sampling of “all” data and the latter implying the sampling of a small number of sites for approximating or estimating complete distributions to a prespecified level of accuracy. Since mapping has been relegated primarily to research laboratories, there have never been standards for lead systems. Thus, there is a great variety in the

■ Figure 31.2

Three QRS “frames” (isopotential distributions) from a normal subject showing early, mid, and late distributions.

number and placement of recording sites. “Complete” sampling lead systems published in the literature include provision to measure 64, 120, 128, 192, and 242 body surface sites. Since the purpose of extensive sampling is to define the spatial character of the cardiac generated potentials, these systems are designed to sample most of the thoracic surface. In most systems, electrodes are placed in evenly separated rows and columns over the thorax. Modifications to this basic arrangement include increased spatial sampling density in the precordial region (doubling the number of rows and columns in this region) and reduced sampling density on the posterior surface (halving the number of rows and/or columns) and placement of leads lower on the torso and higher, including the shoulders. It is important to note that the rationale for a particular lead system is dictated by the presumption that all ECG information will be sampled. Also, however, lead systems may be tied to the type of displays used. Complete lead systems were used initially because of the lack of knowledge concerning the detailed spatial character of ECG distributions or the extent of redundancy. By measuring data at all sites, direct display of the distributions and later analysis demonstrated that, for practical purposes, complete sampling was not necessary. This led to the development of a variety of “limited lead” systems for estimating complete maps [2–4]. The mechanisms by which complete ECG distributions may be “derived” from such limited lead sets include interpolation, modeling, and estimation.

### 31.3.1 Interpolation

Interpolation relies on mathematical formulae that provide smooth approximations to data within the regions between measurement sites. Simple linear or bilinear interpolation may be used, or curve or surface fitting may be applied. Another interpolation approach is to assume a periodic structure for the data, a strictly correct assumption when applied to the circumferential aspect of the torso. This permits use of Fourier series to build interpolation polynomials from which potentials may be approximated at unmeasured sites [5].

### 31.3.2 Modeling

Modeling approaches rely on physical characteristics of measurement sites – geometric location, conductivity of the torso, and its inhomogeneity – in conjunction with the field equations that *model* the problem to predict aspects of the distributions in unmeasured regions.

### 31.3.3 Estimation

Estimation techniques, on the other hand, utilize information obtained from complete lead systems in order to develop statistical transformations for estimating unmeasured data from that measured at limited lead sites. Ultimately, potentials  $\Phi_u$  at  $N_u$  unmeasured sites, are to be estimated from potentials  $\Phi_m$  at  $N_m$  measured sites, by a linear transformation,  $T$ , such that

$$\Phi_u = T\Phi_m$$

Theoretically, a perfect transformation exists for each subject and each cardiac state. However, an average transformation may function sufficiently well to permit its use in a practical system. In one implementation of this approach, the transformation,  $T$ , may be determined as the linear, least mean squared error estimator given by

$$T = K_{um}K_{mm}^{-1}$$

where,  $K_{um}$  is the cross covariance matrix between unmeasured and measured sites and  $K_{mm}$  is the covariance matrix of measured sites defined using the expectation operator,  $E$ , as

$$K_{um} = E[(\Phi_u - \overline{\Phi_u})(\Phi_m - \overline{\Phi_m})^T]$$

and

$$K_{mm} = E[(\Phi_m - \overline{\Phi_m})(\Phi_m - \overline{\Phi_m})^T]$$

where

$$K = \begin{bmatrix} K_{mm} & K_{mu} \\ K_{um} & K_{mm} \end{bmatrix}$$

In general, the covariance between any two sites  $i$  and  $j$ ,  $k_{ij}$  is given by

$$k_{ij} = E[(p_i - \overline{p_i})(p_j - \overline{p_j})] = \rho_{ij}\sigma_i\sigma_j$$

in which  $\rho_{ij}$  is the correlation coefficient between potentials at sites  $i$  and  $j$ ,  $\sigma_i$  and  $\sigma_j$  are the potential standard deviations at sites  $i$  and  $j$ . Regardless of the method for assigning potentials to the unmeasured sites, a variety of error criteria for assessing the adequacy of lead systems have been developed which permit selection of lead systems to suit one's needs. These criteria include root-mean-square (rms) error, correlation coefficient, peak error, and others, all of which compare estimated data with that obtained from a complete lead system. Depending on the number and placement of leads, estimation errors approaching the system and recording noise levels are possible. This approach has formed the basis for estimating BSPMs and even the 12 lead ECG from small numbers of leads.

## 31.4 Utilization of Body Surface Potential Map Information

There are two primary uses of map data, both ultimately aimed at understanding and characterizing normal and abnormal cardiac electrophysiology. The first and original use relates to the characterization of cardiac state, specifically with respect to disease, by direct correlation of map features with independent documentation of cardiac physiology and pathology. With regard to this use, emphasis is placed on practical application of measurements for improved, noninvasive diagnosis as compared to the 12 lead ECG. The second use of map data relates to the validation and assessment of forward and inverse models and concentrates on estimation of myocardial current distributions from which underlying physiology can be inferred. The latter is discussed elsewhere in this text and will not be described here. Regarding the former, utilization of map information is accomplished through visual assessment and/or quantitative approaches that permit rigorous analyses, particularly those involving statistical methods. Examples of these now follow.

Since the first maps were recorded, simple observation of the potential distributions has been the primary means of analysis. The sequence of distributions, including dynamics, relative magnitudes and trajectories of positive and negative extrema, and morphology of contours provide a rich characterization of each heart cycle. Classical features of maps on patients with old infarcts, bundle branch blocks, ectopic activation, WPW, etc., provide sufficient information for simple, “eyeball” classification which is often not as clear using the 12 lead ECG alone. For example, cardiac events leading to a marginally abnormal Q wave in a 12 lead examination would likely have a more definitive representation in maps, namely a negative extremum with signature temporal and spatial characteristics. In WPW, a delta wave – small deflection preceding and merging with the QRS – in the 12 lead, is transformed to an early negative extremum, whose location indirectly points to the location of the accessory pathway on the A-V ring. Ectopic ventricular beats and VT exhibit map patterns that consistently identify the location of early depolarization. The latter two illustrations characterize the “atlas” approach to map analysis in which map patterns originating from known cardiac location, whether epicardial, endocardial, or septal and both atrial and ventricular, are catalogued and then used for comparison to patterns from unknown activations [6–8]. Maps obtained from patients having a variety of cardiac pathologies are described in the following chapter. However, a brief introduction to the methods of qualitatively interpreting map distributions might be useful.

### 31.4.1 Qualitative Analysis

The elementary interpretation of potential distributions follows that of conventional ECGs. During the QRS, a positive wave in a unipolar lead is indicative of an approaching activation front and a negative wave reflects a receding front. Hence, Q or S waves signify receding wave fronts as viewed from the measurement site, whereas R or R' waves are indicative of wave fronts approaching the site. In isopotential contour maps obtained during depolarization, body surface regions that are negative primarily reflect the perspective of receding depolarization surfaces, whereas regions that are positive are those which “see” approaching depolarization surfaces. During repolarization, the polarity is reversed, as is the interpretation.

In order to illustrate interpretation of map distributions, two examples are presented. The map in [Fig. 31.3](#) shows data *early* in the QRS of a patient with an old anterior wall myocardial infarct. The dominant anterior negative extremum and left, posterolateral positive extremum, result from a depolarization surface oriented along a dominant anterior to posterior axis. This pattern persists throughout much of the QRS and the lack of anterior positivity is consistent with the loss of active, anterior wall myocardium.

The sequence of map frames shown in [Fig. 31.4](#) shows potential distributions, *early*, mid, and late in the QRS of a patient with right bundle branch block. *The early (top) left to right axis (blue to yellow) of the potential distribution is indicative of a depolarization surface oriented in a left to right direction and would signify early left ventricular depolarization. The mid QRS transitional distribution shows a posterior-to-anterior distribution, likely dominated by LV endocardial-to-epicardial depolarization. The late QRS pattern (bottom) shows a right inferior to left superior axis and suggests a right ventricular depolarization pattern.*

Similar interpretations can be applied to ECGs and body surface maps during *repolarization*, with the exception that polarity reversal must be taken into account. In unipolar ECGs, positive T waves are measured at sites that, on the average, observe recovery receding from them. Contrariwise, negative T waves are detected at sites which observe recovery

■ Figure 31.3

Three QRS frames from a patient with old anterior myocardial infarction.

approaching them. In maps, positive regions are indicative of sites which, on average, observe repolarization receding and negative regions occur where recovery is approaching. A potential distribution during recovery of a normal subject is shown in Fig. 31.5. This distribution, which is quite static in pattern, shows a dominant right superior to left inferior axis on the anterior thoracic surface. This is consistent with the predominant epicardial to endocardial distribution of recovery observed in the normal heart following supraventricular activation.

It should be stressed at this point that the qualitative interpretation of potential distributions is correct in a general sense, although it is far from exact. The potential observed at any site results from a complex superposition of the effects of all active cardiac currents. The complexity of both the cardiac generator as well as the body volume conductor make exact interpretation difficult, if not impossible. The anisotropic, inhomogeneous, time varying nature of the active and passive tissue underscores the difficulty of carrying out unambiguous interpretation of map data from a qualitative approach.

### 31.4.2 Quantitative Analyses of Body Surface Maps

The simplest quantitative approaches to map analysis are those that assign numerical values to visually observable features. Thus, the *trajectories* of positive and/or negative extrema may be parameterized into x, y coordinates varying with time.

■ Figure 31.4  
Three QRS frames from a patient with old right bundle branch block.

■ Figure 31.5  
A T wave isopotential map from a normal subject.

The magnitudes of the extrema may be plotted against time. Then statistics of these features, such as the mean or peak values may then be used for conventional statistical analysis in order to establish classification rules or to demonstrate differences between classes of maps.

### 31.4.3 Distributions of ECG Integrals (Areas)

Another class of quantitative map features makes use of so-called integrals or areas. Segments of the sequence of maps may be integrated and displayed as distributions. Thus, QRS, STT, and QRST integral maps are obtained by integrating all ECGs over the QRS, STT, or QT intervals, respectively, and displaying their distributions. Other specialized areas have been used, including the  $ST_{60}$  in which integration is carried out over the 80 ms following the “end” of QRS, or the “Q zone” map in which the first 30 ms of the QRS is integrated.

There are two ways of interpreting integral distributions, one based on purely signal theoretic considerations and one based on theoretical aspects of cardiac electrophysiology. Thus, the QRS integral distribution may be thought of as the average QRS potential distribution, which it would be if all values determined from the integration are divided by the interval of integration. In addition, it would be the distribution that would result if all cardiac fibers depolarized “simultaneously” with the same dipole direction and strength they normally have. Of course, such an activation sequence is not possible. All other area distributions may be thought of as average distributions for the interval over which the integration was performed. These integrals have been shown to be useful in assessing cardiac state or its change.

The more powerful, theoretic interpretation of areas originated with the concept of the “ventricular gradient” first proposed by Frank Wilson [9]. He argued that in the presence of a homogeneous distribution of action potentials, that is, identical recovery properties, the integral of any ECG over the QT interval should be zero. A corollary to this, suggests that since the measured QRST area distribution is not zero, and, moreover, almost independent of activation sequence, it reflects disparity of recovery properties, that is, action potential shape and duration. Though the exact relationship between QRST area and disparity of recovery properties has not been established, it is clear that a significant one exists. Since the distribution of recovery properties is known to play an important role in some mechanisms of arrhythmogenesis, QRST area distributions may play an important role in assessing a patient’s vulnerability to ventricular arrhythmias. This has been explored by several groups that relate QRST integral distributions to vulnerability [10–13]. Moreover, Plonsey and Geselowitz have provided a theoretical justification for Wilson’s original work [14, 15].

The same theory that predicts that the QRST area should reflect the distribution of recovery properties suggests that the QRS area distribution should reflect the distribution of activation sequence. Experimental support for this hypothesis has been documented and the measurement may prove useful in diagnosing abnormalities of conduction. As a consequence of the relationships of QRS area to activation sequence and QRST area to recovery properties, it follows that the STT area should reflect recovery sequence.

The body surface distributions of QRS, STT, and QRST integrals obtained from a normal subject are illustrated in  Fig. 31.6. Interpretation of these distributions in terms of average activation sequence, recovery sequence, and recovery properties follows along lines similar to those used for interpreting isopotential maps. The superior-right to inferior-left anterior axis of the QRS area distribution is consistent with the dominant direction of depolarization of the left ventricle, namely endocardium to epicardium that presents itself, on average, along a base to apex axis. The facts that the distribution of the STT areas is similar to that of the QRS and that the polarity associated with recovery is reversed compared to depolarization provide evidence that recovery sequence is opposite to that of activation. This epicardial to endocardial sequence of recovery in a normal heart following supraventricular activation is well documented. Finally, the distribution of QRST areas is supportive of the previously observed epicardial to endocardial gradient of recovery properties. In summary, the distributions of deflection integrals provide important information concerning the underlying electrophysiological processes in the heart. These indices and analyses of their spatial character are being examined for utility in providing insight into arrhythmia vulnerability, the extent and nature of conduction defects, as well as other abnormalities of activation and recovery.

QRS, STT, and QRST integral maps from a normal subject.

## 31.5 Statistical Representation of Body Surface Maps

Another approach to quantitative characterization of maps is the use of mathematical or statistical representation [16, 17]. In this technique, maps are characterized using mathematical or statistically derived basis functions. All the data from a patient's map, the complete sequence of potential distributions, may be represented as an  $n$ -dimensional vector that can be used to reconstruct the original maps within a prespecified error. The advantage of this technique over other, quantitative characterizations, is that the representation features are independent and common to all maps and all patients. The vector of representing parameters may be used to compare maps on a beat-to-beat basis within one patient, between patients, or between classes of patients. Furthermore, independence of the parameters greatly simplifies the statistical analysis. The technique has been particularly useful in the non-invasive diagnosis of a variety of classes of heart disease for which diagnostic performance of the 12 lead ECG is ineffective.

In this approach, each map frame (potential distribution) is represented as a linear combination (weighted sum) of 12 *independent*, normalized basis functions. Specifically, if  $\mathbf{P}(k)$  is the  $k^{\text{th}}$  sample in time of an  $N$  dimensional potential vector (map frame), then such a representation is expressed as

$$P(k) = \sum_{i=1}^N \alpha_i(k) \Phi_i$$

$$\Phi_i \bullet \Phi_j = \delta_{ij} = \begin{cases} 0, & i \neq j \\ 1, & i = j \end{cases}$$

where the set of basis vectors  $\{\Phi\}$  can be any  $N$  dimensional mathematical functions. An efficient representation, the so-called Karhunen–Loeve transformation, derives these functions, statistically, from samples of the data that one wants to represent. For the above maps, the covariance matrix,  $K$ , can be defined as

$$K = E[(P - \bar{P})(P - \bar{P})^T]$$

while the solution of the classical “eigenvalue equation”

$$|\lambda_i I - K \Phi_i| = 0$$

leads to solutions of sets eigenvector and eigenvalue pairs,  $\{\Theta\}$  and  $\{\lambda\}$ . These can be calculated from covariance matrices and average potential vectors estimated from large data sets (hundreds of subjects or patients and hundreds of map frames from each subject). Once obtained, for each potential vector,  $P(k)$ , the coefficient “wave forms”  $\alpha_i(k)$  can be obtained from

$$\alpha_i(k) = P(k) \bullet \Phi_i$$

Thus, the sequence of measured map frames,  $\{P(k)\}$  can be replaced by the set of coefficient “wave forms,”  $\{\alpha_i(k)\}$  and since there is considerable redundancy in body surface potential maps, only a few,  $N \approx 10$  or 15 basis functions are needed to represent the entire BSPM. The first three *spatial* body surface eigenvectors for a large set of normal and abnormal body surface maps are shown in [Fig. 31.7](#). These spatial distributions were statistically derived from a set of over 20,000 map frames obtained from maps on over 400 patients and normal subjects. The result of the representation is to convert each frame of 192 potentials that defines the torso potential distribution at a given instant, to a set of 12 numbers. This 16:1 reduction in data removes spatial dependence or redundancy in the distributions. Importantly, the representation process is reversible in the sense that the 12 representation variables, in combination with the 12 feature distributions, may be used to reconstruct the original, measured distribution to an error of only .044 mV rms. The effect of this spatial representation procedure is to replace the sequence of map frames of a complete BSPM with a set of 12 waveforms that are the time varying weights of each of the feature frames. The process of representation can be continued for the time domain, that is, the coefficient waveforms can be represented by basis functions derived from the coefficient waveforms,  $\{\alpha_i(k)\}$ . The overall effect of first spatial and then temporal representation is to replace the original BSPM (100,000 potential measurements/QRST) with an equivalent set of 216 independent variables. This “vector” of 216 parameters represents the original BSPM in the sense that from it, the original BSPM may be reconstructed to a high level of accuracy. This vector of representation parameters may then be used in classical statistical strategies for classifying or comparing map data, whether beat-to-beat within one patient, patient-to-patient, or class-to-class.

## 31.6 Summary

The long history of body surface potential mapping, will likely continue. The rapid developments in anatomic imaging, inverse technologies, and computing speed and power will almost certainly lead to practical systems for rapid, non-invasive, or minimally invasive assessment of cardiac electrophysiology. BSPM will play a critical role in that it is the body surface potentials that ultimately are transformed into estimates of myocardial depolarization and repolarization sequences that form the basis for understanding and characterizing regional cardiac electrophysiology, arrhythmias, and disease.

## 32.1 Introduction

---

Body-surface potential maps (BSPMs) present the distribution of cardiac potentials on the chest surface during the cardiac cycle. They provide the spatial as well as the temporal and amplitude components of cardiac electrical activity, whereas the ECG scalar waveforms present only the time–voltage variation in a given lead point.

When an excitation wavefront spreads through atrial or ventricular heart muscle, it generates bioelectric currents, which distribute themselves to all conducting tissues in the body. This wavefront is a thin layer of heart muscle separating resting from excited areas. For the sake of simplicity, reference is made to the “classical” electrical model [1], according to which an excitation front is considered to be equivalent to a uniform dipole layer, where the dipole axis is everywhere orthogonal to the front; moreover, the tissue resistivity is supposed to be homogeneous. According to this model, currents arise from the anterior aspect of the front, flow through the thorax, and finally point to the posterior aspect of the front.

▶ **Figure 32.1** illustrates the distributions of the currents and potentials, in a horizontal thoracic section, arising from an excitation wavefront in the ventricular septum. The locations of the potential maximum and minimum on the thoracic surface are correlated with the topography and orientation of the wavefront. According to the traditional solid angle theory, a potential maximum in a given area on the chest surface indicates that an excitation wave is pointing toward that area; a potential minimum indicates that the posterior or negative aspect of the wavefront is seen from the area where the minimum is present.

However, the relationship between surface potential distribution and wavefront shape is sometimes very complex. In fact, the potential distribution at the surface depends on the location, number, and geometry of the wavefronts in the thorax, the geometry of the torso, and the inhomogeneities of the conducting medium (cardiac and extracardiac tissues). For example, several excitation waves may be travelling simultaneously through the right and left ventricle, giving rise to a complex distribution of currents and potentials. Also, when an excitation wave spreading from the endocardium reaches the epicardial surface, a hole appears in the advancing wavefront. Through this hole or “window,” the currents reenter the heart. If a window is close to the chest wall, a new potential minimum appears on the thoracic surface, in addition to those already present. A similar hole appears in the excitation wavefront when a portion of ventricular wall cannot be activated, because of a local myocardial infarction. In this case too, a potential minimum appears on the chest surface in the region facing the infarcted area. A further cause of complexity arises from the fact that the dipole density is not uniform on the surface of the wavefront, in that a wavefront spreading along fibers generates more current per unit area than a wavefront spreading across fibers [2, 3].

During repolarization, currents proportional to transmembrane potential gradient from the M-cell region flow toward the epicardium and endocardium, the former being of higher amplitude [4, 5]. This amounts to numerous small dipoles distributed in the whole mass of the myocardium. The orientation of these dipoles remains mostly unchanged during repolarization, and their amplitudes change relatively synchronously. Localized repolarization changes further add to the complexity of the body-surface potentials in heart disease.

Every excitation wave and every portion of repolarizing tissue in the heart influence the potential distribution on the entire body surface. It follows that information on the electrical activity of the heart can be recorded not only from the points commonly explored by conventional ECG and VCG leads, but also from the entire body surface. BSPMs provide all the information available on the entire chest surface.

## 32.2 History

---

The first example of a potential map was published by A. Waller in 1889 [6], on the basis of 10–20 ECG recordings from the surface of the human body; the potential distribution resembled that which would have appeared if a dipole had been located in the heart. Later, a few attempts to determine surface potential distributions were made by several authors with rudimentary techniques.

In 1951, Nahum et al. [7] published the first description of isopotential line distribution on the thoracic surface at successive instants during the cardiac cycle in man. They did not detect the simultaneous presence of several maxima and minima but observed that the surface potential distribution was much more complicated than that likely to result from an equivalent dipolar generator. In the 1960s, Taccardi [8, 9] described the instantaneous distribution of heart potentials during ventricular activation in dogs and in normal human subjects. These investigations clearly showed that several potential

Figure 32.1

*Left:* Schematic drawing of a horizontal section of the human thorax illustrating the pathway of the currents, which arise from an excitation wavefront (solid line in septum) spreading through the septum in a left-to-right direction. A indicates the area where the current lines reach the surface; B indicates the area from which the currents dip into the thorax pointing to the posterior aspect of the wavefront. *Right:* Potential distribution in the same thoracic section and at the same instant. The plus sign indicates the location of the potential maximum on the surface (corresponding to point A); the minus sign indicates the location of the potential minimum (corresponding to point B).

maxima and minima may be simultaneously present on the body surface during part of the QRS interval; moreover, an attempt was made to correlate the location of surface maxima and minima with the probable location of excitation wavefronts in the ventricles. The complexity of surface potential patterns, although not physically incompatible with a dipolar source, strongly suggested that a more complex electrical model of the heart should be adopted in order to account for the potential distributions found on the human and canine trunk.

Since then, BSPMs have been recorded from normal subjects (newborns and adults), cardiac patients, and experimental animals by many investigators in different countries.

### 32.3 Methods

Many lead systems have been used to record BSPMs throughout the world differing in the number of leads as well as in electrode location on the thorax. In theory, the optimal lead system should have a number of leads large enough to detect all details of the potential distribution on the torso surface. However, transformation methods have been proposed to estimate BSPM in a particular lead system from the BSPM data measured by using another lead system [10].

Techniques for recording, processing, and displaying the potential maps are illustrated in [Chap. 31](#).

Different methods of analysis of BSPMs have been used to extract relevant information. These are described below.

#### 32.3.1 Instantaneous BSPMs

The distribution of chest potentials in each instant of the cardiac cycle can be analyzed qualitatively, by visual inspection, or quantitatively by considering a number of numerical parameters relating to location, amplitude, and migration of potential maxima and minima.

#### 32.3.2 Integral Maps

Since differences between maps of normal subjects and patients cannot easily be quantified by inspection of the sequence of instantaneous potential distributions, the potential–time integral maps have been considered. This approach has been proved to allow a reduction in the amount of data to be analyzed without substantial loss of information [11]. With this method, only a few maps are required to represent a cardiac cycle (QRS, ST-T, QRST, or other intervals for particular

purposes). In addition, this technique permits the calculation of average maps for groups of subjects without the need for time-phase alignment.

An approximation of the potential time integral, relating to a given interval of the cardiac cycle, is obtained by computing, at each lead point, the algebraic sum of all the instantaneous potential values throughout the interval considered, multiplied by the sampling interval. The values, expressed in mVms, are transferred to a diagram representing the thoracic surface explored, and isointegral contour lines can be drawn (► Fig. 32.2).

■ Figure 32.2

Integral maps in a normal subject during the QRS interval (*top*) ST-T interval (*middle*) and QRST interval (*bottom*). The left half of each map represents the anterior face of the thorax, the right half represents the posterior face. Continuous dark lines represent positive isointegrals, dashed lines represent negative isointegrals. The grey continuous line represents the zero integral line. The legend under each map indicates by (+) the maximum integral value on the respective map, by (-) the minimum integral value and (:) the gradient between isointegral lines, in 10 mVms.

### 32.3.3 Principal Component Analysis

Reduction of the information in body-surface ECG recordings can be achieved by decomposing individual integral maps or population-wide sets of recordings or the matrix of potentials in time over an interval (such as the ST-T) into components, which are independent of (noncorrelated to) each other. For example, singular value decomposition of the matrix of instantaneous repolarization potentials in time can be written as a sum of components each consisting of a potential distribution on the body surface, changing in time. The relative spatial distribution of the potentials of each component is constant, and the only thing that changes in time is the general amplitude of the component.

Figure 32.3 shows the first four components of the ST-T potentials in a normal subject. The first component contains normally over 75% of the potential amplitude, and is probably due to the general transmural gradient of the ventricular action potential. The second component is usually opposed (inversely correlated) to the QRS integral and likely corresponds to the repolarization gradient secondary to the depolarization sequence. The relative contribution of the first or

Figure 32.3

The first four components resulting from singular value decomposition of the matrix of instantaneous repolarization potentials versus time in a normal recording. Each component is represented by the body-surface potential distribution (*right*) (distance between isopotential lines is arbitrary) and the variation of its amplitude in time (*left*) (time on *x*-axis and relative amplitude on *y*-axis). The first component is at the *top*, the fourth at the *bottom*.

first two components to the repolarization potentials is decreased in most pathological states and may be indicative of the presence of arrhythmogenic repolarization heterogeneity.

Reduction of the information in body-surface ECG recordings to a few numerical indices can be achieved by analysing individual recordings or population-wide sets of recordings into components that are independent of (not correlated to) each other. One method is principal component analysis in which a set of signals, either instantaneous body-surface distributions at different instants in time, or time-based signals from different leads, or integral maps in a group of individuals are decomposed into eigenvectors (components, usually sets of potentials) and eigenvalues (numbers which quantify the contribution of each eigenvector to the general variability of the overall data). Ventricular repolarization is particularly suitable to this type of analysis, as most of the variability of normal repolarization potentials in most instants over the ST-T interval can be described by a single component.

### 32.3.4 Autocorrelation Maps

Autocorrelation (AC) maps are square matrices of values between -1.0 and 1.0, which represent the correlation coefficients of every pair of instantaneous potential distributions from a set of successive instants in time [12]. The same time interval appears on both coordinates of the map and the matrix is symmetrical with respect to the first diagonal. Values on the first diagonal are always 1.0, representing correlations of each instantaneous map with itself.

Autocorrelation maps reflect only phenomena taking place in the ECG source (myocardium) and are very little influenced by the geometry of the volume conductor (thorax) that connects it to the lead system [13]. AC maps are very sensitive to variations in the activation sequence. For example, [Figs. 32.4](#) and [32.5](#) show recordings in two healthy individuals in whom the 12 lead ECGs and QRS integral maps look very much alike, but differences in the activation sequence are evident in the instantaneous potential maps, especially in the AC maps.

The AC map of the ST-T interval is normally quite close to 1 as the normal repolarization pattern shows little change, apart from the amplitude. The extent of change can be quantified by choosing the map at the peak of T (on the root mean square signal) as a reference map and calculating the average difference from one of the lines that goes through that instant on the AC map over the S-T peak and T peak-end intervals. We call these average differences the early and late repolarization deviation indices (ERDI and LRDI), respectively.

## 32.4 Normal Maps

### 32.4.1 Atrial Excitation and Recovery

At the onset of atrial excitation, a potential minimum is generally observed near the right sterno-clavicular joint, in the right supraclavicular region, or in the right mammary area ([Fig. 32.6a](#)) [14, 15]. The potential maximum or minimum is here defined as a point on the thoracic surface where the potential value is higher or lower in relation to all the surrounding points. Mirvis [16] did not observe a clear-cut minimum, but only a broad area of negative low-level potentials over the upper back and the right chest during the initial phase of atrial excitation. A potential maximum is initially located either in the right submammary area or in the lower sternal region ([Fig. 32.6b](#)). During the subsequent stages of atrial activation, the maximum moves leftward, gradually reaching the left mammary region, the left lateral chest wall and, in some cases, the dorsal region ([Fig. 32.6c](#)). The minimum moves slightly downward. During the leftward migration of the maximum, a secondary potential maximum sometimes appears on the left lateral wall of the thorax. The movement of the potential maximum from right to left is most likely correlated with the spread of the excitation wavefronts from the right to the left atrium.

During atrial recovery ([Fig. 32.6d](#)), surface potential maps resemble those recorded in the early stages of atrial excitation, but with reverse polarity [15–17]. A potential minimum is generally located on the sternal and left mammary region and a maximum on the right shoulder both in adults and infants. This finding suggests that repolarization advances through the atrial walls in approximately the same order as does excitation. This is in agreement with experimental data, demonstrating that the atrial regions that depolarize first are also the first to recover [18].

Figure 32.4

Different representations of depolarization potentials of the same cardiac cycle in a normal subject. (a) Successive, instantaneous potential maps during the QRS; conventions are as in Fig. 32.2, except that the lines are isopotential and are measured in mV; the label above each map indicates the timing of the instantaneous map. (b) Integral map with the same conventions as in Fig. 32.2. (c) Autocorrelation map of the QRS interval; the same time interval is on both *x*- and *y*-axis, and each point on the map represents the correlation coefficient between instantaneous potential distributions at the instants of its *x*- and *y*-coordinates, using shades of gray from black for -1.0 to white for 1.0, as indicated on the scale at right. (d) Standard ECG reconstructed from leads corresponding to the standard ECG leads, extracted from the body-surface lead system.

■ **Figure 32.5**

The same representations of ventricular activation as in [Fig. 32.4](#), for one cardiac cycle in a different healthy individual. This recording was selected from a set of 236 in healthy people as a recording with an almost identical QRS integral as that in [Fig. 32.4](#). Note the similarity of the 12-lead ECG, the visible differences in the instantaneous potentials and the striking differences in the AC map.

Figure 32.6

Averaged surface maps relating to atrial activation and recovery in a normal subject, at the instants or time indicated by the vertical line crossing the ECG at top of each figure. The time interval between the (a) and (d) is 88 ms. The zero equipotential line is dashed. The plus and minus signs indicate the value of the positive and negative peaks in microvolts; +P and –P indicate the step (in microvolts) between adjacent positive and negative equipotential lines.

### 32.4.2 Ventricular Activation

Body-surface potential distributions during ventricular excitation have been described by many investigators in adults [9, 19–21], children [22, 23], and infants [24, 25].

The main features of maps observed in adults are as follows. At the beginning of the QRS, a potential maximum appears in the upper or mid-sternal area, and a minimum is generally located in a lower position on the left thoracic wall or on the back (Fig. 32.7a). This potential pattern can be related to septal excitation, which occurs in a predominantly left-to-right direction [26, 27] and probably also to right ventricular free wall activation.

Later, the minimum migrates dorsally. In 25% of subjects, the migration is discontinuous: a separate low-amplitude dorsal minimum appears before the left lateral initial minimum has disappeared. Thus, in these subjects, two distinct minima are simultaneously present during the initial 15–20 ms of QRS [28]. The minimum then moves toward the right shoulder and finally appears in the right clavicular area (Fig. 32.7a, b). In some cases, the minimum moves horizontally around the back and reaches the right axillary region. This behavior has been observed particularly in subjects with left axis deviation in the standard 12-lead ECG. Meanwhile, the maximum migrates downward to the left mammary region (Fig. 32.7c). The events described above are temporally related to the spread of excitation in an endo-epicardial direction through the walls of both ventricles, with a mean direction from base to apex.

Thereafter, a new minimum often appears in the midsternal area (60% of cases in the authors' studies), at 14–44 ms after the onset of ventricular activation (Fig. 32.7d). This minimum is considered to be the surface manifestation of the right ventricular breakthrough, that is, of the presence of a “window” in the advancing wavefront, through which the currents reenter the heart. In the following instants, the sternal minimum and the right clavicular minimum merge to form a single, broad anterior negative area (Fig. 32.7e). In about 40% of the cases, the sternal minimum does not appear as a separate entity, and the sternal area becomes negative as a result of the migration of the main minimum.

■ Figure 32.7

Body-surface potential maps during normal ventricular activation. Each map refers to the instant or time indicated by the vertical line crossing the ECG (*bottom*). The potential values are expressed in millivolts.

■ Figure 32.8

The shaded areas encompass all locations of the potential maxima (a) and minima (b) throughout the QRS interval in 50 normal subjects. The *arrows* indicate the main direction of migration of the principal maximum (a) and minimum (b). (After Taccardi et al. [15]. © Clarendon, Oxford. Reproduced with permission.)

Later, the maximum moves toward the left thoracic wall and then dorsally (▶ Fig. 32.7f). In about 55% of adults, a new maximum appears in the upper sternal area during the last 20–30 ms of the QRS interval (▶ Fig. 32.7g). In the great majority of cases, the second maximum appears while the dorsal maximum is still present, the time overlap being 10–30 ms. These potential patterns most likely indicate the presence of two separate excitation waves travelling through the heart. The dorsal maximum may be related to the activation of the posterobasal portions of the ventricles, and the upper sternal maximum to the excitation of the crista supraventricularis and pulmonary infundibulum. The time relationships between the two maxima may provide some indirect information about the time-course of excitation waves in the heart.

Green et al. [21] defined the range of normal body-surface potentials in a large population (1,113 subjects, aged 10–80 years) as a function of age, sex, and body habitus. On average, QRS potentials decreased with increasing age. Potential pattern distributions remained constant from 10 to 40 years; about 30% of the subjects older than 40 years had early negative potentials recorded more diffusely over the right thorax. This resulted in more vertically oriented zero equipotential lines. Only minor differences concerning QRS potential amplitude and distributions were noted when male and female subjects were compared within groups of similar age and body habitus.

■ Figure 32.9

AC maps of body-surface recordings during the QRS interval in 12 healthy individuals, which are representative of the normal variability of ventricular depolarization. Same conventions as in ▶ Fig. 32.4c.

Interindividual variability is due to variability of the thorax conductor [29] and source variability [30]. Normal variability of the ventricular activation may be due to the well-known variability of the conduction system.

We computed AC maps in 236 normal recordings from the dataset of Dr. F. Kornreich (Vrije University of Brussels, Belgium). We sorted them using divisive clustering analysis taking the correlation coefficient as a measure of distance between AC maps. Twelve prototype cases spanning the whole spectrum of variability of AC maps of normal activation are shown in ▶ Fig. 32.9. In each activation AC map, the size of white ( $R > 0.8$ ) regions along the main diagonal corresponds to periods of relative stability of body-surface distribution of potentials (apart from amplitude). Sometimes, these regions are distinct, as the transition from one pattern to the next is sudden (as in types 3 and 4), while in other cases, it is less distinct, as the transition is gradual (as in type 10). Usually, three such phases can be identified, the first two being separated by the ventricular breakthrough. The dark region, which occurs symmetrically between the first two phases, corresponds to the relatively opposed disposition of potential extrema on the body surface before and after ventricular breakthrough. The third phase corresponds to activation of the basal regions of the ventricles and pulmonary infundibulum and has a very variable relationship with the first two.

The amplitudes and surface distributions of time integrals during ventricular activation were firstly reported by Montague et al. [31] in 40 men and 15 healthy women and subsequently by many other authors. The QRS integral map is characterized by a dipolar distribution with a minimum in the mid-sternal area and a maximum in the left mammary-axillary region (▶ Fig. 32.2).

In children, the main features of the maps are similar to those observed in adults. There are, however, minor differences; for instance, the sternal maximum during the last stage of QRS was present only in a small percentage of children [22], but invariably appeared during peak inspiration in the series of subjects studied by Flaherty [32]. According to Liebman et al. [23], the location of the terminal maximum can be right superior-anterior, anterior-superior, or right posterior, probably suggesting that the end of activation is in the right ventricular outflow tract, in the superior septum, or in the posterobasal left ventricle.

In newborn infants, Tazawa and Yoshimoto [24] observed that during ventricular excitation, the initial potential maximum migrated to the right instead of moving to the left and dorsally as in normal adults. This behavior of the maximum was attributed to the physiological predominance of the right ventricle in the newborn heart. Benson et al. [25] described the evolution of the surface potential during ventricular excitation and recovery in the first year of life. There was a progression of change in the body-surface QRS potential distribution: at birth. A single QRS maximum migrated to the right during the second half of QRS; at several months of age, the initial maximum evolved into two maxima: one moving to the right, and the other to the left; at 9–12 months of age, the initial maximum moved to the left lateral

thorax, while the right maximum almost disappeared. Moreover, the age-related changes of the QRS maps were associated with similar changes on the repolarization maps; with increasing age, movement of both the excitation and the recovery positive potentials to the right chest progressively disappeared.

### 32.4.3 Ventricular Repolarization

Sizeable recovery potentials usually appear at the surface of the body before the end of the QRS interval [14] (● Fig. 32.7h). This finding was confirmed and quantified by Spach et al. [33], who also reported that the time overlapping of excitation and recovery potentials varied in different age groups, being greater in younger classes (8–12 and 20–29 years). In some subjects, the overlap lasted for 12–28 ms. The first signs of repolarization consist of a potential maximum, which generally appears on the sternal area, on the left precordium or, in a few cases, even more laterally, on the left axillary region (● Fig. 32.7h). In the latter case, the maximum soon moves toward the central anterior chest area (● Fig. 32.10a). During the early phase of recovery, the minimum is often ill-defined. The most negative areas can be found anywhere around the maximum, in the anterior lower part of the torso, in the lateral wall, or in the back [14].

This potential distribution is essentially in agreement with that described by Spach [33] in subjects 8–60 years old during the first 50 ms of ventricular recovery. Within 100–150 ms from the onset of ST the most negative potentials concentrate in an area covering the right scapular region, the right shoulder, the clavicular, and the upper sternal regions (● Fig. 32.10). In a minority of adult subjects, the most negative areas are located in the right clavicular or scapular regions from the beginning of repolarization. During the T wave the minimum is consistently found in the right clavicular or scapular areas and the maximum in the precordial region [12, 14]. Slight shifts of the potential extrema are usually observed during the entire T interval (● Fig. 32.10).

In a large normal population, Green et al. [21] observed that ST-T potentials decreased with age in both sexes. Moreover, in female subjects over the age of 40, there were more extensive low-level negative potentials over the precordium during the ST segment than in men. On the other hand, male subjects consistently showed greater T potential amplitudes.

The early repolarization deviation index (ERDI, see ● Sect. 32.3.4) is about twice as high as in females compared to males [34]. LRDI is higher in males. As the correlation coefficients between instantaneous potentials in the same subject are invariant to the features of the thorax conductor [13], it proves that gender differences in repolarization potentials are not entirely due to the systematic anatomical differences in thorax shape and conductivity between the genders, but must be due, at least in part, to differences in myocardial repolarization gradients.

■ Figure 32.10

Body-surface maps during normal ventricular recovery. Each map refers to the instant or time indicated by the vertical line intersecting the ECG. (After Taccardi et al. [15]. © Clarendon, Oxford. Reproduced with permission.)

■ Figure 32.11

Location of potential maxima and minima during the U wave in 55 normal subjects aged 8–60 years. (After Spach et al. [17]. © American Heart Association, Dallas, Texas. Reproduced with permission.)

The integral maps of QRST deflections are thought to provide valuable information on the ventricular recovery process [35]. Areas of QRST deflection mainly reflect the intrinsic recovery properties and are largely independent of the ventricular excitation sequence. Actually, at the body surface, negative QRST integrals should be recorded from areas facing myocardial regions with longer recovery durations, whereas positive values are recorded from the thoracic surface facing cardiac regions with shorter recovery durations.

In normal subjects the ST-T and the QRST integral maps show a bipolar distribution of the values with a minimum on the right clavicular–upper sternal areas and a maximum on the mammary region (▶ Fig. 32.2).

A few descriptions of accurate recordings of potential distributions during the U wave have been reported [17, 36, 37]. Spach and associates [17] studied 11 children aged 1–7 years and 55 subjects aged 8–60. In the 11 children, no measurable U wave was found. In the remaining subjects, positive U-wave potentials were located within a broad area on the anterior and left lateral chest surface (▶ Fig. 32.11); the magnitude of the potential maximum varied from 30 to 140  $\mu\text{V}$ . The highest U voltages were confined to the precordial area where the highest T voltages occurred. In most subjects, the specific locations of T-wave and U-wave maxima were coincident; in 17 subjects, the U-wave maximum was slightly to the right of the T-wave maximum. Clear-cut negative U waves were found in only 10 of the 55 subjects. The negative peaks varied from  $-20$  to  $-50$   $\mu\text{V}$  and occurred on the right clavicular or scapular areas (▶ Fig. 32.11).

## 32.5 BSPM in Heart Disease

### 32.5.1 Ischemic Heart Disease

#### 32.5.1.1 Myocardial Infarction

Descriptions of the potential distribution on the body surface in patients with anterior or inferior myocardial infarction (MI) have been published by many authors [38–53].

An attempt was made to define quantitatively the characteristic features and the range of variation of surface maps in anterior and inferior myocardial infarction during ventricular activation and recovery [38].

In patients with anterior MI (▶ Fig. 32.12), at the onset of ventricular activation, the potential minimum was located in the sternal or left mammary region. In some patients, the minimum lay outside the area where the minima were located in normal subjects. In MI patients, the minimum remained confined to a limited zone on the anterior chest wall throughout the QRS interval, whereas in normal subjects, it migrated leftward and dorsally.

■ Figure 32.12

Body-surface maps in a subject with anterior MI. Each map refers to the instant of time indicated by the vertical fine crossing the ECG. Potential values are expressed in millivolts.

■ Figure 32.13

Body-surface map of a patient with an old anterior MI not revealed by the 12-lead ECG. During the early phases of the QRS interval an abnormal potential minimum is present on the left mammary region above the area explored by the standard precordial leads.

The persistence of a negative area on the anterior chest surface could be ascribed to the presence of an infarcted region in the underlying ventricular wall. This region did not depolarize and thus acted as a current sink. Occasionally, the minimum was located above the area explored by conventional precordial leads; in these cases, as in [Fig. 32.13](#), the 12-lead ECG did not reveal any sign of anterior MI although there are suspicious changes in the inferior leads III, aVF, and the anterolateral leads V4–V6. In 13 subjects with anterior MI, the highest absolute value of the potential minimum varied between 1.06 and 4.77 mV (mean  $2.78 \pm 0.3$ ) and was significantly higher than in normal subjects ( $p < 0.01$ ).

At the onset of ventricular activation, the location of the potential maximum was normal in the majority of cases. However, the migration of the maximum was clearly abnormal, as could be expected since the area through which the maximum should normally have passed during its migration was occupied by the potential minimum. During the first 30 ms of ventricular activation the behavior of the maximum varied. In the majority of cases, it moved superiorly toward the neck, then posteriorly toward the left scapular region, and finally reached the left axillary region; in other patients (▶ Fig. 32.12), the maximum migrated inferiorly on the anterior chest wall and reached the left axillary region; in two cases, in which the maximum was located in the left submammary region, it stayed in the same area. These various trajectories were probably related to the different extent and topography of the infarction. During the following phases of ventricular excitation the behavior of the potential maximum was within normal limits. The highest value reached by the potential maximum was significantly lower than that observed in normal subjects (mean 1.29 mV  $\pm$  0.23 standard error;  $p < 0.01$ ). Moreover, the highest positive value was reached later than in normal subjects ( $p < 0.01$ ), occurring between 30 and 66 ms (mean 41.8  $\pm$  2.6).

At the beginning of the ST interval, the surface potential values were very low and the potential minimum was ill-defined, whereas the maximum was usually well developed, as occurs in normal subjects. The electronegative areas were located either on the left lateral wall of the chest, or on the lower part of the back, or both. These features are similar to those observed in normals. During the T interval, a clear-cut minimum generally appeared in the left mammary or submammary region. This location is definitely abnormal (see ▶ Fig. 32.10). In some patients, another minimum was simultaneously present in a normal area; that is, the upper sternal region. The location of the T minimum over the precordial area facing the infarction could be explained by assuming that the infarcted area did not generate recovery currents of its own and acted as a sink for repolarization currents originating in the surrounding, uninjured myocardial tissues. The highest values reached by the recovery maximum were significantly lower than in normal subjects ( $p < 0.01$ ), whereas the highest values reached by the minimum were significantly higher ( $p < 0.01$ ).

During the ST interval and the initial portion of the T wave, the recovery maximum was located within the normal area on the anterior chest wall (▶ Fig. 32.12e). During the second half of the T wave, in the majority of cases, the potential maxima moved away from the area where they had appeared (▶ Fig. 32.12f), and mainly scattered over the anterior lower thoracic surface. This late migration of the potential maximum was not observed in any of the normal subjects. This phenomenon is quantified by the late repolarization deviation index (LRDI, see ▶ Sect. 32.3.4), which increases in non-ischemic ventricular hypertrophy [54] as well as in old myocardial infarction compared to normal [55], even when adjusted for gender, being higher in males [34].

In the 14 cases of inferior myocardial infarction (▶ Fig. 32.14), the potential minimum was located within or near the normal area at the beginning of the QRS interval. It then moved to the inferior half of the posterior or anterior chest wall, thus passing beyond the limits of the normal scatter for the relevant instants of time. At 20 ms, the minimum was located outside the normal area in the great majority of patients. The low position of the minimum, which was observed in all patients with inferior MI at 20–30 ms, was most likely related to the presence of an infarcted area in the diaphragmatic wall of the heart. This area of non-depolarizing tissue acted as a “window” through which the depolarization currents generated by normal cardiac muscle reentered the heart.

During the following instants, the minimum migrated toward the midsternal region in some patients; in the other patients (▶ Fig. 32.14b), a new separate minimum appeared in the sternal region between 22 and 42 ms after the beginning of the QRS interval, while the first minimum was disappearing. Here, as in normal subjects, the sternal minimum was attributed to right ventricular breakthrough.

The highest absolute value of the negative potential varied between 0.45 and 1.67 mV (mean 1.3  $\pm$  0.1) and was significantly lower than in the authors' normal subjects ( $p < 0.01$ ). The low absolute value reached by the sternal minimum could be explained by the fact that the solid angle viewing the negative aspect of the wavefront from the sternum was smaller than in normal conditions because the wavefront did not extend over the entire diaphragmatic wall of the heart. In the authors' experience, in patients with inferior myocardial infarction, the behavior of the potential maximum during the QRS interval (▶ Fig. 32.14), its area of distribution, and its highest absolute value were within normal limits.

At the beginning of the ST interval, electronegative areas could be found on the lower half of the trunk anteriorly and posteriorly, as in normal subjects. During the T wave, the recovery minimum moved to or remained in the inferior half of the trunk (▶ Fig. 32.14e). The abnormally low location of the minimum during the T wave could be ascribed to the presence of an infarcted area in the diaphragmatic wall of the heart, which acted as a sink for recovery currents.

■ **Figure 32.14**

**Body-surface map of a patient with inferior MI. Each map refers to the instant of time indicated by the vertical line crossing the ECG. Potential values are expressed in millivolts. The time interval between successive bars is 15 ms.**

The location of the recovery maximum was within the normal area, i.e., the sternal or left mammary region, during the entire recovery process (► Fig. 32.14e). The highest absolute values reached by the recovery maximum and minimum were not significantly different from those observed in normal subjects.

Potential patterns similar to those mentioned above were also described by Vincent and coworkers [43] in 28 subjects with inferior MI. These authors were also able to detect on BSPMs the characteristic features of inferior infarction in eight patients, whose ECGs had returned to normal or were nondiagnostic for the previous infarction. Similar findings were obtained by Osugi et al. [47].

Hirai et al. [48] described an abnormal location of the minimum at 15 ms into the QRS in 26 of the 32 cases of anterior myocardial infarction with a normal 12-lead ECG.

The possibility of detecting signs of myocardial infarction by means of body-surface mapping, even when the conventional ECG was within normal limits, was also demonstrated by Flowers et al. [41, 42]. Using departure maps, abnormalities of potential distribution were found in patients with anterior or inferior MI at the onset of ventricular excitation (corresponding to the Q wave in the conventional ECG) and during the mid-phases and late phases of the QRS interval [41].

Ohta et al. [46] compared body-surface maps with left ventriculographic findings in 24 patients with old infero-posterior MI. Using the departure-map technique as proposed by Flowers [41], they found surface potential abnormalities owing to infarction during specific phases of the QRS interval and in specific areas on the chest surface, depending on the location and extent of ventricular asynergy. In particular, some patients with inferior MI and, in addition, severe asynergy of the anterior, apical, or septal segments but without ECG or VCG signs of anterior MI, exhibited definite abnormalities of departure maps, which were different from those related to purely inferior MI.

De Ambroggi et al. [39] recorded BSPMs in 30 patients with old inferior myocardial infarction. Of these, 15 had no signs of necrosis in the conventional ECG. A number of variables relative to the instantaneous potential distribution and to integral maps were considered. The most accurate diagnostic criterion was derived from the integral values of the first 40 ms of QRS, with a sensitivity of 73% in patients without signs of necrosis in the 12-lead ECG, and of 100% in patients with pathological Q waves in the ECG, with a specificity of 83%.

In non-Q myocardial infarction of the anterolateral wall, the integral maps of the first 40 ms of QRS provided a good sensitivity (67%) in detecting signs (areas of values two standard deviations lower than normal) of the old necrosis in a group of patients with normal ECG [40].

Medvegý et al. recorded BSPM in 45 patients with documented non-Q-wave MI [52]. The main abnormality revealed by BSPM was the loss of electrical potential, but different features were characteristic for each region of the heart, so that they were suitable for the detection and localization of non-Q-wave MI, in the clinical setting of unstable coronary artery disease.

### 32.5.1.2 Acute Myocardial Infarction

Since the late 1970s, a simplified method of electrocardiographic mapping has been widely used in acute MI in order to obtain data on the infarct size and to assess the efficacy of various therapeutic interventions aimed at limiting myocardial injury [56].

The simplified method consists in recording 35–70 ECGs from the left hemithorax and in calculating the sum of the amplitudes of ST-segment elevations at all electrode sites, and the number of points with ST elevation. Similar procedures have also been used to evaluate the appearance of pathological Q waves and the reduction of R waves on the thoracic area explored.

The use of thoracic maps for assessing infarct size is based on experimental observations in animals demonstrating that any intervention that provokes an extension or reduction of the epicardial ischemic areas produces similar variations of the precordial areas, in which ST elevation is recorded [57, 58]. The use of these simplified methods of electrocardiographic mapping for assessing the extent of the infarction has aroused much criticism [59, 60]. In fact, there are several factors, other than the dimensions of the infarct, which can influence the ST segment elevation and, to a lesser extent, the QRS complex. These factors consist of local intraventricular conduction disturbances, electrophysiological changes in the myocardium outside the ischemic area, electrical cancellation phenomena, intra-extracellular electrolyte levels, pericarditis, heart rate, and autonomic nervous system activity. Despite the above considerations, the method does offer some definite advantages in monitoring patients with acute MI, in that it can reveal variations in the extent and severity of the ischemic process earlier than other methods, such as enzyme levels and myocardial scanning.

A description of the ST-T potential distribution on the entire chest surface in acute MI was reported by Mirvis [61], who observed a characteristic early appearance of the repolarization potentials in both anterior and inferior MI, with a longer than normal overlap between final excitation and recovery potential patterns. During the ST-T interval, the potential distributions were characterized in anterior MI by a single maximum on the left anterior chest that remained fixed in location but increased in amplitude as repolarization progressed; in inferior MI, there was a single minimum generally located on the left anterior-superior thorax, with positive potentials covering the lower thoracic portions.

The distribution of QRS and ST potentials in acute inferior myocardial infarction (mean 76 h after the onset of symptoms) has been studied by Montague et al. [62]. They computed integral maps in a group of 36 patients with acute inferior MI, and found negative areas over much of the inferior torso with extension of the positivity to the superior torso, during the first half of the QRS interval (Q zone); conversely, the ST segment integral map was characterized by abnormally positive inferior distributions and concomitant negative precordial distributions. Moreover, patients with right ventricular involvement tended to have a greater area of negative Q zone over the right anterior inferior thorax and greater inferior and rightward extension of ST segment positivity as compared with patients with exclusive left ventricular infarction. Thus, in acute inferior MI, BSPMs make it possible to detect definite abnormalities of both depolarization and repolarization potentials, which indicate right ventricular involvement.

More recently, Menown et al. [63] confirmed the ability of BSPMs (using 80 leads) to improve, with respect to conventional ECG, the classification of inferior acute MI with posterior or right ventricular wall involvement.

The same group demonstrated that the BSPM diagnostic algorithm detected acute MI with higher sensitivity than a 12-lead ECG diagnostic algorithm or a physician's interpretation, without loss of specificity [64]. They also showed the superiority of BSPM versus the 12-lead ECG in detecting acute MI in the presence of left bundle branch block (LBBB) [65].

### 32.5.1.3 Myocardial Ischemia

In angina patients, the resting ECG is very often normal between attacks. This can indicate that cardiac electrogenesis is normal or that there are electrical abnormalities, which are not revealed by the conventional ECG because they are too small, or because they are projected to surface areas not explored by conventional leads.

In several patients with proven angina pectoris and a normal resting ECG, surface maps exhibited an abnormal distribution of recovery potentials [66]. In these patients, the location of the potential minimum during recovery was outside the normal range during some phases of the ST segment and of the T wave, often on the lower left lateral region of the chest (► Fig. 32.15a).

■ **Figure 32.15**

(a) BSPM of a patient with angina and normal resting ECG. The map refers to the early ST interval, as indicated by the vertical line crossing the ECG. This potential pattern lasted about 200 ms. Potential values are expressed in millivolts. (b) BSPM at the instant indicated by the vertical line crossing the ECG, in a patient with angina but normal T waves on the resting ECG. The map shows a complex potential distribution with one maximum and two minima.

During the entire ST-T interval the potential maximum was located within the normal area in most patients with angina. Only in a few subjects was the location of the maximum abnormal during the final phases of ventricular recovery. In some of these patients with angina and a normal resting ECG, a complex potential distribution was observed (● Fig. 32.15b), with one maximum and one minimum located normally and a second minimum placed in an abnormal position.

In a study [67] performed on 14 patients with stable angina and a normal resting ECG, the analysis of BSPMs was extended to a new series of quantitative aspects; that is, temporal evolution during the ST-T interval of the highest potential on the chest, lowest potential, highest potential difference, integral of the absolute value of the potential function extended over the entire chest surface, and the percentage of the total thoracic area with positive potentials. By deriving a number of voltage-related variables from these time functions and by submitting them to multivariate analysis, it was possible to separate more than 90% of the ischemic patients from normal subjects. It has been shown [68] that, in some patients with typical angina but no evidence of MI, QRS potentials can differ from normal at some chest locations, which are not explored by the standard 12 leads.

BSPMs were also used to study the potential variations before, during, and after coronary angioplasty (PTCA). During balloon inflation in the anterior descending or right coronary artery, specific changes of QRS instantaneous and integral maps were observed, suggesting a regional conduction delay due to myocardial ischemia [69].

Shenasa et al. [70] demonstrated potential patterns 40 ms after QRS end during inflation that were specific to the three major coronary arteries dilated. The left anterior descending coronary artery was associated with the largest ST-segment shifts with a precordial maximum and negative potentials over the back; for the right coronary artery, negative potentials covered the upper left torso with a left mid-axillary minimum and positive potentials over the rest of the torso; for the left circumflex coronary artery, negative potentials covered the anterior torso with a precordial minimum and positive potentials over the back. These changes disappeared rapidly after balloon deflation. Thus, BSPMs provide a comprehensive

approach for the evaluation of electrocardiographic changes and the development of optimal leads for the detection of acute occlusion of a coronary artery.

BSPMs were also used to evaluate the clinical efficacy of PTCA and were proved useful to detect restenosis [71].

### 32.5.1.4 Exercise Maps

Potential maps have been obtained during exercise in normal subjects and patients with angina.

Some authors [72] recorded ECGs from 16 points located on the left anterior thorax, using traditional methods. This technique should be more appropriately considered as a system of multiple precordial leads rather than surface mapping. The 16-lead system, however, has shown greater sensitivity than 12 standard leads or three orthogonal leads [73], although this has not been confirmed by other groups.

Other investigators studied the instantaneous potential distribution on the anterior thorax [74, 75] or on the entire chest [76–79]. A complete and accurate study on the QRS and ST-T wave changes induced by exercise was performed by Spach's group in healthy subjects [76]. These authors were able to obtain high-quality potential maps during exercise without averaging ECG waveforms, by using their system for calculating total body potential distributions from 24 chest leads. Exercise induced consistent changes in potential patterns. During the first 20 ms of QRS, the minimum stayed on the lower left chest, while, in the resting condition, it gradually migrated toward the upper back. In mid-QRS, the magnitude of the anterior potential maximum was approximately 60% of that observed in the map at rest while the duration of the QRS interval usually increased (2–10 ms) at peak exercise. On the basis of these findings, it was suggested that the decrease in the magnitude of the precordial potential maximum in the midportion of QRS (R wave in lead V5) might result from changes in the sequence of activation of the ventricles, rather than from blood volume variations (Brody effect).

In the early stage of ventricular repolarization (early ST segment), a potential minimum usually developed on the lower left thorax during exercise. This minimum generally decreased in magnitude in a short time after exercise. During the subsequent instants of the ST interval, the lower left precordial region became less negative and was usually positive by the early portion of the T wave. At the peak of the T wave the potential pattern showed slight changes during and after exercise with respect to the resting condition. However, the amplitude did change considerably. In particular, immediately after exercise, the magnitude of T-wave potentials increased rapidly, reaching its highest value 30–90 s after the end of exercise, before gradually decreasing; in some subjects, the potential values were still higher than resting values 10 min after exercise.

In patients with angina, Simoons and Block [77] reported some typical changes induced by exercise. The recovery minimum was located in the lower part of the left side of the chest and attained  $-90 \mu\text{V}$  or more 60 ms after the end of the QRS complex. This repolarization pattern was found in 21 out of 25 coronary patients, but in none of the normal subjects (sensitivity 84%, specificity 100%).

Yanowitz et al. [79] recorded BSMs before and after exercise in 25 males with documented coronary disease. By considering the integrals of the first 80 ms of the ST interval, they found abnormal negative values in 18 cases. Moreover, in 25% of the cases, BSPMs after exercise showed maximal depression of the ST-segment area at sites not sampled by the leads usually employed in exercise testing. This finding suggests that BSPMs may increase the sensitivity of the exercise testing for coronary disease.

### 32.5.2 Right Ventricular Hypertrophy

Hypertrophy may involve various portions of the right ventricle in different forms of heart disease. In children BSPMs were recorded in the following types of right ventricular hypertrophy (RVH) [80]: dilation of right ventricle and hypertrophy of the crista supraventricularis owing to secundum atrial septal defect; hypertrophy of the entire right ventricle, including the outflow tract, secondary to valvular pulmonic stenosis; hypertrophy of the proximal portion of the right ventricle between the tricuspid valve and the infundibular stenosis, with normal thickness of the right ventricular wall in the outflow tract, beneath the pulmonary valve (tetralogy of Fallot).

While, in normal subjects, during the second half of the QRS interval, the potential maximum moves from the precordial area toward the left axillary region and then to the back, in all patients with RVH, it migrated toward the right chest.

The movement of the maximum on the right thorax was different according to the various pathological conditions [80]. In atrial septal defect (ostium secundum) the maximum moved to the right mammary region, finally reaching the upper sternal region. In tetralogy of Fallot with infundibular stenosis, the maxima migrated toward the right lateral thoracic wall. In valvular pulmonic stenosis, the maximum migrated on the anterior right chest toward the upper central area, as in atrial septal defect; the potential values, however, were markedly higher.

These surface potential patterns were correlated with the spread of excitation through the right ventricular wall, as determined in the same patients at surgery. In all three types of RVH, the activation wavefront moved on the epicardial surface in a rightward direction. In atrial septal defect, the latest epicardial events were recorded along the atrioventricular groove and gave rise to a right-chest maximum. However, after completion of epicardial excitation on the right ventricle, a potential maximum persisted over the upper sternal area. This terminal maximum was probably related to an activation wavefront spreading through the upper part of the septum and the crista supraventricularis, which is most likely hypertrophied in right ventricular volume overload.

In valvular pulmonic stenosis, as the wavefront moved laterally across the right ventricular free wall, it produced a maximum over the right chest while a minimum was positioned over the left precordium. The terminal excitation wavefront spread superiorly through the outflow tract of the right ventricle and gave rise to the upper sternal maximum.

In tetralogy of Fallot, after right ventricular breakthrough occurred, the wavefront moved laterally toward the atrioventricular groove and produced a maximum over the lower mid-right chest with a minimum in the left precordial region. The latest portions of the right ventricle to be depolarized were along the lateral inferior part of the atrioventricular groove. The final orientation of the wavefront was such that it resulted in a maximum in the right axillary region with a minimum over the central chest. Thus, maps enable the different types of RVH to be recognized to a greater extent than does the 12-lead ECG.

Body-surface maps in adult patients with RVH owing to mild-to-moderate valvular pulmonic stenosis were obtained by Sohi et al. [81]. Using departure maps, they observed a delayed appearance of the sternal negativity, which is usually related to right ventricular breakthrough, and an abnormal positivity located in the upper anterior chest.

### 32.5.3 Left Ventricular Hypertrophy

Body-surface maps in patients with left ventricular hypertrophy (LVH) owing to mild-to-moderate aortic stenosis were studied by Sohi et al. [81], using the departure-map technique. They observed an abnormal delay of early negativity on the anterior right chest and a potential maximum on the upper anterior chest, which peaked later and lasted longer than normal.

An assessment of left ventricular mass in patients with LVH was attempted by Holt et al. [82] on the basis of chest-surface potential distribution. They used a mathematical model in which the ventricles and the septum were represented by 12 dipoles. The dipole activity was assumed to be proportional to the amount of viable myocardium in that region; the strength of each dipole as a function of time was determined by measuring potentials at 126 locations on the thoracic surface and by applying suitable transfer coefficients. A good correlation was found between left ventricular mass determined by angiography and that determined by surface potentials ( $r = 0.85$ ). Moreover, the correlation coefficient was much higher using BSMs than other electrocardiographic recordings (12 standard ECG leads or VCG).

Yamaki et al. [83] used BSPMs recorded with 87 leads to determine the severity of LVH in 57 patients with concentric hypertrophy and in 30 with left ventricular dilatation. A number of parameters related to QRS voltages and ventricular activation time were measured, and some of them were proven useful in determining the severity of LVH.

Kornreich et al. [84] studied BSPMs during the entire cardiac cycle (PQRST) in 122 patients with LVH. Best classification results were achieved with ST-T features, followed by features from the P wave, QRS, and PR segment. Cumulative use of ST-T and P features yielded a specificity of 94% with a sensitivity of 88%.

Hirai et al. [85] studied QRST integral maps in patients with LVH (10 with aortic stenosis, 12 with aortic regurgitation, and 22 with hypertrophic cardiomyopathy). Abnormalities in patients with hypertrophic cardiomyopathy were manifest even in mild LVH and a greater disparity of repolarization was found in hypertrophic cardiomyopathy than in LVH due to aortic valve disease.

We reported the results on BSPMs recorded in 16 patients with LVH due to aortic stenosis, focusing on the analysis of ventricular repolarization, with the aim of searching for subtle alterations not revealed by the usual ECG processing, which are likely to reflect ventricular repolarization heterogeneities [54].

The classical signs of LVH in the standard ECG (increased QRS voltage and ST-T changes) are reflected on BSPMs as (1) increased amplitude of the QRS integral map and of the STT integral map, (2) relatively low amplitude of the QRST integral map, due to the cancellation between the depolarization and repolarization potentials, and (3) opposing aspects of the QRS and STT integral maps.

In order to detect possible minor electrical disparities of repolarization not apparent from visual inspection of the ST-T and QRST maps, we analyzed the morphology of all the recorded ST-T waves, using principal component analysis. In our patients, the “similarity index,” defined as the first eigenvalue divided by the sum of all eigenvalues, was slightly but significantly lower than in control subjects (0.73 vs 0.77;  $p = 0.027$ ), suggesting the presence of a degree of heterogeneity of repolarization higher than in the normals. The repolarization deviation indices were also computed, as described in the methods. In our LVH patients, the changes during early repolarization, as reflected by ERDI, were similar to those observed in our control group and also in the larger group of 159 normal subjects from the database of Dr. F. Kornreich (Vrije University of Brussels, Belgium). Then, we focused on the analysis of the T peak-T end period, during which possible heterogeneities of repolarization should be more likely to be detected. The LRDI was significantly higher ( $p = 0.005$ ) in LVH patients than in normals. The values of similarity index and LRDI found in LVH patients suggest a higher than normal degree of repolarization heterogeneity, not detected by the usual electrocardiographic analysis.

#### 32.5.4 Right Bundle Branch Block

Several types of potential patterns have been observed in patients with right bundle branch block (RBBB) [86–88]. During the initial phases of ventricular activation, the surface potential distribution was similar to that observed in normal subjects with a maximum located on the sternal or left mammary region and a minimum on the left chest wall or in the dorsal regions (▶ Fig. 32.16b). The sternal minimum, which indicates right ventricular breakthrough and which occurs in normal subjects 14–44 ms after the onset of the QRS complex, did not appear. Only at a later stage (38–70 ms after the onset of ventricular activation) did a second minimum appear, which, however, was located in an abnormal position, that is, in the left mammary region (▶ Fig. 32.16d). It should be noted that this second minimum usually occurred to the right of the potential maximum located on the left precordium. This maximum was attributed to the spread of excitation through the left ventricular wall, while the delayed minimum was interpreted as the result of excitation arriving on the surface of the left ventricle, most probably in the left paraseptal region or in the apical area.

Shortly after the appearance of the second minimum, a new potential maximum appeared on the right precordium (▶ Fig. 32.16c). This led to a complex potential distribution with two maxima (left and right) and two minima (on the right clavicular region and on the left precordial area), indicating the simultaneous presence of two excitation waves spreading into the left and right ventricles. Subsequently, the two negative areas merged, while the left maximum shifted to the back (▶ Fig. 32.16g) and eventually disappeared, as in normal subjects, about 80 ms after the onset of the QRS complex. Thus, during the final stages of the QRS interval, only the signs of delayed right ventricular activation persisted, with a maximum on the right anterior chest wall and a minimum on the left precordial area (▶ Fig. 32.17a–c). At the end of the QRS complex, early recovery potentials could often be observed before the last excitation potentials disappeared. Usually, the activation maximum and minimum shifted slightly to the right, and the recovery maximum appeared in the left mammary region, giving rise to patterns with three extrema (▶ Fig. 32.17d). Later, only two extrema remained: the recovery minimum in the sternal or right mammary region and the recovery maximum in the left mammary area (▶ Fig. 32.17e). This pattern persisted throughout the ST and T intervals (▶ Fig. 32.17f) and approximately represented a mirror image of the potential distribution observed during the last phases of ventricular activation.

In some patients, a different behavior of the potential maximum and minimum was observed during the midportion of QRS; that is, the anterior maximum, after reaching the precordial area, did not complete its leftward migration but reverted to the sternal region and then moved to the right precordium, thereby taking over the role of the second maximum observed in typical RBBB. The second minimum did not appear in the left parasternal region to the right of the maximum, as in typical cases, but to its left, in the external part of the left mammary region. The electrophysiological mechanism giving rise to this peculiar sequence of potential patterns observed could not be identified.

The values of equipotential lines are expressed in millivolts. (After Taccardi et al. [86]. © Churchill Livingstone, New York. Reproduced with permission.)

### 32.5.5 Left Bundle Branch Block

BSPMs have been described in uncomplicated left bundle branch block (LBBB), with or without left axis deviation [89–91] and in LBBB complicated by additional heart disease [90, 92].

In the uncomplicated LBBB studied by Musso et al. [90], at the onset of QRS (▶ Fig. 32.18a), the potential maximum was consistently found in the sternal area. The minimum was generally located on the right chest, anteriorly or posteriorly. A few milliseconds later a new potential distribution developed, with a minimum in the presternal area and a maximum on the left mammary region. In some patients, the minimum migrated to the sternal area from its previous location. In other cases, an independent, secondary minimum appeared in this region and subsequently increased in magnitude, while the old minimum faded away. In both cases, the minimum settled in the sternal area earlier than in

■ **Figure 32.17**

Same subject as in ▶ Fig. 32.16. BSPMs relating to second half of ventricular activation (a–d) and recovery (e, f). At instant d (end of QRS) recovery potentials are already present on the left side of the chest. (After Taccardi et al. [86]. © Churchill Livingstone, New York. Reproduced with permission.)

normal subjects. An early appearance of this minimum, which indicates right ventricular breakthrough, was also found by other investigators [91].

In LBBB, the initial phase of ventricular excitation differs from the normal sequence, in that the first electrical event occurring in the normal ventricles, that is, the excitation wavefront spreading through the septum from left to right and anteriorly, is missing. Therefore, ventricular excitation starts later than it would if the left bundle branch was functioning normally. As a consequence, the onset of ventricular activity as a whole is delayed in relation to His-bundle excitation.

The lack of left ventricular activity may explain the differences between the maps recorded in the early stages of QRS in LBBB patients and in normal subjects. The occurrence of the presternal minimum may be attributed, as in normal subjects, to the excitation wavefront reaching the right ventricular surface (right ventricular breakthrough). The shorter breakthrough time is not surprising since this time is calculated from the beginning of QRS, which is delayed in LBBB, as indicated above.

In the subsequent stages, the maximum moved to the left axilla, while the minimum persisted in the midsternal area. This distribution was a constant feature in the second half of QRS (▶ Fig. 32.18b). In this interval, the potential maximum and minimum reached their peak value. However, the positive peak appeared later than the corresponding one in normal subjects. The surface patterns mentioned above can be related to the wide excitation wavefront, which, at these stages of the cardiac cycle, spreads through the septum from right to left and then invades the left ventricular walls.

In most cases of uncomplicated LBBB, 10–20 ms before the end of QRS a new maximum appeared in the upper sternal area (▶ Fig. 32.18c). The maximum progressively increased in voltage and persisted throughout the ST-T interval. For this reason it was considered to be an early manifestation of the recovery process. The recovery minimum was located in the left axillary region (▶ Fig. 32.18d), whence it generally moved toward the dorsal area at the end of the T wave. These events may be interpreted by inferring that (a) measurable repolarization potentials originate from the right ventricle before left ventricular depolarization is completed because the right ventricle is the first to depolarize and (b) the left ventricle behaves as a current sink during most of the recovery process, because of its delayed repolarization resulting from delayed activation.

Subjects with LBBB and left axis deviation described by Sohi et al. [91] differed from those with normal axes in that during the second half of the QRS interval, the maximum was generally located on the left shoulder and back. This pattern was attributed to a further selective slowing of depolarization in the anterobasal portions of the left ventricle.

BSPMs in complicated LBBB have been described by two groups of investigators [90, 92]. According to Preda et al. in LBBB associated with anterior MI, the middle third of the anterior chest wall remained negative during the final phases

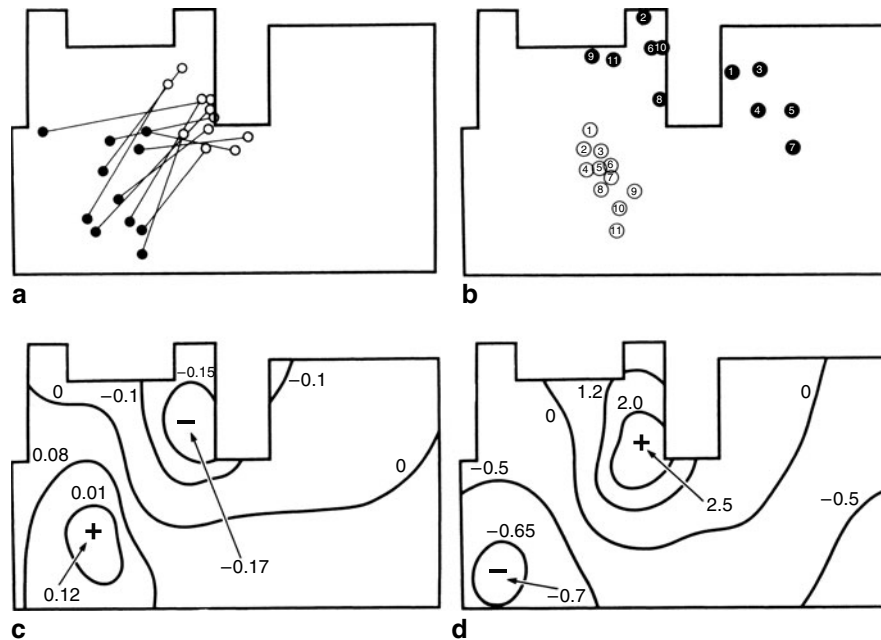

Figure 32.18

Patient with uncomplicated LBBB. BSPMs relating to four instants of time during ventricular excitation and recovery. The zero equipotential line is dashed. The plus and minus signs indicate the value of the positive and negative peaks (in microvolts). +P and -P indicate the step (in microvolts) between adjacent positive and negative equipotential lines.

of QRS. The authors attributed this finding to the lack of activation of the anterobasal region of the left ventricle, owing to the presence of the necrosis. In patients with infero-posterior MI, a persistent negativity was observed during the central portion of the QRS in the lower border of the chest, on the left lateral or posterior regions. Later, the negativity moved to the right side of the back. These findings were not confirmed by Musso et al. [90]. They studied LBBB complicated by anterior or inferior MI, LVH, myocardial ischemia, or a combination. By visually inspecting the maps, Musso et al. were unable to identify any potential pattern that could be uniquely found in a given LBBB group. However, several differences among groups were observed if the voltage values, rather than the potential patterns, were taken into account [90]. Generally, higher voltages were measured in patients with LVH and lower voltages were found in the MI groups as compared to uncomplicated cases of LBBB. These observations prompted Musso et al. to measure a set of voltage-related variables with a view to discriminating among different LBBB groups. The variables were derived by curves illustrating the behavior as a function of time during QRST of the highest instantaneous negative and positive potentials on the chest, the highest potential difference, the integral (extended to the entire chest surface) of the absolute value of the potential function, the size of the electropositive (or electronegative) thoracic areas, and so on. The statistical evaluation of the data (canonical variates analysis) permitted the classification of most complicated and uncomplicated patients into the correct group.

### 32.5.6 Left Anterior Fascicular Block

In left anterior fascicular block (LAFB), without MI or hypertrophy, one or more abnormal features could be detected in all patients. At the onset of QRS interval, in 8 out of 11 patients (unpublished data), the potential distribution was clearly abnormal in respect of (a) the location of the minimum, which was at a higher thoracic level with respect to the corresponding maximum, and/or (b) the anomalous position of the maximum (Fig. 32.19a). This potential pattern

■ **Figure 32.19**

*Top:* Location of potential maxima (black circles) and minima (white circles) on the chest surface (a) at the onset of ventricular activation and (b) after 55 ms in 11 subjects with LAFB. The potential maximum and minimum relating to a given patient are indicated by the numbers inside the circles. *Bottom:* Subject with LAFB. Potential distribution at 10 ms (c) and at 46 ms (d) after the onset of ventricular activation. Potential values are expressed in millivolts.

could be related to the direction of the activation wavefront, which spreads inferiorly and rightward. This anomalous direction is probably owing to the lack of early excitation of the anterosuperior portion of the left septal surface, as found in experimental studies [93].

During the mid- and late-QRS interval, a characteristic potential distribution was observed in all patients, by the authors and others [94]. After 28–30 ms from the onset of ventricular activation, the potential maximum was invariably located in the upper portion of the anterior or posterior chest surface, above the horizontal plane passing through the corresponding minimum (► Fig. 32.19b). The minima clustered on the lower anterior chest wall (► Fig. 32.19b) while the lower part of the chest was constantly electronegative. This potential distribution accounts for the left axis deviation in the standard ECG and can be attributed to the abnormal sequence of ventricular excitation in LAFB and particularly to the delayed activation of the anterosuperior part of the left ventricular wall.

The motion of the maximum to the upper thoracic areas occurred as follows. In 5 cases out of 11, the maximum did not migrate to the back, as in normal subjects, but moved directly from the left mammary region to the upper sternal or left clavicular areas. In the remaining six cases, it moved to the back and remained there (five cases) or reached the anterior left shoulder. It is suggested that in those patients where the maximum moved dorsally, a lesser degree of asynchronism existed between the activation of the posterior and anterior basal portions of the left ventricle. The variety of patterns observed may result from different degrees of delay in the anterior fascicle and/or from individual variations in the anatomical distribution of the peripheral conducting fibers.

### 32.5.7 Wolff–Parkinson–White Syndrome

It is well known that the Wolff–Parkinson–White (WPW) syndrome is a result of the early excitation of some portions of the ventricles through anomalous conduction pathways. These can be found at almost any location around the AV

ring, including the ventricular septum. Conventional ECGs and VCGs provide useful information on the orientation and direction of propagation of the pre-excitation wavefront, but they do not enable the location of the pre-excited area to be determined reliably. A number of investigations have shown that much more information on the location of the pre-excitation focus can be gained by measuring the instantaneous potential distribution on the entire chest surface [95–102].

Yamada et al. described three types of surface maps in 22 WPW patients on the basis of QRS potential distributions [95]. Type I potential patterns were ascribed to pre-excitation of the posterior aspect of the left ventricle, type II to pre-excitation of the basal part of the right ventricle, and type III to pre-excitation in the proximity of the posterior right AV groove close to the ventricular septum.

In a group of 42 WPW patients, De Ambroggi et al. [96] were able to recognize six types of maps, on the basis of the following considerations and criteria, derived mainly from previous studies on physical, mathematical, and physiological models [1, 103, 104].

At the onset of the delta wave, the pre-excitation wavefront is small and can be approximated by a single equivalent dipole, at least as far as surface potential patterns are concerned. When the two potential extrema on the body surface have nearly equal strength, the dipole is equidistant from the surface extrema and its depth in the chest is proportional to the distance between the extrema. When one extremum is stronger than the other, the dipole is closer to the stronger extremum. The direction of the dipole is approximated by a straight line joining the two extrema. After the delta wave, the body-surface potential patterns are not clearly related to the location of the pre-excitation wavefront. However, the appearance of a sternal minimum indicating a normal right ventricular breakthrough may suggest a left or posterior localization. On the basis of these simple rules, we proposed the following classification of the patients studied.

*Type 1* (► Figs. 32.20a, ► 32.21). During the delta wave, the maps of the 23 patients belonging to type 1 exhibited a potential maximum on the precordial area and a minimum on the back. It is suggested that the pre-excitation wave was located deep in the thorax, most likely in the posterobasal wall of the heart and spread in a postero-anterior direction. Between 40 and 90 ms after the onset of ventricular activation, a second minimum appeared on the sternal area in most patients, while the dorsal minimum reached the upper anterior chest wall. The second minimum was attributed to the right ventricular breakthrough. Its appearance suggested that the right anterior ventricular wall was excited through the normal pathways and was therefore not affected by pre-excitation.

■ **Figure 32.20**

Location of potential maxima (black circles) and minima (white circles) on the chest surface during the delta wave in WPW patients belonging to type 1(a), 2(b), 3(c), 4(d), 5(e), and 6(f). The potential maximum and minimum relating to a given patient are indicated by the numbers inside the circles. (After De Ambroggi et al. [96]. © American Heart Association, Dallas, Texas. Reproduced with permission.)

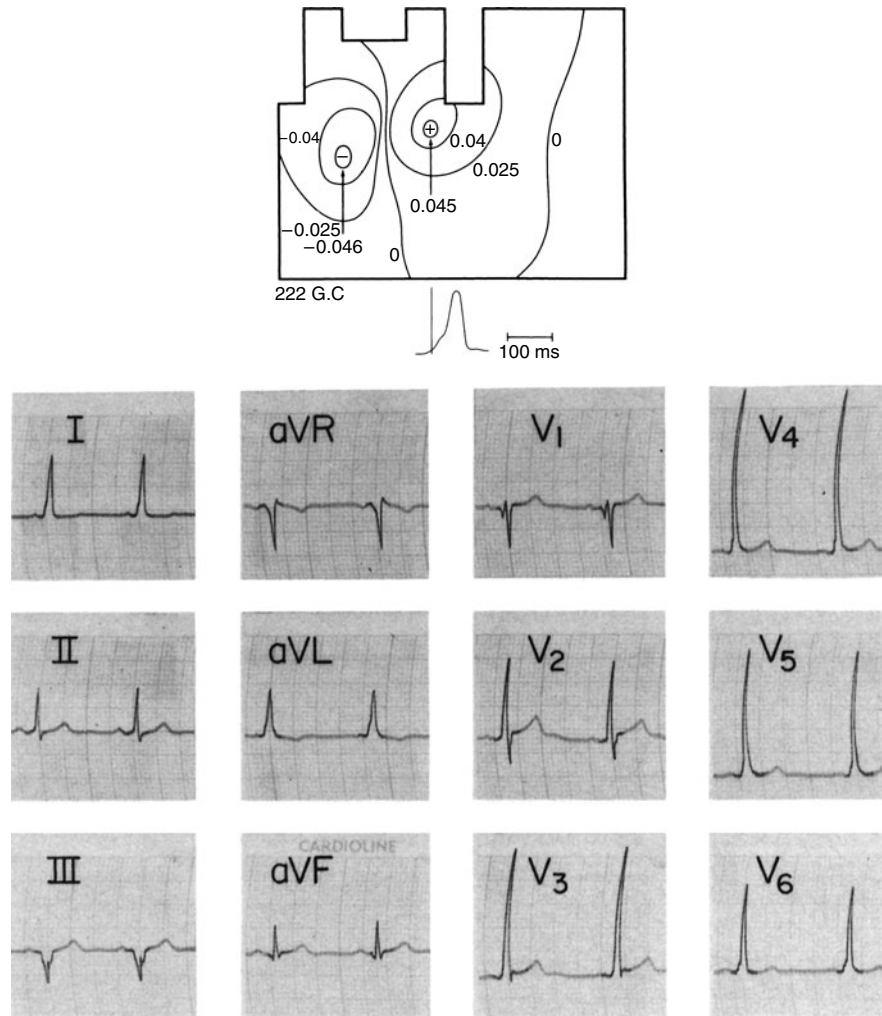

■ Figure 32.21

BSPM during the delta wave, at the instant indicated by the vertical line crossing the reference ECG in a WPW subject belonging to type 1. The 12-lead ECG shows a type A WPW pattern. (After De Ambroggi et al. [96]. © American Heart Association, Dallas, Texas. Reproduced with permission.)

*Type 2* (► Figs. 32.20b, ► 32.22). During the delta wave, in the eight patients belonging to type 2, the minimum was located on the inferior half of the right anterior chest wall and the maximum on the sternal or left mammary region. The location of the minimum and maximum suggests that the pre-excitation wave moved leftward and upward and probably spread from the lateral inferior portion of the AV groove through the right ventricular wall. In no patient of this group did a second minimum appear on the sternal area. This suggested that the right ventricular wall was not activated through the normal conducting pathways.

*Type 3* (► Figs. 32.20c, ► 32.23). During the delta wave in the four type-3 patients, the minimum was initially on the back and then moved to the right subclavicular area; the maximum was located in the mid-sternal area. This potential distribution suggested that an excitation wave was spreading through the anterior wall of the right ventricle from the upper part of the right AV groove, downwards and to the left. A second minimum did not appear in the sternal area in the patients of this group, suggesting that the right ventricular wall was not excited through the normal pathways.

■ **Figure 32.22**

BSPM during the delta wave in a WPW patient belonging to type 2. The ECG shows a type B WPW pattern. (After De Ambroggi et al. [96]. © American Heart Association, Dallas, Texas. Reproduced with permission.)

*Type 4* (▶ Fig. 32.20d). Two patients were classified as type 4. During the delta wave, both the maximum and minimum were located on the left anterior chest wall, with the maximum being on the mammary region, and the minimum on the upper sternal area. This potential distribution suggested that pre-excitation probably started in the anterior portion of the left AV groove or in the anterior portion of the septal AV ring, spreading toward the apex of the left ventricle. A right-sided location was unlikely since neither extreme was on the right-chest surface. In agreement with this interpretation, a second minimum appeared on the sternal area in one patient. This minimum indicated a normal right ventricular breakthrough and showed that pre-excitation did not involve the anterior wall of the right ventricle. In the other patient, there was no second minimum; this patient, however, exhibited a sequence of surface potentials indicating right bundle branch block, which usually prevents the appearance of the sternal minimum.

*Type 5* (● Fig. 32.20e). Type 5 was represented by a single subject. The potential minimum was located in the left axillary region and the maximum on the inferior part of the left anterior chest wall. This potential distribution indicated

93 M.S.

**Figure 32.23**

BSPM during the delta wave in a patient belonging to type 3. The ECG shows a type B WPW pattern. (After De Ambroggi et al. [96]. © American Heart Association, Dallas, Texas. Reproduced with permission.)

that pre-excitation most probably spreads through the left ventricular wall, starting from the anterolateral portion of the left AV groove and then moving downward and to the right.

*Type 6* (● Fig. 32.20f). Type 6 was also represented by a single patient. The ECG showed an unusual pattern of ventricular pre-excitation. A delta wave was not clearly detectable; a small Q wave was present in V1 and the QRS duration was within normal limits. Intracardiac recordings showed a short HV interval but during ajmaline administration, the Q wave in V1 disappeared and the HV interval rose from 15 to 40 ms. At the onset of ventricular excitation, the potential distribution was characterized by a minimum at the right lower sternal border and a maximum on the left scapular area. Twenty five minutes after the onset of ventricular activation, a normal sequence of potential patterns was observed. The initial location of the minimum and maximum indicated that an excitation wave was probably spreading in an antero-posterior direction, leftward and slightly superiorly. An acceptable location for such a wavefront might be in the right

side of the interventricular septum. The most likely mechanism for right septal pre-excitation would be through Mahaim fibers, stemming from the initial part of the right bundle branch.

In a number of patients belonging to types 1, 2, 3, 5, and 6, the site of pre-excitation as deduced from surface maps was in good agreement with that independently established using intracardiac recordings, epicardial maps, or surgical results [105].

Benson et al. [99] attempted to localize the site of pre-excitation in 49 WPW patients, where the location of the anomalous pathway was determined by intracardiac electrophysiological studies or surgical ablation. These authors were able to predict accurately at least seven pre-excitation sites on the basis of surface potential distribution during the QRS (at 40 ms after the onset of delta wave) and ST segment. Moreover, they found the potential distribution during early ST segment more useful than QRS maps for localizing the pre-excited area. Their classification was in reasonably good agreement with our classification previously presented.

Kamakura et al. [100] studied 41 WPW patients to determine the most reliable index for predicting the site of a single accessory pathway. They found that the location of the ventricular insertion of the accessory AV connection (determined at electrophysiological study or during surgery) is well estimated at the time the amplitude of the negative surface potential is  $-0.15$  mV. On the basis of the chest position of the minimum with a potential of  $-0.15$  mV, the location of the accessory AV connection was correctly predicted in 36 of 41 cases.

Liebman et al. [101] recorded BSPM in 34 patients with WPW syndrome in whom the site of ventricular insertion of the anomalous AV connection was localized by an electrophysiologic study and, in 18 cases, at surgery. Attempts were made to identify the 17 ventricular insertion sites along the AV groove described by Guiraudon et al. [106] mainly using QRS analysis (location of the initial minimum, occurrence of right ventricular breakthrough). The ventricular insertion sites determined by BSPM and EPS at surgery were identical or within one mapping site (i.e., 1.5 cm or less) in 14 of 18 cases; three of the four exceptions had more than one accessory AV connection, and the other had a very broad ventricular insertion. BSPM and EPS locations of accessory pathways correlated very well in the 34 cases despite the fact that BSPM determined the ventricular insertion and EPS the atrial insertion site of the accessory AV connection. BSPMs of QRS were very accurate in predicting the right ventricular versus left ventricular postero-septal AV connections, known to be particularly difficult at EPS in three of four surgical cases. Typical right ventricular breakthrough occurs in all patients with left ventricular free wall accessory connections, but was not observed in cases with right ventricular free wall or anteroseptal accessory AV connections.

In 1993, Dubuc et al. [102] reported on the use of BSPM to guide catheter ablation of accessory AV connection in 30 WPW patients. The catheter used for radiofrequency ablation was first placed in the vicinity of the ventricular pre-excitation site predicted by BSPMs previously recorded during the delta wave. BSPMs were then recorded during pacing with this catheter; the comparison between the pre-excited and paced BSPMs indicated whether the pacing site was too anterior or posterior with respect to the pre-excitation site, and the catheter was moved accordingly. This process was repeated until the pre-excited and paced BSPMs were almost identical, i.e., showed high correlation coefficient ( $>0.8$ ) during the delta wave, and ablation was then attempted. In this way, it was possible to successfully ablate the accessory pathway in 93% of cases.

## 32.5.8 Arrhythmogenic Cardiopathies

### 32.5.8.1 Postinfarction Ventricular Tachycardias: Identification of Site of Origin of Ventricular Tachycardias

Extensive investigations were made by Sippens-Groenewegen et al. to assess the value of BSPMs in localizing the site of origin of ectopic ventricular activation in patients with a structurally normal heart and with myocardial infarction [107–109]. In patients with normal cardiac anatomy, the QRS maps allowed discrimination among 38 different LV and RV segments of ectopic endocardial impulse formation [107]. The use of 62 lead BSPMs instead of the 12-lead ECG during endocardial pace mapping technique enhanced the localization resolution of this technique and thus enabled more precise identification of the site of origin of postinfarction VT episodes [108].

In patients with previous anterior and inferior myocardial infarction, the same authors demonstrated that QRS integral maps enabled a precise localization of the origin of postinfarction ventricular tachycardia in 62% and regional

approximation (identification of a segment immediately adjacent to the actual endocardial segment of origin) in 30% of tachycardias [109].

More recently, McClelland et al [110] were able to compute epicardial potentials from BSPM (80 leads) using an inverse solution method. They were able to reconstruct in 5 patients epicardial isochronal maps demonstrating the exit site and the re-entry circuit of ventricular tachycardias.

### 32.5.8.2 Susceptibility to Ventricular Arrhythmias

Eigenvector analysis [111] was applied to QRST integral maps of two groups of patients with old myocardial infarction (11 patients with episodes of sustained ventricular tachycardia and 62 without arrhythmias) and in a control group of healthy subjects [112]. This method makes possible the detection and quantification of nondipolar components not evident on visual inspection of the integral maps. The cumulative contribution of the eigenvectors beyond the third to an individual map, expressed as percentage contribution of the total map content, has been considered a “nondipolar content” of that map. On average, the nondipolar content was significantly greater in patients with MI than in controls ( $8.3 \pm 6.4\%$  vs  $4.1 \pm 2.2\%$ ,  $p < 0.001$ ) and, among patients, in those with ventricular tachycardia ( $7.2 \pm 5.3\%$  vs  $16.6 \pm 8.5\%$ ,  $p < 0.001$ ). These findings were in agreement with those reported by Abildskov et al. [113]. Thus, the high nondipolar content of QRST maps in patients with ventricular tachycardia suggests the presence of local disparities of repolarization and it may be considered a useful marker of susceptibility to malignant arrhythmias.

Huble-Kozey et al. [114] derived 16 eigenvectors from the total set of 204 QRST maps (102 patients with ventricular tachyarrhythmias and 102 patients without) but did not find a statistically significant difference in dipolar content between the two groups ( $13.1 \pm 9.7$  vs  $12.9 \pm 10.2\%$ ,  $p > 0.05$ ). Because the nondipolar content did not perform well in their study population, the authors examined how individual eigenvector patterns contribute to QRST integral maps in each group of patients. Statistically significant differences were found between the values of Karhunen-Loeve coefficients in VT and non-VT groups for the 6th, 4th, 13th, 5th, 1st, 2nd, and 11th eigenvectors, in order of significance levels. Using stepwise discriminant analysis, they selected features subsets that best discriminated between the two groups. For an optimal set of eight spatial features, the sensitivity and specificity of the classifier for detecting patients with VT in 1,000 test sets were  $90 \pm 4\%$  and  $78 \pm 6\%$ , respectively. The authors concluded that the multiple body-surface ECGs contain valuable spatial features that can identify the presence of an arrhythmogenic substrate in the myocardium of patients at risk of ventricular arrhythmias.

Recently, Korhonen et al. [115] studied the complexity of T-wave morphology in BSPM of patients with recent myocardial infarction and cardiac dysfunction, by applying principal component analysis. They found that the 3rd principal component derived from BSPM was a significant predictor of arrhythmic events in this population.

### 32.5.8.3 BSPM and Ventricular Late Potentials

Vulnerability to arrhythmias has also been related to the existence of areas of delayed conduction at the end of the ventricular activation process. Ventricular late potentials recorded on signal-averaged ECG are the expression of this phenomenon. BSPM can be applied to detect these high-frequency, low-amplitude potentials [116, 117]. Maps not only made it possible to reveal the presence of late potentials, but also to determine the spatial distribution of late potentials in patients with ventricular tachycardia. Thus, BSPM may provide additional information about the thoracic location of ventricular late potentials, which can be related to the sites of conduction delay and possibly to the sites of origin of ventricular tachycardia.

### 32.5.8.4 Long QT Syndrome

BSPMs in patients with idiopathic long QT syndrome were described by De Ambroggi et al. [118]. No peculiar features were observed during the QRS interval, while the ventricular repolarization presented some abnormalities in addition to QT prolongation.

■ Figure 32.24

Mean integral maps of QRST and ST-T intervals in the control and LQTS groups. Difference maps are illustrated in the third column. Values are expressed in  $\mu\text{Vs}$ . (After De Ambroggi et al. [118]. © American Heart Association, Dallas, Texas. Reproduced with permission.)

The visual inspection of instantaneous BSPMs revealed that the potential distributions were grossly abnormal (location of the potential extrema, presence of multiple peaks) in only a few cases. On the other hand, in most patients, BSPMs revealed less marked abnormalities in the instantaneous potential distribution. For instance, in several patients the negative potentials during the entire repolarization covered an area on the anterior thorax larger than in control subjects.

Differences between normals and LQTS patients were better quantified by analyzing ST-T and QRST integral maps. The mean integral map from the LQTS patients showed a potential distribution similar to that of the mean integral map from the control subjects. Nevertheless, the difference map (LQTS mean map minus control mean map) showed that LQTS patients had lower values on the inferior half of the trunk and on the right anterior thorax and higher values on the left anterior thorax compared with control subjects (► Fig. 32.24). In 13 patients, the negative values covered almost entirely the right anterior thorax. In six patients, there was a multipole distribution of the integral values. The prominent negative area on the anterior chest in LQTS patients could result from a delayed repolarization of the underlying anterior wall so that it remains electronegative longer than other cardiac regions. Moreover, the multipole distribution may reflect local inequalities in recovery times. ST-T integral maps were substantially similar to QRST maps, but a multipole distribution was observed in a few more patients.

Eigenvector analysis [111] was also applied to QRST and ST-T integral maps. As already mentioned, this method makes possible the detection and quantification of nondipolar components not evident on visual inspection of the integral maps. The percent contribution of nondipolar eigenvectors (all eigenvectors beyond the third) to maps was significantly higher in LQTS patients than in normals. Moreover, eight patients who had a high nondipolar content did not show a multipole distribution on their integral maps. This demonstrates that eigenvector analysis can detect nondipolar components not evident on integral maps.

To identify markers of dispersion of the ventricular repolarization, in a subsequent investigation on 40 patients with LQTS [119], we applied principal component analysis to all the recorded ST-T waves in each subject studied. We defined the ratio between the information content of the first principal component and the total information of the original data as “similarity index.” Actually, a high value of similarity index indicates a great similarity of all waveforms to one fundamental waveform, that is, a great similarity of all waves to each other. On the contrary, a low value of similarity index indicates a large variety of ST-T waves and is considered a marker of repolarization disparities. In the 40 patients affected by congenital LQTS [119], the mean value of the similarity index was significantly lower than in healthy control subjects ( $49 \pm 10$  vs  $77 \pm 8\%$ ,  $p < 0.0001$ ). A value lower than 61%, corresponding to two standard deviations below the mean value for controls, was found in 35 of 40 patients and in only one control subject (sensitivity 87%, specificity 96%). In our experience, the similarity index has proved to be a more sensitive marker than multipole distribution of QRST integral maps in revealing electrical disparities of ventricular repolarization.

### 32.5.8.5 Arrhythmogenic Right Ventricular Cardiomyopathy

Characteristic features of BSPMs were described in patients with arrhythmogenic right ventricular cardiomyopathy (ARVC). De Ambroggi et al. studied 22 patients affected by ARVC, nine with episodes of sustained ventricular tachycardias (VT) and 13 without [120]. The QRST integral maps showed in most ARVC patients a larger than normal area of negative values on the right anterior thorax. This abnormal pattern could be explained by a delayed repolarization of the right ventricle. Nevertheless, it was not related to the occurrence of VT in our patient population. To detect minor heterogeneities of ventricular repolarization, the principal component analysis was applied to the 62 ST-T waves recorded in each subject. We assumed that a low value of the first or of the first three components (Co 1, 2, 3) indicates a greater than normal variety of the ST-T waves, a likely expression of a more complex recovery process. The mean values of the first three components were not significantly different in ARVC patients and in control subjects. Nevertheless, considering the two subsets of patients with and without VT, the values of Co 1, of Co 1 + 2, and of Co 1 + 2 + 3 were significantly lower in the group of ARVC patients with VT. Values of Co 1 < 69% (equal to one SD below the mean value for controls) were found in six of nine VT patients and in one patient without VT (sensitivity 67%, specificity 92%). A low value of Co 1 was the only variable significantly associated with the occurrence of VT.

QRST integral maps with an abnormal negative area on the anterior thorax were also observed by Peeters et al. [121] in eight out of eight patients with ARVC, but in only two of eight patients with idiopathic right ventricular tachycardia.

### 32.5.8.6 Brugada Syndrome

The Brugada syndrome is a familial, “primary” electrical disease of the heart due to gene mutations encoding for the sodium channel and is characterized by a delayed activation of the right ventricle, with a QRS complex resembling that of right bundle branch block in V1, early ST elevation (J wave) in the right precordial leads, normal QT duration, inducibility of ventricular tachycardia, and a high risk of sudden cardiac death [122].

ECG changes have been quantified by 120-lead BSPMs: the QRS integrals were higher over the upper-right precordium and lower than normal over the lower left precordium; steeper negative ST gradients compared to normal were present over the upper left precordium and more positive ST gradients compared to normal over the lower left precordium [123].

Early ST elevation ( $\geq 0.2$  mV) was observed on a variable area over the right precordium. If this area is larger than  $50 \text{ cm}^2$ , it has a 92% positive and a 62% negative predictive value for inducibility of ventricular tachycardia, but similar predictive power was found for ventricular late potentials in the same patients [124].

Amplitude of maximal ST elevation was also used to differentiate Brugada syndrome patients with inducible ventricular tachycardia from asymptomatic patients [125].

## 32.6 Conclusions

The most general advantage of BSPMs is the fact that they record cardiac potentials from broad areas of the chest, thus enabling the detection of significant physiologic and possibly diagnostic information outside the precordial regions usually explored. Moreover, BSPMs provide the spatial as well as the temporal and amplitude components of cardiac electrical activity, whereas the ECG scalar waveforms present only the voltage variation with time in a given site.

As reported in the previous pages, investigations by different authors so far published clearly demonstrated a higher diagnostic content of BSPMs, compared with conventional ECG, in various pathological conditions.

Nevertheless, a widespread or even limited clinical application beyond the research laboratories of BSPM has not occurred up to day for several reasons: (a) the recording and processing of large numbers of leads and the displaying of maps have been complex and time-consuming, (b) a completely automated instrumentation was not commercially available, (c) use of many lead systems in different laboratories, differing in the number and placement of leads, and (d) difficulty in interpreting BSPM. The last reason is probably the most important obstacle that hampers the clinical use of BSPM.

In recent years, some of these obstacles have been overcome. BSPM recording systems, even those not widely marketed, have been (and can) relatively easily be developed and produced by several laboratories. Today's computer facilities make the recording and the data analysis easier than in the past. The time for applying electrodes and for data acquisition and analysis has been reduced considerably. Procedures, which reduce the number of leads that are necessary for reconstructing surface maps without losing too much information, have also been proposed; among these, the 32-lead system of Lux is the most commonly used [126]. Moreover, methods for converting multilead ECGs from one lead system to another have been proposed and satisfactorily applied [10].

The problem of interpreting surface maps still remains; in general, it may be approached essentially in two ways. The first approach is based on statistical methods, that is, defining the normal variability range of a number of parameters derived from maps relating to healthy subjects of different age, sex, and body shape, and then comparing these parameters by means of multivariate statistical procedures with those recorded from patients. The second approach is "deterministic"; that is, it consists of establishing the relationships between the intracardiac current sources (i.e., number, shape, location, and motion of excitation wavefronts and sequence of repolarization) and surface potential distribution (i.e., number, location, and motion of potential maxima and minima). This can be made in different ways, by using physiological or mathematical models. For instance, the distribution of currents and potentials has been determined experimentally in conducting media surrounding isolated hearts [127] thus enabling epicardial potentials to be compared with potentials recorded at a distance from the heart. Intracardiac current sources of known location have been produced by simultaneously stimulating the heart at multiple sites [128]. This allowed surface potential patterns to be correlated with known distributions of generators. The relationships between epicardial and body-surface potentials during activation and recovery were studied in intact chimpanzees [129, 130] and mathematical procedures for solving the direct and inverse problem (i.e., calculating surface potentials from internal sources and vice versa) were proposed by different authors (see [Chaps. 8](#) and [9](#)).

In the intact dog, Spach et al. succeeded in calculating accurately body-surface potentials from epicardial potential distributions during activation and recovery [131]. As regards the inverse problem, epicardial potentials have been calculated from potential distributions at the body surface in dogs [132–137]. In this respect, particularly important are the studies of Rudy and coworkers. They demonstrated the ability to compute noninvasively epicardial potential distribution and epicardial activation sequences from measured surface potentials. They called this new electrocardiographic modality as "ECG imaging," which, of necessity, has to utilize BSPM recording. The ECG imaging has been successfully applied in humans [138–141], using geometrical information from computed tomography and a mathematical algorithm, in different situations including the normal heart, a heart with a conduction disorder (right bundle branch block), focal activation initiated by right or left ventricular pacing, focal atrial tachycardia and flutter. A simplified method of inverse solution, which adopts a general torso model in which the same anatomic data are used irrespective of the body habitus, was applied by McClelland et al [110]. Despite these limitations they were able to reconstruct epicardial potential or isochronal maps identifying the left ventricular pacing site or indicating the exit site and the re-entry circuit of ventricular tachycardias. Very recently improvements to the inverse solution method were made by A. van Oosterom and coworkers [142]. The required computation time and the quality of the results obtained should favour the applications of this inverse procedure in a clinical setting.

In addition to all the reasons discussed above, the lack of expansion in the clinical setting of BSPM, which indeed can be considered an "advanced electrocardiographic method," is partially due to the fact that electrocardiology in recent years has lost some of its importance compared with newer sophisticated imaging techniques. The anatomic and functional information on several heart conditions (e.g., hypertrophy, location and extension of myocardial infarction, and so on) that, in the past, was obtained with varying degrees of accuracy by means of electrocardiographic techniques, can be more precisely and directly obtained today by other techniques such as echocardiography, magnetic resonance, multislice computed tomography, and nuclear imaging. On the other hand, electrocardiology still has a unique, primary role in the field of arrhythmias and conduction disturbances, into which no other technique can provide relevant insights. In particular, ECG imaging, based on the solution of the "inverse problem," which is the final aim of electrocardiology, hopefully will be able in the near future to provide, noninvasively, information on the epicardial and intramural excitation and recovery processes. This could give the possibility of identifying, with sufficient accuracy, intramural heterogeneities, transmural re-entry and intramural focal arrhythmias, and of defining ischemic or necrotic areas within the myocardium. The future of body-surface potential maps should be in that direction.

sVT = sustained Ventricular Tachycardia

### 33.1 Introduction

---

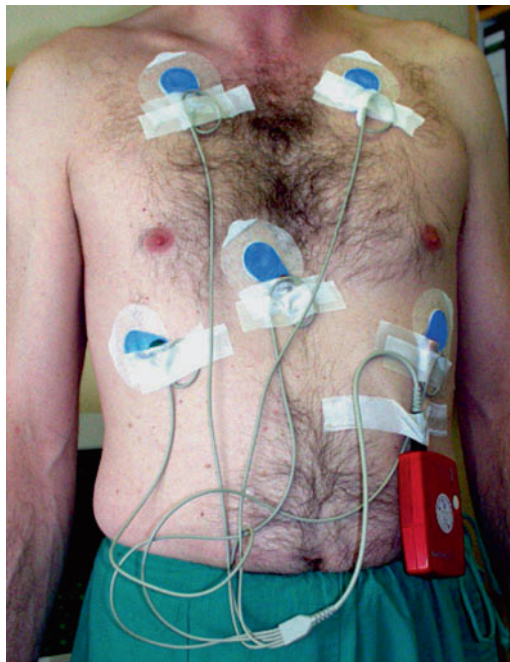

Ambulatory electrocardiography (AECG) is a diagnostic procedure, which involves recording the electrical activity of the heart using a technique first described by Holter [1–5]. The method is therefore also known as Holter electrocardiography

or Holter (ECG) monitoring. The technique has been most commonly employed for the detection of arrhythmias and transient ST-T changes. However, due to increased use of multichannel, digitized, and telemetered signals, this traditional use has been expanded to the analysis of heart-rate variability (HRV), heart-rate turbulence (HRT), QT-dispersion (QTD) and variability (QTV), and signal averaging of long-term ECGs for retrieval of P-wave duration (PWD) and ventricular late potentials (VLP). Current AECG equipment consists of a recorder and an analysis system and provides the basis for the detection and analysis of the above-mentioned parameters. A complete set of recommendations for equipment standards was proposed in 1985 [6], and more recently the official ACC/AHA guidelines on technical aspects and clinical applications of AECG have been published [7].

## 33.2 Holter Monitoring Hardware and Software

### 33.2.1 Electrodes and Electrode Preparations

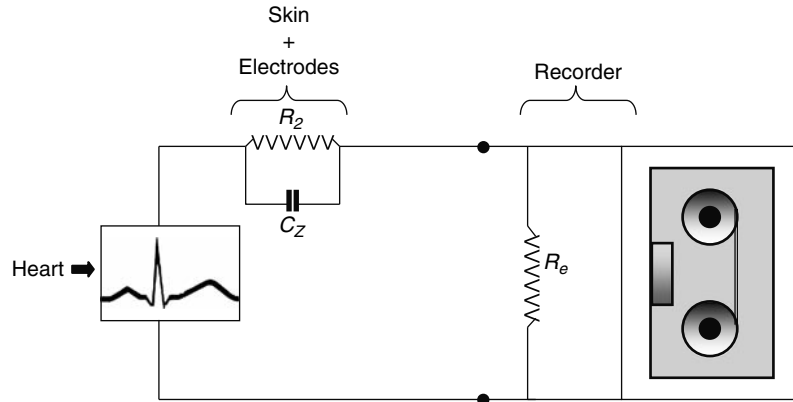

By convention, bipolar leads (see [Chap. 11](#)) are normally used to record a potential difference between two sites on the thorax. The electrodes most commonly employed are disposable electrodes that are pregelled and self-adhesive. They usually have a true silver/silver chloride sensing element mounted on a self-adhesive tape or foam material, which is nonirritating and hypoallergenic to skin ([Fig. 33.1](#)). It is the electrode adhesiveness and extent of skin irritation that generally affect the quality of the ambulatory electrocardiographic signal by producing baseline wander, a low signal-to-noise ratio, and a short duration of adequate performance. The coupling of the skin and electrode (the skin–electrode interface) acts as an additional circuit with a resistance and capacitance between the heart and the recorder ([Fig. 33.2](#)).

**Figure 33.1**

Electrode arrangement for three-channel AECG recording. Five pregelled disposable electrodes are used to record a  $CM_5$  lead and a bipolar transthoracic lead. The fifth electrode is an indifferent electrode. The choice of these two bipolar leads provides high-amplitude ECG signals and the possibility of detecting the majority of changes in repolarization.

■ Figure 33.2

A model of the electrical circuit utilized in AECG recording. The coupling between skin and electrodes consists of a resistance and capacitance in parallel, which is responsible for diminishing the amplitude of the ECG signal if its impedance is high.

The total impedance of this circuit depends mainly on the preparation of the skin. The surface-skin oil and dirt should be removed prior to recording by cleaning the skin with gauze moistened with ether, making the skin slightly erythematous. If necessary, the skin over the electrode area should be shaved, gently abraded with emery tape, and thoroughly cleansed with an alcohol swab. One electrode can then be placed on each of the prepared skin-surface sites (● Fig. 33.1), taking care to place the gelled pad firmly in contact with the abraded skin surface. The adequacy of the skin preparation for obtaining an optimum electrocardiographic signal can be checked by measuring the electrical impedance between the positive and negative poles of each bipolar lead. The measured resistance between electrodes should be  $\leq 5 \text{ k}\Omega$ , preferably  $\leq 2 \text{ k}\Omega$ . The impedance increases when the frequency of the signal decreases.

### 33.2.2 Selection of Lead Positions

Most AECG recorders utilize five or seven electrodes attached to the chest, which record two or three bipolar leads onto two or three channels [7–9], although systems employing multiple unipolar leads are now commercially available allowing a 12-lead ECG to be recorded. The first two channels may be used for arrhythmia and ischemia in the inferior myocardial wall. The lead positions recommended by the American Heart Association [6] are illustrated in ● Fig. 33.1, which provides an example of a three-bipolar lead/three-channel lead positioning. The practical advantages of multichannel Holter recording are increased reliability of the recorded ECG, improved recognition of ectopic cardiac beats, and enhanced detection of myocardial ischemia.

#### 33.2.2.1 Leads for Recording Arrhythmias

A variety of bipolar lead configurations are used, the most common being a modified  $V_5$  ( $CM_5$ ), a modified  $V_3$  ( $CM_3$ ) or  $V_2$  ( $CM_2$ ), and a modified inferior lead (aVR, reverse Nehb I, Nehb D). No study has yet established the superiority of one lead over another; indeed, the choice of leads will differ according to the aim of the individual examination. A bipolar lead with positive electrode in the  $V_1$  or  $V_2$  position usually identifies atrial activity most clearly, showing the characteristic QRS patterns of right and left bundle branch block which help to distinguish supraventricular ectopic beats with aberrant conduction from ventricular ectopic beats. A bipolar lead with positive electrode in the  $V_5$  position and the negative electrode in one of several other positions, such as the manubrium (lead  $CM_5$ ), is the most sensitive single lead for the detection of ischemic ST-segment depression and provides a high-voltage ECG signal. However, with each of these two leads, some problems can occur in the presence of myocardial ischemia. One problem is that ST-segment depression

might exist in only one lead (usually  $V_5$ ), while the second ( $V_1$  or  $V_2$ ) remains quite normal, as shown in [Fig. 33.3](#). If, during the period of ischemia, the first lead becomes unsuitable due to artifacts, some false-positive diagnoses may be made. For example, in [Fig. 33.3](#), the run of ventricular tachycardia (VT) might have been interpreted as not being a result of myocardial ischemia, so, for example, an antiarrhythmic drug (AAD) would have been prescribed instead of an antianginal drug. A second problem is that leads  $V_1$  and  $V_5$  may fail to record ST-segment elevation owing to spasm of the right coronary artery or circumflex coronary artery. In such a situation, an inferior lead is useful, and the most convenient one is probably a bipolar anteroposterior lead. In [Fig. 33.4](#), lead  $V_5$  shows ST-segment depression (mirror image), while the anteroposterior lead shows ST-segment elevation owing to spasm of the right coronary artery as was demonstrated by coronary angiography. Thus, where coronary artery disease (CAD) is concerned, a combination of a bipolar  $V_5$ -type lead and an anteroposterior or inferior lead is probably the best. With standard 12-lead ECG, a simultaneous recording of leads III or aVF or Nehb J together with  $V_3$  can detect almost all cases of ST-segment elevation. With 3-lead Holter monitoring, a combination of two bipolar precordial leads together with an inferior lead is recommended for ST-segment elevation monitoring. In the absence of suspected CAD, the recording of  $V_1$ - or  $V_2$ -type ( $CM_2$ ) and  $V_5$ -type ( $CM_5$ ) leads (see [Chap. 11](#)) provides the best chance of obtaining an ECG tracing with sufficient details to make an accurate diagnosis of any cardiac arrhythmia.

**Figure 33.3**

Sinus rhythm with a run of VT in a patient with variant angina. The two-channel recording confirms the diagnosis showing the characteristic marked ST elevation in the lower  $CM_5$  lead. In the top channel (like  $V_1$ ), only minor changes in repolarization occur. If the second lead had not been recorded, the variant angina would not have been detected and the VT would be considered as nonischemic in origin.

**Figure 33.4**

A two-channel recording in variant angina. The *left-hand* panel shows the baseline recordings while the *right-hand* panel shows the acute changes in the same patient. Note the characteristic marked ST elevation in the lower right  $CM_5$  lead, whereas the mirror image in the other lead (like aVF) on its own might have led to a diagnosis of myocardial ischemia, but not of the variant form in the presence of chest pain.

### 33.2.2.2 Leads for Recording ST-Segment Depression (Myocardial Ischemia)

For the detection of ischemic ST-segment depression, specially adapted 3-lead Holter recordings are recommended. In a study of Lanza et al. [8] of simultaneous recordings of a 3-lead AECG and a conventional 12-lead ECG recording during an exercise test, CM<sub>5</sub> was the single lead with the highest sensitivity (89%) in detecting myocardial ischemia. The addition of CM<sub>3</sub> to CM<sub>5</sub> increased the sensitivity to 94%, particularly for improved detection of isolated inferior myocardial ischemia, and the combination of all 3 AECG leads had a sensitivity of 96% with only 2% more than the best combination of 2 AECG leads (CM<sub>5</sub> plus an inferior lead). Osterhues et al. [9] could detect myocardial ischemia in 23 out of 54 patients (43%) with single vessel disease using standard CM<sub>2</sub> and CM<sub>5</sub> Holter leads (total number of ischemic episodes = 372). When adding a bipolar Nehb D-like lead, the detection rate could be increased to 30 out of 54 patients (55%, total number of ischemic episodes = 1,048), and the Nehb D-like lead was most sensitive for the detection of inferior ischemia in patients with right CAD. Alternatively, the use of an inverse Nehb J lead, in which the positive electrode is placed on the left posterior axillary line, may enhance the sensitivity to detect ischemia, as well [10]. Thus, routine identification of ischemic ST-segment deviation may only require two leads, most favorably the combination of CM<sub>5</sub> with an inferior lead (aVF, inverse Nehb J, Nehb D) [11].

### 33.2.3 Electrode Leads and Cable

Electrode lead wires are individually insulated and have a silver contact (► Fig. 33.1). The recorder cable is a shielded cable connected to the Holter recorder and is generally specific for each manufacturer's equipment. The electrode wires and the cable can both malfunction and be sources of artifacts.

### 33.2.4 Esophageal and Intracardiac Leads

One of the major problems in AECG with conventional electrode placements is the accurate detection of atrial depolarization. On account of various artifacts, P waves cannot always be recognized on a two- or three-channel recording, even during sinus rhythm. Moreover, during ectopic beats or tachycardia, the recognition of the P wave is often problematic. Therefore, the performance of ambulatory monitoring for the accurate diagnosis of arrhythmias remains doubtful compared to the more definitive results of an electrophysiological study (EPS). Several groups have attempted to record atrial activity during AECG using an esophageal bipolar lead [12, 13]. When the patient swallows the capsule, which contains a bipolar electrode, it is positioned so as to obtain an ECG signal with sufficient amplitude after the capsule has dissolved. The electrode wire should be fixed to the patient's cheek. However, difficulties experienced to date indicate that this technique cannot be easily used for the following reasons:

1. Difficulty is encountered in swallowing the capsule on account of its size (30 mm length).
2. The positioning of the electrode for recording an appropriate atrial ECG signal without significant ventricular depolarization is time consuming.

Nevertheless, the approach has been proved to be of considerable diagnostic value [13].

Some centers have preferred to use endoatrial leads to record atrial activity using a floating-catheter electrode. This technique permits a better atrial ECG signal to be obtained than does an esophageal lead. However, this procedure converts the AECG monitoring to an invasive examination [14]. The risk of local and general complications exists even if it appears relatively low. Thus, the use of intracardiac atrial leads remains confined to a few cases where an earlier attempt at recording the arrhythmia was unsuccessful and did not provide an exact diagnosis in patients in whom it is essential to determine the mechanism of the arrhythmia. In this case, AECG monitoring competes with an EPS because the benefits of the noninvasive technique disappear.

In practice, the interest of this technique remains confined to some cases where the knowledge of the exact mode of initiation of a tachycardia is useful for the management of the patient or in other patients in whom electrophysiological studies have been unable to provoke the arrhythmia.

### 33.2.5 Holter Recorders

Modern conventional AECG recorders are small, light-weight devices (110–320 g) that record two or three bipolar leads. They use a quartz digital clock and a separate recording track to keep time. The recorders are generally powered by a 9-V disposable alkaline battery (only rarely a rechargeable nickel–cadmium battery) and a calibration signal automatically inserted when the device is energized. In addition, a patient-activated event marker is conveniently placed on the device surface for the patient to note an event or indicate the presence of symptoms. The conventional format of the “first-generation” Holter recorders has been magnetic cassette-tape for directly recording the varying DC signals via the recording head onto the magnetic tape. Frequency-modulated (FM) systems are also available, although they are somewhat more prone to the generation of artifact. The tape-transport mechanism is driven by a hysteresis-synchronous motor assembly at speeds that are usually in the range of 1–2 mm/s; the speed is kept constant by an optical speed sensor on the flywheel and a crystal-controlled phase-locked loop.

#### 33.2.5.1 Tape Recorders

Typically, such a unit records the ECG signal for between 24 and 48 h on a cassette or small magnetic tape, providing a permanent record of all electrical activity throughout the recording period and a playback as well as interrogation of the entire recording period (so-called “full disclosure”).  Figure 33.5a shows the first Holter recorder developed by Avionics based on reel-to-reel magnetic-tape recording. This technology is adequate to detect abnormalities of conduction or rhythm, but it may be limited for recording low-frequency signals such as the ST segment. In some amplitude-modulated (AM) systems, an inadequate low-frequency response or a marked phase shift from the higher-frequency QRS signal may cause an artifactual distortion of the ST segment, which may be incorrectly interpreted as ischemic. It is usually claimed that only the FM type of recording system provides the necessary low-frequency response (down to 0.05 Hz) and less phase shift for accurate ST recording and reproduction, but this has to be counterbalanced against the higher costs, more baseline noise, and less clear display of such systems. This fact has been commented upon by Bragg-Remschell et al. [15]. More recent AM systems have been designed with improved low-frequency recording and playback characteristics and shown to record accurately ST-segment deviations [16, 17] and even T-wave alternans [18].

Caution should, therefore, be exercised with the older types of recorders in case ST-segment “depression” is a technical rather than a physiological phenomenon. One former development (Oxford Medical) has been the incorporation of a microprocessor inside the Holter recording unit itself so that signal analysis and classification can be carried out in real time. The ECG is also recorded on tape continuously because most cardiologists wish to have the acquired signal available for visual confirmation and assessment of any arrhythmia or ST-segment shift. Lastly, but not least, it should be noted

 Figure 33.5

(a) Avionics 660 magnetic-tape recording system (one of the earliest systems used). (b) Mortara 12-lead Holter recorder (modern, solid-state recorder).

that regardless of whether AM or FM recording techniques are used, the tape itself may stretch and consequently distort the electrical signal.

### 33.2.5.2 Solid-State Recorders

Owing to the rapidly evolving technologies, nowadays direct recordings of the ECG signal in a digital format using solid-state recording devices are available (“second-generation” Holter recorders, [▶ Fig. 33.5b](#)). Such direct digital recording avoids all of the biases introduced by the mechanical features of tape-recording devices and problems of analog recording formats that require analog-to-digital conversion before quantitative analysis. Digital ECG signals can be recorded up to 1,000 samples/s, which allow for the extremely accurate reproduction of the ECG signal necessary for highly sophisticated analysis methods like signal averaging or T-wave alternans measurements. Solid-state ECG recordings can be analyzed immediately and rapidly, and some recorders are equipped with microprocessors that can provide “on-line analysis” of the QRS complex and the ST segment and T waves as they are acquired. Also, the patient can be given feedback immediately in case of the detection of specific abnormalities, for example, ST-segment deviations. In addition, the solid-state format provides for ready electronic data transfer to a central analyzing unit. Limitations of this technology are the limited storage capacity of digital data, reliance on a computer algorithm in case of online analysis for identification of specific abnormalities, and the expense of the devices.

A full 24-h recording includes approximately 100,000 QRS-T complexes and requires about 20 megabytes (MB) of storage per channel. Therefore, compression of data is necessary, and at least two methods have been proposed, the “lossy” compression with very high compression ratios and the “loss-less” compression technique combined with an enhanced storage capacity. The problem with “lossy” compression is that the user is entirely dependent on the reliability of the microprocessor to distinguish important physiological abnormalities from artifact or wandering baseline, since, because of the lack of “full disclosure,” confirmations of the decisions of the microcomputer cannot be made from the primary data, which are not recorded in their entirety and cannot be retrieved without error. Moreover, the accuracy of online interpretations may also be different for arrhythmia versus ischemia analyses [19]. However, it is essential for a physician using Holter monitoring that representative ECG tracings from all ischemic or arrhythmic episodes be confirmed by an experienced physician or technician, and thus, the lack of full disclosure may limit the reliability of the “lossy” compression method. The “loss-less” compression method in combination with enhanced storage capacity compresses ECG data by a factor of 3–5 by reducing the sampling rate from 256 to 64 or 16 Hz, respectively. Later, when the data are recalled, playback computer techniques recreate these abbreviated waveforms, whose sampling is often “weighted” about the R wave, to reproduce stored “full-disclosure” continuous electrocardiographic data. Some manufacturers have adopted the solid-state storage to their regular electrocardiographic instruments, whereby the recorder stores two channels of ECGs over 24 or 48 h on the recorder device, which subsequently is interfaced to the manufacturer’s standard ECG cart or a data printer to provide 24 hourly continuous “full disclosure” printouts of all data recorded for visual interpretation.

Modern solid-state recorder devices provide special features such as an LCD display to control the quality of the ECG immediately after placement of the electrodes either by direct display (e.g., MT-101 from Schiller™, Lifecard from Delmar/Reynolds™, CardioMem from Getemed™), or by transfer via infrared to a Palm™ microcomputer (Medilog AR4 or AR12 from Oxford Instruments™). Some devices have a special loudspeaker incorporated for patient interaction, and most recorders provide pacemaker detection. Some provide recording of thoracic or respiratory activity as well (e.g., CardioMem from Getemed™, Medilog AR4 or AR12 from Oxford Instruments™). After the transfer of the full 24- or 48-h digital data, most analysis systems allow not only the analysis and presentation of normal and abnormal QRS complexes including bradycardias or tachycardias, but also the analysis of ST-segment deviations, HRV, QT duration and variability, and pacemaker function. Data transfer is usually completed within 2 min.

### 33.2.5.3 Storage Media

The storage media available are flash memory card or portable hard drive. Flash cards are about the size of a credit card, and have the capacity to store 20–40 MB of data ([▶ Fig. 33.14](#)). After completion of the recording, the flash cards are removed from the recording device and are inserted directly into the analysis unit or into a separate device by which

the data can be transmitted electronically to another analyzing unit where the data can be played back and analyzed. Miniature hard drives can store more than 100 MB of data, and unlike flash cards, are not removed from the recorder, but the data are downloaded to another storage device or may be electronically transferred to a remote analysis unit.

#### 33.2.5.4 Event Recorders

In contrast to the conventional 24-h Holter monitoring, both sampling and trans-telephonic devices record noncontinuous AECG data of an intermittent nature. There are two types of intermittent patient-worn recording devices (so-called event recorders), one that records and stores only a brief period of ECG activity, either by predefined criteria analyzed by the microcomputer (e.g., tachycardia, arrhythmia, bradycardia) or when activated by the patient in response to symptoms, and the other that records the ECG in a continuous manner but stores only brief periods of ECG recording (e.g., 5–300 s) in a memory when activated by the patient using the event marker at the time of a symptom (the so-called loop recorder). These event recorders can be used for prolonged periods of time, for example, many weeks, to identify infrequently occurring symptoms or arrhythmias that would not have been retrieved from a conventional 24-h AECG monitoring. A patient-activated event recorder needs rapid placement of electrodes, such as paddles connected to the recorder or a wrist bracelet, to record the ECG at the time of symptoms, whereas loop recorders use continuously worn electrodes. The recorded signal can be saved in memory and transferred at a later time to a central analysis unit or be transmitted to a receiving station by online transfer. Event recorders have the advantage of small size and light weight, their use is easy and they can be programmed to record many short episodes during an extended period of time (30 days to several weeks), and moreover, 1-, 2-, 3-, and mathematically reconstructed 12-lead formats are available.

A special type of event recorder is the implantable loop recorder (ILR), which may be used for identifying infrequent and transient symptoms of patients by long-term intermittent recordings. This device, of about the size of a pack of chewing gum is inserted under the skin at about the second rib on the left front of the chest and is activated by passing a special magnet over the device. It is capable of recording and storing up to 42 min of a single ECG channel, which can be partitioned for 1–7 episodes, with up to 20 min of preactivation ECG saved for subsequent downloading to a programming unit for analysis. The device can be configured to store patient-activated episodes, automatically activated recordings via, for example, low and high heart-rate limits, or a combination of both [20].

### 33.3 Artifacts in AECG Recording

An inherent problem with ambulatory monitoring is the almost inevitable occurrence of artifacts specific to this type of recording, resulting from a failure of one or more of the components of the system [4, 21–23]. Acknowledging these artifacts is of major importance because their misinterpretation can lead to erroneous clinical diagnoses and inappropriate therapeutic interventions. In addition, it is important to determine the cause of the artifact so that any fault in the equipment can be corrected. The major causes of artifact in Holter recordings are discussed in the following subsections. These essentially apply to recorders employing cassette tapes, as little experience has yet been gained with the newer solid-state technology (though problems with battery, electrodes, or cables are likely to be common to old and new systems).

#### 33.3.1 Battery Failure

The most common artifact encountered during tape-based Holter monitoring is certainly the “pseudotachycardia” owing to the failure of the battery toward the end of the recording, as can be seen in [Fig. 33.6](#), where a tachycardia characterized by a narrowing and lower voltage of the QRS complex occurs abruptly. The rhythm may be regular or irregular, simulating a paroxysmal supraventricular tachycardia (SVT). The replacement of the disposable or rechargeable batteries and, if necessary, the cassette or magnetic tape, could correct these artifacts. As a general rule, a new battery should be used with each recording, particularly in research studies where failure to record on a specific date can invalidate the whole study.

■ Figure 33.6

An illustration of one form of artifact encountered during AECG, where failure of the batteries toward the end of the recording has produced a “pseudotachycardia,” with a decrease of P, QRS, and T-wave durations in particular making the diagnosis straightforward.

■ Figure 33.7

Cyclic slackening of the magnetic tape on account of mechanical difficulty within the recorder.

■ Figure 33.8

An illustration of artifact resulting from the use of magnetic tape, which has not been erased properly before being used a second time, resulting in the superposition of two ECG tracings.

### 33.3.2 Failure of the Magnetic-Tape Recording

Less frequently, a recording problem can occur intermittently, especially if some mechanical difficulty is present at each rotation of the cassette or magnetic tape. The characteristics of the artifact are the same as in battery failure, but they occur at periodic intervals (🔍 Fig. 33.7). The use of a cassette or tape, which has not been properly erased, during a subsequent recording, can lead to the superposition of two ECGs and make the interpretation of the new ECG signals impossible, as shown in 🔍 Fig. 33.8. Therefore, as a rule, new cassette tapes should be used for each new patient AECG study in order to avoid these tape problems.

### 33.3.3 Failure of Electrodes, Lead Wires, or Patient Cable

Any dysfunction of electrodes, lead wires, or patient cable contributes to artifacts. Permanent failure, such as a break in the cable or loss of electrode contact, is easily identified, as a permanent defect occurs in one of the two recording

■ Figure 33.9

An example of the value of using two-channel recording during AECG. The lower channel shows artifact caused by intermittent failure of the ECG cable, with temporary loss of the ECG tracing and marked baseline shift producing “pseudo-QRS” waves marked by asterisks.

■ Figure 33.10

“Pseudo-VT” is produced by shaking the ECG cable during Holter recording. This artifact can be identified by the presence of normal QRS complexes, as marked by arrows within the runs of pseudo-VT.

leads. An intermittent failure, however, is more difficult to interpret. The use of at least two simultaneous leads in modern Holter recorders has considerably improved the detection of these artifacts. In a majority of cases, they occur only (or principally) in one lead as in [Fig. 33.9](#). The intermittent loss of electrical contact in one of the two leads induces abrupt movements of the baseline without any recording of the ECG at that particular instant. However, in the other lead the normal ECG appearance easily permits the recognition of artifact. It should be noted that many analyzers, while displaying two channels, essentially analyze only one of the leads.

In some cases, the artifact can be present simultaneously in the two leads, particularly in the case of displacement of the patient’s cable. In [Fig. 33.10](#), the diagnosis of artifact is particularly difficult, because the presence of genuine VPBs can lead to an erroneous diagnosis of VT. Fortunately, two indices point to the diagnosis of artifact:

1. The second episode of pseudo-VT is not present in the upper tracing as it is in the lower tracing; and
2. The normal QRS rhythm can be observed within the artifact and coincides with the normal rhythm before and after the event.

As seen in the two preceding examples, the use of a second lead in the Holter recorder provides the most obvious means of identifying an artifact. In the absence of any displacement of the baseline, it is the only way to obtain an accurate diagnosis. In [Fig. 33.11](#), for example, during a very short loss of electrical contact, only one PQRST complex disappears. In lead I, this is evidenced by a small undulation of the baseline. The presence of a normal QRS complex in lead II

■ **Figure 33.11**

Transient loss of electrical contact in a lead wire or an electrode in the top channel producing the absence of one QRS complex (marked by a star). Its presence on the simultaneously recorded second channel permits its detection.

■ **Figure 33.12**

An example of an artifact during AECG recording producing pseudoatrioventricular block on account of a sudden decrease of QRS voltage owing to an increase of skin-electrode coupling impedance. The residual QRS complexes identified by stars may be wrongly identified as blocked P waves. The bar indicates the duration of the artifact.

makes it possible to exclude the diagnosis of a transient sinoatrial (SA) block. ▶ [Figure 33.12](#) provides an example of pseudo-atrioventricular (AV) block due to a sudden decrease of QRS voltage.

## 33.4 Equipment for Analysis

### 33.4.1 Analog Holter Tape Recording

All methods of analysis require some form of playback system [4, 24–26] including those, which undertake real-time analysis of the AECG. All playback systems contain at least a magnetic-tape replay unit, while some older systems have an audio speaker and an ECG writer, which can provide samples. In addition, an oscilloscope or screen, an arrhythmia detector, a microprocessor-based analyzer (nowadays often a personal computer), an automatic ST-segment analysis system, and a fiber-optic or laser printer might form a part of such a system. Most current playback systems use generic computer hardware platforms and proprietary software protocols for data analysis and report generation. Signals recorded in analog format by magnetic tape are digitized at either a rate of 128 or 256 samples/s for subsequent analysis. The clock track on the tape can compensate for tape speed variations by a phase lock loop circuit. The resolution is usually at least eight bits and the sampling rate 128/s. The signal amplitude can be adjusted by the physician or technician based on the calibration signal recorded automatically at the beginning of each recording. Tape playback and scanning options include rapid playback with either superimposition of up to 1,000 times with or without audio-speaker control or page-type displays. Facsimile, modem, network, and internet integration allow for rapid distribution of AECG data and analyses throughout a hospital or larger health-care system.

The magnetic-tape unit, if required for playback, is a motor-driven assembly, which operates normally at 60 or 120 times the original recording speed, although more recently developed systems can function at 480 times the original recording speed. The magnetic heads detect and reproduce the original ECG signal for onward transmission to the

**Figure 33.13**

Full disclosure of long sequences of a single ECG lead for quick paging up or down (*top*) and an arrhythmia-scanning mode (*right*) for rapid detection of phases of arrhythmias, three-channel real time ECG (*bottom*) (Oxford MedilogDarwin system).

remainder of the system. In FM systems, it is necessary for the replay unit to demodulate the signal in order to retrieve the original waveforms. In most modern tape-recording systems, the analog signal from the tape is digitized for quick and convenient quantitative data analysis.

In every Holter system, an oscilloscope or flat panel screen is an essential part to control and guide the whole analysis procedure. Practically, all Holter analysis systems have the option of presenting data in a superimposed fashion at 30, 60, 120, 240, or 480 times the original recording speed, which when coupled with an audio speaker constitutes the AVSEP (audiovisual superimposition electrocardiographic pattern) display. In the majority of instruments, the use of a storage oscilloscope makes it possible to “freeze” the display of a real-time ECG for a period of 2–3 s up to 180 s if desired. Either one or both recorded leads may be displayed in this way. By using a technique for “jogging,” it is possible to jump forward or backward for a variable time in order to inspect quickly a series of “frozen” ECG displays (▶ Fig. 33.13). More recent systems sometimes use a graphics screen attached to a personal computer rather than a custom-engineered display (see ▶ Sect. 33.4.2).

In some older analog Holter systems, an audio speaker is incorporated that produces an audible sound, which is dependent on the detection of the R wave of the QRS complex. The tone can rise to a more shrill note in the presence of a fast heart rate or when an ectopic beat creates an isolated short R–R interval. On the contrary, with slow heart rates or longer R–R intervals, a low-pitched sound occurs. In some of the less-expensive units where there is no display, it is claimed that the ECG can be analyzed purely by listening to the audio signal produced by the replay unit.

The conventional form of a laser printer-ECG writer is incorporated into all Holter analysis systems and provides for up to three channels of ECG data to be written on standard (graphic) paper with an accompanying time printed on the edge track. It is evident that the production of specific examples of ECG abnormalities form a necessary part of the AECG report, providing essential material to enable the physician to interpret the 24-h recording. Moreover, graphic and tabulated AECG data, as well as a total 24-h ECG printout are provided by modern laser printers. Thus, this type of printout has supplanted the older fiber-optic printout system, which was able to print all or part of the ECG in a real-time format produced at high speed with a time reference frame. As previously mentioned, the display of the whole 24-h ECG on paper has become known as “full disclosure.” This technique is very useful for giving information on the quality of the recording and for studying rare events, particularly when the major part of the Holter recording is normal. As can be

seen in [Fig. 33.13](#), a second degree AV block is easily detected on a compressed ECG tracing. However, this technique requires that the technician or physician who must examine the complete 24-h ECG tracing spends some considerable time in doing so. The most recent AECG analyzing units provide abnormal sequences such as pauses, arrhythmias, etc. automatically for direct technician or physician review. Usually, one lead is printed, but if necessary the two leads could be printed separately. For time reasons, the use of full AECG disclosure is normally confined to quality control, verification of rare events, evaluation of AAD efficacy, and similar specialized functions and is not recommended for widespread routine use. The most modern solid-state Holter analyzing units provide abnormal episodes within the full disclosure ECG (e.g., pauses, arrhythmias, etc.) automatically, line-by-line for direct and quick control by the technician or physician.

### 33.4.2 Solid-State Holter Recording

The newer solid-state Holter systems consist of the digital recording (solid-state) device, the electronic interface to transfer the data from flashcard or hard drive to the personal computer, the flat panel screen, the alpha-numeric keyboard, the personal computer with the proprietary software protocols for data analysis and report generation, and a laser printer ([Fig. 33.14](#)). Some solid-state recorders are equipped with a microprocessor that provides “on-line analysis” of the QRS complex, the ST segment, as well as the T wave as they are acquired. Thus, a quick analysis and overview on the whole set of AECG data is immediately available at the technician’s or physician’s convenience, which facilitates and speeds up the interactive final analysis of the full 24h AECG. Details of the analysis workflow are given below.

### 33.5 Methods of Analysis

The approach to the analysis of 24-h ECG recordings varies from one manufacturer to another, and there are many systems commercially available worldwide. However, the different methods can be broken down into two very broad categories. Using discriminators, the hardware essentially differentiates between a normal (or dominant) QRS waveform and all others. The critical thresholds used to achieve the discrimination may (optionally) be adjusted by a technician. These are likely to be based on QRS width, amplitude or area, or some combination or derivative of these parameters. Various criteria based on the R–R interval, or the number of abnormal beats detected consecutively, can be set up to facilitate the detection and printout of arrhythmias. Using the method of a classifier, in microprocessor-based equipment the software automatically groups QRS complexes into a number of different categories (“templates”). This may be done in the recorder itself or in the laboratory-based analyzer. Thereafter, an operator may (optionally) adjust the classifications. Analysis of rhythm is then based on a study of the beat classifications, R–R intervals, and similar criteria. There are intermediate solutions where, for example, the second approach is used in the recorder to collect samples of arrhythmias

**Figure 33.14**

Modern type of solid-state recorder systems: digital AECG recorder of Medset (*top left*), digital AECG recorder (*bottom left*), and complete analysis system of OxfordDarwin (*right*) with personal computer, keyboard, flatpanel screen, and laser printer.

only, although details of heart rate over 24 h may also be stored. With some types of analyzers in either of the above categories, it is possible for the operator to view several minutes of an ECG on the screen in order to check visually for abnormalities or assess the quality of the recording.

### 33.5.1 Analog Tape Recordings

---

The first approach, that is, the use of the discriminator type, has the advantage that it can be used with a minimum of intervention by the operator and is thus suited to routine and automatic analysis of a large number of Holter recordings. On the other hand, experience shows that operator intervention can be valuable. The aim of using the discriminator approach in older Holter systems is not to provide an exact number of abnormal complexes (as is the case in the second approach), but to indicate their relative global frequency and, above all, to detect any arrhythmias. The principle of the technique is to use only a single pass of the tape (taking 12 or 24 min for 60 or 120 times real speed, respectively) in order to obtain data (e.g., trend plots) without intervention of the operator, or with minimal intervention such as an adjustment of the QRS width threshold, prior to the commencement of analysis, or to print any arrhythmias detected. This type of semiautomatic beat classification cannot provide the exact number of abnormal events because inevitably artifacts will be incorporated into QRS counts or because some normal QRS complexes will be considered abnormal or vice versa. However, if the original analog ECG signal is sufficiently high in amplitude without major artifacts, the QRS count is generally satisfactory with only a small percentage error. It is then possible to use such a system in order to obtain relatively quickly a large variety of presentations of the data contained on the recording.

### 33.5.2 Digital Solid-State Recordings

---

The most recent generation of automatic analyzers either undertakes the QRS analysis in real time using a microprocessor built into the recorder, or after replay using a similar technique whereby 64 or 128 different types of QRS complexes can be stored within the microprocessor memory. Each new QRS complex is compared with the different types already stored, and if it compares satisfactorily to one of these, the total count for that particular pattern is increased by one. If not, a new QRS morphology is then stored. At the end of the analysis, the various QRS morphologies can be displayed together with a count of beats in each group (▶ Fig. 33.15a, b). In some systems, it is possible for the operator to decide that a certain group of complexes consists of artifacts and have them deleted from the analysis. Alternatively, if there are only subtle differences between different groups, they can be merged and finally a categorization of normal or abnormal premature ventricular complexes (PVCs), premature supraventricular complexes (PSVCs), and so on can be added to each group so that the various counts can be accurately produced. This approach is now the standard technique of practically all modern AECG monitoring systems. Real-time analysis using the above technique has the advantage that at the end of the recording, the results can be instantly printed out via the appropriate replay and print-out unit.

### 33.5.3 Arrhythmia Analysis

---

#### 33.5.3.1 From Tape Recorders

By using the main criteria, the R–R interval, and the QRS width, it is possible to develop algorithms that are able to detect automatically many types of arrhythmias in Holter analog tape recordings [27–29]. Each beat is classified as normal, ventricular ectopic, supraventricular ectopic, paced, other, or unknown, and a template for each type of abnormality is created. Enlarged premature beats (premature ventricular contractions (PVCs) or atrial premature beats (APBs) with aberrant intraventricular conduction) and narrow premature beats (supraventricular premature beats or PVCs narrower than sinus beats) are the easiest arrhythmias to detect. The ease of detection of such abnormalities, as well as of couplets does not differ greatly compared to that of isolated extrasystoles. However, all these phenomena can be detected more confidently with the assistance of an experienced technician to run the analyzer. All users of Holter monitoring know that the first generation of PVC counters could be grossly inaccurate in analyzing the ECG tracings in the presence of artifact.

Figure 33.15

(a) Overview on the analysis forms of the computer program (Medset system) showing real time three-channel ECG (top), templates of QRS complexes (center), and summary of arrhythmias and heart-rate trend (bottom). (b) Overview on the analysis forms of the computer program (Oxford MedilogDarwin system) including heart-rate trend curve (top), QRS complex templates (left), types of available templates (center), selected single lead strips (right), and three-channel real-time ECG (bottom).

In this context, the superiority of human intervention compared to the use of an automatic detector is evident. However, automatic detectors can be used for other purposes with more complex algorithms. An example is the recognition of atrial fibrillation (AF) as opposed to sinus arrhythmia on the basis of studying only the irregularity of the R–R interval distribution. Another example of the utility of the automatic analysis of arrhythmias is the detection of ventricular pauses caused by SA or AV block. Visually, this search is very difficult and the automated approach provides higher sensitivity at the slight expense of a larger number of false-positive reports.

The interactive technique, which requires an operator, uses variable criteria for the recognition of arrhythmias, principally for ventricular or supraventricular extrasystoles. The simplest method is to use the classical criteria of recognition, but with the possibility of modifying the thresholds of prematurity and QRS width according to the characteristics of the particular ECG under study. However, more sophisticated detectors have appeared recently using different criteria in order to obtain an improved separation between “normal” and “abnormal” QRS; that is to say, different QRS patterns. These criteria can include the slope of the first component of the QRS complex, its derivative, the QRS area, or the morphological pattern calculated from the analog signal or from a digitized ECG. These criteria can be utilized separately or together in order to define the similarity between each QRS complex and the basic “normal QRS,” which is usually learned by the machine with some prompting by the operator at the onset of the recording. With this operator-based approach to setting up criteria, which can be adjusted – if necessary – during the tape analysis, the separation between supraventricular and ventricular complexes is usually achieved satisfactorily. Table 33.1 summarizes some important causes of false positive and false negative findings in the analysis of arrhythmias from AECG.

### 33.5.3.2 From Solid-State Recorders

In solid-state digital AECG systems, the total number of QRS complexes is analyzed and classified in different templates, which can be interactively controlled and categorized into normal or abnormal premature ventricular complexes (PVCs) or PSVCs. Together with the R–R intervals, every type of bradyarrhythmia, tachyarrhythmia, supraventricular, or ventricular premature complexes can be quantified by the computer protocol. A comparative real-time ECG printout provides interactive control of the classification result of the computer (Figs. 33.15 and 33.16). In addition, most solid-state

Table 33.1

Some technical causes of false-positive and false-negative findings in arrhythmia detection and classification from the ambulatory electrocardiogram (AECG)

1. Battery failure with “pseudotachycardia”
2. Recorder malfunction with variable tape drive or inaccurate storage
3. Incomplete degaussing or erasure of data from previously used tapes or memory storage
4. Noise interference or lead-electrode baseline drift or artifact
5. Low-voltage recording
6. Physiologic variations in QRS form and voltage
7. Inadequate computer QRS detection and classification algorithms
8. Incorrect time stamping of AECG tracings
9. Inadequate or incorrect technician interpretation during analysis

Figure 33.16

systems provide a separate channel for pacemaker spike analysis, and software for analyzing HRV either in the time or frequency domain or both.

After replay and digitizing the analog ECG signals from Holter magnetic tapes or – in case of solid-state ambulatory Holter systems – following transfer of the digital AECG data from the recorder to the computer via an interface, subsequent analysis of all ECG data is relatively easy, quick, and convenient if an appropriate software program is available. With most solid-state systems, a primary computer-based automatic analysis is performed and these data are presented on the screen as simultaneous multiple trend curves of heart rate (maximum, minimum, mean), PSVCs, PVCs, ST-segment deviation, and QRS complex templates together with a strip of two or three channels of the original ECG (Figs. 33.15b and 33.17). Using the cursor at each time of the heart-rate trend or arrhythmia strip, a control and reclassification of QRS templates, arrhythmia classification, or ST-segment analysis can be made instantaneously. Moreover, further trend curves of pacemaker activity, HRV trends and instantaneous values at a given period of the 24 h recording, and respiratory activity may be displayed. Some modern systems also provide a 12-lead ECG, which is either recalculated mathematically from the 3-lead orthogonal X–Y–Z data using a transformation or an actual 12-lead ECG where the limb electrodes are placed on the chest (see Chap. 11). Alternatively, a full disclosure ECG may be presented first page by page and by

quick paging up or down and reading all ECG sequences. Abnormal episodes such as bradycardias, pauses, PVCs, or tachycardias can easily be identified, marked by the mouse, presented in real-time, and finally confirmed or corrected if necessary.

### 33.5.4 ST-Segment Analysis for Myocardial Ischemia

#### 33.5.4.1 Technical Aspects – Analysis of Ischemic Episodes

With respect to ST-segment analysis for detecting myocardial ischemia, some important technical, electrocardiographic, and clinical aspects have to be considered, for which the following recommendations have been given [7]. The QRS-T morphology must be carefully scrutinized to ensure that it is suitable for interpretation. Cardiac rhythm should be sinus rhythm, the baseline ST segment should have  $\leq 0.1$  mV deviation, and the ST segment ideally should be gently upsloping with an upright T wave. A flat ST segment associated with an inverted T wave may still be interpretable. However, downsloping or scooped ST-segment morphology should be avoided. The height of the R wave of the monitored lead should be  $\geq 1.0$  mV. The lead selected for ischemia monitoring should not have a Q wave  $\geq 0.04$  s or marked baseline ST-segment distortion. Patients with left-ventricular hypertrophy in the 12-lead ECG, left bundle branch block, nonspecific intraventricular conduction delay  $\geq 100$  ms, or pre-excitation are not suitable for monitoring myocardial ischemia in the AECG. Medication with digitalis or some antidepressant drugs may distort the ST segment and preclude accurate interpretation of ST-segment deviations. ST-segment deviation is tracked by the use of a cursor within the PR segment to define the isoelectric reference point, and another cursor at the J-point and/or 60–80 ms beyond the J point to identify the presence of ST-segment depression. Myocardial ischemia is diagnosed by a sequence of flat or downsloping ST-segment depression of  $\geq 0.1$  mV, with a gradual onset and offset that lasts for a minimum period of 1 min. Each episode of transient ischemia must be separated by a minimum duration of at least 1 min, during which the ST segment returns to baseline (the so-called  $1 \times 1 \times 1$  rule [30, 31]). Many investigators prefer a duration of at least 5 min between episodes, and the ACC/AHA Task Force also recommends a 5-min interval between episodes because the end of one episode and the onset of the next will take longer than 1 min to be physiologically distinct. Episodes of ST-segment deviation are characterized by identification of an onset and offset time, magnitude of deviation, and heart rate before and during the episode. Representative ECG strips at the time of ST-segment deviation in real time should be provided in the report format.

**Table 33.2**

**Some causes of false-positive and false-negative findings in detection and interpretation of myocardial ischemia from the ambulatory electrocardiogram (AECG)**

1. Inadequate lead system employed
2. Incorrect or lack of lead calibration
3. Inadequate recording fidelity
4. Recording signal processing that compresses or filters the data, altering the ST-segment characteristics
5. Height of R wave <1.0 mV and Q wave $\geq 0.04$ s
6. Downsloping or scooped ST-segment morphology
7. Positional changes on the ST-segment
8. Hyperventilation
9. Vasoregulatory or Valsalva-induced ST segment changes
10. Sudden excessive exercise-induced ST segment changes
11. Preexcitation (WPW-syndrome)
12. Intraventricular conduction disorders (LBBB, RBBB)
13. Undiagnosed or unappreciated left ventricular hypertrophy
14. ST segment changes secondary to tachyarrhythmias
15. False ST segment changes from atrial fibrillation or atrial flutter
16. ST segment changes secondary to electrolyte disturbance or drugs

Trend curves and/or a summary table of all ischemic episodes may be displayed in the final report. Alternatively, a miniaturized full-disclosure display can be printed out for all or part of the 24-h recording [7]. [Table 33.2](#) summarizes some important causes of false positive and false negative findings regarding ST-segment analysis from the AECG.

One special problem is ST-segment elevation in variant angina, where the role of Holter monitoring is of considerable importance. During the playback analysis, the ST segment can be studied in two ways, either by visual examination or by automatic measurement, which can provide a trend of the ST amplitude. Some systems continuously monitor the ST amplitude, which is automatically compared to the baseline, defined by the onset of the accompanying QRS complex. In this case, the point of measurement can usually be placed by the operator at an appropriate distance from the J point in order to eliminate the detection of “physiological” ascent of the ST-segment depression. Other systems measure ST-segment depression automatically during the 24-h recording. This approach is subject to error in relating the ST measurement point to a fixed QRS trigger, which may vary with different QRS morphologies, that is, from patient to patient.

### 33.5.4.2 Beat-to-Beat Analysis

The most recent technical developments are fully automatic algorithms for beat-to-beat ST-segment amplitude measurements. Rather than identifying discrete sequential short episodes of ST-segment deviation, this approach utilizes frequency distributions of the ST-segment amplitude measurements for each 24-h recording (typically of 50,000–100,000 beats) in order to yield a better global perspective of ST-segment shifts that have occurred during the whole recording period [32, 33]. Following QRS detection and elimination of abnormal complexes, beat-by-beat isoelectric baseline estimation by cubic splines, and noise determination, the initial (R-ST1) and end point (R-ST2) of the regression line of the ST-slope is determined by the computer algorithm using the empiric formula for timing of the two points:  $R-ST1 = 40 + K1\sqrt{RR}$  and  $R-ST2 = 40 + K2\sqrt{RR}$ . For a heart rate of 60 bpm, K1 was set to 70 ms and K2 to 110 ms, and the whole range of K1 and K2 was evaluated over a spectrum of heart rates up to R – R intervals of 1,600 ms. From the frequency distribution (histogram) of the average displacement of the ST-segment (AVD) time series over 24 h, several parameters indicative of transient myocardial ischemia were extracted. As expected, transient and ischemic episodes lasting only several minutes were shown to be skewed to the left and to be asymmetrically spread around an average deviation of

less than 0 mm, whereas nonischemic frequency distribution was narrow and symmetric with an average deviation close to 0 mm. Using several parameters like percentiles, spread measures, skewness, and clustering, the authors were able to distinguish between a normal cohort of 63 individuals and 37 patients with CAD by a cut-off point of 0.45 for the estimated probability of ischemia in ambulatory monitoring [32]. In a second study, the influence of the autonomic nervous system (ANS) on ST-segment variability was tested [33], using the same technique of computerized ST-segment analysis including a demodulator algorithm to compensate for respiratory baseline shifts. Nine healthy volunteers underwent the following experimental protocol: control period (breathing room air at 10 cycles/min = 0.17 Hz for 5 min), fast respiration period (breathing room air at 15 cycles/min = 0.25 Hz for another 5 min), metabolic period (breathing 100% oxygen at 10 cycles/min for about 8 min), and neurogenic period (after 10 min breathing pure air, administration of atropine iv. with breathing room air at 10 cycles/min for other 10 min). Analysis of power spectral densities of the AVD signal during the four different periods of the experimental protocol showed no effect of 100% oxygen inhalation, only a small effect of mechanical respiratory activity, but a significant decrease of both total variability and relative power with atropine intervention. The results were similar for HRV, and the conclusion of this study was that the ANS plays a significant role in the regulation of AVD time series. This is a new important physiological finding and should encourage further systematic studies by using the ST segment not only as a simple detector of myocardial ischemia, but rather as a target and component of comprehensive cardiovascular equilibrium [33].

### 33.5.5 Analysis of HRV

Twenty-four-hour Holter AECG recordings represent a near ideal source for both short- and long-term assessment of HRV. Analysis of HRV itself refers to beat-to-beat oscillations of the R – R interval, which in the absence of physical activity, postural changes, or emotional stimuli represents the balance between cardiac sympathetic and parasympathetic (vagal) efferent activity and in particular the autonomically mediated alterations of the sinus node discharge rate (R – R tachogram, Fig. 33.18). In general, two methods of HRV analysis have been described, namely, time domain and spectral analysis [34, 35]. The term “time domain” reflects the fact that the majority of methods used provide measures in units of time (e.g., milliseconds) and time domain parameters involve computing indexes that are not directly related to specific cycle lengths. This method offers a simple means of defining patients with decreased variability in the mean and standard deviations of the R – R intervals. In general, two methods of time domain analysis – statistical and geometric – are in use [34].

Figure 33.18

Trend of heart-rate tachogram (center) during sinus rhythm (extreme left and extreme right) and AF (left and right center) as a rough overview on HRV. Real time two-channel ECG (top) and heart-rate trend (bottom) are also included (Medset system).

Figure 33.19

Trend curves of different time domain parameters of HRV (SDNN, rMSSD, SDNN50, and pNN50) and heart rate (*center and bottom*) together with a two-channel real-time ECG (*top*), same patient as in Fig. 33.18 (Medset system).

### 33.5.5.1 Statistical Methods for HRV Analysis

Among the statistical methods, time domain parameters analyzed include the mean R – R interval, the mean coupling interval between all normal beats, SDANN = standard deviation of the averaged normal sinus R – R intervals for all 5-min segments of the entire 24-h recording, SDNN = standard deviation of all normal sinus R – R intervals, SDNN index = mean of the standard deviations of all normal R – R intervals for all 5-min segments of the entire recording, NN50 = count of the number of pairs of adjacent R – R intervals differing by more than 50 ms in the entire recording, pNN50 = the percentage of adjacent R – R intervals that varied by more than 50 ms, and the rMSSD = root mean square of the difference between the coupling intervals of adjacent R – R intervals. Solid state recorders provide hour-to-hour trend analyses of different time-domain parameters (Fig. 33.19). rMSSD, NN50, and pNN50 correlate highly and are markers of high-frequency variations (vagal influence) in heart rate [34]. Of all parameters, rMSSD seems the most statistically stable (in standard clinical populations, the distribution of rMSSD data is more normal than that of pNN50 or NN50 values) and should be preferred, particularly since it correlates highly with others.

### 33.5.5.2 Geometric Measures for HRV Analysis

The main practical limitation of statistical methods is the time-consuming and extensive offline-manual editing of the ECG signals in order to ensure good quality R – R interval series. The use of filters to exclude outliers of R – R intervals, for example, perhaps those differing by more than 20% of the preceding R – R interval, is sometimes unsuccessful and may provide substantially inaccurate results. Therefore, a solution to eliminate incorrect R – R intervals is geometric measures, that is, the conversion of R – R interval data into a geometric pattern, such as the sample-density histogram of R – R interval duration, the sample-density histogram of the differences between successive R – R intervals (there exists little experience with this method), and the duration of each R – R interval against the immediately preceding R – R interval (so called Lorenz plots or Poincaré maps) (Fig. 33.20). Since the incorrect R – R intervals are usually substantially shorter (due to premature ectopic beats) or longer (due to sinus or compensatory pauses) than the population of correct R – R intervals, these incorrect R – R intervals fall outside the major peak of the distribution histogram and can easily be suppressed. Of the three geometric methods, the triangular index is the most important and most frequently used measure of HRV. It is calculated by dividing the total number of all R – R intervals by the height of the histogram of all R – R intervals measured on a discrete scale with bins of 7.8 ms, when using a sampling frequency of 128 Hz. A modification of the triangular index is the triangular interpolation of the R – R interval histogram (TINN), which is less dependent on the sampling frequency. This method interpolates the R – R interval histogram by a triangle, which has its base on the horizontal axis and its peak at the maximum point of the histogram, whereby the computation of the method identifies a triangle for which the square

■ Figure 33.20

**HRV histogram:** Trend curve of heart rate (*top row*), histogram of the R–R interval differences (*center left*), R–R interval histogram (*center*), scatterplot with plotting the duration of each R–R interval against the immediately preceding R–R interval (so called Lorenz plots, *center right*), and three-channel real-time ECG (*bottom*) (Oxford MedilogDarwin system).

difference between the histogram and the triangle is the minimum among all possible triangles. The length of the base of such a triangle is used as the measure of HRV. Both the HRV triangular index and TINN, measured over 24 h, express overall HRV and are more influenced by lower than by higher frequencies [34].

Because many studies in the past have used different HRV parameters leading to a lack of standardization and given that many measures correlate closely, the ESC/NASPE Task Force developed guidelines [36] to standardize nomenclature and methods of measurement. They recommended four time-domain HRV parameters:

1. SDNN (as an estimate of the overall HRV)
2. HRV triangular index (as an estimate of overall HRV)
3. SDANN (as an estimate of long-term components of HRV), and
4. RMSSD (as an estimate of short-term components of HRV)

### 33.5.5.3 Frequency-Domain Analysis of HRV

The basic assumption underlying the technique of frequency-domain analysis is that every periodic signal such as systolic arterial pressure or heart rate (R – R intervals) may be decomposed into a series of oscillatory components with different frequency and amplitude. When considering short-term recordings (5–10 min), spectral analysis of HRV is characterized by three components:

1. A high-frequency (HF) band in the range of 0.15–0.40 Hz, which can be considered as a measure of the physiological respiratory sinus arrhythmia;
2. A low-frequency (LF) band in the range of 0.04–0.15 Hz that corresponds to the LF rhythmicity of systolic arterial pressure frequently observed in conditions of sympathetic activation; and
3. A very low-frequency (VLF) band in the range of 0.0033–0.04 Hz that often shows a progressive decrease of power instead of a discrete spectral peak [37].

Figure 33.21

Trend curves of frequency-domain parameters of HRV (bottom) and numeric printout for the various parameters ULF, VLF, LF, and HF for every 5 min interval (top) (Oxford MedilogDarwin system).

Table 33.3

Correlation of the different time and frequency components of heart rate variability (HRV)

Spectral component	Time-domain correlates	Normal measures for 24 hours
HF	rMSSD pNN50	< 15 h < 0.75%
LF	SDNN index	< 30 ms
VLF	SDNN index	< 30 ms
ULF	SDNN SDANN HRV index	< 50 ms < 40 ms ...
TP	SDNN HRV index	< 50 ms ...

Abbreviations: VLF = very-low frequency; ULF = ultra-low frequency; TP = total power; SDNN index = mean of standard deviation of R-Rs; HRV index = integral of the total number of normal R-Rs divided by the maximum of the density distribution

In practical terms, parasympathetic tone is primarily reflected in the HF component, the LF component is influenced by both sympathetic and parasympathetic nervous systems, and the LF/HF ratio is considered a measure of sympathovagal balance, reflecting sympathetic modulations [37]. The spectral profile of long-term recordings is completely different from that of short-term recordings, because most of the energy (up to 90% of total power) is distributed within the ultra-low-frequency (ULF) range ( $\leq 0.003$  Hz) and the VLF range, whereas power of LF and HF accounts for only 10% of total power. Therefore, an alternative approach to the analysis of long-term recordings is to divide the entire 24-h period into a series of around 250 consecutive 5-min periods that are analyzed as short-term recordings [36, 37] (Fig. 33.21). In general, it should be stressed that the two analytical techniques of time and frequency-domain HRV are complementary in that they are different mathematical analyses of the same phenomenon, which explains why certain time and frequency-domain variables correlate strongly with each other, as shown in Table 33.3.

### 33.5.5.4 Pitfalls and Limitations of HRV Analysis

Some technical aspects and pitfalls of HRV analysis have to be borne in mind. HRV increases with increased periods of observations, and it is important to distinguish ranges on the basis of duration of recordings. In practice, long-term 24-h and short-term 5-min recordings are used. Frequency-domain methods are preferable for short-term, and time-domain methods are mainly used for 24-h recordings (e.g., using SDNN, SDANN, and HRV triangular index), but also for short-term recordings (e.g., using rMSSD). The recording period should last at least ten times the duration of the wavelength of the lowest frequency under investigation (for HF components at least 1 min, for LF components 2 min). Most systems contain and use computer-digitized data with a sampling rate of 128 Hz, which is suboptimal for some experimental short-term recordings, but useful for long-term recordings in adults. In such cases, template matching or interpolation algorithms should be used to optimize the temporal accuracy of R-wave peak identification. If an analog recorder is used, the digitization rate is not relevant, but magnetic tape data may introduce errors related to noise, motion-related artifacts with missing R waves or spuriously detected beats, or other errors in R-wave timing such as might be related to magnetic tape stretch. In addition, arrhythmias may introduce difficulties in the analysis of HRV, for example, persistent AF renders HRV analysis impossible. If more than 20% of the detected beats are ectopic, because the interval before and after each ectopic beat is usually eliminated from the analysis, numerical estimates of HRV will not be accurate. Two methods exist for handling abnormal heartbeats, namely interpolation of occasional abnormal beats [38] and limiting analysis to segments that are free of abnormal beats, respectively.

### 33.5.6 Analysis of Heart-Rate Turbulence (HRT)

#### 33.5.6.1 Pathophysiological Background

The new parameter of heart-rate-turbulence (HRT) was initially described by Schmidt et al. in 1999 [39]. The concept depends on the influence of single ventricular ectopic beats on the post-extrasystolic oscillations of baroreflex activity. Heart rate is controlled by vagal nerve activity with its direct effect on sinus node depolarization rate and AV-nodal conduction, the latency time is very short (450–700 ms) and thus, the heart responds in a beat-to-beat manner to any changes in vagal nerve activity [40, 41]. Following a single VPB, an instant drop of systolic and diastolic blood pressure ensues with a compensatory pause both in normals and in patients with compromised cardiac function that unloads carotid and aortic baroreceptors with a subsequent decrease of tonic vagal nerve activity [40]. In healthy normals, the drop of blood pressure is prolonged for the first 2–4 post-VPBs together with a transient loss of vagal activity, which seems to be responsible for the acceleration of heart rate. There then follows a steady increase of blood pressure with subsequent baroreceptor loading and an increase of vagal activity leading to a final deceleration phase of cardiac rhythm. In patients with depressed LV function, there is a sudden increase of systolic and diastolic blood pressure in the first post-VPB beat due to post-extrasystolic potentiation that compensates for the drop of blood pressure and activates the baroreceptors. The ensuing increased vagal nerve activity limits the initiation of early acceleration phase and prevents late deceleration phase of cardiac rhythm, that is, HRT cannot be observed [40]. HRT is therefore considered as a parameter of baroreflex sensitivity (BRS) that can be measured much more easily than the classic and complicated baroreflex testing approach.

#### 33.5.6.2 Parameters of Heart-Rate Turbulence

HRT can be quantified by two parameters: turbulence onset (TO) and turbulence slope (TS). TO quantifies the brief phase of early acceleration (usually lasting for 2–4 sinus cycles) and is defined as the difference between the mean duration of the first two sinus beats following a VPB and the mean duration of the last two sinus beats preceding the VPB, divided by the mean duration of the last two sinus beats preceding the VPB. TO is expressed as a percentage. TS describes the speed of the late heart-rate deceleration phase and is defined as the maximum positive slope of a regression line assessed over any sequence of five subsequent R – R intervals within the first 20 sinus rhythm intervals after a VPB. TS is expressed in ms/R – R interval. In patients at low risk for mortality, VPB triggers an early acceleration of heart rate followed by a late deceleration phase, whereas in high-risk patients, HRT is blunted. For prognostic use of HRT, it is important to have

appropriate cut-off values. TO and TS cut-off values were calculated by the group of Schmidt et al. [39, 42] with the use of a “training sample” composed of 100 patients with AMI. The log-rank test statistics for all possible cut-off points revealed optimal dichotomies of 0% for TO and 2.5 ms/R – R interval for TS.

### 33.5.6.3 Pitfalls and Limitations

It is important to note that Holter AECG data are very useful for evaluation of HRT, in case single VPBs are present in the entire recording, because different interesting time periods can be analyzed separately and, for example, diurnal variations of HRT in relation to clinical events can be detected. Some limitations of this method have to be mentioned. HRT analysis is limited to patients with dominant sinus rhythm. It cannot be used in patients with atrial flutter (AFL) or fibrillation, nor in those with second degree AV block or complete sinoatrial block. It cannot be used in patients with permanently firing cardiac pacemakers, while it is clear that the presence of VPBs in short- or long-term AECG recordings is essential for estimating HRT.

## 33.5.7 Analysis of QT Interval Variability (QTV)

### 33.5.7.1 Pathophysiological Background

QT interval (QTI) measurements, particularly in AECG recordings are of special interest, since prolonged ventricular repolarization with abnormal T-wave configuration and increased dispersion of QT-interval duration has been associated with increased risk of life-threatening ventricular arrhythmias both in congenital and in acquired conditions. In normal individuals, the QTI is modulated by multiple factors such as heart rate, circadian rhythm, and autonomic nervous-system activity. Acquired QT prolongation can be induced by myocardial ischemia, cardiac failure, electrolyte imbalances, diabetic neuropathy, and certain cardiac or non-cardiac drugs, while congenital QT prolongation and variability is caused by the abnormal function of cardiac ion channels following specific gene mutations. The main problems that limit the routine measurement of QTI are the absence of unequivocal criteria for determining T-wave offset, particularly in the presence of superimposed U waves, the absence of a general consensus on the best formula for adjusting the QTI to heart rate, and the diffusion of appropriate age- and gender-related normal values for corrected QTIs [43].

### 33.5.7.2 Technical Aspects

In 12-lead as well as in 3-lead Holter ECG recordings, the end of the T wave for assessing QTI may be determined either by the tangent method (drawing a tangent to the steepest point of downslope of T wave with T-wave offset being at the crossing of the tangent with the isoelectric line) [44], or visually by the return of the T wave to the TP baseline. In the case of U waves interrupting the T wave, the QT offset is measured at the nadir of the curve between T and U waves [45]. Finally, for AECG recordings analyzed by a computer-based technique, T-wave end may be automatically defined on a beat-to-beat basis by calculating the first derivative of the ECG signal and comparing it in the vicinity of expected T end with a threshold value [46].

The dynamic assessment of QTI during AECG monitoring requires computerized automatic measurements, with some technical problems due to low sampling rates, isoelectric baseline shifts, low signal-to-noise ratio, and difficult determination of the T-wave end at faster heart rates [43]. A low-noise ECG can be generated by averaging procedures that require the alignment of several consecutive beats over a given time interval with respect to R-wave peak (generally estimated by parabolic interpolation), and the averaged templates are then analyzed by specific algorithms that automatically detect QRS-T-wave features [47]. Averaging methods provide robust QTI measurements, but they lose the instantaneous variations in QT duration in the function of cycle length changes. Beat-to-beat analysis can explore instantaneous fluctuations of QT duration as a function of cycle length. However, this approach often requires the removal of large proportions of non-physiological data due to baseline noise. Therefore, beat-to-beat QTI measurements are best applied in short-term high-quality ECG recordings obtained under controlled conditions.

For evaluating long-term QTI dynamicity, two methods have been proposed, namely, the evaluation of the circadian excursion of the rate-corrected QTI (QTc), and the long-term evaluation of the QT/R–R relation, based on either beat-to-beat or averaging procedures. These two methods are increasingly implemented on modern commercial Holter systems and thus, are now available for routine clinical application.

### 33.5.8 Analysis of QT Dispersion (QTD)

#### 33.5.8.1 Pathophysiological Background

The concept of measuring inter-lead variations of the QTI as a noninvasive parameter of QTD is based on observations made early in the 1950s, when Lepeschkin and Surawicz [44] reported QTI differences of 40 ms between leads I, II, and III, and of observations of Han and Moe, who demonstrated that nonuniform (asynchronous) recovery of excitability in the myocardium is an important factor for triggering ventricular tachyarrhythmias. They found meaningful differences in refractory periods even in adjacent (atrial and ventricular) myocardial fibers, for example, for ventricular refractory periods of 43 ms at a cycle length of 700 ms [48]. More recently, Antzelevich et al. showed important differences in refractory periods of myocardial slices due to the significantly longer depolarization and repolarization processes of the M cells in the midventricular myocardial wall compared to cells in the epicardial and endocardial layers [49]. QTD measured as the difference between the longest and shortest QTI within a 128-lead body surface mapping ECG, or a conventional 12-lead or a 3-lead Holter ECG is considered as a parameter of dispersion of ventricular repolarization and might be a prognostic marker of the propensity of a patient to life-threatening ventricular tachyarrhythmias.

#### 33.5.8.2 Technical Aspects

Evaluation of repolarization duration in surface ECGs does not necessarily require a multi-lead system, as demonstrated by Sylvén et al. [50], who showed that the average QT duration computed from Frank's orthogonal leads highly correlates ( $r = .885$ ,  $p < .001$ ) with average QT duration obtained from 120-lead body-surface mapping. Zareba et al. [51] could show that in comparison to 12-lead ECGs, dispersion parameters calculated from 3 orthogonal-like leads (I, aVF,  $V_2$ ) were equally effective in identifying patients who had arrhythmic cardiac death during follow-up. Thus, X, Y, and Z bipolar leads may be used for 24-h Holter AECG recordings to assess QTD at various time segments of the entire recording period.

#### 33.5.8.3 Pitfalls and Limitations

There are several serious arguments against equating QTD with dispersion of ventricular repolarization that have been summarized by Rautaharju (2002) [52]. These arguments are as follows:

1. Measured QTD is determined primarily by dipolar components and does not represent dispersion of ventricular repolarization (the range of QTD in leads generated from strictly dipolar components is of the same order of magnitude as in the original 12-leads)
2. Inter-lead differences of QT duration are largely determined by T-wave “loop morphology” and by the projection of the terminal T-wave vector on individual leads (longest QT occurs in leads with the T-wave vector along the lead axis and shortest when near  $90^\circ$  angle)
3. Abnormal T-wave morphology has a strong influence on QTD (abnormal strictly dipolar morphological patterns can cause large inter-lead QT differences, which represent variability in amplitude/time domain rather than any physiologically meaningful intervals related to repolarization)

4. Overall technical variability of QTD measurement in the short- and long-range is too large to establish feasible thresholds and to separate normal from abnormal QTD (current consensus is that QTD values  $\geq 100$  ms are considered abnormal, but such large variations are commonly occurring with grossly abnormal T-wave morphology)
5. Variations in T-wave amplitude, lead vector strength, and noise level cause additional QTD variation (most  $T_{\text{offset}}$  detection algorithms use fixed thresholds so that T-wave amplitude variations via projection of strictly dipolar components may cause large QTD variations)
6. The presence of non-dipolar components in body surface ECG during repolarization has not been demonstrated as yet (the presence of non-dipolar components is necessary for detection of the end of localized ventricular repolarization and localized dispersion from QT measurements).

Regarding the many positive as well as negative studies on the prognostic value of QTD measurements and these problematic technical and physiological arguments, it is rather unclear at present whether QTD measurements either from 12-lead or from 3-lead Holter AECG recordings should be further used for stratifying patients with structural heart disease prone to sudden cardiac death (SCD) from ventricular tachyarrhythmias [51–53].

### 33.5.9 Signal Averaging of the AECG

#### 33.5.9.1 Pathophysiological Background and Parameters of VLP

The technique of signal averaging was developed in order to retrieve small electrical signals at the microvolt level that arise from areas of slow and inhomogeneous conduction in diseased ventricular myocardium. In the early 1980s, advanced techniques were introduced for refinement of filtering of the signals (bi-directional filtering), the selection of bipolar orthogonal X, Y, and Z leads, and their combination into a vector magnitude for maximal sensitivity. In addition, computer algorithms were developed to identify QRS offset and provide numerical values for signals in the terminal part of the QRS complex [54]. A task force of the ESC, AHA, and ACC [55] published standards for acquisition and analysis of VLP and provided clinical indications for a signal-averaged ECG (SA-ECG). Three common parameters for detecting the presence of VLP have been accepted, and suggested cut-off values were given for two conditions, namely, when noise levels  $< 1 \mu\text{V}$  with 25 Hz high pass filtering or  $< 0.7 \mu\text{V}$  with 40 Hz high pass filtering are obtained:

1.  $f\text{QRS}$  = filtered QRS duration;  $f\text{QRS} > 114$  ms is regarded as abnormal
2.  $\text{LAS}_{40}$  = duration of the low-amplitude  $f\text{QRS}$  signal  $< 40 \mu\text{V}$  immediately prior to QRS offset;  $\text{LAS}_{40} > 38$  ms is regarded as abnormal, and
3.  $\text{RMS}_{40}$  = the root mean square voltage of the terminal 40 ms of the  $f\text{QRS}$ ;  $\text{RMS}_{40} < 20 \mu\text{V}$  is regarded as abnormal.

#### 33.5.9.2 Pitfalls and Limitations

From a theoretical point of view, signal averaging from Holter tapes may have some technical limitations such as those due to speed stability of the recording and playback processes, a possible increase of background noise due to the patient's activities or inadequate electrode contact, and a restricted frequency bandwidth of the tape recorder. Most of these shortcomings can now be avoided with modern solid-state digital recorders, which provide a wide frequency bandwidth for retrieving microvolt potentials and also have an appropriately high sampling rate (between 1,000 and 4,000 samples/s), thus enhancing the quality of SA-ECGs and allowing frequency analysis methods without the current frequency restrictions. Despite some technical differences between ambulatory and real-time signal averaging, both methodologies have examined orthogonal XYZ leads, but AECG signal averaging has shown that bipolar leads  $V_1$ ,  $V_5$ , and  $aVF$  also correlate closely with orthogonal leads XYZ. In addition, despite appreciable differences between real time and AECG signal-averaging technologies for bandwidth sampling rate and bit resolution, clinical studies have found close correlation and percent agreement between the two methodologies [56, 57]. Finally, the ability to record and analyze signal-averaged high-resolution ECGs from Holter tapes or solid-state recorders offers clear advantages: easy handling of the recordings,

the option of several different recording periods during 24-h of registration, and the chance to assess arrhythmias, ST-segment changes, HRV, heart-rate turbulence, QTV, and late potentials from one data source and to correlate the results with each other.

### 33.5.10 Reports

There exists no established standard for an adequate AECG report. Most modern Holter recording systems provide composite trend curves for various parameters such as heart rate, arrhythmias, ST-segment deviations, and/or pacemaker activity, histograms of HRV or pacemaker stimulation, tabular summaries of various data, and ECG strips of relevant events either detected from the recordings or patient activated. Real-time ECG strips should provide samples of the ECG at times during which the patient has complained of symptoms, and present a variety of real-time ECG data including samples of each arrhythmia and any ST-segment changes. In many cases, the use of automated computer-based results together with a laser scanning printout of the ECG is useful, particularly for summarizing the data from a lengthy period of recording.

Twenty-four-hour heart-rate trend curves show a mean trend together with the maximum and minimum heart-rate trends calculated over brief time intervals. The difference between these two curves represents the HRV (🔗 Fig. 33.20). This visual representation is often useful in understanding the causes of events over a relatively long period of time and for comparison with other events, for example, supraventricular or ventricular arrhythmias or ST-segment depression. Combined with the enumeration of the QRS complexes, it provides some indices, which indicate the variation of the dominant heart rate (usually sinus rate) according to the influence of autonomic tone. In general terms, the difference between day time and night time heart-rate curves is a good index of the importance of sympathetic tone. Moreover, depending on the different special features of Holter systems, many manufacturers provide histograms of QT/R – R relation, HRV, pacemaker stimulatory activity (🔗 Figs. 33.22 and 🔗 33.23), or respiratory behavior of the patient.

Diagrams of premature beats are mainly used for displaying counts of PVCs. They express the variation of the number of abnormal events as a function of time and hence give an indication of the 24-h variation. The coupling interval of

Pacemaker analysis: histogram of the intervals of successive pacemaker pulses (*top left*), histogram of the intervals of pacemaker pulses relative to the corresponding R waves (*top right*), trend diagram of pacemaker-induced ventricular stimulation in bpm over the whole monitoring period in a patient with predominant pacemaker activity (*second row*), and three-channel real-time ECG (*bottom*) (Oxford MedilogDarwin system).

Figure 33.23

Pacemaker analysis: histogram of the intervals of successive pacemaker pulses (*top left*), histogram of the intervals of pacemaker pulses relative to the corresponding R waves (*top right*), trend diagram of pacemaker-induced ventricular stimulation in bpm over the whole monitoring period in a patient with intermittent pacemaker activity (*second row*), and three-channel real-time ECG (*bottom*) (Oxford MedilogDarwin system).

the premature beats can also be determined and displayed on a separate diagram. The comparison between the heart-rate trends and the PVC diagram is useful in presenting the relationship between heart rate and PVCs with their daily variations (► Fig. 33.17).

R – R interval or pacemaker stimulation histograms (◀ Figs. 33.22 and ▶ 33.23) are used by almost all manufacturers with some variations. A histogram of the R – R intervals presents all the QRS complexes arranged as a function of the preceding R – R interval. These R – R-interval histograms can be generated at fixed intervals during the 24 h of real time and superimposed to illustrate their progressive variation or the sudden appearance of an arrhythmia. Another type of graphic reporting is that of Lorenz or Poincaré plots, which summarize the data of HRV over a full AECG recording period. Recently, a novel application of these Lorenz plots has been developed for summarizing the full 24-h ECG data of AF (◀ Fig. 33.24) together with hill-like trend curves (► Fig. 33.25).

An essential part of a Holter AECG report is the presentation of a tabular summary of all relevant parameters on an hourly basis, for example, total number of QRS complexes, supraventricular and ventricular ectopic beats, couplets, triplets, or tachycardias, abnormal pauses of cardiac rhythm, HRV criteria both in the time and frequency domain, and pacemaker stimulation as well as pacemaker failures. In addition, full 24-h ECG disclosure – if desired – should be provided, as well as a variety of real-time ECG strips including samples of each arrhythmia or pauses of cardiac rhythm, any ST-segment changes and pacemaker dysfunction.

### 33.6 Incidence of Arrhythmias in Apparently Healthy Individuals

Before interpreting an AECG recording, the physician should be well acquainted with the findings in the apparently normal population. Some general points can be made from the literature [4, 26, 58–65] concerning the usual and unusual findings in apparently healthy persons.

■ Figure 33.24

Lorenz plots in a patient with sinus rhythm (*top row*) and AF for 20 min intervals each (*middle row*) and trend of HRV time domain parameters together with heart-rate trend (*bottom*) (Medset system).

■ Figure 33.25

Hill-like plot of consecutive ECG complexes in a patient with sinus rhythm (*upper and lower segments*) and AF and trend of HRV time domain parameters together with heart-rate trend (*bottom*, Medset system).

### 33.6.1 Maximal and Minimal Heart Rate

In general, the sinus rate tends to diminish with age as judged by AECG monitoring [58]. This is particularly obvious for the maximum heart rate during daytime. In elderly persons, the heart rate does not usually exceed 130 bpm. On the other hand, in a young population, it is not uncommon for the sinus rate to exceed 180 bpm during waking hours. According to the literature, the mean heart rates for 24-h AECG monitoring are  $76.3 \pm 11.8$  bpm, between 10 a.m. and

6 p.m. they are  $79.2 \pm 11.0$  bpm, and between 1 a.m. and 5 a.m.  $66.1 \pm 10.8$  bpm. Women have a significantly higher mean heart rate than men (5–10 bpm higher [59]). The usual definition of sinus bradycardia (less than 60 bpm) is inappropriate for 24-h Holter ECG reports, because in all “normal” populations, a sinus rate between 40 and 60 bpm is commonly registered during sleep. The minimal sinus rate usually occurs at the end of sleep, that is, between 5 am and 6 am in persons with a normal diurnal cycle. Diurnal and nocturnal variations of sinus rate can easily be appreciated by ambulatory monitoring.

### 33.6.2 Sinoatrial Pauses

In association with sinus arrhythmia and bradycardia, sinus pauses ranging from 1.2 to 2 s are commonly encountered in 24-h ECG. However, pauses greater than 2 s have been seen in less than 1% of the normal population, usually during sleep and in young subjects. These pauses are probably caused in part by an enhanced vagal tone. Such findings are common in athletes. Therefore, only sinus pauses in excess of 2 s can be considered as abnormal, and therefore require further attention in adult or elderly subjects.

### 33.6.3 AV Block

First-degree and second-degree AV block are occasionally noted during ambulatory monitoring in healthy individuals. These blocks most commonly occur during sleep and are accompanied by sinus bradyarrhythmia. Second-degree AV block is always of the Mobitz type I, even if in some cases it occurs abruptly, thus making the increase of PR-interval duration less obvious. These episodes, which occur during sleep in young subjects, are always asymptomatic. In some rare cases, more significant conduction disturbances can be recorded, as in the example of [Fig. 33.26](#). The ECGs are from a 37-year-old man submitted to ambulatory monitoring because of atypical chest pain. The symptoms were subsequently found to be unrelated to CAD, which was confirmed by coronary angiography and vasospastic provocative tests. During sleep, two episodes of second-degree AV block occurred with two or three P waves blocked in succession. Another recording performed one week later revealed the same phenomenon. This patient remained free of syncope or dizziness after a 4-year follow-up. [Table 33.4](#) summarizes the arrhythmias that should be considered “normal for age” according to the literature.

**Figure 33.26**

Paroxysmal AV block (blocked P waves are marked with crosses) occurring during the night in a young athletic man with no detectable heart disease. After four years of clinical follow up, this subject remained asymptomatic.

■ **Table 33.4**

**Normal findings of heart rate and arrhythmias on 24-hour ambulatory ECG monitoring according to age**

Arrhythmias	Age ≤ 25 years	Age 25–65 years	Age > 65 years
Sinus pauses	≤ 2500 ms	≤ 2000 ms	≤ 2000 ms
AV block	some occurring at night	none (except in case of regular physical training)	none
APCs	< 10 h <sup>-1</sup>	< 10 h <sup>-1</sup>	< 100 h <sup>-1</sup>
Atrial tachycardia (3 or more APCs)	none	none < 50 years some > 50 years	some
PVCs	< 10 h <sup>-1</sup>	< 10 h <sup>-1</sup>	< 100 h <sup>-1</sup>
Ventricular tachycardia (3 or more PVCs)	none	single < 10 QRS	single < 10 QRS

### 33.6.4 Atrial Arrhythmias

Atrial premature contractions (APCs) detected by AECG are reported to occur in 23–100% of normal persons studied [60–65]. The incidence of APCs increases significantly with age, being nearly absent in children (if it is distinguished from physiological sinus arrhythmia), but almost constantly present in healthy individuals of 65 years and more. Moreover, in these normal elderly patients, it is common to find frequent APCs (>1 min<sup>-1</sup>) and/or episodes of paroxysmal atrial tachycardia (PAT). The incidence of PAT varies greatly from one report to another, but an awareness of the high incidence of PAT is of major importance for the interpretation of 24-h recordings in older patients complaining of symptoms. The discovery of a short isolated PAT in an 80-year-old subject does not imply any relationship with the symptom if it was not simultaneously felt during the recording.

### 33.6.5 Ventricular Arrhythmias

The occurrence of premature ventricular contractions (PVCs) in normal populations as detected by Holter recordings has been reported to range from 17% to 100% of individuals studied [60–65]. Depending on the variable length of ambulatory examination in these studies, one may conclude that the incidence of PVCs is approximately 50% in normal persons examined for 24 h and increases to approximately 75% in those studied for 48 h. Where various age groups have been studied, there is a clear relationship between age and the incidence of PVCs. Normally, healthy individuals have less than 100 PVCs per day without any runs of VT. In some healthy aged persons, however, numerous, perhaps multifocal, PVCs can occur and, more rarely, short runs of VT. In particular, accelerated idioventricular rhythm may occur during sleep.

According to these data, it is possible to consider as unusual the prevalence of frequent (>1 min<sup>-1</sup>) or complex PVCs in individuals less than 65 years old. Such a prevalence and frequency of PVCs is not, of course, necessarily pathologic, but does require further examination to determine whether or not there is an underlying heart disease.

## 33.7 ST-Segment Changes in Apparently Healthy Persons

There are not many reports of ST-segment changes on 24-h ECGs in apparently healthy persons. However, three important studies have been published [66–68] involving 50, 120, and 182 volunteers, respectively.

In the first [66], ST-segment depression was defined as at least 0.1 mV horizontal or downsloping shift of the ST segment persisting 80 ms after the J point of the QRS complex. It occurred in 10–30% of the normal population in these

studies, with multiple episodes in the majority of these during a single 24-h ECG recording. These changes usually took place at the same time as daily exercise, with a cardiac rate of over 100 beats per minute. Isolated T-wave inversion was even more frequent.

The frequency of ST-segment elevation ( $>0.1$  mV) at the J point in these healthy subjects is a matter of some debate, being absent in the study of Armstrong et al. [66] but present in 23% of the volunteers of Quyyumi et al. [67]. In this study, ST-segment elevation occurred preferentially in young men, with a simultaneous low heart rate. At the same time, T waves became upright and peaked. The mean duration was usually very long (several hours). The difference between the two studies is probably caused by a difference in the criteria of positivity, while the pattern of ST changes is different from that observed in spontaneous angina. In these latter patients, ST elevation includes the T wave, with an aspect of the monophasic action potential, and the R wave increases. These modifications are progressive and persist for a few minutes only. Some studies have emphasized the fact that ST-T changes are more frequently encountered in female volunteers than in male volunteers; for example, 18% versus 1% in the Bjerregaard study [68].

Many ST-T abnormalities may be caused by positional change of the subject during the course of 24 h, and every effort should be made to assess whether ST-T change is indeed a genuine phenomenon. It should also be noted that most analyzers available at the present time do not detect major T-wave changes including a complete reversal of T-wave polarity. This is a significant shortcoming of all systems, although the operator could in fact position the ST marker at a point in the early part of the T wave if a search for T-wave changes is particularly desired. According to the literature, ST-segment elevation  $\leq 0.3$  mV at night with T-wave increase upward or downward in individuals at ages below 40 years are considered normal, as is the case for ST-segment depression  $\leq 0.2$  mV during tachycardia with upward or downward sloping ST segment accompanied by all types of T-wave changes as well.

Despite its shortcomings, 24-h ECG examination represents a useful diagnostic procedure in patients with spontaneous chest pain. In subjects with exercise-related symptoms, an exercise test provides more precise data with a higher specificity.

## 33.8 Clinical Relevance of AECG Recording

### 33.8.1 Evaluation of Patient's Symptoms

Patients often complain of symptoms, which are transient but suggest a cardiac origin. Holter ECG is an essential examination in such cases. This noninvasive technique is able to provide an accurate diagnosis, especially if the symptom coincides with any ECG abnormality detected during the recording. The most widely accepted use of AECG is the determination of patient's transient symptoms to cardiac arrhythmias. Some symptoms such as palpitation, syncope, near syncope, or dizziness are commonly caused by transient arrhythmias, whereas other transient symptoms such as shortness of breath, chest discomfort, diaphoresis, weakness, or transient ischemic cerebral attacks are less commonly related to cardiac arrhythmias. In principle, four possible outcomes may be expected with AECG monitoring: (1) typical symptoms may occur with the simultaneous documentation of a cardiac arrhythmia, (2) symptoms may occur at periods with no cardiac arrhythmias seen in the AECG, (3) during cardiac arrhythmias the patient may remain asymptomatic, and (4) the patient may remain symptomatic during AECG recording, and no arrhythmias are documented. With regard to situations (1) and (2), such findings are useful for further management of the patient in that either the symptoms can be related to arrhythmias or arrhythmias are not the cause of symptoms. The finding in the third situation is equivocal and in the fourth situation not helpful for further clarification of the patient's complaints.

#### 33.8.1.1 Palpitations

Many patients complain of a variety of symptoms grouped under the term palpitations [4, 69–71]. If these symptoms are frequent, for example, every day, 24-h Holter ambulatory monitoring is the optimum way for their evaluation. In many cases, an abnormality can be seen at the time of the symptoms, signifying that they are related to a cardiac arrhythmia. Sometimes, a sinus tachycardia represents the electrocardiographic basis for palpitations. In contrast, it is well known

that patients may have quite severe cardiac arrhythmias without being aware of them. This is particularly true for isolated PVCs, for frequent PVCs, and for short runs of VT. In any event, if palpitations are perceived during the recording, an accurate evaluation is easily provided by replaying the cassette tape or computer digitized ECG storage at the corresponding time. The problem is quite different in the absence of palpitations during ambulatory monitoring. In this case, the finding of one normal 24-h recording does not permit any conclusion to be drawn and the surveillance should be continued if symptoms have previously occurred with a reasonable frequency.

More difficult is the problem of the relevance of some arrhythmias recorded during ambulatory monitoring without simultaneous palpitations. Their significance depends on the incidence of the type of arrhythmia in the normal population. The occurrence of PVCs, even with some salvos, in an adult or aged patient, particularly if the patient suffers from coronary heart disease (CHD), is of little relevance; it is of limited importance to conclude that palpitations are caused by paroxysmal VT. Similarly, the discovery of short runs of atrial tachycardia in an elderly patient is irrelevant. However, if the arrhythmia observed is unusual according to the characteristics of the patient, it is probable that it may be the cause of the palpitations. This situation is variable according to the circumstances and the patient's activities. Nevertheless, the certainty of the diagnosis can only be assessed by an ECG recorded simultaneously with the symptom. For all these reasons, AECG monitoring is the preferred diagnostic method of examining such patients and is equally or more sensitive than other reported diagnostic techniques. The major exception is in relation to paroxysmal reciprocating junctional tachycardia where the attacks are very rare. The AECG recording is always normal between the attacks.

### 33.8.1.2 Dizziness or Syncope

Transient disturbances of consciousness producing dizziness or syncope are most commonly caused by a critical circulatory decrease in cerebral blood flow. Sinoatrial pauses or paroxysmal AV block may cause these symptoms, but modifications of heart rate alone may also cause disturbances of cerebral blood flow, mainly through tachycardia [4, 69–71]. It is now clear that healthy persons may tolerate a heart rate as low as 30 bpm and be asymptomatic, but ventricular rates higher than 150 bpm, particularly in elderly subjects or when underlying heart disease is present, often lead to a decrease in cerebral blood flow by causing inadequate ventricular diastolic filling and fall in cardiac output.

In several studies, a continuous ECG recording taken until symptoms have occurred shows that dizziness or loss of consciousness are, in the majority of cases, caused by a paroxysmal tachycardia (of atrial or ventricular origin) and not, as might be expected, by paroxysmal SA or AV blocks. Important inter-individual variations in the tolerance of arrhythmias are now well known. A normal young subject can tolerate an ectopic tachycardia with a heart rate in excess of 200 bpm or ventricular pauses of more than 3 s without producing symptoms of cerebral ischemia, whereas an older patient may faint after a few seconds of atrial tachycardia at 150 bpm. The state of the cerebral vessels, the presence or absence of cardiac disease, the body position and the duration of tachycardia or bradycardia are important considerations, and the occurrence or absence of symptoms depends on a combination of these factors.

Overall, the diagnostic yield of AECG monitoring for syncope or near syncope is relatively low. Seven to thirty-nine percent of patients with symptoms during AECG were reported to have no arrhythmia, and 1–26% to have arrhythmias. In patients without symptoms during AECG, 17–80% had no arrhythmia and 10–41% had episodes of arrhythmias [7]. In the study of Bass et al. [72], the value of three consecutive 24-h monitoring periods was evaluated. A major abnormality within the first 24-h recording was seen in 15% of patients, the additive yield was 11% on the second, and 4.2% in the third sequential recording. In this study, age, male sex, history of heart disease, and initial rhythm other than sinus were identified as factors that identified a useful recording [72].

### 33.8.1.3 Previous Ischemic Strokes

With the development of 24-h Holter recordings, previous ischemic cerebrovascular attacks become an important indication for this examination [73–76]. In most cases of this type of disease, the exact cause of the stroke remains unclear. Thus, the 24-h Holter examination is performed to search for a cardiac arrhythmia that might cause cerebral embolism.

Those arrhythmias able to induce a systemic embolism are almost always paroxysmal atrial arrhythmias and, in a few cases, VT, in the presence of left ventricular thrombus owing to previous myocardial infarction or cardiomyopathy. When an underlying cardiac disease is present, the diagnosis of systemic embolism is easier, but if clinical examination is completely normal, a 24-h AECG recording remains the best way of detecting a paroxysmal arrhythmia. However, the systematic use of this technique in all ischemic strokes is disappointing, since only a small proportion of patients with significant paroxysmal atrial arrhythmias may be identified. The great majority of these patients with previous stroke are over 60 years old and the relevance of these arrhythmias is unclear. As previously described, a significant proportion of “normal” elderly subjects can exhibit some short runs of atrial tachycardia. Therefore, the occurrence of such a disorder in a patient at risk of ischemic strokes does not prove by itself that the arrhythmia is the actual cause of the stroke. Only a sustained atrial tachycardia (lasting more than 10 min) should be considered as relevant in these elderly patients. As a result, the practical consequences (that is, the decision to begin anti-arrhythmic and/or anticoagulant therapy) are rarely directly related to the result of the 24-h AECG recording. In view of the economic and human costs of this technique, it is not recommended that it be performed systematically in all cases of stroke. It is preferable to reserve it for the younger patients (in which case an atrial arrhythmia is definitely relevant) or for cardiac patients, in whom there is the likelihood of a sustained arrhythmia.

#### 33.8.1.4 Chest Pain

Transient unpredictable chest pain is a frequent symptom and may present a diagnostic problem for the clinician. Although exercise stress testing should be the first line of investigation, occasionally AECG may be a more practical and useful diagnostic test, particularly if the chest pain is unpredictable with respect to time of onset or cannot be provoked by exercise. Two- or three-channel AECG recording permits examination of anterior, inferior, and lateral myocardial leads for the detection of ischemic ST-segment changes during episodes of chest pain with or without cardiac arrhythmias [77–82].

Twenty-four-hour Holter ECG has emerged as a primary method of examination in patients with suspected variant angina in whom pain usually occurs unpredictably [78, 79]. The diagnostic value of this technique is demonstrated in the example of [Fig. 33.27](#). In this case, considerable ST-segment elevation occurs during an episode of atypical chest pain, and there can be little doubt about the existence of variant angina probably caused by coronary artery spasm. The absence of ST-segment changes, however, appears to be of lesser value in reassuring the patient and the clinician that ischemic heart disease is absent because of the possibility of false-negative responses owing to inadequate lead positioning, short-lived ST-T changes, which are not detected during visual analysis of the replayed tape, as well as other factors. Finally, it should be stressed that only considerable deviation of the ST segment should be regarded as significant because of the frequency of minor abnormalities in normal persons during continuous ambulatory recordings.

### 33.8.2 Appraisal of the Mechanism of Arrhythmias

---

One of the major advantages of AECG is the facility to clarify the circumstances preceding the onset of arrhythmias. This technique enables the clinician to appreciate the many important characteristics concerning the mechanism of the arrhythmias, in particular the role of the autonomic nervous system (ANS) in more general terms, he/she can deduce the rhythmological explanation of the paroxysmal arrhythmia in question.

#### 33.8.2.1 Sinoatrial Disorders

The main use of 24-h Holter ECG in this particular group of disorders [4, 83] is to indicate whether SA dysfunction is dependent on the daily cycle or on the sinus rate. This appears to be of importance in differentiating between “physiological” vagotonic SA pauses occurring in a young athletic subject during sleep or at rest and “pathological” SA block

■ **Figure 33.27**

An example of an ECG recorded during an episode of variant angina. The ECG is produced as a fiber-optic printout where one line represents 1 min. The time of recording is indicated on the *left*. Note the alteration between deep negative T waves on the one hand (as at 21.40) and marked ST elevation on the other (as at 21.50).

occurring at any time of the day or night. Moreover, in some cases, Holter monitoring is able to indicate that SA dysfunction occurs specifically when the sinus rate increases. This is a strong argument for concluding that a phase III SA block exists, and not merely a transient interruption of sinus automaticity. In this type of conduction disorder, the abnormalities are usually detected during the first 24-h Holter recording. A completely normal AECG recording constitutes a strong argument for the elimination of SA block from the differential diagnosis.

### 33.8.2.2 AV Block and Intraventricular Disorders

AECG monitoring is sometimes able to determine the mechanism of AV or intraventricular conduction disorders. This technique may be able to distinguish between proximal and distal AV block (between Mobitz type I and II) and between physiological and pathological blocks. In general terms, if a nodal AV block exists, it is usually present on numerous occasions during a 24-h recording, while it is easy to differentiate the physiological nodal AV block occurring abruptly during sleep in a young athletic subject from the permanent pathological block (of varying degrees) in an elderly patient. It is much rarer to capture a distal AV block during a single 24-h examination. However, in this case it is sometimes possible to discern a peculiar mechanism such as modifications of sinus rate or occurrence of long or short R-R cycles. A typical pattern of paroxysmal AV block caused by sinus tachycardia (phase III block) is shown in [Fig. 33.28](#). This kind of tachycardia-dependent AV block is characteristic of a distal localization (intra-Hisian or infra-Hisian).

In these examples, all the usual characteristics of the conduction disorder are detected by AECG monitoring and an EPS becomes unnecessary. In the same way, the mechanism of some intermittent intraventricular conduction disturbances can be elicited by 24-h monitoring (phase III or phase IV blocks, succession of long and short R-R cycles). The discovery of an intermittent bundle branch block may be important clinically. A paroxysmal AV block seems less probable in the presence of an isolated intermittent bundle branch block than in the presence of a permanent bundle branch block.

■ **Figure 33.28**

Paroxysmal AV block occurring during sinus tachycardia (phase III block) at 130 bpm (heart rate indicated on figure in bpm). A subsequent EPS showed intra-His bundle AV block reproduced by rapid atrial pacing.

### 33.8.2.3 Paroxysmal Atrial Arrhythmias

In a large number of patients, the reason for the occurrence of a paroxysmal atrial arrhythmia [84, 85] remains unclear, particularly when no morphologic changes of the atria can be found. AECG monitoring is often useful in such cases since on many occasions it demonstrates the importance of the ANS in the genesis of the arrhythmia. Two opposite forms of paroxysmal arrhythmias can then be described, namely, vagally induced arrhythmias and adrenergically induced arrhythmias. With respect to the former, the atrial arrhythmia is preceded by a progressive decrease of sinus rate either during night or at rest, as demonstrated by heart-rate trend curves (e.g., ▶ Fig. 33.29). Usually, this heart-rate threshold is not unduly low (50–60 bpm). Middle-aged patients may experience palpitations, and sometimes peripheral embolisms. The atrial arrhythmia remains in paroxysmal form for a long period, commonly more than 10 years. It becomes progressively more frequent, occurring either daily or several times a day, and appears resistant to conventional therapy. Beta blockers, digitalis, and verapamil usually aggravate the arrhythmia and class I drugs are also unsatisfactory. Only amiodarone may be helpful when taken alone in the initial stages of the disease and in the later stages when combined with a class I drug. In some instances, sinus bradycardia preceding the onset of the atrial arrhythmia occurs abruptly during a few R–R cycles, suggesting a sudden increase in vagal tone as shown in ▶ Fig. 33.30. In these cases, it is sometimes possible to find a gastrointestinal reason for this enhanced vagal tone. Treating this condition may suppress the arrhythmia simultaneously. In some cases, which are resistant to all combinations of drugs, rapid atrial pacing may improve the clinical situation.

The opposite form, the paroxysmal adrenergic atrial arrhythmia, appears less frequent in contrast to the high frequency of palpitations experienced during exercise, emotion, or other high-hyperadrenergic states, which are mainly caused by isolated sinus tachycardia without rhythm disturbances. This type of arrhythmia is preceded by a progressive increase of sinus rate during daytime, which is not necessarily related to physical exercise (▶ Fig. 33.31). Except for some patients with an unsuspected hyperthyroidism, any organic cardiac disease may be present. Beta blockers are able to control the arrhythmia for some weeks or months, after which an escape phenomenon occurs, which requires additional class I drug therapy. Amiodarone or propafenone may be useful due to their noncompetitive inhibitive effect on the beta adrenoreceptors. The distinction between these two opposite forms of atrial paroxysmal arrhythmia often appears to be somewhat theoretical, because many patients cannot be easily classified into one or other type. On many occasions, however, ambulatory monitoring is of great value in these patients to provide a guideline for therapy.

■ **Figure 33.29**

An example of a vagally induced atrial arrhythmia. A progressive sinus bradycardia with changes in atrial depolarization precedes the onset of AF. The change in rhythm marked by the star is also detected on the rate-trend curves.

■ **Figure 33.30**

Another example of a vagally induced atrial arrhythmia. The onset of AF is preceded by a sudden sinus bradycardia.

#### 33.8.2.4 Paroxysmal Junctional Reciprocating Tachycardias

Usually, Holter monitoring is unprofitable in paroxysmal junctional reciprocating tachycardias because of the rarity of the attacks and the normality of the ECG recording between attacks. However, in some patients with frequent episodes of this type of tachycardia, ambulatory monitoring is able to demonstrate the mechanism that triggers its onset. When combined with the data from an EPS detailing the reentry circuit, the knowledge of the triggering mechanism often constitutes a guideline for therapy, for patients incapacitated by their arrhythmia. The most frequent initiation mode of the reciprocating tachycardia appears to be premature atrial contractions (PACs). It is interesting that in some patients, PACs are able to trigger the arrhythmia only if they occur during sinus tachycardia, reflecting an increase in sympathetic tone. This predisposing role of the adrenergic system is well known. Clinicians use isoprenaline during electrophysiological studies to induce the tachycardia more easily by atrial premature stimulation; this is because of the facilitation of conduction through normal and/or accessory pathways. In some of these patients, beta-blocking drugs should be added to previous antiarrhythmic therapy in order to obtain a satisfactory result.

Less frequently, the triggering mechanism of the tachycardia is PVCs, and in some patients with numerous PVCs it is remarkable that the tachycardia occurs only with a couplet and never with isolated PVCs. In a similar manner, during electrophysiological studies, a single ventricular extrastimulus is frequently unable to induce the tachycardia, which occurs with two or more extrastimuli. The practical consequence in this case is that there is a good chance of success for class I or III AADs being able to suppress the repetitive phenomena of PVCs. The three other mechanisms of triggering, specific for accessory pathways, require individual recognition and treatment. Induction of reciprocating tachycardias by sinus tachycardia (owing to a phase III block in concealed anterograde conduction through the accessory pathway) should be treated by beta-blocking agents or by amiodarone. The reverse situation, that is, induction by junctional escape beats (preventing concealed or patent anterograde conduction through a Kent bundle) or sinus bradycardia (with a phase

■ **Figure 33.31**

An example of an adrenergic atrial arrhythmia. Paroxysmal AF is preceded by a progressive sinus tachycardia. The change in rhythm labeled by the asterisk can also be seen on the heart-rate trend curves.

IV block in the Kent bundle) usually requires pacemaker implantation or catheter ablation. The most recent and highly effective mode of therapy is catheter ablation of the accessory pathway based on a detailed mapping procedure using multiple intracardiac catheter electrodes.

### 33.8.2.5 Ventricular Arrhythmias

AECG monitoring is normally less useful than electrophysiological studies in elucidating an electrophysiological mechanism of ventricular arrhythmias [86–88]. The EPS is superior in providing criteria that suggest reentry, for example. In contrast, 24-h Holter monitoring is the examination of choice in the case of parasystolic beats, providing most useful data for the study of these rhythm disturbances [89]. In general, recording the onset of VT often reveals important information on the intrinsic mechanisms of the arrhythmia. Some examples illustrating these findings and their practical consequences are now discussed.

▶ **Figure 33.32** shows a run of VT initiated by a compensatory pause following a single PVC with a morphological pattern different to those of the VT. This is a good demonstration of two different conditions necessary for the initiation of VT; that is, an isolated PVC as the trigger mechanism and a ventricular pause creating local conditions favorable to the sustaining mechanism of VT (focal or intraventricular reentry). In this situation, two therapeutic regimes can be proposed: suppression of the trigger mechanism or depression of the sustaining mechanism. ▶ **Figure 33.33** is another example of a possible duality of the mechanisms involved in the genesis of a VT: an intraventricular reentry (as confirmed subsequently by EPS) triggered by APBs. In this case also, antiarrhythmic therapy may suppress the clinical VT in two different ways. The role of sympathetic tone, often important in the genesis of VT, is easily demonstrated by AECG monitoring, showing the relationship between VT and sinus tachycardia, which reflects an enhanced sympathetic activity. In the case presented in ▶ **Fig. 33.34**, paroxysmal VT occurs and persists during a period of sinus tachycardia owing

■ Figure 33.32

A two-channel Holter ECG showing a run of VT initiated by a PVC of different morphological patterns followed by a compensatory pause. This spontaneous mode of initiation is unusual in patients with reentrant VT, which is easily induced by electrophysiological means.

■ Figure 33.33

An example of bitachycardia (coexistence of atrial and VT) in a patient with cardiomyopathy. A run of VT is initiated by a couplet of APCs indicated by the first pair of stars. Two simultaneously recorded leads are shown. In this case, the VT could be triggered by extra stimulation and was probably caused by a reentrant mechanism.

to psychological stress, and disappears only when sinus tachycardia ceases. In the same manner, in some cases of sudden death, sinus tachycardia indicating an increased sympathetic tone seems to play an important role in the triggering mechanism of the fatal arrhythmia.

The understanding of the mechanism of sudden death in cardiac patients is probably the best recent example. As demonstrated by some important series [90–92], the role of myocardial ischemia is practically confined to asystoles, and the vast majority of sudden deaths caused by a ventricular tachyarrhythmia are not directly caused by ischemia. Iatrogenic (drug-induced) “torsades de pointes” may be responsible for sudden death in noncoronary patients. Ventricular fibrillation (VF) is the usual mode of sudden death in coronary patients without preceding ischemia. VF usually follows a sustained VT, which accelerates before its transformation into VF. The electrophysiological phenomena leading to VT/VF are a shortening of the coupling interval of PVCs, a long R–R cycle (postextrasystolic pause) in half of the cases, an atrial arrhythmia or, more generally, an increase of heart rate reflecting an increase of sympathetic tone. This latter represents the main determinant of VT/VF.

■ Figure 33.34

A fiber-optic printout showing clearly the catecholergic mechanism of a ventricular arrhythmia. The salvos of VT are preceded by a marked acceleration of the sinus rhythm (indicated by *arrows*) and disappear when the sinus rate decreases.

### 33.8.3 Monitoring for Myocardial Ischemia

#### 33.8.3.1 General Considerations

In contrast to previous technical problems and limitations, with recent advancements of recorders with digital ECG and high-sampling rates, it is generally accepted that AECG monitoring provides accurate and clinically meaningful information about myocardial ischemia in patients with CAD [4, 90, 91]. After careful hook-up and testing for nonspecific ST-segment alterations due to hypoventilation or positional changes (testing in supine, prone, lateral, and sitting positions), the patients are asked to keep an accurate and complete diary of symptoms associated with specific events or activities, time of occurrence and disappearance of symptoms, and all other activities before the start of the recording. Upon return of the patient, a thorough review and confirmation of the diary entries has to be performed.

AECG provides a unique insight into the presence and severity of myocardial ischemia in patients with CAD. Unlike stress testing, AECG evaluates patients in their usual environment, allowing for assessment of ischemic jeopardy when the patient is exposed to the emotional or physical stress of daily life. Such insights concerning ischemia are fundamentally different from assessing ischemia in a supervised hospital or laboratory setting, where exercise stress testing is usually performed. The correlations between indices of ischemia during AECG monitoring and stress testing are quite weak [92]. An assessment of ischemic jeopardy by one technique is not a surrogate for ischemic jeopardy by the other technique [91, 93]. Most studies using AECG for ischemia assessment have been performed in patients with CAD, and there is a paucity of data regarding the role of AECG monitoring in asymptomatic individuals without known CAD or peripheral vascular disease. Thus, there is presently no evidence that AECG monitoring provides reliable information concerning ischemia in asymptomatic subjects without known CAD [93].

In addition to providing long-term monitoring for myocardial ischemia in an outpatient setting, AECG monitoring is also useful for detection of myocardial ischemia in preoperative risk stratification for patients who cannot exercise because of peripheral vascular disease, physical disability, or advanced lung disease. Moreover, it can be helpful for evaluation of patients with anginal episodes due to suspected variant angina, in whom an exercise test was negative. Finally, 24–48-h

AECG monitoring can provide information about the circadian pattern of myocardial ischemia and the pathophysiological mechanisms responsible for the ischemic episodes. It is particularly useful for detecting the extent of painless episodes of myocardial ischemia (so-called silent ischemia) that would otherwise remain undiagnosed, for example, by an exercise test.

### 33.8.3.2 Silent Myocardial Ischemia (SI)

The syndrome of painless myocardial ischemia was first described by Gettes in 1974 [94]. Since then, this syndrome, which is now usually referred to as SI, has attracted much attention, particularly its relation to sudden death [95–97]. The pathophysiology of painless (silent) ischemia in patients with stable CAD is not completely understood. Myocardial ischemia may occur either from episodic increase in myocardial oxygen demand, most conveniently identified by heart rate and blood pressure increase, or from an episodic decrease in myocardial oxygen supply related to either transient coronary artery vasoconstriction, transient platelet aggregation, or both. The actual identification of the presence of coronary vasoconstriction is deduced from heart-rate thresholds at which ischemia occurs: if heart-rate thresholds for ischemia vary in a given patient with stable CAD and ischemia occurs at lower heart-rate thresholds, it is likely that intermittent vasoconstriction is responsible, and when vasoconstriction is relieved, or vasodilation occurs, ischemia develops at higher heart-rate thresholds. If heart rate increases by  $\geq 5$  bpm prior to an ischemic episode, this may suggest an increase of myocardial oxygen demand as the cause of ischemia, whereas the absence of heart-rate increase favors a decrease of oxygen supply as the ischemia-producing mechanism [98]. The fact that ischemia can be seen on AECG during normal daily activities at heart-rate thresholds 10–20% lower than heart-rate thresholds for ischemia during an exercise test suggests that episodes of ischemia during normal activities may at least in part be related to intermittent coronary vasoconstriction [92, 99]. Understanding the pathophysiology of ischemia in patients with stable CAD is made more complicated by the fact that many routine daily activities both increase myocardial oxygen demand and provoke coronary vasoconstriction such as mental or physical stress, exposure to cold, or cigarette smoking. In addition, elevated serum cholesterol or estrogen deprivation may create or exacerbate endothelial dysfunction that is responsible for coronary vasoconstriction. These pathophysiological considerations are important, since pharmacological treatment is often quite different with regard to the culprit mechanism of ischemia, and these different treatment options may also have important implications for prognosis.

From the literature, it is quite clear that the vast majority of episodes of transient ST-segment deviation during AECG monitoring occur in the absence of symptoms. Episodes of asymptomatic ischemia occur in 20–50% of patients with all types of CAD, that is, stable angina, unstable angina, and AMI, and the asymptomatic episodes may outnumber the symptomatic episodes by more than 20-fold. Explanations for the fact that some episodes are painful and some produce no symptoms include the following:

1. Episodes of silent ischemia may be less “severe” than symptomatic episodes, so the anginal threshold is not reached [100].
2. Disorders of the peripheral autonomic nerves, for example, diabetic neuropathy, may blunt the nociceptive signal of ischemia [101].
- h3. Increased beta-endorphin levels may decrease the central perception of myocardial pain [102, 103].
4. Abnormal central processing of afferent messages from the heart may occur due to non-myocardial factors and emotional or personality characteristics (so-called “gate theory”: the cerebral cortex itself modulates the nociceptive signal that it receives) [104].

Cohn [96] has divided patients with SI into three groups:

1. Asymptomatic individuals who may suddenly die from CHD
2. Asymptomatic survivors of AMI; and
3. Anginal patients who have painless, as well as painful episodes

While detection of groups 1 and 2 relies on exercise testing, Holter monitoring is the most valuable method for detecting group 3. The clinical presentation of these 3 patient groups, as well as their prognosis, may be quite different. However,

myocardial ischemia by itself represents an independent risk factor for patients with all types of CAD, that is, stable angina pectoris as well as unstable coronary syndromes (NSTEMI, STEMI).

### 33.8.3.3 Prevalence and Prognostic Significance of Myocardial Ischemia

In patients with stable CAD and angina pectoris, the prevalence of myocardial ischemia in AECG monitoring ranges between 20% and 45%, and in patients with unstable angina or with a previous myocardial infarction, it is between 30% and 40% [7]. Between 60% and 80% of ischemic episodes detected by AECG monitoring are reported to be asymptomatic. As to the prognostic significance in AECG monitoring, silent as well as symptomatic myocardial ischemia identifies patients at a significantly higher risk of future cardiac events and cardiac death [105–116]. Table 33.5 shows the results of these studies: at a mean follow-up between 10 and 37 months, the event rate for death, cardiac death, myocardial infarction, unstable angina, or revascularization ranged from 3% to 42% in patients without ischemic episodes, compared to event rates from 23% to 56% in patients with documented episodes of myocardial ischemia. These differences were statistically significant for all studies cited. Moreover, some studies have shown that ischemia detected by AECG monitoring can provide prognostic information additional to that obtained from established parameters during exercise testing [93, 106, 111, 115].

In the past, AECG monitoring has also been used to define the risk of perioperative events in patients without clinical evidence of CAD undergoing surgery for peripheral vascular disease. These patients were reported to have evidence of myocardial ischemia in 10–40% of cases, and the perioperative event rates were between 1% and 16% in those with a negative test as compared to those with event rates of 4–15% with a positive test [7]. From a clinical point of view, it should be emphasized that an exercise test alone, eventually combined with an echo or other imaging study, should suffice for preoperative evaluation. Only in patients who cannot undertake an exercise test, AECG monitoring for ischemia can be used for further evaluation.

AECG monitoring has also been used for evaluation of anti-ischemic therapy in patients with CAD. In this respect, it should be stressed that due to the significant day-to-day variability of ischemic ST-segment alterations, prolonged monitoring periods of at least 48 h should be performed. A number of studies have shown that 48-h AECG recording performed at baseline and after initiation of antianginal therapy can provide reliable information about the anti-ischemic efficacy and the prognosis of the patients. Some randomized clinical trials have demonstrated that suppression of myocardial ischemia as evaluated by AECG monitoring may improve the outcome in patients with CAD (Table 33.6): the event rates in patients on antianginal drugs versus placebo, or for 100% responders versus non-100% responders, were significantly lower in patients with successful antianginal or anti-ischemic therapy [117–121]. Since data on this important application of AECG monitoring are relatively sparse, further large-scale prospective randomized clinical trials are needed to confirm these results, and to evaluate the definite role of AECG monitoring in the anti-anginal or anti-ischemic management of patients with CAD.

### 33.8.3.4 Limitations of Holter Monitoring for Myocardial Ischemia

When assessing patients with suspected myocardial ischemia, it is important to mention again that ST-segment changes and other repolarization abnormalities can occur for reasons other than myocardial ischemia, for example, LV hypertrophy, LV dysfunction, hyperventilation, systemic hypertension (SH), postural changes, conduction abnormalities, preexcitation, tachyarrhythmias, fluctuations of sympathetic tone, AADs, digitalis, psychotropic drugs, and electrolyte abnormalities. Moreover, the importance of proper electrode placement to retrieve myocardial ischemia from all parts of ventricular myocardium by using at least one anterior and one inferior lead has already been emphasized. A further potential limitation is the marked day-to-day variability in the frequency, degree and duration of ST-segment alterations, and ischemic episodes that makes the assessment of the effects of therapeutic interventions on ischemic indices very difficult. This problem may be overcome by prolonging the AECG recording period to 48 or 72 h and assessing similar physical and emotional activities of the patients during the serial monitoring sessions. Finally, in some patients, changes in T-wave polarity and morphology can be observed during Holter monitoring, but there are presently no data to suggest that such changes are specific for myocardial ischemia [7].

**Table 33.5** Observational studies on the incidence and prognostic significance of daily life ischemia (modified according to Cohn PF 1998)

Authors, year	No. patients	Incidence of AECG ischemia (%)	End points	Mean follow-up (months)	Event rates (%)		P-value	Comments
					With AECG ischemia	Without ischemia		
Rocco (1988)	86	57	Death, MI, UA, revasc.	12.5	40	3	0.003	Patients monitored once off Rx
Tzivoni (1988)	118	33	Cardiac death, MI, UA, revasc.	28	51	20	< 0.001	All patients with previous MI

### 33.8.4 Assessment of Risk in Patients with Cardiac Disease

When trying to stratify survivors of AMI or patients with congestive heart failure (CHF) with respect to their risk of dying from an arrhythmic death, specific noninvasive risk-stratification methods like detecting the type and frequency of ventricular arrhythmias, signal-averaged ECG, HRV, heart-rate turbulence, QTV, QTD, and, last but not least, assessment of LV function (ejection fraction) are mainly used. From an epidemiologic as well as therapeutic interventional point of view, a risk-stratifying test should provide a high positive predictive accuracy (PPA) combined with a reasonably high sensitivity, so that as few patients as possible are unnecessarily exposed to treatment. Moreover, the current tests used should not only predict total mortality, but also specific causes of death, particularly death from life-threatening ventricular arrhythmias. Another practical prerequisite for using different tests is that they should be available not only in specialized referral centers, but also to physicians in all hospitals that take care of cardiac patients. The performance of each of the tests should be properly standardized.

#### 33.8.4.1 Post Myocardial Infarction

##### Prevalence of Ventricular Arrhythmias

Due to the widespread use of thrombolytic agents, and more recently due to routine acute mechanical recanalization (PCI) of occluded coronary arteries as well as the routine use of aspirin, beta blockers, and ACE inhibitors, in-hospital mortality of patients with AMI has substantially decreased from 16% to 20% in the late 1970s to 6–10% in the early 1990s, while the 1-year risk of developing a malignant arrhythmia in AMI survivors after hospital discharge is 5% or less [7]. Arrhythmogenic death accounts for approximately 40–50% of total mortality in the first year after AMI, and thereafter, the risk of dying from a malignant arrhythmia decreases significantly in the next 12–24 months to below approximately 10%. It should be mentioned that mortality rates reported from controlled randomized trials are lower than those derived from more unselected consecutive series of patients due to strict adherence to exclusion criteria resulting in exclusion of

higher risk patients such as older patients, those with recurrent MIs, MI after coronary bypass grafting, or ineligibility for thrombolysis or PCI.

#### Prognostic Significance of LV Function

For more than 20 years, depressed LV function assessed either by ejection fraction (EF) or by clinical signs of CHF represents the principal method of determining the risk of postinfarction patients. Numerous studies both in the pre- and post-thrombolysis, as well as the PCI era have demonstrated that depressed left ventricular ejection fraction (LVEF) < 35–40% is the most powerful predictor of total mortality in the first year after MI, while in patients with LVEF < 15–20% the vast majority of deaths are due to pump failure [7]. In a literature survey, Bailey et al. [121] have shown from 20 studies involving a total of 7,294 patients that sensitivity and PPA of impaired LV function was between 45% and 87% and between 9% and 33%, respectively, with a relative risk of 1.9–16.2 and an odds ratio of 2.0–21.6. It is quite clear that since the MADIT I and II trials in patients with an LVEF < 15–30% no further risk stratification is necessary and that these patients should receive an implantable cardiac defibrillator (ICD) [122]. In the remaining patients, at least in those with an LVEF  $\geq$  35–40%, further tests for risk stratification have to be performed.

#### Prognostic Significance of Ventricular Arrhythmias

Since the 1970s, premature ventricular contractions (PVCs) are considered as the “traditional” risk markers after AMI [123]. [Table 33.7](#) with results from 20 studies in more than 11,000 patients [124–142] shows that sensitivity and positive predictive value (PPV) of PVCs was between 16% and 82% and between 7% and 52%, respectively, with a relative risk of 1.9–16.2 and an odds ratio of 2.0–21.6. In general, frequent PVCs (e.g.,  $\geq$ 10/h) and high-grade ventricular ectopy (e.g., repetitive PVCs, multiform PVCs, and non-sustained or sustained ventricular tachycardia (sVT)) have been associated with a higher mortality, but once the patients have at least 6 PVCs per hour, the risk of an arrhythmic event does not increase with more frequent PVCs [123]. The prognostic role of nonsustained VTs (nonsustained ventricular tachycardia [nsVT]) has received special interest. In contrast to previous findings, the GISSI investigators demonstrated that nsVT after AMI failed to predict arrhythmic death [123]. Similar results were reported by Hohnloser et al. [142], who could demonstrate that the prevalence of nsVT at the time of hospital discharge early after the index infarct was very low (95 of 325 consecutive infarct survivors) in a general postinfarction population of patients treated according to current therapeutic guidelines. During a mean follow-up of 30 months, the presence of nsVT was not an independent predictor of either arrhythmic or nonarrhythmic cardiac death. On multivariate stepwise regression analysis for the primary study endpoint of cardiac mortality and arrhythmic events, only the status of the infarct-related artery, HRV, and LV ejection fraction were found to be independent predictors.

In the MADIT I Trial, nsVTs were also used as a risk marker for inclusion of the patients into the study. In long-term survivors of MI with reduced LV function, it was shown that ICD implantation reduced the mortality rates by about 50% in MI survivors with reduced LVEF ( $\leq$ 35%) and at least one symptomatic episode of nsVT, and in whom ventricular fibrillation or sustained VT was reproducibly induced during EPS and not suppressed by intravenous administration of procainamide [122]. At present, it is more or less accepted that in the thrombolysis or mechanical recanalization era (PCI in AMI patients), nsVT on its own is not a useful risk stratifier in patients after MI, but rather PVCs in general with a PPV between 5% and 15% should be combined with other risk markers such as impaired LV function, signal-averaged ECG (SAECG), parameters of HRV or of HRT to improve their prognostic impact.

#### Prognostic Significance of VLP

In the 1980s, the signal-averaged ECG (SAECG) was used to look for VLPs in patients after MI. VLPs were regarded as a sign of slow conduction in the peri-infarct zone that may facilitate the initiation of malignant ventricular tachyarrhythmias. Since then, numerous studies have been published on the prognostic significance of VLPs in survivors of MI before hospital discharge. In summary, the survey of Bailey et al. [121] on 22 studies in a total of 9,883 patients found that sensitivity and PPA of VLPs in the SAECG was between 35% and 83% and between 8% and 35%, respectively, with a relative risk of 1.8–31.5 and an odds ratio of 1.9–41.3. In this study, the SAECG was proposed as the first-step risk stratifier together with depressed LV function (see below). In a recent study on 1,800 consecutive survivors of MI in sinus rhythm and under 76 years, Bauer et al. [151] reported that the presence of VLPs before hospital discharge was not associated with the primary endpoint (SCD and serious arrhythmic events) in univariable and multivariable analysis after a follow-up

**Table 33.7** Yield of ventricular arrhythmias within the AECG for predicting arrhythmic events after acute myocardial infarction (AMI)

Author (year)	No. of Patients	Criteria	End points	Sensitivity, %	Specificity, %	PPV, %	NPV, %

period of median 34 months. In contrast, low LVEF ( $\leq 30\%$ ) (hazard ratio 9.6, 95% CI 4.1–22.4), HRT turbulence category 1 (either TO or TS abnormal) (hazard ratio 5.1, 95% CI 1.9–14.4), and HRT category 2 (TO and TS abnormal) (hazard ratio 7.5, 95% CI 2.4–23.9) were significant predictors of the primary endpoint in both univariable and multivariable analysis.

### Prognostic Significance of HRV

The sympatho–vagal balance and its regulatory activity on the circulatory system is disturbed in survivors of myocardial infarction, as can be determined from a decrease of HRV and BRS, as well as from a blunted heart-rate turbulence (HRT). The specific mechanism of decreased vagal modulation remains unknown. Pragmatically, HRV, BRS, and HRT decrease early after MI with a nadir of 2–3 weeks and then increase back to normal levels by 6–12 months. Decreased HRV and BRS as well as blunted HRT are independent predictors of increased mortality rates, including sudden death, in patients after MI (▶ Table 33.8) [131, 134, 136, 142, 143–149]. The optimal time-domain parameters of HRV for analysis of risk are SDNN and HRV triangular index, and high-risk patients have either an SDANN  $< 70$  ms, an HRV triangular index  $< 15$ , a BRS  $< 3$  ms/mm Hg, or HRT parameters TO  $\geq 0\%$  and TS  $\leq 2.5$  ms/R – R. Overall, the PPV of HRV parameters, BRS and HRT criteria using the cut-off points mentioned is relatively low in the range of 8–13% at a sensitivity level of 40% [141].

### Prognostic Significance of Heart-Rate Turbulence

Heart-rate turbulence (HRT) has also been shown to be of prognostic significance in survivors of MI [150, 151]. In the validation study of the PILP-cohort and the EMIAT placebo arm cohort, a strong and significant association of TO and TS with total mortality was observed [153]. Two recent studies on large cohorts of postinfarction patients (1,800 and 3,130 consecutive patients, respectively) have substantiated the prognostic power of HRT. In the first study [143], both TO and TS were predictive of death or SCD with hazard ratios of 5.3 and 7.5 in multivariable analysis, and in the second study [145], reduced post-ectopic TS (hazard ratio for SCD 5.9) and nsVT (hazard ratio 2.3) were also significant predictors. However, the general problem is that using these predictors alone PPV is too low (between 6% and 13%), and the PPV can be increased by a combination of several parameters (HRV plus VLPs plus HRT plus LVEF) at the cost of constantly lowering the sensitivity down to 10% [7].

### Stepwise Risk Stratification

To overcome these practical problems, Bailey et al. [121] proposed a clinically applicable risk stratification procedure in three steps, based on the total number of 25,543 patients collected with a weighted overall estimated two-year major adverse event (MAE) incidence of 7.9%, which was used as a prior probability. Furthermore, to explore the implications of combining tests, the analysis was simplified by using only the composite weighted mean values for sensitivity and specificity. The *first step* was the combination of LVEF and SAECG. If the two tests were both negative or both positive (as would be true for 64.2% of the patients), further testing would not be done, as the two-year probability of a MAE would be as low as 2.2% in the former, and high enough (38.7%) in the latter situation to warrant consideration of ICD implantation. The *second step* would be the performance of a 24-h AECG in the 35.8% of patients who had only a low LVEF or a positive SAECG, resulting in an intermediate two-year risk of 10.6% for a MAE. If severe ventricular arrhythmia (SVA) and abnormal HRV were both present or absent (25% of patient population), no further testing would be needed, because in the former case the posterior probability is still below the original prior probability, despite having either a low LVEF or an abnormal SAECG, and in the latter situation, the posterior probability would again be high enough to warrant consideration of ICD implantation. The *third step* would refer to the remaining 10.8% of the original patients, who would have an intermediate two-year risk of 17.5%. They would undergo an EPS, and 2.6% of the original group would have a positive EPS, again with a two-year risk of 45.1%, which is high enough to justify consideration of ICD implantation. At the end of applying all three stages of risk stratification, there remains a small proportion (8.2%) of unstratified patients with essentially the same risk of 8.9% as the original prior probability of 7.9% [121]. It should be noted that with the exception of assessing LVEF (by echocardiography, left ventricular angiography or cardiac magnetic resonance imaging [MRI]), all other parameters of step one and two can be derived from one 24-h AECG recording using modern solid-state digital recorder devices, so that only two investigational tools are necessary to reach step three, if applicable, according to the results of the different test parameters described.

### 33.8.4.2 Chronic Heart Failure

#### Prognostic Significance of Ventricular Arrhythmias

The majority of patients with CHF suffer from advanced structural heart disease, either ischemic or idiopathic dilated cardiomyopathy (IDCM), with progressive symptoms. Death results mostly from VT or fibrillation, bradyarrhythmia or asystole, progressive pump failure, recurrent ischemia or infarction, electromechanical dissociation, stroke, pulmonary emboli, or renal complications. Ventricular arrhythmias are extremely common in patients with CHF [153]. Ambient ventricular ectopic beats can be detected in  $\geq 90\%$  of these patients, frequent VPCs in 70–95% of DCM and heart failure, while many of these patients have complex and multiform PVCs and episodes of nsVT. In the Captopril–Digoxin Multicenter study of 295 patients with mild to moderate heart failure and reduced LVEF  $< 40\%$ , the frequency of VPBs was significantly higher in older patients, in those with LVEF  $< 20\%$ , or IDCM. In such high-risk group patients, 50% also had episodes of nsVT compared to 30% with nsVT in the overall study. By multivariate analysis, only nsVT frequency was an independent predictor of risk of sudden death. Patients with frequent occurrences of nsVT ( $>2/\text{day}$ ) had an almost threefold increase in total mortality [154]. In the V-HeFT II study on 715 patients, ventricular couplets were seen in 98% of patients and 28% had one or more episodes of nsVT. The presence of nsVT and ventricular couplets identified a group of patients with increased mortality [155]. In the GESICA-Trial [156], 34% of 516 patients showed nsVT. These episodes of nsVT were more frequent in patients with advanced heart failure, higher heart rate, lower systolic blood pressure, increased creatinine, or with Chagas disease. During a three year follow-up, the presence of nsVT was associated with an increased risk of total mortality (relative risk 1.69,  $p < .0002$ ) and an increased rate of SCD (relative risk 2.77,  $p < .001$ ). It can be concluded from these three large studies that in patients with advanced heart failure, the presence of nsVT identifies a subgroup with an increased risk of overall cardiac mortality and SCD. However, despite identifying this population with an increased relative risk of an adverse event, AECG monitoring for analysis of ventricular arrhythmias is either not sensitive enough or reveals a PPV that is too low for patient management purposes.

#### Prognostic Significance of HRV

The prognostic significance of HRV in patients with CHF was unclear in the past. In one of the first studies in 40 patients with CHF, compared with normals and those with a history of nsVT and normal cardiac function, there was no significant difference in the HRV parameters despite a significantly lowered HRV in heart failure patients [157]. In a prospective study of 71 patients with IDCM and CHF, Hoffman et al. [158] studied HRV by time- and frequency-domain methods. After a follow-up period of  $15 \pm 5$  months, no significant difference of time or frequency-domain indices of HRV among patients with arrhythmic events compared with those without major arrhythmic events was found. In a further study of 159 patients with IDCM and CHF, 30 patients died during follow-up. There was a significant correlation between LVEF, increased SDNN, and pNN50 with an increased risk of cardiac death. However, the risk of SCD correlated only with LVEF in contrast to an increased low-frequency power (LFP) and impairment of pNN50 that strongly correlated with an increased risk of death from progressive pump failure. Further, two studies showed that HRV was reduced in patients with CHF and there was a strong correlation between HRV and LV function and peak oxygen consumption [159, 160].

More recently, several studies on larger patient populations have been published that showed a positive prognostic power of HRV in patients with CHF (► Table 33.9). Ponikowski et al. [161] studied 102 consecutive patients with CHF from ischemic or dilated cardiomyopathy, using AECG monitoring to assess all parameters of HRV both in the time and frequency domain. During follow-up of  $584 \pm 405$  days, 19 patients died. In multivariate analysis, HRV parameters SDNN, SDANN, and LF were found to predict survival independently of NYHA functional class, EF, peak oxygen consumption, and the presence of VT within the AECG. The Kaplan–Meier survival curves revealed SDNN  $< 100$  ms to be a useful risk factor. Szabo et al. [162] investigated 159 patients with CHF due to ischemic or dilated cardiomyopathy, in whom both time and frequency-domain parameters were measured at entry to predict the endpoint of cardiac mortality. During a follow-up of 23 months (range 1–67), 30 of 159 patients died of cardiac causes. Both pNN50  $< 2.0\%$  and SDNN  $< 108$  ms predicted cardiac death with a RR of 2.1 and 1.5 respectively, whereas pNN50 and LF power  $> 14 \text{ ms}^2$  predicted death from pump failure with a RR of 5.4 and 6.8, respectively. Boveda et al. [163] reported on 190 patients with CHF and found the time-domain parameter SDNN  $< 67$  ms to be significantly predictive for total death (RR 2.5, CI 1.5– 4.2). In the VA trial,

Table 33.9

Prognostic significance of heart rate variability (HRV) for predicting cardiovascular and total mortality in patients with congestive heart failure (CHF)

Author (Reference)	No. of patients	Criteria	End points	Adjusted RR (95% CI)

Bilchik et al. [164] reported on 179 patients with CHF, in whom the lowest quartile of patients were compared with the remaining, using SDNN as the sole HRV parameter. Among 127 patients meeting the inclusion criteria, SDNN < 65.3 ms (the lowest quartile) was the sole independent factor predictive of survival in a multivariate model ( $p = .0001$ ). A Cox proportional-hazards model revealed that each increase of 10 ms in SDNN conferred a 20% decrease in risk of mortality ( $p = .0001$ ). Furthermore, patients with SDNN < 65.3 ms had a significantly increased risk of sudden death ( $p = .016$ ). Thus, in this study, HRV was the only independent predictor of overall mortality and was significantly associated with sudden death. Aronson et al. [165] measured time and frequency HRV parameters from 24-h Holter recordings in 199 patients with NYHA class III or IV hospitalized for decompensated CHF, and during a mean follow-up after discharge of  $312 \pm 150$  days, 40 patients (21.1%) died. Kaplan–Meier analysis indicated that patients with decreased values of SDNN over a 24-h period, SDANN, total power, and ULF power in the lower tertile were at higher risk of death. In a multivariate Cox regression model, the same indexes in the lower tertile were independent predictors of mortality (RR from 2.2 to 2.6). The conclusion was that the severity of autonomic dysfunction during hospital admission for CHF decompensation, as reflected by measures of overall HRV, can predict survival after hospital discharge.

La-Rovere et al. [166] developed a multivariate survival model for the identification of sudden (presumably arrhythmic) death from data of 202 consecutive patients with moderate to severe CHF. Both time- and frequency-domain HRV parameters obtained from 8-min ECG recordings at baseline and during controlled breathing were challenged against clinical and functional parameters. This model was then validated in 242 consecutive patients referred for CHF as the validation sample. Sudden death was independently predicted by a model that included LFP of HRV during controlled breathing  $\leq 13 \text{ ms}^2$  and left ventricular end-diastolic diameter  $\geq 77 \text{ mm}$  (RR 3.7, 95% CI 1.5–9.3 and RR 2.6, 95% CI 1.1–6.3,

respectively).  $LF \leq 11 \text{ ms}^2$  during controlled breathing and  $\geq 83$  VPCs per hour on Holter monitoring were both independent predictors of sudden death (RR 3.0, 95% CI 1.2–7.6, and RR 3.7, 95% CI 1.5–9.0, respectively). The conclusion was that reduced short-term LFP during controlled breathing is a powerful and independent predictor of sudden death in patients with CHF. Similar results from the same group were reported by Guzzetti et al. [167], who studied 330 consecutive CHF patients. Using time, frequency, and fractal analyses, the risk of pump failure and of sudden death could be differentiated as follows: depressed power of night time HRV ( $\leq 509 \text{ ms}^2$ ), VLP ( $< 0.04 \text{ Hz}$ ), high-pulmonary wedge pressure ( $\geq 18 \text{ mm Hg}$ ), and low left-ventricular EF ( $\leq 24\%$ ) were independently related to pump failure, while reduction of LFP ( $\leq 20 \text{ ms}^2$ ) and increased left ventricular end systolic diameter ( $\geq 61 \text{ mm}$ ) were linked to sudden (arrhythmic) mortality. The dilemma, however, remains that there is no evidence that reducing the frequency of repetitive ventricular arrhythmias or increasing the HRV with medications can significantly reduce the incidence of total death or sudden death in patients with severe CHF.

From a technical point of view, it is interesting to note that HRV parameters may also be retrieved from the memory of implanted devices, as has been shown by Adamson et al. [168]. In 397 patients, continuous HRV was measured as the standard deviation of 5-min median atrial–atrial intervals (SDAAM) sensed by the biventricular pacing device.  $SDAAM < 50 \text{ ms}$ , when averaged over 4 weeks, was associated with increased mortality risk (hazard ratio 3.2,  $p = .02$ ), and SDAAM was persistently lower over the entire follow-up period in patients who required hospitalization or died. Automated detection of decreases in SDAAM was 70% sensitive in detecting cardiovascular hospitalizations, with 2.4 false-positives per patient-year follow-up.

#### Prognostic Significance of Heart-Rate Turbulence

Koyama et al. [169] measured heart-rate turbulence (HRT) in 50 patients with CHF, 34 with IDCM, and 16 with MI and compared this with 21 patients without obvious heart disease as a control group. HRT slope and HRT onset were measured by the original definition using digitized Holter ECG recordings, and cardiac pump function was assessed by echocardiography. The value of the HRT slope was significantly lower in CHF than in controls ( $3.7 \pm 1.7$  vs  $16.4 \pm 5.3$ ,  $p < .01$ ). The value of HRT onset in patients with CHF was significantly higher than in control patients ( $-1.1 \pm 1.9$  vs  $-3.6 \pm 1.7$ ,  $p < .05$ ). The HRT slope and onset in CHF patients with VT were nearly identical to those without VT. It was concluded from this study that HRT slope appears to be a powerful prognostic marker that shows significant differences between CHF subgroups when divided by clinical events such as death or hospitalization from CHF. Kawasaki et al. [170] investigated 104 hypertrophic cardiomyopathy (HCM) patients, 44 MI patients, and 56 normal controls using HRT onset and slope. The latter parameters were abnormal in MI patients, but not in HCM patients as compared with normal control subjects. During a follow-up period of  $27 \pm 10$  months, 7 HCM patients and 10 MI patients either died from cardiac death or were hospitalized for CHF. In MI patients, HRT onset was higher and the HRT slope was lower in patients with cardiac events than in patients without, whereas in HCM patients, the HRT onset or slope was similar between patients with and without cardiac events. It was concluded that, unlike MI patients, the HRT variables in selected HCM patients were not abnormal and failed to predict the clinical prognosis.

In the study of Grimm et al. [171] involving a cohort of 242 patients with IDCM, HRT analysis was performed in a blinded fashion. During  $41 \pm 23$  months of follow-up, 54 patients (22%) died or underwent heart transplantation. On Cox univariate regression analysis, abnormal HRT onset, HRT slope, HRT onset combined with HRT slope, LV ejection, LV size, and NYHA functional class III showed a significant association with total mortality or the need for heart transplantation. On multivariable analysis, abnormal HRT onset identified patients without transplant-free survival, as did LV size and NYHA class III heart failure. Major arrhythmic events were observed in 42 patients (17%) during follow-up. On univariate analysis, abnormal HRT onset with HRT slope, male sex, NYHA class III, LV ejection fraction, and LV size were associated with a higher incidence of major arrhythmic events. On a multivariate analysis, only LV ejection fraction remained a significant arrhythmia risk predictor. It was concluded that in IDCM patients, HRT onset is a significant predictor of transplant-free survival, as well as LV size and NYHA class. For arrhythmia risk stratification, however, only LV ejection fraction remains a significant risk predictor. Again, the main problem is that, when using HRT parameters alone, their PPV is too low though sensitivity is reasonably high. In conclusion, at present there is not sufficient evidence to support routine use of AECG for HRT parameter analysis for therapeutic or prognostic purposes in patients with CHF.

### 33.8.4.3 Hypertrophic Cardiomyopathy (HCM)

The prevalence of ventricular arrhythmias detected from AECG monitoring is relatively high in patients with HCM [172, 176]. It is widely accepted that the presence and severity of ventricular arrhythmias in HCM are related to severe impairment of left ventricular function (LVF). Moreover, SCD and syncope are common among patients with HCM. There are studies showing that there is some association between ventricular arrhythmias and adverse events. However, they differ on the nature of this association [173–176]. Studies on HRV in patients with HCM are sparse and the results equivocal, for example, Counihan et al. [177] found no association between HRV indexes and adverse events in HCM. Reduced HRV on ambulatory monitor recordings appears to be less useful in risk stratification in patients with HCM, as compared to those after acute MI, and thus is not widely used in this patient population. The features that most reliably identify the 10–20% of HCM patients at high risk of sudden death include prior cardiac arrest or sVT, multiple and repetitive episodes of nsVT, young age < 30 years at diagnosis (especially in those with extreme left ventricular hypertrophy (LVH) and wall thickness  $\geq 30$  mm on echocardiography), a family history of HCM with sudden death, an abnormal blood pressure response to exercise especially in patients younger than 50 years, and genetic abnormalities associated with increased prevalence of sudden death [178]. In conclusion, the specific role of AECG monitoring to retrieve risk factors for prognostic reasons, such as ventricular (tachy-) arrhythmias, reduced HRV, or blunted HRT, remains unclear in the day-to-day treatment of HCM patients.

### 33.8.4.4 Valvular Heart Disease

The frequency of PVCs and the grade of arrhythmia (repetitive forms) are significantly correlated with LVEF, but neither is related to the severity of valvular lesions (estimated valvular surface area or hemodynamically measured regurgitation). The occurrence of salvos of VT during an AECG recording in a patient with valvular disease (e.g., aortic stenosis or mitral regurgitation) is related in particular to a low LVEF and to an increased risk of sudden death [179]. Thus, the existence and severity of ventricular arrhythmias in valvular heart disease has an important prognostic value indicating poor myocardial performance, whatever the importance of the valvular lesion is.

A close relationship is now generally accepted between mitral valve prolapse and an increased frequency of ventricular arrhythmias during AECG monitoring compared to a normal population [180–183]. However, the prognostic significance of these findings remains unclear. Ventricular arrhythmias are unrelated to the severity of valvular disease. The prevalence of SVTs has been reported to be 5–10%. However, it includes usually only short runs of atrial beats and non-sustained tachycardias.

In conclusion, at present, the presence of mitral valve prolapse, chronic mitral regurgitation, aortic stenosis or regurgitation, or an aortic valve prosthesis without symptoms does not establish the need for AECG monitoring for analyzing the spectrum of ventricular arrhythmias, nor the parameters of HRV or HRT [7].

### 33.8.4.5 Systemic Hypertension (SH)

In most patients with SH, LVH is present. This is associated with an increased incidence of complex ventricular arrhythmias (VEA) and an increased risk of MI and sudden death [184, 185]. Because patients with SH and LVH with complex or frequent VEA have only a marginally significant risk of dying after adjusting for age, sex, and other clinical factors [186], AECG monitoring is of uncertain value in the management of asymptomatic patients with LVH. With respect to HRV, a few studies have shown an increase of low-frequency components of HRV in hypertensive patients compared to normals, with blunting of circadian patterns and reduced parasympathetic activity in hypertensives. In the Framingham Study, the predictive power of HRV parameters for the incidence of hypertension was tested and after adjustment for factors associated with hypertension, multiple regression analysis revealed that low-frequency components were associated with incident hypertension [187]. In the ARIC study of 2,061 normotensives, 64 participants developed hypertension during a 3-year follow-up, and a statistically significant inverse association between baseline HF band and the risk of incident hypertension was observed [188]. In a further study on dipper and non-dipper essential hypertensive individuals, both the LF and HF band were significantly lower in non-dipper hypertensives than in dipper hypertensive subjects throughout

the day. In dipper hypertensives, the LF band showed a nocturnal decrease and the HF band an increase, whereas these diurnal changes in LF and HF bands were significantly blunted in non-dipper subjects [189]. These data show that hypertensives, and particularly non-dipper hypertensives, are characterized by decreased physiological circadian fluctuations of the ANS. However, because of paucity of relevant clinical data, the true role of HRV in the diagnosis and treatment of patients with essential hypertension remains unclear. In conclusion, there is not sufficient evidence to support routine use of AECG for arrhythmia or HRV parameter analysis for therapeutic or prognostic purposes in patients with essential hypertension and LVH.

#### 33.8.4.6 Miscellaneous

Diabetes is associated among other things with diffuse degeneration of sympathetic and parasympathetic small nerve fibers, and more than 50% of patients with symptomatic diabetic neuropathy will die within 5 years [190]. High-frequency components of HRV may detect small changes in autonomic function in diabetic patients [191, 192] and distinguish diabetic subjects with neuropathy from those without neuropathy [193]. The clinical utility of HRV analysis as a reliable test for cardiac parasympathetic function is limited in diabetics due to the fact that a large number of diabetic subjects have reduced HRV and that there is no evidence that early identification of subclinical neuropathy will lead to improved patient outcomes. Therefore, routine HRV testing in diabetic subjects is not indicated at this time [7].

Patients with chronic renal failure who are on chronic hemodialysis bear an increased risk of CAD and of dying from a cardiovascular event. They show an increase in ventricular ectopy during dialysis. Hemodialysis patients with known CAD or peripheral vascular disease display the highest risk of having an abnormal AECG recording [194]. Though patients with higher grade VEA have a decreased survival compared to those without this type of VEA, it is unclear at present, whether AECG monitoring should be routinely performed in these patients [7].

Regarding pre- and postoperative evaluation, no association has been found between preoperative VEA and postoperative events when AECG monitoring was used before surgery in high-risk patients without myocardial ischemia and depressed LV function, who underwent non-cardiac surgery [195]. In addition, no association has been found between the occurrence of complex VEA after coronary artery bypass surgery and death after controlling for other clinical factors [196]. Therefore, at present there is no general recommendation for the routine use of AECG monitoring for risk stratification in preoperative and postoperative patients [7].

### 33.8.5 Evaluation of Therapeutic Interventions

#### 33.8.5.1 Pacemaker and ICD Function

Once a pacemaker or ICD is implanted, an AECG is useful in assessing postoperative device function and in guiding appropriate programming of enhanced features such as rate responsiveness and automatic mode switching. Sometimes, the AECG can be a useful adjunct to continuous telemetric observation or pacemaker/ICD-based monitoring in assessing device function, though the present generation of pacemaker/ICD has limited monitoring capacity that is not capable of entirely supplanting conventional AECG. Tabular data derived from complexes classified by the pacemaker algorithm according to whether or not they are preceded by atrial sensed or paced beats can be obtained from the pacemaker memory, which summarizes the number or percentage of atrial and ventricular events that were either sensed or paced, including a separate quantification of sensed ventricular events preceding atrial activity. Current pacemaker devices do not generally provide electrogram confirmation of the counts, so the accuracy provided by the devices depends on accurate sensing and pacing functions. These tabular data can be used to broadly determine the frequency of VPBs, but the resolution of the data does not allow for minute-to-minute counts or detailed characterization of repetitive ventricular ectopy (rate, duration, or morphology of VT). Therefore, there is an important role for AECG monitoring in evaluating patients' symptoms, despite pacemaker implantation, or in detecting details of pacemaker failure.

Syncope, dizziness, and palpitations may persist or sometimes reappear in up to 30% of patients after pacemaker implantation, and persistent symptoms are frequently due to various types of arrhythmia. Thus, indications for AECG

Figure 33.35

Arrhythmia overview in a patient with pacemaker-mediated tachycardia including counts of single arrhythmic events (*left*), single lead arrhythmic episodes extracted from the overview on left side, survey on QRS templates over the full 24-h period with 30 s segments (*right*), and three-channel real-time ECG and single lead “full disclosure” ECG (*bottom*) (Oxford MedilogDarwin system).

monitoring in patients with an implanted pacemaker include evaluation of frequent symptoms of palpitation, dizziness, syncope, or near syncope despite or due to pacemaker stimulation, for example, due to failure to sense, oversensing, failure to capture, or pacemaker pauses (myopotential inhibition) as well as due to pacemaker mediated tachycardia (endless loop tachycardia) (▶ Fig. 33.35). Moreover, AECG monitoring may assist in the programming of simple (lower rate interval, AV interval, ventricular and postventricular refractory period, and upper rate response of DDD pacemakers) and of enhanced features like rate responsiveness and automatic mode switching. Evaluation of suspected component failure by AECG monitoring is particularly important in cases where device interrogation is not definitive in establishing a conclusive diagnosis. Pacemaker syndrome is another important symptomatic situation that needs AECG recording to exclude the presence of pacemaker malfunction and to detect the appropriateness of atrio-ventricular synchrony. Pacemaker syndrome as first described in patients with VVI pacemakers may also occur in dual-chamber pacing systems when the programmed AV delay does not allow enough time for the atria to contract against open atrio-ventricular valves. This phenomenon may be observed in the following conditions: (1) programmed prolonged AV delay, (2) DDI or DDIR pacing modes, (3) pacemaker-mediated tachycardia, (4) sinus bradycardia below the lower limit in the VDD pacing mode, (5) pace mode switching from DDD(R) to VVI(R), and (6) rate smoothing or fallback during DDD pacing. In some cases, it may be difficult to differentiate severe pacemaker syndrome from vasovagal syncope, and in these patients head-up tilt-testing may help to clarify the situation. Finally, the efficacy of AADs to suppress concomitant intermittent tachycardias, for example, paroxysmal AF or frequent VPBs that interfere significantly with pacemaker function, can also be assessed by AECG monitoring.

Patients following ICD implantation for the management of ventricular tachyarrhythmias often have ICD shock therapy during follow-up. AECG monitoring can be a useful alternative or adjunct to continuous telemetric monitoring or interrogation of ICD memory in establishing the appropriateness of such therapy. Moreover, the rate of SVTs (sinus tachycardia or AF with high ventricular rates) that eventually interfere with the cut-off parameters of the ICD device, with the consequence of the delivery of inappropriate shocks, may be evaluated and the efficacy of adjunctive pharmacological therapy in suppressing spontaneous arrhythmias in an attempt to minimize the frequency of device activation can be assessed by the AECG, as well.

### 33.8.5.2 Antiarrhythmic Drugs (AADs)

AECG monitoring has been widely used in the past to assess the effects of antiarrhythmic therapy, because it is a non-invasive technique that provides quantitative ECG data and permits correlation of symptoms with ECG phenomena. However, there are important limitations of AECG as a therapeutic guide such as the significant day-to-day variability in the type and frequency of arrhythmias in many patients, a lack of correlation between arrhythmia suppression after an intervention and subsequent outcome, uncertain guidelines for the degree of suppression required to demonstrate an effect, either clinical or statistical, and an absence of quantifiable spontaneous asymptomatic arrhythmias between episodes in many patients with a documented history of life-threatening ventricular tachyarrhythmias [7, 197].

AECG monitoring with quantitative analysis has not been widely used to guide the therapy of supraventricular arrhythmias because of the limited day-to-day occurrence of these arrhythmias and the uncertain significance of asymptomatic non-sustained atrial ectopy. But for evaluating the effects of AADs in patients with supraventricular arrhythmias, particularly AF, intermittent monitoring to confirm the presence of an arrhythmic episode during symptoms and to document arrhythmia-free intervals has become more or less a standard approach. Moreover, the AECG may also be used to monitor the effects of AV nodal blocking agents on heart rate in patients with atrial arrhythmias (beta blockers, digitalis, calcium channel blockers), particularly in AF. Since short-term reproducibility of the frequency and type of arrhythmia, especially in ventricular arrhythmias, between repeat AECG recordings is rather poor, a large reduction between 60% and 90% in arrhythmia frequency is required to ensure that the change is due to an antiarrhythmic effect of any intervention [7].

The best way of assessing the efficacy of a drug is probably to select a group of patients with the same arrhythmia and to measure the spontaneous variability between a control and a placebo period. If the variability is small with a good correlation between the two periods, a drug trial appears possible. It is then feasible to compare the respective efficacy of two drugs in the same group of patients. The appropriate statistical method (such as that developed by Sami et al. [198, 199]) uses a one-tailed 95% confidence interval calculated between baseline and placebo PVC measurements. The appreciation of the antiarrhythmic effect is based on the comparison with the relation between drug and control (● Fig. 33.36). If a drug shifts a PVC value under the 95% confidence interval line, its effectiveness can most likely be assumed in that patient. If a drug A shifts more patients under the 95% confidence interval line than drug B, A is probably more effective than B in this selected arrhythmia. This method is largely used to compare a new drug with an established treatment chosen as reference. An important limitation is the necessity to observe several periods without treatment (control, placebo, follow-up). Patients with severe symptomatic arrhythmias cannot be included in these studies. Open studies are indicated in such patients.

The data from the CAST trial, in which a higher mortality rate during follow-up was observed in those patients who had suppression of spontaneous VPBs after a titration phase and then received chronic encainide or flecainide therapy as opposed to placebo, led to a revision of the former concept that suppression of PVCs by AADs would improve the prognosis of patients with structural heart disease. Indeed, the trial showed that antiarrhythmic therapy with encainide or flecainide may be harmful to patients. More or less similar inconsistent results have been obtained with the empiric use of amiodarone, since some studies such as the BASEL, CASCADE, or GESICA trials showed a benefit in patients with preserved or depressed LV function [200–203], while others like EMIAT or CAMIAT revealed no significant change in mortality rate [204–206]. In one trial, amiodarone produced a significant reduction in arrhythmia frequency but had no effect on mortality rate [206].

In contrast to supraventricular tachy(arrhythmias), placebo-controlled trials of antiarrhythmic interventions in patients with sustained life-threatening ventricular tachyarrhythmias are problematic. Although in the study of Lampert et al. [207] improvements in arrhythmia-free survival in CHD patients who met certain criteria for drug response during serial AECG were reported, it is not possible to estimate the effects of the “healthy responder” phenomenon [208] on these observations, which means that patients who responded to the AECG-guided drug therapy had a different (more favorable) prognosis than those who did not. With respect to the method of choice for monitoring the outcome of an antiarrhythmic intervention, AECG as well as EP testing may be used. The ESVEM study [209], which used both tests in a randomized fashion on patients with an entry criterion of inducibility of sVT on two occasions and  $\geq 10$  VPBs/h showed that there was no significant difference in predicting long-term success in either group, once a drug was determined to be effective (EPS: suppressing inducible VT, AECG: suppression of VPBs). However, AECG monitoring had the advantage in that it identified an AAD predicted to be effective more often than EPS in these patients. For practical reasons, despite

■ Figure 33.36

Results from a crossover comparative trial of quinidine ( $1\text{ g day}^{-1}$ ) and amiodarone ( $400\text{ mg day}^{-1}$ ) in 30 patients with frequent PVCs using the statistical methodology of Sami et al. [198, 199]. Each diagram shows a correlation line with a one-tailed 95% confidence interval indicated by the dashed line. In the top diagram, the control and placebo periods are compared with respect to the incidence of PVCs while similar comparisons are shown in the middle diagram for control versus quinidine and in the lower diagram for amiodarone versus control. The symbol  $N$  represents PVC frequency per hour. The effectiveness of the AAD therapy can be judged by the number of points beneath the 95% confidence interval line. In other words, the incidence of PVCs in patients on these drugs is lower than in control or placebo periods. It can also be seen that the antiarrhythmic efficacy is higher in patients with amiodarone than in those with quinidine.

the many criticisms of the ESVEM trial, it may be concluded that AECG monitoring may be used to assess AAD efficacy in patients with frequent VPBs, but not in those with spontaneous sustained VTs.

The same holds true for assessing the phenomenon of proarrhythmia, which is defined as the aggravation of an arrhythmia, particularly of VEA, for example, either the increase of the number or complexity of VEA or the new incidence of a given ventricular arrhythmia, as well as sinus node dysfunction, or new or worsened AV conduction abnormalities. Proarrhythmia may occur early or late during the course of therapy, and an increase of arrhythmia needed to differentiate proarrhythmia from day-to-day variability may be estimated statistically on the basis of baseline arrhythmia frequency [198, 199, 210, 211]. A particular type of proarrhythmia is the induction of torsades de pointes that may be induced by drugs that prolong the QTI (e.g., class III AADs, tricyclic antidepressants, antihistamines, antibiotics, etc.). In such cases, AECG monitoring may be useful for the evaluation of new markers of this type of proarrhythmia, such as alternating QTIs or T waves, or altered QT-interval adaptation to changes in heart rate.

### 33.8.5.3 Antianginal Drugs

Most antianginal drugs are commonly assessed by counting the frequency of anginal attacks, and the number of nitroglycerin tablets consumed. This kind of investigation relies entirely on subjective symptom appreciation. Changes in lifestyle, environmental conditions, or daily activity may deeply affect the results. ST-segment monitoring provides an objective technique, as does stress testing, which is now routinely performed to evaluate these therapies. Thus, physicians should use repetitive stress tests or continuous AECG monitoring in cases of exercise angina. Twenty-four-hour ECGs are more efficient for characterizing the pharmacological properties of the drug, such as delay and duration of effect. In the case of spontaneous (Prinzmetal's) angina, ambulatory monitoring is the optimum technique allowing an accurate evaluation of the drugs, which are used in this condition (calcium antagonists) [212]. The development of AECG has also revealed that all patients with spontaneous angina exhibit painless episodes of ST-segment elevation in addition to experiencing painful attacks. When an antianginal treatment such as a calcium antagonist is not completely effective, only painless episodes persist. Repeated 24-h ECGs are then necessary to assess the efficacy of treatment and the need for an increase in dosage or a change to another drug. Thus, suspected Prinzmetal's angina is obviously a good indication for ambulatory monitoring, which is useful both as a diagnostic procedure and for evaluation of therapy.

## 33.9 Pediatric Patients

Similar to adult patients, the purposes of AECG monitoring in pediatric patients include the evaluation of symptoms, risk assessment in patients with cardiovascular disease, with or without symptoms of an arrhythmia, and the evaluation of cardiac rhythm after an intervention like drug therapy or device implantation [7]. Selection of the method of monitoring, for example, continuous versus patient activated recording, is predicated on the frequency and symptoms of the arrhythmia. AECG monitoring may be useful for evaluation of symptoms in patients with known cardiovascular disease and for medical therapy and intervention. In children with asymptomatic congenital heart block, a yearly Holter monitor is recommended. The escape rate at resting conditions is used as one criterion for the need of pacemaker implantation. In general, a resting heart rate greater than 60 bpm in children under 2 years, greater than 50 bpm in children 2–10 years, and greater than 40 bpm in children over 10 years of age is considered to be an adequate escape rhythm. In addition, the mean heart rate, the slowest heart rate, and the longest pause on AECG monitoring can also be used as supportive data, and the presence of ventricular ectopy (as single escape beats) is another indication for pacemaker implantation.

### 33.9.1 Evaluation of Symptoms

AECG in pediatric patients may be used for the evaluation of symptoms including palpitations, dizziness, syncope or near syncope, and chest pain and their relation to an underlying arrhythmia. Because of the paroxysmal nature of palpitations, an event recorder is usually recommended to detect the cause of these symptoms. In 10–15% of young individuals, an arrhythmia, in most cases SVT, has been reported to correlate with symptoms (213–218), (Table 33.10), whereas ventricular ectopy or bradycardia was demonstrated in only other 2–5%. Interestingly, in about 50% of palpitations, sinus

tachycardia was found, whereas 30–40% of young patients have no symptoms in AECG monitoring. Thus, one of the primary uses of AECG monitoring in pediatric patients is to exclude an arrhythmia as the cause of palpitations [7]. Recently, the value of transtelephonic monitoring (TTM) in the evaluation of symptoms in young persons has been clearly demonstrated by Saarel et al. [219] in a large cohort of 420 patients with palpitations, 43 with chest discomfort, and 32 with presyncope and syncope. Fifty-two percent ( $n = 257$ ) of patients failed to transmit an ECG while experiencing symptoms. Of 238 symptomatic patients, 35 (15%) had SVT, and all patients with SVT had palpitations. The overall sensitivity of the TTM test was 83% (35 of 42) for detection of SVT, and the NPV was 99% in this patient population. The conclusion was that TTMs are useful for the evaluation of children and adolescents with palpitations but not with isolated chest pain, syncope, or presyncope.

Because of the intermittent nature of transient neurological symptoms such as dizziness, syncope, or near syncope in pediatric patients without structural heart disease, the efficacy of 24-h or 48-h AECG monitoring is low and thus, its ability to clarify patients' symptoms is limited. Therefore, prolonged AECG monitoring is only recommended in those individuals with known heart disease or with exertional symptoms, in whom the presence and significance of an arrhythmia may be increased [220, 221]. An alternative diagnostic tool may be the implanted loop recorder (ILR) in case conventional investigations have failed to identify the cause of syncope or palpitations. In a small series of 4 children with congenital heart disease, who suffered from presyncope ( $n = 1$ ), syncope ( $n = 2$ ), and palpitations ( $n = 1$ ), an ILR was implanted. All patients experienced typical symptoms and activated the device appropriately at a median of 86 days (46–102) after implantation. In 2 of 4 cases, a likely cause for the symptoms was identified, with exclusion of more malignant arrhythmic diagnoses in all patients. The conclusion from this study was that an ILR can be implanted in young children without difficulty and that this device may prove to be very useful for excluding malignant arrhythmias as a cause of symptoms in patients at high risk [222]. Chest pain is a relatively rare symptom, and a cardiac cause is identified in only 5% or less of pediatric patients, so that the primary role of AECG monitoring in these patients may be to exclude rather than diagnose a cardiac cause [7].

### 33.9.2 Evaluation of Patients with Known Cardiovascular Disease

AECG monitoring may be particularly useful in pediatric patients after surgery for congenital heart disease, but the frequency of recording periods has to be based on the type of defect, ventricular function, and late postoperative arrhythmias. Uncomplicated repairs of simple defects such as atrial or ventricular septal defects or with aortic or pulmonary stenosis have a low incidence of late postoperative arrhythmias, whereas complex repairs or those with residual hemodynamic abnormalities display a high incidence of late postoperative arrhythmia. High grade ambulatory VEA associated

with ventricular dysfunction seems to identify patients at an increased risk of late sudden death [223–227]. Major atrial surgery such as Mustard's or Senning's operation for transposition of great arteries or Fontan's operation for functional single ventricle hearts is often associated with sinus node dysfunction and with unusual types of AFI (which is called incisional atrial re-entrant tachycardias = IART). Major ventricular surgeries such as tetralogy of Fallot repair, repair of double outlet right ventricle, etc. may predispose to serious ventricular tachyarrhythmias in the long run. In the past, complex VEA or nsVT were considered as risk stratifiers in those patients. However, Cullen et al. [225] showed, at least in patients after repair of Fallot, that after a follow-up of 12 years, asymptomatic VPBs were common and the presence of complex VEA or non-sustained VT were not prognostically significant in this patient group. Nevertheless, if complex ventricular arrhythmias are detected with AECG monitoring in post-operative high-risk pediatric patients with depressed ventricular function, there is a need for further investigation, even in the absence of overt clinical signs or symptoms [228].

A second group of pediatric patients may benefit from periodic AECG monitoring, namely, those with hypertrophic or dilated cardiomyopathy as well as with the congenital long QT syndrome because of the tendency of progression of these diseases and the need to adjust medication doses with growth [7]. The rate of 9–15% of sudden death as a first symptom in young patients with these types of disease is significantly higher than in adults, and AECG monitoring is needed to identify occult arrhythmias that may indicate the need for reevaluation of therapy in asymptomatic patients, though the absence of an arrhythmia during one or several monitoring periods does not necessarily indicate a low risk of arrhythmic sudden death. There is no doubt that unexplained syncope or cardiovascular collapse in young patients with known cardiovascular disease generally requires in-hospital continuous ECG monitoring and sophisticated (e.g., by MRI) or invasive evaluation when the cause of the event is uncertain. But if a cause cannot be established by MRI or invasive methods, AECG monitoring may be used for subsequent surveillance to possibly detect both transient brady- and tachyarrhythmias [7].

### 33.9.3 Evaluation of Medical Therapy or Intervention

---

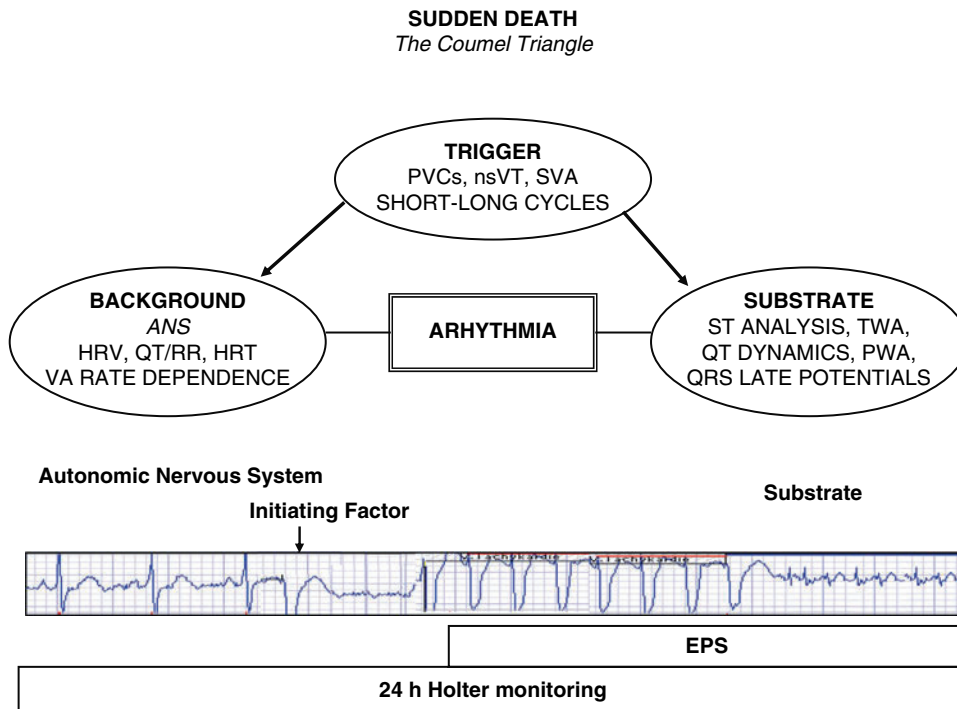

AECG monitoring may be helpful to evaluate both beneficial and potentially harmful effects of pharmacological therapy as well as to detect possible causes of symptoms in patients with pacemakers or after radiofrequency catheter ablation or cardiac surgery, particularly when complicated by transient AV block [229, 230]. Another important indication for AECG monitoring is the evaluation of cardiac rhythm after treatment of incessant tachyarrhythmias, which have been associated with progressive ventricular dysfunction [231]. In this context, the above mentioned technical aspects and limitations of AECG monitoring (e.g., day-to-day variability of arrhythmias, etc.) have to be taken into account.

### 33.10 Future Perspectives of Ambulatory Monitoring

---

Further advances in AECG monitoring analysis include better characterization of duration and dispersion of ventricular depolarization (QTI), the detection of T-wave alternans, the identification of different patterns of onset of arrhythmias (short–long–short sequence, tachycardia versus bradycardia dependence of arrhythmias), the computation of heart-rate turbulence indexes, and the evaluation of P wave and QRS-wave morphology including P-wave averaging and late potential analysis, from high-quality AECG signals [232]. By this means, old and new markers derived from AECG monitoring could be integrated to provide a comprehensive noninvasive AECG test, to fully characterize all three components of the triangle of risk factors (▶ Fig. 33.37) that may lead to electrical instability and SCD: the electrophysiologic (arrhythmia) substrate, the triggers for malignant ventricular arrhythmias provoking SCD, and the modulation of the (background) sympatho–vagal balance of the ANS [233].

Thanks to the availability of larger storage capacities, in the near future long-term (weeks–months) continuous high-quality AECG monitoring may become available. Moreover, devices for long-term long-distance telemetric surveillance using transtelephonic transmission of ECG data for high-risk cardiac patients have already become a reality. Some modern digital recorders already have the capability for multichannel (8–12 channels) simultaneous ECG recordings, which

■ Figure 33.37

Schematic representation of the triangle of risk factors that may lead to electrical instability with subsequent ventricular fibrillation, including the different parameters that can be derived from AECG monitoring: the electrophysiologic substrate, the balance of the ANS, and the triggers of malignant ventricular arrhythmias that provoke SCD. Abbreviations: PVCs: premature ventricular contractions, nsVT: non-sustained VT, SVA: supraventricular arrhythmias, HRV: heart-rate variability, QT/R-R: QT/R-R interval relation, HRT: heart-rate turbulence, VA: ventricular arrhythmias, TWA: T-wave alternans, PWA: P-wave duration from averaged ECG (Modified from Coumel 1990).

might be interesting for ischemia monitoring. Finally, multichannel digital recordings will allow the retrieval of different biological signals by appropriate sensors, such as arterial pulse pressure, respiratory rate, peripheral oxygen tension, EEG, and others. This will transform AECG monitoring into ambulatory polycardiography that will allow the comprehensive evaluation of patients with complex disorders, such as CHF, cor pulmonale, or sleep apnea syndromes, and the detection and quantification of underlying interactive pathophysiological mechanisms [232].

## 34.1 Background

### 34.1.1 Historical Background

The first mobile coronary care unit was reported by Frank Pantridge in 1967 [1]. He described 352 patients with presumed acute myocardial infarction who were treated prior to hospital admission. Ten of them were successfully resuscitated following an out-of-hospital cardiac arrest. In 1970, electrocardiographic telemetry from ambulances was first described [2]. At that stage, only rhythm strips were transmitted. However, in the 1980s, at the time of the introduction of fibrinolysis, many ambulance organizations started to routinely record a 12-lead electrocardiogram (ECG). This was originally done with the sole purpose of detecting ST-segment elevation, thereby starting treatment with fibrinolysis prior to hospital admission. However, when this research area was in its infancy, it was thought that all patients with an impending myocardial infarction could perhaps benefit from this treatment [3] and the need for a prehospital ECG was therefore not obvious [4].

In an important meta-analysis published in 1993 [5], it was clearly shown that patients who would benefit from fibrinolysis were those with ST-segment elevation or left bundle branch block and that the earlier the treatment started, the better it would be. This important finding put the 12-lead prehospital ECG in focus. However, in large screening studies, it was shown that only a minority of patients with acute chest pain, who were transported by ambulance, had these changes on their prehospital ECG [6]. At this early stage, it was shown that other ECG changes, such as ST depression, were also an alarming ECG sign, but the prehospital treatment for these changes was not established.

During the last few years, the use of the prehospital ECG has become more and more widespread, with the aim not only of starting prehospital fibrinolysis but also improving the prehospital triage of patients with acute chest pain. Parallel to this, research on out-of-hospital cardiac arrest has been going on for the past 3 decades. In this case, the prehospital ECG is the most important tool when it comes to advising optimal treatment. During the last decade, ECG research has focused on the opportunity to predict the outcome of defibrillation in ventricular fibrillation based on wave-form analysis.

### 34.1.2 Ideological Background

Two major pathophysiological considerations constitute the principal background for the need for a prehospital ECG when a heart attack is suspected: (1) "Time is saved myocardium" and (2) the occurrence of life-threatening arrhythmias in myocardial ischemia and myocardial infarction, which is most common in the very early phase.

1. The opportunity to limit myocardial damage with early medication was first described in dogs in 1971 [7]. These findings have been followed by a very large number of studies in humans, showing that early treatment with medical [8] or mechanical [9] reperfusion and with antiplatelet [10] and anti-ischemic agents [11] will improve the outcome in a threatening myocardial infarction.

Although we lack absolute proof of the value of prehospital initiated aspirin versus aspirin started after hospital admission [12–14], for example, our current knowledge strongly indicates that the earlier the various interventions in acute coronary syndrome are started, the better it would be. The question of whether to start treatment prior to or after hospital admission is more a cost-benefit issue. Based on such thinking, the most optimal solution for every single patient with any suspicion of acute coronary syndrome should be that he or she has an ECG recorded prior to hospital admission.

2. The fact that life-threatening arrhythmias are most frequent in the early phase of acute coronary syndrome and nearly half the deaths from ischemic heart disease occur outside hospital (mostly as sudden deaths) underlines the importance of research in this area [15]. More knowledge on the information that is hidden in the electrocardiogram in this scenario might improve the outcome for these patients.
3. At present, we do not know whether a prehospital ECG might be of benefit in other clinical scenarios in the prehospital setting. Theoretically, there are conditions such as stroke [16].

### 34.1.3 Three Major Objectives

The three major objectives for a prehospital ECG are:

1. Detection of myocardial ischemia/infarction.
2. Detection of arrhythmias.
3. Remaining objectives, of which little is known, but heart rate variability and stroke are interesting aspects.

In what follows, these three objectives will be evaluated in more detail.

### 34.1.4 Symptoms that Indicate a Prehospital ECG

The indications for a prehospital ECG should be liberal, since a variety of symptoms might be caused by an acute coronary syndrome. These symptoms are listed in [Table 34.1](#). Although the typical symptom in acute coronary syndrome is acute chest pain, the disease can present with pain in other locations and various other symptoms. The symptoms that are listed in the table often appear in combination.

### 34.1.5 Benefits

The principle behind the proposed benefit of using a prehospital ECG is shown in [Table 34.2](#). The detection of the presence or absence of ECG abnormalities will improve the triage in patients in whom it is used. In selected patients, this will result in the earlier treatment of myocardial ischemia/infarction or arrhythmias, which are associated with hemodynamic consequences. It is to be hoped that this will then result in an improved outcome.

## 34.2 Detection of ECG Abnormalities

The various ECG abnormalities (excluding arrhythmias) that the ambulance crew or other health-care providers should look for in the prehospital setting are shown in [Table 34.3](#). The percentage of patients with an abnormal or

QRST signs indicating previous myocardial damage

pathological ECG depends on the study population. Reported studies have comprised patients who call for an ambulance due to acute chest pain or other symptoms raising suspicion of an acute coronary syndrome [17–19]. In these reports, a high percentage have an abnormal ECG (● Fig. 34.1). It is important to stress that patients who call for an ambulance represent a population with high comorbidity and a high likelihood of underlying cardiac pathology as compared with other chest pain populations [20–22]. So, if a prehospital ECG was recorded among patients who visited a general practitioner because of acute chest pain, the percentage of patients with a pathological ECG could be expected to be lower, since these patients are less likely to have a cardiac pathology [23]. The most common ECG abnormalities in the prehospital ECG among patients with acute chest pain are those indicating myocardial ischemia/infarction and various rhythm abnormalities.

■ **Figure 34.1**

A 12-lead ECG report from a Lifepak15. This simulated example shows ST elevation that is correctly detected and highlighted.

### 34.2.1 Myocardial Ischemia/Infarction

Myocardial ischemia/infarction have been reported in about 50% of patients who called for an ambulance due to acute chest pain and in whom a prehospital ECG was recorded [17–19, 24]. Signs of myocardial ischemia/infarction include ST-segment deviation, Q waves and T-wave inversion. The relative importance of these changes will be described separately. In overall terms, when any of these are present in association with acute chest pain, the likelihood of a fresh myocardial infarction is high and the presence of any of them are mostly equivalent to an acute coronary syndrome. The presence of ECG changes indicating acute ischemia/infarction is also an alarming sign with regard to the risk of early death [25].

Difficulties in interpretation arise when a complete left bundle branch block is present. If this abnormality is new, it could indicate an extensive myocardial infarction and is therefore an indication for early reperfusion [5]. However, there are difficulties in the prehospital setting when it comes to determining whether the left bundle branch block is new or not, as no previous ECG is generally available for comparison. Similar difficulties might also arise for other ECG indicators of myocardial ischemia/infarction.

### 34.2.2 Arrhythmias

The rate of occurrence of various arrhythmias is entirely dependent on the study population. Among patients with acute chest pain who call for an ambulance, life-threatening arrhythmias leading to cardiac arrest are found, but only among a small percentage [19, 24]. On the other hand, among patients found in cardiac arrest and in whom resuscitation was attempted, about one third are found in ventricular fibrillation [26]. However, in such a study population, particularly if there is a cardiac etiology, a much higher percentage (about 80%) is thought to have ventricular fibrillation at the onset of cardiac arrest [26].

Supraventricular arrhythmias, such as atrial fibrillation, during ambulance transport have been reported to occur in about 10% of patients with acute chest pain [24] and in less than 10% of patients with ST-elevation acute myocardial infarction [27–29]. The occurrence of various arrhythmias during continuous ECG monitoring will be described later in this chapter.

### 34.2.3 Other

---

Other ECG abnormalities suggesting a cardiac pathology, including signs of a previous acute myocardial infarction, pacemaker ECG, and signs of left ventricular hypertrophy, are frequently seen in patients transported by ambulance with acute chest pain (between 10% and 20%) [18, 19]. It was recently reported that, among patients with trauma, the evaluation of heart rate variability in the prehospital setting might improve triage, if information on the Glasgow Coma Score (the degree of consciousness) was not available [30] and also independent of the Glasgow Coma Score [31].

## 34.3 Improved Triage

---

To date, the prehospital ECG has primarily resulted in the improved triage of patients with an acute coronary syndrome and patients with various arrhythmias. This improvement will have a number of consequences.

### 34.3.1 Direct Transport to Coronary Care Unit

---

Information on the percentage of patients with acute coronary syndrome or ST-elevation acute myocardial infarction, who are directly transported to a coronary care unit, bypassing the emergency department, is limited. In one previous study, it was reported that 67% of patients transported by ambulance fulfilled these criteria and that these patients had improved survival [32]. Experience from Sahlgrenska University Hospital in Göteborg, Sweden, indicates that among ambulance transported patients, 50% of patients with ST-elevation myocardial infarction have been directly transported to a coronary care unit and that this has been associated with a marked improvement in long-term survival [33].

### 34.3.2 Direct Transport to Catheterization Laboratory

---

Today in urban areas, there are single ambulance organizations which can transport the vast majority of patients with ST-elevation acute myocardial infarction directly to the catheterization laboratory with a median delay between the onset of symptoms and the start of percutaneous coronary intervention (PCI) of less than 2 h (unpublished observations). If the nearest hospital has facilities for PCI, effective collaboration can increase the opportunity for very early coronary intervention.

### 34.3.3 Direct Transport to Remote Hospital

---

Since primary coronary intervention is currently regarded as the preferred treatment strategy in ST-elevation acute myocardial infarction, it has been suggested that these patients should be transported to hospitals with these facilities, even if the transport time is prolonged [34]. It has been stated that patients admitted to noninterventional hospitals should be immediately transferred to interventional hospitals for primary coronary intervention, if the time from the first medical contact to balloon inflation is kept at less than 90 min [35–38]. Recent data indicate that an even longer delay might be acceptable [39].

In previous studies, patients have waited between 30 min and more than 1 h at local hospitals before being transferred to the intervention hospitals [37, 38, 40]. This local hospital delay may be reduced or even eliminated by prehospital diagnosis if a combined strategy of rerouting patients directly to an intervention hospital is implemented. However, limited evidence is available about the benefit, safety and feasibility of this kind of re-routing strategy. However, programs to further evaluate the possible benefits of such a procedure have been described [35].

## 34.4 Earlier Start of Treatment

---

### 34.4.1 Earlier Start of Fibrinolysis

---

#### 34.4.1.1 Prior to Hospital Admission

A number of studies have shown that, if a 12-lead prehospital ECG is recorded and is followed by prehospital fibrinolysis, the potential time saved with regard to the start of fibrinolysis varies between 45 and 125 min [3, 6, 28, 29, 41–47]. In a national perspective (Sweden) it has been shown that treatment can start  $\leq 2$  h after the onset of symptoms in half of patients [27]. However, such figures will vary between countries due to local facilities. It has been suggested that more patients can be treated at an early stage in urban areas compared with rural areas [48].

#### 34.4.1.2 In Hospital

It has also been shown that a prehospital ECG reduces the in-hospital delay to the start of fibrinolysis (door-to-needle time) [49]. A systematic review in which 1,283 citations were identified and five studies met the inclusion criteria [50] indicated that the introduction of a 12-lead prehospital ECG and advanced emergency department notification reduced the mean door-to-needle time by 36 min (95% confidence limits 9–63 min).

In a national registry of acute myocardial infarction in the USA, the mean door to in-hospital drug time was reduced from 35 to 25 min with a prehospital ECG ( $p < 0.0001$ ) [51]. A meta-analysis comprising four studies (99 patients) from an original 2,129 publications revealed a shortening of the in-hospital delay to reperfusion by 25 min (95% confidence limits 17–37 min) with the introduction of a prehospital ECG [52].

### 34.4.2 Earlier Start of Percutaneous Coronary Intervention (PCI)

---

A study from North Carolina revealed that prehospital wireless transmission of an ECG to a cardiologist's hand-held device reduced the median door-to-reperfusion time (PCI) by about 50 min [53]. In a national survey in Sweden, it was shown that, among patients who were transported by ambulance and had ST-elevation acute myocardial infarction, those who did not have a prehospital ECG had a delay between the onset of symptoms and reperfusion (PCI) of 240 min as compared with 181 min among patients with a prehospital ECG ( $p < 0.0001$ ) (a time saving of 59 min) [54]. In the National Registry of Acute Myocardial Infarction in the USA, it was shown that, with a prehospital ECG, the in-hospital delay time to PCI was reduced from 1 h 49 min to 1 h 34 min [51]. A number of studies performed during the last few years have further confirmed these data, strongly suggesting a clear reduction in delay to PCI in ST-elevation acute myocardial infarction where a prehospital ECG is used and communicated to hospital appropriately [55–59].

### 34.4.3 Earlier Start of Antiplatelet and Antithrombotic Therapy

---

Various antiplatelet agents such as aspirin [60] and clopidogrel [61] and various antithrombotic agents such as heparin [62] have been shown to improve the prognosis in acute coronary syndrome. A prehospital ECG improved the opportunity to start this treatment prior to hospital admission. Aspirin treatment can then start as early as 1–2 h after the onset of symptoms. Similar findings have been reported for heparin and low molecular weight heparin [63].

### 34.4.4 Earlier Start of Anti-Ischemic Therapy

---

Beta-blockers have been shown to improve the prognosis in acute myocardial infarction [11], and intravenous treatment with beta-blockers, started prior to hospital admission, has been shown to relieve pain [24]. A prehospital ECG increases the opportunity to select the right patients for this treatment in the prehospital setting.

### 34.4.5 Earlier Start of Antiarrhythmic Therapy

---

Based on findings in the prehospital ECG, a number of antiarrhythmic drugs are of potential value in the prehospital setting when it comes to treating supraventricular and ventricular arrhythmias [64]. They include adenosine [65, 66], verapamil [67], diltiazem [68], and amiodarone [69].

## 34.5 Improved Outcome

---

### 34.5.1 Reduced Mortality

---

A systematic review found one study that revealed a nonsignificant reduction in all-cause mortality from 15.5% to 8.4% associated with the introduction of a prehospital ECG and advanced emergency department notification as compared with no such intervention [50].

In an observational study in Sweden on patients who had ST-elevation acute myocardial infarction, were transported by ambulance, and were treated with percutaneous coronary intervention, it was shown that a prehospital ECG was an independent predictor of reduced 30-day mortality [54]. Field triage of patients with ST-elevation acute myocardial infarction has also been shown to reduce mortality in Australia [70]. A similar trend was also found in the USA [71].

### 34.5.2 Reduced Morbidity

---

We are not aware of any study evaluating morbidity (various complications associated with the disease) changes associated with the introduction of a prehospital ECG. It can be assumed that there are subsets of patients in whom the duration of hospital stay (number of days in hospital) might be shortened. In a recent report, field triage with a prehospital electrocardiogram was associated with a preserved left ventricular function [70].

### 34.5.3 Health Economy

---

The use of health-economic analyses to assess the value of medical technologies is well established, but these analyses have been under-used in studies of ECG. One article [72] has outlined a general framework for the economic evaluation of the ECG and applied these methods to the development of an economic analysis protocol for assessing the economic attractiveness of the wireless transmission of ECG data to the cardiologist making the treatment decision.

## 34.6 Negative Consequences

---

There are two major negative consequences of the prehospital ECG.

### 34.6.1 Increase in Delay

---

The delay to arrival at hospital will increase, particularly among patients in whom the ECG does not show any pathological changes. However, it has been shown that the on-scene time is not dramatically prolonged by the recording of a 12-lead ECG [73, 74]. A systematic review revealed that the on-scene time increased by 1.2 min (95% confidence limits 0.8–3.2 min) [50].

### 34.6.2 False Information

---

The second major negative consequence is that ECG abnormalities may mimic myocardial infarction, but may in fact be caused by other conditions [75]. It has been reported that, among patients with chest pain and ST elevation in the prehospital setting [76] and at the emergency department [77], 85% and 51% respectively had diagnoses other than myocardial infarction. Conditions in which misinterpretation has occurred and in which fibrinolytic treatment can be detrimental include intracranial hemorrhage [75] and aortic dissection [78].

Negative consequences associated with technical problems will be dealt with in the implementation part of this chapter.

## 34.7 Implementation

---

### 34.7.1 Education and Training

---

There is currently a wide range of teaching techniques that can be used to train healthcare professionals in the use of 12-lead ECG-monitoring equipment and ECG interpretation.

The methods identified range from

1. Traditional teaching methods including (a) books, (b) lectures, (c) videos, (d) hospital placements (using patients), and (e) practical laboratory sessions (using volunteers) to
2. Advanced teaching methods including (a) PC-based ECG software packages (b) 12-lead ECG signal generators, and (c) advanced training mannequins (patient simulators) [79].

The traditional teaching methods have some disadvantages in terms of patient or volunteer consent and discomfort and also in terms of teaching effectiveness. The more advanced teaching methods make use of simulation which can be either screen based (computer software) or physical (realistic models or mannequins).

There are a number of ECG simulators on the market that can be connected to an ECG machine. Various models of ECG simulators that are connected to a mannequin are also available.

### 34.7.2 Technical Problems

---

The transmission of ECGs is the most common technical problem associated with the use of a prehospital ECG. With a few exceptions, the transmission of an ECG is associated with problems at the start. Most EMS systems experience a learning curve when a 12-lead ECG transmission technology is first implemented. One study reported a 33% failed transmission rate after initiating the system, but it had been reduced to 11% 6 months later [74].

### 34.7.3 Practical Implementation

---

Implementing a prehospital ECG program represents a significant investment in terms of time, effort, personnel and resources. The implementation has three phases: (1) phase I is a retrospective baseline analysis; (2) phase II is a feasibility and safety assessment; and (3) phase III involves the implementation of the accurate and routine prehospital identification of candidates for various aspects of treatment of an acute coronary syndrome, such as candidates for treatment with fibrinolysis or percutaneous coronary intervention [80]. Eligibility for fibrinolysis or percutaneous coronary intervention can be determined by means of a check list, the results of which can be sent to either the base or the receiving physician [81]. A written protocol including clinical algorithms for prehospital personnel should be established [80]. Finally, an effective quality assurance and improvement program should be initiated before implementing a prehospital ECG program [81].

Prehospital 12-lead ECG programs should be strongly considered by all EMS systems with advanced life support capability. Prehospital 12-lead ECG programs should be implemented through a systematic process that encompasses every facet of the EMS system [82].

#### 34.7.4 Process Monitoring

---

One of the principal aims of the introduction of a prehospital ECG is to reduce the time to reperfusion in ST-elevation myocardial infarction. In order to evaluate the impact on this important end point, the delay from the first medical contact to the start of reperfusion either with fibrinolysis or with percutaneous coronary intervention must be continuously monitored. Although, as previously stated, the short-term impact on delay to reperfusion with a clear-cut reduction is impressive, the results in the long-term perspective are less well described. It is to be hoped that, in the long term, the teamwork between prehospital and in-hospital health-care providers will improve with a successive decline in the time to reperfusion over the years.

However, the results so far are disappointing. In a recent 10-year survey, it was shown that the delay from door to primary coronary intervention was not sustained [83]. In the first year of the intervention (including the implementation of the prehospital ECG), the time from hospital arrival to primary coronary intervention was 80 min. In years 2, 3, and 4, this delay was 93, 85, and 94 min, respectively. In 2003, 10 years after the intervention, the delay had increased to 113 min [83].

Experience from the Swedish registry on heart intensive care indicates that the time between admission to hospital and the start of reperfusion has remained unchanged during the last few years [84].

### 34.8 Interpretation

---

The category of health care professionals who interpret the prehospital ECG varies markedly. They include cardiologists, emergency physicians, anesthesiologists, general practitioners, nurses, semi-nurses (nursing assistants), paramedics, and emergency technicians. The educational levels of these various categories vary considerably. So, when discussing the problem of interpreting the prehospital ECG, each category of health-care professionals must be discussed separately, and separate educational programs should probably be implemented for these various groups.

There are different ways to interpret the prehospital ECG.

#### 34.8.1 In-Field Interpretation

---

##### 34.8.1.1 By Health-Care Providers

In-field interpretation by health-care providers without assistance requires a high educational level. This type of interpretation is most common when a physician is on board the ambulance or when a general practitioner sees the patient prior to the arrival of the ambulance. In several countries such as France, this is the most common way of interpreting the prehospital ECG. However, it has been suggested that highly trained paramedics in an urban EMS system can identify patients with ST-elevation acute myocardial infarction as accurately as blinded physician reviewers [85]. This has been supported by others [86] and it seems as though paramedics as well as CCU nurses can learn to conduct live reperfusion decision making in ST-elevation myocardial infarction [87].

##### 34.8.1.2 With Computer Assistance

Computer algorithms for the diagnosis of ST-elevation myocardial infarction may also be considered [88, 89]. This strategy has, however, previously been restricted to the diagnosis of large ST-elevation myocardial infarctions with cumulative ST elevation above 600–1,000  $\mu$  V [90, 91]. Interpretation in the field with computer assistance has been reported to be a

relatively safe procedure [92]. Recently, a new acute coronary syndrome computer algorithm for interpreting prehospital ECGs was suggested [93]. The results demonstrated that, with the assistance of the new algorithm, the emergency physician and cardiologist improved their sensitivity when it came to interpreting acute myocardial infarction by 50% and 26% respectively, without any loss of specificity. The patients' age and gender were taken into consideration in the algorithm. However, it was recently suggested that a correction should be made to obtain optimal results in the automated analysis of ECGs [94].

## 34.9 Wireless Transmission

---

### 34.9.1 To Nearest Hospital

---

The in-field transmission of the prehospital ECG to the emergency department, coronary care unit, another hospital ward, or directly to the on-call cardiologist for interpretation by a more experienced health-care provider is common [53]. This mode of interpretation is more common when the ambulance is manned by a nurse and or a paramedic.

Studies have shown that cardiologists' diagnoses of cardiac abnormalities on a liquid crystal display are very similar to their interpretation of the same ECG displayed on paper [95, 96]. Furthermore, there was no significant difference with regard to cardiologists' decisions to initiate reperfusion therapy when interpreting study-displayed ECGs versus ECGs displayed on a liquid crystal display screen [97]. In many countries, this is a widespread means of communication between the prehospital and in-hospital health-care providers [27].

### 34.9.2 To Remote Hospital

---

Even in urban areas, up to 80% of ambulance-transported ST-elevation myocardial infarction patients can be diagnosed prehospitally using telemedicine [98]. In principle, a strategy of this kind could be adapted in any region covered by a mobile phone network and the health-care providers (mostly a physician) responsible for the diagnosis can be located at a central unit serving a large catchment area [34, 35, 98, 99]. It is possible to speculate that primarily low-risk patients (limited ST elevation) will be found to be eligible for prehospital referral directly to an intervention centre [98]. However, the opposite has been found, that is, patients transported directly to the intervention center were those with a more pronounced ST elevation [98]. It is most likely that there is a geographical border, at a certain distance or transport time from the intervention center, beyond which patients may obtain a beneficial effect from prehospital fibrinolysis or even in-hospital fibrinolysis.

An attractive way of solving the problem is to obtain an ECG on the scene for subsequent transmission to the intervention center. A physician on call will evaluate the ECG, phone the ambulance, possibly interview the patient who is in the ambulance and equipped with headphones, and thereby establish the prehospital diagnosis [34]. An ECG could also be sent to an attending cardiologists mobile telephone for rapid triage and transport to a primary PCI center [100].

### 34.9.3 Elsewhere

---

The in-field transmission of the ECG to an advanced mobile phone outside hospital was recently described [101]. This is an alternative when a helicopter is very far from the hospital, and an emergency medical service physician capable of interpreting the ECG is at a shorter distance, for example. He can then view the ECG on his advanced phone and give recommendations about fibrinolysis or other treatment alternatives. A novel approach is to use a cell phone with a camera feature. This method will allow transfer of ECG images to the local hospital and the PCI center [102].

## 34.10 ECG Indicators for Myocardial Ischemia/Infarction and Adverse Outcome

---

More than 10 years ago, it was shown that, in the prehospital setting, a pathological ECG was a strong predictor and was associated with a fourfold increase in the risk of a cardiac pathology as the etiology of acute chest pain [17]. It has also been shown that, if the patient has chest pain and/or other symptoms indicating acute coronary syndrome, signs of myocardial ischemia (including new ST-T wave changes or Q waves) are associated with a marked increase in 30-day and 1-year mortality, particularly if there is simultaneous elevation of biochemical markers prior to hospital admission [25].

### 34.10.1 ST Elevation

---

Among patients with chest pain and/or other symptoms of acute coronary syndrome, the presence of ST elevation in the prehospital ECG has been reported to increase the likelihood of acute myocardial infarction nearly 50 times when simultaneously considering other risk indicators including the elevation of biochemical markers [103].

### 34.10.2 ST Depression

---

It is important to stress that, from ECG studies in which the ECG was recorded directly after hospital admission, ST depression in the ECG among patients with symptoms indicating acute coronary syndrome has been reported to be associated with an adverse long-term prognosis [104, 105]. Among patients with chest pain or other symptoms of acute coronary syndrome, the presence of ST depression in the prehospital ECG has been reported to be associated with a fourfold increase in the risk of acute myocardial infarction [103].

Although by tradition patients with ST elevation or (presumed) new left bundle branch block have formed the group demanding urgent revascularisation in acute coronary syndrome, there are subsets among patients showing ST depression who also suffer from a critical coronary stenosis or occlusion and who therefore most likely would benefit from a similar treatment strategy. These include patients with marked ST depression in anterior leads and those with extensive ST depression where a large number of leads is involved.

A gender perspective has been found. If there are symptoms of acute coronary syndrome, the presence of ST depression in the prehospital ECG appears to be more strongly associated with acute myocardial infarction in men than in women [106].

### 34.10.3 T-Wave Inversion

---

Although the presence of T-wave inversion without simultaneous changes in the ST segment might indicate myocardial ischemia [107], these changes are less frequently associated with an ongoing acute myocardial infarction [103].

### 34.10.4 Other Changes

---

Needless to say, the presence of Q waves might also indicate acute myocardial infarction [103, 106]. However, as things stand, it is not possible in the prehospital setting to make comparisons with previous ECG findings and a Q wave in isolation without concomitant ST-T wave changes might therefore be a sign of an old myocardial infarction. Other ECG abnormalities found in the prehospital ECG, such as pacemaker ECG, bundle branch block, and signs of left ventricular hypertrophy, are less specific for acute myocardial infarction but are, on the other hand, often indicators of an adverse outcome in a long-term perspective [25].

## 34.11 Prehospital Continuous ECG Monitoring

---

### 34.11.1 Background

---

Little is known about the natural course of myocardial ischemia and the development of arrhythmias in the prehospital phase of acute coronary syndrome. Small pilot studies indicate a relatively high prevalence of tachyarrhythmias during prehospital ECG monitoring as compared with the first ECG recording in hospital [19]. Recent reports suggest that prehospital ECG monitoring should have the potential to detect myocardial ischemia in the prehospital phase much more frequently than a standard 12-lead ECG [108].

### 34.11.2 Method Development

---

This has been done in particular by Drew et al. [19]. A system was developed that: (1) synthesizes a 12-lead ECG from five electrodes, (2) measures ST amplitudes in all 12 leads every 30 s and (3) automatically transmits an ECG to the target emergency department if there is a change in ST amplitude of 200  $\mu$  V in one lead or more or 100  $\mu$  V in two contiguous leads or more lasting 2.5 min.

### 34.11.3 Occurrence of Arrhythmias

---

Among all the patients involved in the first part of a randomized clinical trial [19] (the ST SMART Study;  $n = 433$ ), one third overall (33%) had some arrhythmias during continuous prehospital ECG monitoring as compared with 29%, according to the initial hospital ECG diagnosis among patients with chest pain – anginal equivalent ( $p < 0.001$ ). The corresponding figure for patients with acute coronary syndrome was 30% versus 26% ( $p < 0.001$ ). In overall terms, more tachyarrhythmias (sinus tachycardia, atrial fibrillation/flutter, supraventricular tachycardia of unknown mechanism and sustained ventricular tachycardia) were observed in continuous prehospital ECG monitoring, whereas more bradyarrhythmias (complete heart block, sinus arrest with junctional or ventricular escape rhythm) were observed in the first hospital ECG.

### 34.11.4 Wide QRS Complex

---

Among patients with acute coronary syndrome, 15% had a rhythm with a wide QRS complex and secondary repolarization abnormalities that confound the diagnosis of myocardial ischemia. These ECG confounders included left bundle branch block (6%), right bundle branch block (6%) and ventricular pacing rhythm (3%) [19].

### 34.11.5 Advantages of Continuous Prehospital ECG Monitoring

---

In the area of early reperfusion with percutaneous coronary intervention in acute coronary syndrome, a rerouting strategy may result in some patients being transported longer distances without any accompanying staff skilled in the diagnosis and treatment of malignant arrhythmias. Continuous real-time, one-lead ECG transmission from ambulance to hospital may then allow physicians to support ambulance personnel in the treatment of arrhythmias during this kind of transportation [98]. Furthermore, continuous prehospital ST monitoring indicates that patients with ST-elevation myocardial infarction are heterogeneous and various types of dynamic change in the prehospital setting might indicate a more favorable or a more adverse prognosis [109]. A pre-specified ST-monitoring classification may therefore be useful for stratifying patients at the time of percutaneous coronary intervention into groups with a low, intermediate, and high-risk profile [109].

### 34.11.6 Number of Electrodes for Detection of Myocardial Ischemia/Infarction

The optimal number of electrodes that should be used in the diagnosis of myocardial infarction/ischemia has been debated over the years [110]. An alternative to the 12-lead ECG, such as the five-electrode-derived EASI ECG, has been tested in the prehospital setting [111, 112]. It offers the advantages of using only five electrode positions (four active and one ground) over easy-to-locate, bony structures on the torso. The E electrode is therefore placed on the lower extreme of the sternum, the A and I electrodes in the left and right mid-axillary lines respectively and at the same transverse level as the E electrode, and the S electrode on the sternal manubrium.

The five-electrode-derived EASI ECG has been compared with the paramedic-acquired 12-lead ECG using Mason–Likar limb lead configuration in patients with chest pain [111, 112]. Both appear to produce a similar difference compared with standard ECGs in terms of wave forms. It has been suggested that either method can be used as a substitute for standard ECGs for monitoring, but neither should be regarded as being equivalent to the standard ECG for diagnostic purposes [111].

Parallel to this research, studies have been performed using 80-lead prehospital ECG mapping [113]. In these studies, the sensitivity has increased to 80% as compared with 57% for a 12-lead ECG [113]. The specificity remained unchanged (92%) for an 80-lead ECG versus 94% for a 12-lead ECG [113].

## 34.12 Different Technical Models

### 34.12.1 Medtronic Lifepak

The *Medtronic Lifepak15* (🔗 Fig. 34.2) is a traditional system transmitting a standard 12-lead ECG and is capable of defibrillation. The principle for this system is that it registers a snapshot ECG. This procedure can be repeated if the patient's symptoms change during transportation to hospital. One Lifepak version is able to transmit continuous ST monitoring while using a reduced number of electrodes [114].

■ Figure 34.2

The Lifepak15 in use. The ECG (cf 🔗 Fig. 34.1) report is produced directly from the machine as shown.

■ **Figure 34.3**  
The Ortivus Mobimed.

■ **Table 34.4**

**Clinical determinants of patient instability**

Altered mental status
Significant hypotension
Pulmonary edema
Ischemic chest pain
Ischemic electrocardiographic changes (or other evidence of significant hypoperfusion)

### 34.12.2 Ortivus Mobimed

*Ortivus Mobimed* (▶ Fig. 34.3) is a prehospital concept presenting data in a Windows setup. This system is able to transmit a 12-lead ECG, continuous vector trends, or ST analysis and collect data such as patient files. This system requires a separate defibrillator.

### 34.12.3 Other

Several other manufacturers offer equipment for prehospital ECG recording and defibrillation. There are variations between countries in respect of choice of machine and a complete review is not appropriate here.

## 34.13 Various Types of Arrhythmia

The use of the prehospital ECG to detect various arrhythmias is particularly important when there are signs of clinical instability [64]. These signs are listed in ▶ Table 34.4.

### 34.13.1 No Cardiac Arrest

---

#### 34.13.1.1 Bradyarrhythmias

Limited data are available on the occurrence of various bradyarrhythmias and the value of various treatments such as atropine and the use of pacemakers in these conditions. Continuous ECG monitoring among patients with chest pain indicated that 2% had sinus bradycardia (heart rate < 50 beats/min), 0.7% had heart block, and 0.7% had sinus arrest with ventricular escape rhythm during ambulance transport [19].

#### 34.13.1.2 Tachyarrhythmias

##### Paroxysmal Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia is usually a regular narrow-complex tachyarrhythmia caused by a reentry, which may or may not be accompanied by underlying cardiovascular disease. Many of these patients are clinically stable and in these patients a prehospital ECG will be a support for improved triage rather than improved treatment. Among patients with acute chest pain, supraventricular tachycardia (unknown mechanism) was reported to occur in 2% [19].

##### Atrial Fibrillation/Flutter

Because the disorder is not commonly seen by emergency medical system providers (the reported incidence among ambulance-transported patients ranges from only 0.2–0.7%) [58], there is no consensus on the optimal prehospital therapy. Among patients with acute chest pain, continuous ECG monitoring in the prehospital phase revealed atrial fibrillation/flutter in 11% of cases [19]. Almost every patient with rapid atrial fibrillation has another underlying disease, such as heart failure, chronic obstructive pulmonary disease, or ischemic heart disease.

##### Perfusing Ventricular Tachycardia

Hemodynamically stable monomorphic ventricular tachycardia can be treated either pharmacologically or with synchronized cardioversion [58]. Cardioversion is the therapy of choice for unstable patients and for those with marginal blood pressure in whom there may not be enough time or stability to allow for drug infusion. Among patients with chest pain who underwent continuous ECG monitoring during transport, sustained ventricular tachycardia was reported to occur in 0.2% of cases [19].

### 34.13.2 Cardiac Arrest

---

Every year, between 40 and 50 patients per 100,000 inhabitants suffer an out-of-hospital cardiac arrest, and in such cases, it is regarded as meaningful to attempt resuscitation [115]. The prehospital ECG is used most importantly in order to distinguish patients with a shockable rhythm from those without. However, detection of ST elevation immediately after return of spontaneous circulation, has also been shown to reflect the presence of acute myocardial infarction as the underlying etiology behind cardiac arrest [116].

#### 34.13.2.1 Ventricular Fibrillation

The percentage of patients found in ventricular fibrillation among cardiac arrest victims has been reported to have decreased during the last 2 decades [117, 118]. The mechanism behind this decrease is unclear. The earlier a prehospital ECG is recorded, the more likely is it to find the patients in a shockable rhythm. Out-of-hospital cardiac arrest has therefore been regarded by many as a community problem rather than an ambulance problem, as the ambulance frequently reaches the patient too late in the course of events. Over the years, a strong relationship has been reported between the delay from cardiac arrest and defibrillation, that is, the earlier the patient is defibrillated, the higher the likelihood of survival [26].

### 34.13.2.2 Pulseless Electrical Activity

The percentage of patients suffering an out-of-hospital cardiac arrest in whom resuscitation was attempted and who were found in pulseless electrical activity has been reported to be about 20% [119]. These patients have been reported to have a low chance of survival (1–2%). However, other studies have shown more encouraging results, indicating that some of these patients can be successfully resuscitated [120, 121]. The data do not indicate a strong relationship between the delay from cardiac arrest to the arrival of the rescue team and survival [119].

### 34.13.2.3 Asystole

The percentage of patients suffering an out-of-hospital cardiac arrest in whom resuscitation was attempted and who were found in asystole has been reported to be about 50% [122]. The longer the delay from cardiac arrest to ECG recording, the greater the likelihood of finding the patients in asystole. In one study, it was reported that, the earlier the mobile coronary care unit arrived at the patient's side, the greater the likelihood of survival [122].

## 34.14 Electrocardiographic Factors Associated with Outcome in Cardiac Arrest

---

### 34.14.1 Ventricular Fibrillation

---

#### 34.14.1.1 Waveform Analysis

The determination of the optimal time for delivering a defibrillatory shock has focused on the ventricular fibrillation wave form in many studies [123–128]. It has been suggested that a characteristic pattern of median frequency could be used to estimate the duration of ventricular fibrillation [124, 125]. Eftestøl et al. described a combination of spectral features in the ventricular fibrillation wave form from which they developed a probability function for successful defibrillation in a study of ventricular fibrillation in cardiac arrest patients [129]. They were subsequently able to confirm their findings in an independent data set [130].

Following these findings, wavelet transform methods of ventricular fibrillation that could be useful in identifying patients for whom shocks would be ineffective were described [131, 132]. Further support for ECG analysis in order to predict outcome in ventricular fibrillation was given by Snyder et al. [133].

It was recently reported that the accuracy of shock outcome prediction could be further increased by using filtered ECG features from higher ECG subbands instead of features derived from the main ECG spectrum [134].

A new method, based on the roughness of the ventricular fibrillation waveform, called the logarithm of the absolute correlation, has been suggested to better predict the duration of ventricular fibrillation and thereby the chance of successful defibrillation [135].

By calculating the mean slope of the electrocardiogram it has been possible to estimate the association between the time without chest compression and the probability of return of spontaneous circulation [136].

By calculating the median slope of the electrocardiogram, a new indicator of a chest compression quality measurement has been developed [137]. The configuration of the waveform has also been shown to be helpful in the identification of acute myocardial infarction as the underlying etiology behind ventricular fibrillation [138].

It has been hypothesized that interventions with thrombolytic therapy in ventricular fibrillation will change the wave form with increased amplitude and thereby increase the chance of successful defibrillation [139].

### 34.14.2 Pulseless Electrical Activity

---

Previous ECG studies performed in animals and patients demonstrated a progression of ECG characteristics in pulseless electrical activity with the time from the onset of anoxia. In a retrospective study comprising 503 patients whose prehospital initial rhythm was pulseless electrical activity, Aufderheide et al. found that patients who were successfully

resuscitated had significantly higher initial heart rates, a higher incidence of p-values, and shorter average QRS and QT intervals than patients who did not respond to therapy [140]. It has been suggested that pulseless electrical activity often follows prolonged untreated ventricular fibrillation and that the characteristics of initial post-countershock pulseless electrical activity may predict the resuscitation outcome [141].

In animals, it has been shown that those with post-countershock pulseless electrical activity, which were converted to spontaneous circulation, had fewer shocks prior to the onset of initial post-countershock pulseless electrical activity, greater ventricular fibrillation wavelet amplitude prior to initial post-countershock pulseless electrical activity, and short QRS intervals and a higher heart rate [141]. It is therefore possible that various ECG characteristics among patients suffering from pulseless electrical activity might be used in order to predict outcome in these patients.

## 34.15 Use of a Prehospital Electrocardiogram in a Global Perspective

### 34.15.1 Use and Transmission of a Prehospital ECG

This information is based on rough estimations by leading authorities in the field. One exception is the USA, where data are collected from a reference [142]. The use of or response to a prehospital ECG is mainly dependent on the level of education among the EMS personnel who are in charge of the EMS vehicle. In cases where there is a physician in the ambulance (as in Spain and France), ECGs are usually interpreted on line by a doctor and there is usually no need for ECG transmission from the patient/ambulance to the hospital. However, in cases where a paramedic or a registered nurse (as is mostly the case in Scandinavia, Canada, and the USA) is in charge of the ambulance, the ECG must be transmitted to a nearby hospital. Printable copies of the ECG can be transmitted to the hospital emergency department, coronary care unit, or intensive care unit through a cellular phone or using the patient's regular phone. The doctor on call and the EMS personnel can then jointly discuss the ECG findings, patient symptoms, and risk profile. In some countries (like the Netherlands), an effective computerized algorithm is used to support the nurse when assessing the patient.

This estimation of the global use of prehospital ECG is unfortunately restricted to Europe and North America. In a large US survey among patients suffering from myocardial infarction 172,059 patients used the ambulance. Among them, only 6% had a prehospital ECG recorded. In a large database in the USA, it was recently shown that among 12,097 patients with ST-elevation myocardial infarction 59% used EMS and among them 27% had a prehospital ECG [71]. In contrast to these data, the 200-City survey in the USA previously reported that 67% of all emergency medicine service organizations do have a 12-lead ECG system (🔗 Table 34.5) [142]. Thus, with regard to the USA there is some uncertainty of the actual proportion of ambulance organizations using a prehospital ECG. The estimation indicates that, in overall terms, a prehospital ECG is implemented in the routine prehospital care of patients with a presumed acute coronary syndrome more frequently in Europe than in North America. However, the proportion of patients with presumed acute coronary syndrome in whom a prehospital ECG is recorded is not known.

### 34.15.2 Important Prehospital ECG Research Projects

Perhaps the most important ongoing clinical trial of the use of a prehospital ECG is the ST SMART trial in the USA [114]. This is an ongoing study which aims to evaluate the impact of implementing prehospital ST monitoring with the automatic mobile telephone transmission of ST events to the target hospital. It is a prospective, randomized trial using these ST data for real-time clinical decision-making. The first patient had been randomized by November 1, 2003 and randomization should continue for 5 years. All subjects calling 911 for chest pain or anginal equivalent symptoms receive prehospital, synthesized, 12-lead, ST-segment monitoring with the manual transmission of an initial ECG and the automatic transmission of subsequent ST-event ECGs to the target hospital. The experimental group of patients has incoming ECGs from the field conveyed to clinical staff at the hospital, heralded by an audible voice message and printed out at the emergency department. The control group of patients have no field ECGs printed out and the first ECG is recorded after hospital admission. It is to be hoped that this study will document the value of prehospital ECG monitoring in a presumed acute coronary syndrome.

■ **Table 34.5**

**Use of prehospital ECG in a global perspective<sup>a</sup>**

Country	Overall prehospital ECG use %	Transmission	Comments
Norway	> 90%	Yes	Mostly no physician – 1
Sweden	> 90%	Yes	No physician – 2
Denmark	> 90%	Yes	Mostly no physician – 3
Spain	> 90%	No	Physician operating – 4
Netherlands	> 90%	No/Yes	No physician but online computerized ECG – 5
France	> 90%	No	Physician operating – 6
Canada	25%	Yes	No physician – 7
USA	67% <sup>b</sup>	Yes	Williams D JEMS 2005;30:42–60

<sup>b</sup> In ref [71], it was reported that only 27% of EMS transported patients with ST-elevation myocardial infarction received a prehospital ECG in 2007 in the USA.

### 34.16 Future Perspective

A number of important implementation and research issues remain to be addressed in the near future with regard to the prehospital ECG. The most important one is to implement a prehospital ECG in all EMS systems. The use of a prehospital ECG is probably the most important part of the prehospital care of patients suffering a heart attack. It seems as though the speed of this process varies in different parts of the world. It remains to be proved whether continuous ECG monitoring will improve the prehospital care in a presumed acute coronary syndrome as compared with a single 12-lead ECG recording on the arrival of the rescue team.

The optimal number of electrodes for use in the prehospital ECG has not been clarified. Should we use a 12-lead ECG or should we reduce or increase the number of electrodes? Wave-form analysis in ventricular fibrillation could perhaps be improved still further in order to optimize the timing of defibrillation. Finally, we need to decide whether there is hidden information in the ECG among patients suffering a cardiac arrest and pulseless electrical activity, which could guide us in the management of these patients.

But, most likely, the most important challenge for the future is to overcome barriers to the implementation and integration of the prehospital electrocardiogram into systems of care for acute coronary syndrome [143, 144].

## Introduction

---

Changes of pulse rate and rhythm have attracted the attention of physicians since the earliest stages of medicine. Only recently, with the advance of computer techniques that allow for parsing heart rate variability (HRV) into components, which potentially yield information about the autonomic nervous control of cardiac activity, has there been an increased clinical interest. The technical advances, however, have not resulted in bedside application of HRV methods and evidence of their usefulness in real-world clinical practice is still limited. Moreover, from the point of view of the physician, complex approaches to HRV phenomena and the use of complicated mathematical formulae may have a rather limited implementation in everyday practice. In this chapter, several aspects of HRV are thoroughly reviewed giving priority to their physiological and pathophysiological meanings in order to render HRV more clinically useful. For that reason, technical descriptions are limited to providing only the necessary background information.

### 35.1 Historical Note

---

Fluctuations in heart rate were first recorded by ancient physicians. Disturbances of heart rate due to changes in psycho-emotional state were revealed by Erastratos, an Alexandrian physician, in the third century B.C. [1]. Similarly, a description of pulse-shift in relation to emotion or illness is ascribed to Galen (129–199 A.D.) [1]. A decrease in heart rate variation was recognized by the Chinese physician Wang Shuhe (265–317 A.D.) as a sign which could predict the onset of death [2] (Fig. 35.1). Later, many physicians raised the examination of the pulse rate to the level of an art. An excellent example of this is given by Józef Struś, Polish physician to Zygmunt August, King of Poland, in his work “*Sphigmicae Artis*” (Basel 1555) [3].

The fundamentals of current knowledge are usually credited to the observations of Stephen Hales (1733) and Carl Ludwig (1847). Hales first found, in the horse, that the pattern of blood pressure was dependent on respiration [4, 5]. Ludwig, armed with the smoked kymograph, recorded a quickening of the pulse rate with inspiration and a slowing with expiration in the dog [5]. He is credited with the term *respiratory sinus arrhythmia (RSA)* [5, 6]. Two decades later, F.C. Donders (1868) followed up this research to describe the role of the vagus nerve in RSA. Traube (1865) advised on the importance of the medullary respiratory centers in modulating the brainstem nuclei controlling heart rate. Hering (1871) put forward an alternate explanation for RSA, namely the consequence of a reflex modulation of the central oscillator by pulmonary afferent feedback [5]. A few years later, Mayer (1877) established that longer-wave oscillation in blood pressure was due to vasomotor tone. Continuing these efforts, Hering (1910) first stated that the function of vagi could be quantified in humans by means of RSA [6]. Next, in 1920 Bainbridge reported on the effects of thoracic pressure changes with respiration and their association with RSA [6]. German psychiatrists Eppinger and Hess (1915) focused on the clinical application of RSA as a measure of vagal tone and first made observations on the effects of cholinergic agents [6]. This was further emphasized by the study of Samaan (1935) in which stimulation of a section of vagus nerve abolished RSA [7].

With the advent of electrocardiography (ECG), accurate and continuous recording of the electrical activity of the heart became possible. Not surprisingly, the first recording of RSA was made in the first decade of the twentieth century by Samojloff in 1909. Schlomka, in 1936, provided the first quantitative measures of RSA from short-term ECG tracings. He also reported on an age-dependency of RSA and the reduction of RSA in patients with advanced heart failure (After [8]).

The seminal works listed in Table 35.1 have provided a solid grounding for the current knowledge and application of HRV in cardiology. Interestingly, well before HRV analysis was appreciated in cardiology, its usefulness had been documented in obstetrics and psychology [5, 6, 10, 11].

### 35.2 Definitions, Synonyms, Abbreviations

---

*Heart rate (HR)* – frequency of the heart beating usually calculated as the average of four or more consecutive heartbeats, expressed in beats per minute (bpm).

■ Figure 35.1

HRV and an ancient medicine (From [2]).

*Instantaneous heart rate (HR<sub>i</sub>)* – heart rate confined to a given sinus cycle duration on a beat-to-beat manner (60/R–R interval).

*Intrinsic heart rate (iHR)* – heart rate after cessation of the autonomic influences (pharmacological or surgical denervation), i.e., in situ heart rate.

*Heart period (HP)* – the duration of a given cardiac cycle, usually calculated as a period between two consecutive R-waves or P-waves, expressed in seconds (s) or milliseconds (ms). Unless indicated otherwise, cardiac cycle is defined as a presumed sinus (in origin) cycle irrespective of the polarity of the P-waves. Sometimes, if the signal is acquired using a technique other than the ECG, heart period is referred to as a *pulse interval* or an *interbeat interval (IBI)*.

*R–R interval* – description of heart period based on detection of the R-wave instead of the P-wave. The “R” labeling is used in short-term ECG recordings and assumes sinus origin of the heartbeat. However, in a few studies such a labeling indicates any depolarizations, irrespective of their origin (usually noted).

*N–N interval* – description of heart period for long-term ECG recordings, where sinus (supraventricular) origin of the heartbeat is assumed and labeled as normal (N).

*Heart rate variability (HRV)* – a variation in the duration of HP (which might not be consecutive). It can be quantified using various methods in the time, frequency, and nonlinear dynamics domains.

*Heart period variability (HPV)* – a term similar to HRV.

*Time-domain analysis* – an analytical approach to HRV quantification in which the sequence of heartbeats is generally ignored. It usually gives information about the magnitude of heart beat variation around its mean value.

*Respiratory sinus arrhythmia (RSA)* – heart period fluctuations due to breathing. RSA can be quantified preferably by using spectral analysis; however, time-domain analysis and other approaches are possible.

*Spectral analysis* – an analytical approach for decomposition of frequency components in a signal time series, which requires strict maintenance of R – R interval sequence. A graphical presentation is usually given as a plot of the amplitude of variation (cycle, bpm, s, or ms), variance or power (cycle<sup>2</sup>, bpm<sup>2</sup>, s<sup>2</sup>, or ms<sup>2</sup>), or power spectral density (cycle<sup>2</sup>/beat, bpm<sup>2</sup>/Hz, s<sup>2</sup>/Hz, or ms<sup>2</sup>/Hz) against various period or frequency ranges (beats/min, Hz).

*High frequency component (HF)* – part of the power spectrum that (in adult humans) is contained within the arbitrary frequency band between 0.15 and 0.40 Hz (or higher). The HF component represents short-term (2.5–6.0 s) heartbeat variation within the frequency of respiration. Its relative contribution to the total power decreases exponentially as duration of a time series is increasing; it is also cited as the RSA-related or vagally-related power.

*Low frequency component (LF)* – part of the power spectrum within the frequency band from 0.04 (0.05) to 0.15 Hz (in humans) and represents medium-term (6–25 s) heartbeat variation within the frequency of Mayer waves of blood pressure. Its relative contribution to the total power decreases exponentially as the duration of a time series is increasing.

*Very low frequency component (VLF)* – part of the power spectrum that (in humans) is contained within the frequency band between 0.003 and 0.04 Hz and represents long-term (> 25 s) heartbeat variation. Its relative contribution to the total power decreases as the duration of a time series is increasing.

*Ultra low frequency component (ULF)* – part of the power spectrum that (in humans) is contained within the frequencies below 0.003 Hz and represents very long-term (> 5 h) heartbeat variation. It cannot be reliably evaluated from a short time series. It constitutes the main contribution to the total power from a 24-h signal recording. Day–night difference is the most prominent oscillation within the ULF component.

*Nonlinear dynamics* – a field applying a variety of analytical approaches to the study of R – R interval variations that are not linearly related, and presumed not to be random. These approaches allow evaluating different properties of heartbeat variation in terms of its determinism, predictability, sequence, scale-invariant similarity, patterns, complexity, information flow, and other features.

*PEB(s)*–Premature ectopic beat(s)

*PNS*–Parasympathetic nervous system

*PSD*–Power spectrum density

*s*–Second(s)

*SAN*–Sino-atrial node

*SIDS*–Sudden infant death syndrome

*SCD*–Sudden cardiac death

*SNR*–Signal-to-noise ratio

*SNS*–Sympathetic nervous system

SR—Sinus rhythm  
VF—Ventricular fibrillation  
VT—Ventricular tachycardia

### 35.3 Methods for HRV Assessment

Heart beat variation can be examined by replacing the complex waveform of an individual heartbeat recorded in the ECG with the time of occurrence of the contraction as a single number. Thus, the sequence of heartbeat duration can be expressed as a function of its duration (*tachogram*) (Time series derived from the occurrence time of the R-wave. The term is applicable also for cardiac events series, interval tachogram, interval function, instantaneous heart rate, heart timing signal, and low-pass filtered event series.). Sometimes, by interpolating and resampling the R – R sequence, the HRV signal can be presented as a function of time. Since the presence of sinus rhythm is formally defined as the onset of normally oriented P-waves, heartbeat variation assessment should ideally be based on a calculation of time-intervals between consecutive P-waves. Because the shape of the P-wave is unfavorable for its automated detection with currently used commercial equipment (difficulties in fiducial point determination, relatively low SNR), two important assumptions are made [26]. First, that the detection of the P-wave can be replaced by the detection of the R-wave, and second, that interbeat duration between consecutive R waves equals that of consecutive P waves. Since the variability of the P – R interval is approximately — two to three orders lower than that of the P–P or R–R intervals [27], it is assumed that the P–R interval variability does not influence the HRV measurements. Thus, in practice the QRS complex (R-wave) is commonly used to determine the time period between consecutive heartbeats.

#### 35.3.1 Time Domain HRV Analysis

Techniques used in time-domain analysis provide the simplest measures of heartbeat variation over time. These measures are simple to calculate and relatively easy to understand. Time-domain methods describe the overall magnitude of R–R interval fluctuation around its mean value. One class is the statistical descriptors of beat-to-beat intervals (not necessarily consecutive) or of differences in the duration between adjacent heartbeats. Another class is the geometrical method (frequency distribution representations).

##### 35.3.1.1 Statistical Methods

The earliest quantitative indices for HRV (RSA) have been described in studies by Schlomka et al. and Schäfers et al. (after [8]) in the 1930s, as the difference between the sum of the — three to four longest and — three to four shortest R–R intervals either as absolute values (*arrhythmia magnitude*) or as normalized data for the mean HR (percentage of the mean, *arrhythmia index*). Similar measures are still in use and referred to as the *variation range* (*VR, absolute*) and *coefficient of variation* (*CV, normalized*). Simple measures of cardiac vagal activity from standard ECG recordings have been described recently [28, 29].

The most widely used time-domain measure is the standard deviation (*SDNN* or *SDRR*) (Table 35.2), which is equal to the square root of the variance of all normal-to-normal or R–R intervals, respectively [30]. Depending on data-length and signal representation (HRi, HP) various SD-based measures are in use. This simple HRV measure can be drawn from a time series of any duration.

From 24-h ECG recordings, two other measures allow the quantification of the average N–N interval or SD changes over predefined periods, usually of 5-min duration (*SDANN* and *SDNNI*, respectively) [30]. If a permutation of SD is applied to the differences between consecutive N–N (R–R) intervals, a widely used and recommended index is derived, referred to as the *RMSSD* [30] (Table 35.2). The SD-based measures represent a coarse quantification of overall variation, while RMSSD represents a more accurate quantification of short-term beat-to-beat variation. More recently, a new index has been derived which is the ratio SD/RMSSD [31].

■ **Table 35.2**

**Time-domain HRV measures from short- and long-term ECG recordings**

Parameter	Units	Description
SDRR	ms	Standard deviation of all quantifiable R–R intervals over a period of recording
CV	%	Coefficient of variation, i.e., SDNN normalised for mean RRI
VR	ms	Variation range, i.e., difference between the longest and shortest RRI over a period of recording
DSCL	ms	Maximal difference between two consecutive R–R intervals (sinus cycles) over a period of recording
AAD	ms	Average absolute difference, i.e., the average of the differences between successive R–R intervals ignoring their sign
SDSD	ms	Standard deviation of differences between successive R–R intervals
RMSSD	ms	Root mean square of successive differences in R–R intervals, i.e., the square root of the mean squared differences of successive R–R intervals
CIPA	units	Cardiac index of parasympathetic activity
SDNN	ms	Standard deviation of all quantifiable N–N intervals
SDANN	ms	Standard deviation of the averages of N–N intervals in all quantifiable 5-min epochs of the entire recording
SDNNI	ms	Mean of the standard deviations of all N–N intervals for all quantifiable 5-min epochs of the entire recording
RMSSD	ms	The square root of the mean squared differences of successive N–N intervals
NN50 count		Absolute number of pairs of successive R–R intervals that differ by more than 50 ms; three variants are possible counting all such R–R interval pairs or only pairs in which the first or the second interval is longer
pNN50	%	Percentage of pairs of successive N–N intervals that differ by more than 50 ms, i.e., NN50 count divided by the total N–N intervals' number
HR6%	%	Number of consecutive heartbeats that differ in their instantaneous heart rate by more than 6%

A separate type of statistical analysis is based on counting of events defined as the occurrence of consecutive heartbeats that differs above a pre-selected (arbitrary) limit of values or bins (absolute or relative). The index NN50+ expresses the number (“counts”) of consecutive heartbeats that differ by 50 ms or more [22, 30]. Conventionally 6% bpm (HR6%) or 50 ms difference (NN50 or pNN50) is used. However, those arbitrary cut-off values represent only one of a family of possible statistics (NNx) [32]. The unfavorable statistical properties of count-derived indices (▶ Fig. 35.2) has led experts to advise against their use [4]. Logarithmic transformation of the pNN50 was proposed to improve count-derived index statistics and their reproducibility. A novel proposal that may help to overcome statistical limitations suggests the expression of the pNN50 after the logit transformation (logit50) [33]. The  $\text{Logit50} = \text{Ln} [\text{pNN50}/(100-\text{pNN50})]$  is the natural logarithm of the odds of the occurrence of preset R–R interval differences >50 ms (▶ Fig. 35.2).

Statistical measures are the most commonly used method despite their sensitivity to extreme values (such as true or false) and which requires time-consuming review of the data-series to obtain reliable values [34]. Dependence on the duration of recording excludes comparisons of short-term and long-term data, even if they are closely correlated [4]. It might also influence the reproducibility of the statistical measures. As these indices provide only crude information, they do not allow different HRV patterns (or dynamics) to be distinguished. Moreover, various patterns of HRV with similar statistical properties can be erroneously gathered into one class of HRV [35].

### 35.3.1.2 Geometric Methods

Graphic representations of event distribution and their quantitative evaluation can be obtained by plotting the frequency of occurrence of values in selected ranges or bins. This is referred to as a *histogram*. Classic descriptors of such representation are skewness and kurtosis, which quantify symmetry and peakness, respectively. Such descriptors are frequently used in HRV studies [36].

A histogram of time series can be analyzed using the absolute or relative number of “frequencies” within bins [37]. The most frequent bin is termed the mode of the histogram and its “height” can be measured as the number of R–R

■ Figure 35.2

Unfavorable distribution of pNN50 (*left plot*) and its improvement if expressed as the Logit50 values. Data from 290 healthy subjects (author's data).

intervals with modal duration. The area of the histogram is equal to all R–R intervals. Assuming that the major peak of the histogram is a triangle, the simplest measure of any HRV geometric method can be derived. It is referred to as the *HRV Triangular index (HRVI)* [37, 38]. Here, if the number of intervals in the  $i$ th bin centered at  $t_i$  is represented as  $b(t_i)$ , then HRVI is defined as (35.1):

$$\text{HRVI} = \frac{\sum_{i=1}^{N_b} b(t_i)}{\max_i b(t_i)} = \frac{N - 1}{\max_i b(t_i)} \quad (35.1)$$

where  $N_b$  is the number of bins (► Fig. 35.3). Usually, a constant bin is used with a width of  $1/fs = 7.8125$  ms, where  $fs$  is the sampling frequency. A selection of bin widths is critical for HRVI and other histogram-derived indices [39].

A modification of the HRVI, less dependent on the sampling frequency, is the *Triangular Interpolation Index (TIRR or TINN)* depending on whether the selected intervals are R–R or N–N, which is the base of a triangle that approximates the highest peak of the sample density histogram by means of the minimum square difference interpolation [40] (► Fig. 35.4). Generally, a uniform distribution representing large variability gives large values and a distribution with a single large peak provides small values.

The HRVI and TINN are dependent on the distribution of R–R intervals and are suitable for a reliable HRV estimation only if one dominant peak is present. Such a pattern is usual in a stable in-hospital environment. In ambulant patients and in normal subjects a bimodal distribution is more common, therefore, the HRVI or TINN underestimates the global HRV.

Similar approaches can be applied to data derived from the differences between successive heartbeats (*differential histogram*). Interestingly, a negative exponential interpolation of a differential histogram (specifically the slope of the interpolation curve) appears to be a robust method that is useful for the automatic assessment of HRV [41].

Another technique of differential histogram analysis referred to as a *sample asymmetry analysis* quantifying R–R interval deviations from the median (or mean) values has been proposed recently [42]. Two quantities representing the sum of the weighted deviation to the left ( $R1(\alpha)$ , HR accelerations) and to the right ( $R2(\beta)$ , HR decelerations) can be calculated, where  $\alpha$  and  $\beta$  are parameters describing the degree of weighting from the median value ( $\alpha = \beta = 2$  are chosen). The ratio of  $R1/R2$  represents the sample asymmetry. For a symmetric histogram,  $R1$  and  $R2$  are equal.

The *differential index ( $D_{diff}I$ )*, obtained from a differential histogram, defined as the width of the base of a triangle constructed by using the width of the histogram at 10,000 R–R intervals and at 1,000 intervals, plotted on a semilogarithmic scale [43]. Data for healthy subjects and the prognostic value in subjects with angina pectoris have been obtained by using 16 ms bins [43, 44].

Figure 35.3

Calculation of the HRV triangular index (From [A30], Springer, with permission).

Figure 35.4

Calculation of the TINN index. For the computation of the TINN measure, the values  $N$  and  $M$  are established on the time axis and a multilinear function  $q$  constructed such that  $q(t) = 0$  for  $t \leq N$  and  $t \geq M$  and  $q(X) = Y$ , and such that the integral  $\int_0^{+\infty} (D(t) - q(t))^2 dt$  is the minimum among all selections of all values  $N$  and  $M$ . The TINN measure is expressed in milliseconds and given by the formula  $TINN = M - N$  (From [4]).

In general, histogram-based methods require a sufficient data length, so they are less applicable to a short data-series. They are also sensitive to the sampling frequency.

### 35.3.1.3 Return Map Evaluation

This geometric method is based on a *return map* (Plot of a time series as a function of the current and of the previous values. Known also as a Lorenz plot, scatterplot and less appropriately as a Poincaré plot.), which is a plot of each R-R interval ( $RR_n$ ) (on the abscissa) against the following interval ( $RR_{n+1}$ ) (on the ordinate) (Fig. 35.5). The first approaches

■ **Figure 35.5**

Examples of patterns of a return map. Upper panel, comet (left) and torpedo (right) pattern (usual in healthy subjects), lower panel, fan (left) and complex (right) pattern (usually abnormal) (From [47] with permission).

based on the return map for ventricular rhythm assessment in atrial fibrillation were reported by Arnoldi (1927) and Soderstrom (1950) [45]. Nakanishi et al. were the first to use this method for HRV analysis [46].

In this section, time-domain measures that can be drawn from the return map are described. Possible nonlinear approaches are discussed in a later section.

A qualitative evaluation of the return map is based on the overall shape of distribution (● Fig. 35.5) [47]. The shape of the return map can be classified into several pattern-based categories, such as a comet or torpedo in healthy humans, while fan-like or more complex patterns may occur in patients with certain cardiovascular pathologies or after autonomic blockade. The use of qualitative evaluation is limited because of the subjective nature of evaluation and there is a probability of a misleading interpretation. However, a qualitative approach remains a unique and valid method for the assessment of the quality of the ECG recordings [4]. Recently, a subject-independent method for scatterplot pattern recognition has been proposed [47].

Several measures for return map quantification have been proposed. To be reliably calculated, longer ECG recordings are usually necessary. However, solutions for quantifying return maps from short-term recordings have been reported [46, 48–50].

The simplest measures can be derived from the regression line (slope, intercept, or correlation coefficient). The slope or the intercept of the regression line does not seem to have any advantage over simple max–min R–R interval difference or mean RRI itself. The Pearson correlation coefficient of the return map was shown to correlate with short-term variation

[50, 51]. Successive Pearson correlation coefficients calculated for each 1-min return map from long-term ECG recordings were proposed to reveal distinct patterns of sleep–wake states (🔗 Fig. 35.6) [52].

The most frequently used quantitative analysis of the return map includes calculation of its width- and length-derived parameters [53–60]. Schechtman et al. applied those parameters for HRV analysis in newborns with aborted SIDS [54–56]. They proposed calculating all following intervals for the given percentile value of the preceding R–R intervals, specifically at the 10th and 90th percentile [53]. Alternative methods were proposed by Kamen et al. [57] and Tulpo et al. [58] (🔗 Fig. 35.7). The derived indices  $SD1$  (standard deviation of intervals over the minor axis),  $SD2$  (standard deviation of intervals over the major axis), and their ratio  $SD1/SD2$ , all enable the approximate estimation of autonomic cardiac control [54–56]. Toichi et al. [59] calculated the length of the return map over transverse  $T$  and longitudinal  $L$  axes and derived two indices, referred to as the *Cardiac Vagal Index* ( $CVI = \log_{10}(L \cdot T)$ ) and the *Cardiac Sympathetic Index* ( $CSI = L/T$ ) (🔗 Fig. 35.8). They showed that only 100 R–R intervals ( $\sim 2$  min.) were necessary for a reliable calculation of those indices. Copie et al. [60] manually determined both  $L$  and  $T$  of the scatterplot in order to calculate the scatterplot area. Another variant of HRV partitioning has recently been proposed [61]. Unfortunately, in the presence of more complex patterns of the return map, width and length-related metrics cannot be used.

The introduction of a “ $z$ ” coordinate as the next time lag (i.e.,  $R - R_{n+2(\text{or})}$ ) was proposed for evaluating the return map in 3D space [62]. Such an approach gives a novel insight into the complexity of heartbeat dynamics, yet no clinically useful index has been proposed.

Another proposal is to represent the number of pairs ( $RR_n, RR_{n+1}$ ) that lie within predefined bins, related to the percentiles [55], sampling interval (usually 7.8 ms) [63] or R–R ranges [64], equally spaced in “ $x$ ” and “ $y$ ” axes. In this way, a “ $z$ ” axis represents a density function and a pseudo-3D graphic presentation can be obtained. In this proposal, for

■ **Figure 35.6**

Return map coefficients use to follow transitory changes following various sleep stages. Profiles of 1-min interbeat autocorrelation coefficient  $r_{RR}$  (middle panel) and of R–R interval (lower panel) together with sleep pattern (upper panel). Slow wave sleep (stage 3 and 4) lies in shaded areas.  $r_{RR}$  and RR curves smoothed using the moving average method over a 5-point span (From [52]).

Figure 35.7

Example of quantification of a return map (from [A35], with permission).

Figure 35.8

Quantitative assessment of the return map from short-term recordings. The length of the transverse axis,  $T$ , and the length of the longitudinal axis,  $L$ , can be determined. The derived indices of vagal (CVI) and sympathetic (CSI) are proposed and can be calculated as simple product (decimal log) or ratio of the  $L$  and  $T$  (From [59]).

each rectangular area of the plot, the relative number of  $RR_n/RR_{n+1}$  samples is determined. Then, the maximum density of samples for each size of the area of the plot is calculated. Schechtman et al. found this approach useful for studying the changeable pattern over sleep–wake states in neonates [55]. Hnatkova et al. have proposed the logarithmic integral of the density function to express numerically the compactness of the plot in post-infarct patients (the *Compactness Index*) (Fig. 35.9) [63].

■ Figure 35.9

Three-dimensional representation of the return map from long-term ECG recordings. Two examples of 3-D return map (*right panel*) of low (*upper panel*) and high risk (*lower panel*) post-infarct patients clearly mark differences between both cases with nearly identical 2-D return map (*left panel*) (From [63]).

Sosnowski et al. proposed a simplified method for 3D return map evaluation [64, 65]. The distribution of pairs of neighboring heartbeats (counts) within R–R interval ranges with 100 ms resolution (bins) is presented (● Fig. 35.10). Then, the density of counts in the two highest grid boxes (the area for each grid box being  $0.01 \text{ s}^2$ ) can be determined by applying a  $16 \times 16$  array to the scatterplot between 200 and 1,800 ms. Such a 3D view of the return map allows for an easy determination of the density function in normal subjects, patients with sinus rhythm (● Fig. 35.11), with premature beats and atrial fibrillation. The derived index of HRV referred to as the *HRV Fraction (HRVF)* is calculated according to the following formula (35.2):

$$\text{HRVF} = \left[ 1 - \frac{\text{RR}_1 + \text{RR}_2}{\text{RR} - \text{RR}_{50}} \right] * 100[\%] \quad (35.2)$$

where  $\text{RR}_1$  and  $\text{RR}_2$  represent two highest counts (from squares that are not necessarily adjacent),  $\text{RR}$  (total beat number) and  $\text{RR}_{50}$  (the number of intervals that differ from a succeeding interval by 50 ms or more).

The HRVF possesses unique properties that make it useful for HRV quantification irrespective of heart rhythm [65]. Actually, the HRVF is the only time-domain index allowing for HRV assessment in the presence of AF (● Fig. 35.11). Significantly, a similar range of normal and abnormal HRV can be applied for subjects with sinus rhythm and atrial fibrillation [66]. The HRVF is normally distributed (as HR itself). This makes any statistical performance straightforward, contrary to most time-domain statistical measures, which frequently require transformation (usually logarithmic) before any statistical analysis (● Fig. 35.12). In addition, its calculation is not affected by the distribution of data-points, so it can be applied to more complex patterns of the return maps. Physiological meaning of the HRVF as a global HRV index appears to be similar to that of other global HRV measures (i.e., SDNN). At present, only the author has evidence of the potential clinical utility of this method.

Moraes et al. have presented a somewhat different approach to return map construction [67]. A plot of  $\text{RRI}$  (on the  $x$  axis) against  $\text{RR}_i - \text{RR}_{i+1}$  (on the  $y$  axis) and number of pairs within the bin of 7.2 ms duration (on the  $z$  axis) can be

■ Figure 35.10

Simplified 2-D view of a return map of RR against  $RR_{i+1}$ . The boxes with two highest number of RR interval pairs is easily seen as black boxes lying between 0.6 and 0.8 s. These two numbers are RR1 and RR2 in the HRV Fraction equation. All heartbeats in the range of 0.2–1.8 s are included, irrespective of their origin (normal, supra-ventricular or ventricular) (From [64]).

obtained. The derived index MN is the product of parameters derived from the three axes (► Fig. 35.13). Its clinical utility remains unknown.

#### 35.3.1.4 Time-Domain Analysis for Parsing Frequency Components

Peak-to-valley (“*peak-to-trough*”) statistics is the time-domain method introduced for distinguishing respiratory-related oscillation from nonrespiratory periodic components [5, 6, 49, 68]. Accordingly, the RSA is quantified as the average difference between the shortest sinus cycle associated with inspiration and longest sinus cycle within expiration. This method is vulnerable to artifacts associated with low frequencies. In addition, a separate measure of respiration is required. This method has become popular in psychological studies [5, 6, 68, 69].

The second time-domain method that allows for HRV distinction within specified frequency bands is the *moving polynomial method* [69]. By using this method, the statistical variance of the data within the respiratory frequency is obtained. However, it requires epochs of data points before and after the analytical time series to “prime” the polynomial filter. This method and other variants are extensively used in psychological studies [5, 6, 68–71].

Repeated calculations of the coefficient of return maps with increasing time-lag ( $RR_n$  vs.  $RR_{n+i}$ ,  $i = 1-6$ ) can reflect the RSA pattern from relatively short-term recordings (~2,000 heartbeats) [72]. Even shorter epochs (~70 heartbeats) are reported to be suitable for quantifying the pattern underlying RSA [73].

#### 35.3.1.5 Time-Domain Analysis of the HR-HRV Relationship

Only a few attempts have been made to quantify the relationship between HR and HRV from long-term ECG recordings. The HRV Fraction is one example, as the probability of a certain value strongly depends on the mean RRI [65]. The most recent attempt is referred to as the *HRV Footprint*, which is a plot of heart rate against SDANN. This plot renders the likelihood (or density) of a particular HRV change occurring at each intrinsic HR over a 24-h period. The

3D return map view in a patient with sinus rhythm and in a patient with atrial fibrillation. Two examples of R – R interval distribution in patients with depressed LV systolic function. Upper graph from a patient with sinus rhythm, lower – with AF. Values of HRV Fraction, as well as mean R – R interval are comparable, while SDNN was three times higher in AF-patient, reaching value far above the lower normal limit (Author's data).

Figure 35.12

Plot of HRVF values distribution in healthy subjects against standard normal deviate (author's data).

footprint-area is calculated and expressed as a percentage. An example of the HRV Footprint in a patient with heart failure is shown in Fig. 35.14. [74]. Its usefulness has recently been documented in HF-patients with implantable cardiac resynchronization devices [74, 75].

### 35.3.2 Frequency-Domain Analysis

Time series collected from biological signals may be considered as a sum of oscillations (usually overlapping). Different mathematical analytical techniques used for the conversion of time series representation from time-domain to frequency-domain present the opportunity to quantify various amplitude and distinct frequencies that contribute to the underlying signal [4, 5, 17, 20, 23, 76–82].

Such a representation is termed *spectral analysis* and displays the distribution of the amplitude of each oscillation (usually a sine wave) as a function of its frequency. The squared contribution of each frequency is actually the *power* of that particular frequency contribution to the total power spectrum. The duration of the recording should be at least ten times the wavelength of the lowest frequency band of the investigated spectral component. According to *Parseval's theorem* (Parseval's theory states that the sum of squares measured among the time samples is equal to the sum of squares of the Fourier transform results, when frequency samples are included from zero to the sampling frequency ( $f_s$ )), the total power spectrum, defined as the area under the curve of the power spectrum, equals the variance irrespective of data length. For physiological and clinical information to be obtained, a post-processing of the power spectral density spectra is necessary.

The power spectrum of heartbeat variation in healthy humans consists of three or four major frequency peaks depending on the duration of data recordings (usually 5-min or 24-h period). Although they do not have fixed periods and the central frequencies may vary considerably, by convention [4, 5] these peaks lie within the following ranges: *high frequency* (HF) 0.15–0.4 Hz (cycle length 2.5–6 s), *low frequency* (LF) 0.04–0.15 Hz (6–25 s), and *very low frequency* (VLF) <0.04 Hz (>25 s) (Fig. 35.15).

In 24-h recordings the VLF is subdivided into the VLF component 0.003–0.04 Hz (25 s–6 min) and the *ultra-low frequency* (ULF) component <0.003 Hz (cycle length > 5 h).

■ Figure 35.13

Presentation of 3-D distribution of RRI. The plane (*upper graph*) depicted intercept the distribution across maximum density (counts). The P1 (*middle graph*) is measured at maximum density taking into account the tangent of the angle. Other parameters (P2,P3, *lower graph*) are simply maximum longitudinal and transverse ranges. An MN index is a product of P1, P2 and P3 ( $\times 10^{-3}$ ) (From [67]).

The power of an individual frequency component is the area under the proportion of the curve related to each component. The power of the ULF, VLF, LF, and HF components is usually expressed as square milliseconds and the PSD is expressed as milliseconds per Hertz. The ratio between LF and HF components (LF/HF ratio) is commonly calculated [4, 5, 79–81]; however, it has not been resolved whether absolute or normalized values should be included for the LF/HF calculation.

The relative LF and HF power can be expressed in normalized units (or percentages) by dividing the power of the LF and HF components (in  $\text{ms}^2$ ) by the total power from which the power  $<0.04$  Hz is subtracted and multiplying by 100 [79–81]. The normalization procedure tends to minimize the effect of changes in total power on the HF and LF components. However, it seems important to quote both the absolute and normalized values in order to describe the distribution of power within the spectral components completely.

Figure 35.14

HRV footprint. A graphical representation of SDANN scatter occurring at each intrinsic sinus rate over a 24-h period. Colors indicate the frequency of HR and SDANN occurrence (third dimension, i.e., density) (From [75]).

Because of statistical properties, the absolute values of the total power spectrum (or PSD) and their components are usually reported after logarithmic conversion (either natural or decimal) [79].

The spectral measures of HRV are most widely applied in current clinical investigations. Their prognostic power is fully documented in a variety of populations [4, 5, 79–81].

A new index called *prevalent low frequency* (PLF, Hz) has been proposed by the St. George's Hospital Investigators Group [83]. Here, with 1/60 Hz resolution, the LF band contains seven power spectrum values at frequencies of 0.033, 0.050, 0.067, 0.083, 0.100, 0.117, and 0.133 Hz. In each spectrum, local peaks (spectral position with the PSD greater than both adjacent power spectral densities) are detected within the LF band, and the greatest powered peak is included in the PLF computation. Frequencies of all maximum peaks ( $\leq 1$  per each 5-min segment) are averaged over the entire Holter recording to obtain the single value of PLF. Detectable peaks in  $\geq 10$  segments are necessary for valid PLF calculation. At present, only the authors have found evidence of the potential clinical use of this method [83].

### 35.3.2.1 Nonparametric Spectral Analysis

Nonparametric methods are traditionally used for the evaluation of rhythmic events presented in a signal. The Fourier transform is the most common method for the decomposition of the signal. It provides an evaluation of the contribution of all frequencies, irrespective of whether its frequency components show specific spectral peaks or broadband powers. Thus, FFT techniques include all data independent of their deterministic or stochastic properties. These frequencies are multiples (harmonics) of the basic frequency, which is a reciprocal of time series data-length. For a reduction of the number of computations, the fast (a discrete) Fourier transform (FFT) is commonly employed [79, 84, 85]. The fast Fourier transform allows for obtaining the PSD of a signal directly from the time series by means of *periodogram* (Estimate of power spectral density on the basis of the modulus squared Fourier transform.) expression (see 35.4):

$$\text{PSD}(f) = \left| \frac{1}{N\Delta t} \Delta t \sum_{k=0}^{N-1} y(k) \exp(-j2\pi kf\Delta t) \right|^2 = \frac{1}{N\Delta t} |Y(f)| \quad (35.3)$$

where  $\Delta t$  is the sampling period,  $N$  is the number of samples, and  $Y(f)$  is the discrete Fourier transform of  $y(k)$ .

The FFT method uses a relatively simple algorithm with high-speed processing. It requires strict periodicity and stationarity (Property of a time series in which probability distributions involving values of the time series are independent of time translations.) of data. Also, the length of data for an FFT requires to be long enough (at least 256–512 consecutive heartbeats) for a reliable PSD estimation [79, 84].

■ Figure 35.15

Interval tachogram of 256 consecutive RR values in a normal subject at supine rest (a) and after head-up tilt (b). The HRV spectra are shown, calculated by parametric autoregressive modeling (c and d) and by a fast Fourier transform-based non-parametric algorithm (e and f). Mean values ( $m$ ), variances ( $s^2$ ), and the number ( $N$ ) of samples are indicated. For c and d, VLF, LF, and HF central frequency, power in absolute value and power in normalized units (n.u.) are also indicated together with the order  $p$  of the chosen model and minimal values of the prediction error whiteness test (PEWT) and optimal order test (OOT) that satisfy the tests. In e and f, the peak frequency and the power of VLF, LF, and HF were calculated by integrating the power spectral density (PSD) in the defined frequency bands. The window type is also specified. In c through f, the LF component is indicated by dark shaded areas and the HF component by light shaded areas (From [4]).

Since the FFT is theoretically defined on an infinite time series, its application to real data of finite length leads to unavoidable errors. The assumption of zero-value of the data outside the recording window is necessary and results in a *spectral leakage* (Spectral leakage is the effect whereby power is removed from the correct frequency and distributed in the neighboring frequencies. This is a case when periodicities are not precise factors of the epoch length.) in the PSD. Therefore, different window functions are used to connect the side samples to zero smoothly. The rectangular, triangular (Bartlett), cosine, Han, Hamming, Blackman-Harris, Lanczos, and Welch, window tapers are among the most popular. Spectra which are better formed are obtained at the expense of *frequency resolution* (Spectral resolution is related to the number of discrete harmonic components, each of which is separated in frequency by a given range (i.e., 0.0005 Hz). If the frequency difference between adjacent components is small, the power is distributed amongst more components, each of which must therefore be smaller.) [4, 79, 80].

A further reduction in the frequency resolution can be reached by smoothing the rapid oscillation of the spectrum [79, 80]. Different procedures of averaging and overlapping are used. One of the most popular methods is the Welch periodogram (Periodogram estimate is based on the splitting of the time series in overlapped segments multiplied by data windows, and on the ensemble average of periodograms computed in each data window.). In this method, data segments are allowed to overlap by 50% or 70%, and each data segment is weighted with a window function before calculating the periodogram. Sometimes it is necessary to approximate a periodogram more closely, which can be done by using the zero padding procedure [79, 85]. Zero padding actually interpolates the values of the measured spectrum at additional frequencies, producing a smoother spectrum.

Rüdiger et al. [86] proposed a new approach for the FFT use based on trigonometric regression. This method, similar to the cosinor method [87], creates the  $k$ th rhythmic part with amplitude  $a_k$ , frequency  $\omega_k$ , and a phase shift  $\varphi_k$  as a regressively estimated function by using the method of least squares in the form (see 35.4):

$$u_k(t_i) = a_k * \sin(\omega_k t_i + \varphi_k) \quad (35.4)$$

This method provides a clear separation of rhythmic from nonrhythmic information. It is robust and does not require interpolation for artificial or missing segment deviations. Oscillations with a variance part  $\varepsilon < 1\%$  are stored as general residual variance. Estimation of the residual variance (nonrhythmic component) in four frequency bands from the FFT analysis showed that the total variance within each frequency band contains a substantial amount of the residual variance, especially in the VLF range (~13–17%) and in the HF range (~6–10%) [86]. The clinical usefulness of this method remains unknown (► Fig. 35.15).

### 35.3.2.2 Parametric Spectral Analysis

Autoregressive modeling (AR) uses a raw signal to identify a best fitting model from which the spectrum is derived [78–81, 88–92]. AR modeling is based on the assumption that each value of the series depends on a weighted sum of the previous values of the same series with noise.

AR models are completely independent of the characteristics of the biological system, simply representing the “black-box” approach. The AR methods are suitable for identifying the central frequency driven by a fixed-rate oscillator. Thus, the AR method allows concentration on the most significant peaks, excluding noise-related frequencies. As a result, the AR analysis provides a better spectral resolution, where the components are smoother and easier for post-processing. AR enables spectral estimation from shorter time periods than the FFT approach [79, 89].

In the AR model, a priori choice of the structure and the order of the model are crucial. The order is usually empirically selected based on the investigator’s expertise or by comparing the AR power spectra with those computed from other techniques. Too low a model order results in a low resolution power spectrum and too high a model order can generate false peaks in the spectrum [90].

Different criteria may help to determine the value of the order of the model (*Akaike, Rissanen, Parzen*) [79, 80, 90–92]. A correct identification of the model is required by using a posteriori tests of reliability. Changing the model order across different physiological conditions may introduce a new variable into the computation of the power spectrum. A fixed model order seems to be a practical rule for AR spectral estimation. This approach, although attractive in its

Table 35.3

simplicity, is criticized as unrealistic as it assumes the same model for all subjects, independent of their clinical characteristics and physiological conditions, as well as of signal sampling rate and SNR [90]. Moreover, in contrast to the FFT-based estimation, the amplitude of AR peaks does not faithfully reflect the actual power of the associated spectral component [89].

Many algorithms are proposed for obtaining estimates of AR parameters, for example, methods based on estimation of the Yule-Walker autocorrelation sequence, the Burg algorithm, and the Kay-Marple least squares linear prediction algorithms (including the modified covariance method) [79, 80, 85, 92]. There are also adaptive algorithms such as mean or recursive least square (*RLS*) which permit updating the parameter estimates as a new data sample becomes available [91].

### 35.3.3 Time-Frequency Spectrum Analysis

An evaluation of the power spectral density for short time series when the stationarity is met and subsequent repetition through the entire recording allows changes in signal variation over time to be quantified in a continuous manner. Several time-varying spectral approaches have been proposed [93–105]. These methods are particularly suitable for evaluating power and frequency transient alterations over time in response to physiological (body movement, exercise, mental tasks, sleep), pathophysiological (ischemic episodes, cardiac arrhythmias), or treatment (drugs, interventions) stimuli. However, the patterns of signal variation that are present across the entire spectrum, including long-range control mechanisms, are hidden with time-variant spectral analysis. A classification of time-frequency methods is given in Table 35.3 [93]. Most of these methods use frequency bands corresponding to those arbitrarily chosen in the frequency domain analysis. Only those that have a clinical application are described below. More in-depth review of these methods is beyond the scope of this chapter (see references [93, 94, 98]).

#### 35.3.3.1 Nonparametric Methods

##### Short-Time Fourier Transform

The short-time Fourier transform (STFT) is a linear time frequency representation of changes in the signal that vary with time. The Fourier transform does not explicitly show the time location of the frequency components, but some form of time location can be obtained by using a suitable pre-windowing  $g(s)$ . The STFT can be defined for  $x(t)$  as a local spectrum of the signal  $x(s)$  around the analysis time as (see 35.5):

$$S_x^g(t, \omega) = \int x(s)g(s-t)e^{-j\omega s} ds \quad (35.5)$$

The time-frequency resolution of the STFT is limited by the time-frequency product, that is, having a small time resolution means poor frequency resolution, or vice versa. The resolution is also constant as a function of the frequency, which is due to the window chosen for the STFT. Also, it depends on the bandwidths of the analysis functions and the length of the window, which are unlikely to be optimally chosen [99–101].

Figure 35.16

Wavelet analysis of HRV. (a) A theoretical example of wavelet analysis, (b) Wavelet analysis applied to HRV signal. For explanation see text and ref [103].

### Wavelet Analysis

Continuous wavelet analysis (CWA) is another method that provides time–frequency decomposition of a continuous signal. This method is usually devoted to the analysis of non-stationary signals [98, 102, 103]. Conversely to STFT, CWA allows temporal evolution of the spectrum of frequencies contained in the signal to be followed.

A basic function of CWA is the wavelet (Wavelet – wave of finite duration and finite energy, which is correlated with the signal.) function, denoted as  $m\psi(t)$ . This function, used to decompose the analyzed signal in the time–frequency plane, is localized both in time and in frequency (and must have the spectral pattern of a band-pass filter). The initial function should be adequately regular and is the localized “mother” wavelet. There are a number of mother functions (Daubechies’s fourth coefficient wavelet, Haar wavelet, Morlet wavelet). Starting from the mother wavelet, a family of wavelets is set by scaling (contracting or dilating) and shifting in time (Fig. 35.16). The resulting wavelets coefficients indicate the evolution of the correlation between the signal  $x(t)$  and the mother wavelet in different time-intervals and frequency-levels. Particular wavelets are defined as (35.6):

$$\psi_{k,j}(t) = a_0^{-\frac{1}{2}} \psi \left( a_0^{-j} \left( t - ka_0^j T \right) \right) \quad (35.6)$$

where  $a_0$  is the dilation factor,  $j$  and  $k$  are integers that determine dilation (scale) and the time-position of the wavelet, respectively, and  $T$  is the sampling interval. The corresponding wavelet coefficients are (see 35.7):

$$C_{k,j} = \int x(t) \psi_{j,k}^*(t) dt \quad (35.7)$$

By using CWA, the signal can be analyzed in different scale levels. Low scale levels (small  $j$  value) correspond to rapidly changing details (i.e., high frequency), whereas high scale levels (higher  $j$  values) correspond to slow changes (i.e., low frequency).

### Wigner-Ville Technique

The energy distribution of the signal in the time and the frequency domain can be obtained simultaneously if the PSD of the signal is evaluated by Fourier transformation of the instantaneous autocorrelation function (central covariance function) [95, 97]. Obtaining the time–frequency distribution is known as the Wigner-Ville distribution (WVD) (see 35.8):

$$\text{WVD}(t, f) = \int_{-\infty}^{+\infty} x\left(t - \frac{\tau}{2}\right) x^* \left(t + \frac{\tau}{2}\right) e^{-j2\pi f\tau} d\tau \quad (35.8)$$

It preserves the time  $t$  and frequency  $f$  shift of the signal. The time (of frequency) integral corresponds to the signal's instantaneous power (or power spectrum). The instantaneous frequency can also be estimated.

As the WVD introduces the cross-term interference due to nonlinearity of the transformation, the *kernel function* (Gaussian (known as Choi-Williams), Bessel, korn-shaped, and others) is used to remove this interference, obtaining the Cohen's class. The kernel performs a 2D filtering (in both domains) and determines the properties of the distribution. However, its choice influences the time and frequency resolution and optimal selection of the kernel requires knowledge about the signal. For the analysis of HRV data, the *smoothed pseudo-Wigner-Ville transform* (SPWV) has largely been used. It introduces time and frequency windows which determine SPWV resolution [97, 101].

### Huang-Hilbert Transform

By using the *Huang-Hilbert transform* (HHT), an analyzed signal is represented in the time–frequency domain by combining the *empirical mode decomposition* (EMD) with the Hilbert transform (HT). The first step uses EMD [104]. This procedure decomposes the signal into so-called *intrinsic mode function* (IMF) (IMF defines an oscillating wave if the number of extrema and the number of zero crossings differ only by one and the local average is zero.). A finite number of IMFs can be obtained from a real data-series. The IMFs are produced sequentially with each subsequent IMF being derived from the residual (i.e., the portion of the initial signal not represented by a previous IMF) initial signal. The iterative algorithm is called *sifting*. The first IMF is defined as  $c_1(t)$ . Having separated  $c_1(t)$  from  $x(t)$ , one has the residual signal  $r_1(t) = x(t) - c_1(t)$ . After several iterations (until the residual part becomes a monotonic function or a constant), the  $x(t)$  can be expressed as the combination of  $c_i(t)$  and  $r_n(t)$  (35.9):

$$x(t) = \sum_{i=1}^n c_i(t) + r_n(t) \quad (35.9)$$

Then, the Hilbert transform (HT), given by (35.10),

$$H[x(t)] = y(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{x(\tau)}{t - \tau} d\tau \quad (35.10)$$

is performed on the  $c_i(t)$ , and yields the instantaneous amplitude  $a_i(t)$  and phase  $\vartheta_i(t)$  (35.11):

$$a_i t = \sqrt{[c_i(t)]^2 + H[c_i(t)]^2}; \quad \vartheta_i t = \tan^{-1} \left\{ \frac{H[c_i(t)]}{c_i(t)} \right\} \quad (35.11)$$

The instantaneous frequency is given by (35.12).

$$\omega(t) = \frac{d\vartheta_i(t)}{d(t)}. \quad (35.12)$$

Thus, the Huang-Hilbert transform of  $x(t)$ , denoted as  $\text{HHT}(t, \omega)$ , can be expressed as (35.13):

$$\text{HHT}(t, \omega) = \sum_{i=1}^n a_i(t, \omega) \quad (35.13)$$

The HHT is adaptively data-driven and possesses higher time and frequency resolution than STFT, WVD, and CWA [102].

### 35.3.3.2 Parametric Methods

#### Recursive Autocorrelation

The recursive autocorrelation, also referred to as time-variant spectral estimation, is based on modeling of signal changes [93–97]. Spectral modification of a signal is realized by calculation of a new set of a model parameter  $a(t)$  from the preceding one  $a(t - 1)$  and from the prediction error (35.14):

$$a(t) = a(t - 1) + K(t)[y(t) - \hat{y}(t)], \quad (35.14)$$

where  $y(t) - \hat{y}(t)$  is the *prediction error* estimated by the model through the coefficients evaluated at time  $t - 1$  and  $K(t)$  is the *gain* of the algorithm.  $K(t)$  contains a forgetting factor  $\mu$  that exponentially weighs the past of the signal (the length of the past signal that really contributes to the change). Thus, the most recent terms contribute significantly to changes in a new sample, while the oldest one are progressively forgotten. The gain of the algorithm determines its adaptation and sensitivity to the signal changes. Many algorithms have been proposed for the  $K(t)$  calculation (*RLS, smoothed Kalman filter, directional, Fortesque*). The sequence of spectra can be represented as a contour plot or a spectral array [93–97]. The recursive implementation of the AR models allows monitoring of the spectral components in real time. The advantage of this method is related to its possibility for multiple signal systems analyses for cross-correlation (*time and phase coherence*) evaluation.

#### Temporal Cumulative Approach (TCA)

This relatively simple approach uses a PSD calculation over the frequency range of interests within short-epochs and reconstruction of its cumulative plot against time. This method allows instability in PSD to be overcome from neighboring epochs and reduces the effects of noisy data. The temporal cumulative approach enables temporal changes of interesting spectral components to be tracked, especially those with a relatively undisputable physiological background, i.e., the HF component. The cumulative plot is constructed by summing the PSD of the HF component versus time. This plot is then analyzed by a stepwise linear regression procedure (least squares) that helps time segments with consistent parasympathetic tone to be isolated. The length of these segments is determined automatically in order to find a minimal number of segments that describes the cumulative plot. The intensity of parasympathetic tone at each time-segment is defined by the slope of power units per minute [106].

### 35.3.4 Nonlinear/Chaos-Derived Methods

The majority of biological systems exhibit nonlinear behavior (e.g., the baroreceptor reflex, Starling curve, hemoglobin dissociation, lung hysteresis on a pressure–volume curve, etc.). Attempting to explain such a behavior using linear models does not seem sufficient or even appropriate. Thus, it is not surprising that over the last decade many nonlinear methods have been developed and postulated for HRV evaluation [107–115]. They can be classified according to the main features that they evaluate (Table 35.4.) [107]. Overall, a valid and reliable assessment of HRV nonlinear behavior requires relatively long-term ECG recordings. Some mathematical formulae are provided below and physical meanings are only summarized as necessary. A more in-depth description of these methods does not seem to be of interest to clinicians. However, researchers with an interest are invited to explore more extensive reviews [107–112].

To become familiar with nonlinear methods knowledge and understanding of both the mathematical and physical background are required. Unfortunately, advanced mathematics and physics are areas of limited understanding for the vast majority of physicians. In addition, chaos-theory or nonlinear dynamics derived methods are actually far removed from a definite physiological explanation or interpretation. A statement such as “broken fractal” means little to a physician. Thus, despite being introduced into clinical studies, these methods still remain research tools, and will be unlikely to be commonly used at the bedside. Nevertheless, by providing insight into many aspects of cardiac (heart rate) behavior, their employment (despite being experimental) might widen our understanding of cardiovascular system control [116–120], and in some cases, these techniques might find a practical application [118]. In other words, some of the gaps between science and practice can be demonstrated with HRV analysis. Fortunately, mathematicians, physicists, and

manufacturers have convinced physicians to employ these methods, albeit with their “black box” meaning remaining unresolved.

### 35.3.4.1 Scale Invariant/Fractal Analysis

The scale invariant self-similar nature is a property of *fractals* (Fractal, derived from the Latin word *fractus*, meaning broken or fragmented.), which are geometric structures that have no fixed length [21, 107, 113–115, 121–127]. Their length increases with increased precision (magnification) of measurement, a property that confers a non-integer dimension to all fractals (*fractal dimension* (Geometric dimension of an object which includes fractal objects (Hausdorff dimension  $D_H$ ))). With respect to time series, the pattern of variation appears to be the same at different scales (i.e., magnification of the pattern reveals the same pattern). The self-similar pattern can be recognized in either spatial or temporal aspects (Fig. 35.17).

#### Power-Law Behavior (1/f Fluctuation)

Kobayashi and Musha first reported the dependence of the spectral power on the frequency of the R–R interval fluctuations [21]. Further to this, different methods for a scale-invariant (self-similar) relationship between the magnitude of the effect and its frequency distribution (Fig. 35.18) have been developed [102–105, 118–120].

The power relationship is described by (35.15):

$$f = \alpha E^\beta, \quad (35.15)$$

where  $E$  is the amount of variation (e.g., spectral power),  $f$  is the frequency of observations, and  $\alpha$  and  $\beta$  are constants. Taking the logarithm of both sides the equation gives (35.16):

$$\log(f) = \log(\alpha) + \beta(\log(E)). \quad (35.16)$$

Plotting a graph of  $\log(f)$  against  $\log(E)$  reveals an almost straight line in the range of  $10^{-2}$  to  $10^{-4}$  Hz with  $\beta$  as an *exponent factor* (slope) and  $\log(\alpha)$  referred to as the intercept. The range of log–log representation is consistent with the size and duration of the system. Some authors also calculate the squared coefficient of correlation ( $r^2$ ), referred to as the *coefficient of determination*.

■ Figure 35.17

Fractal nature of heart rate variability. On the left graph heart rate variation appears to have no clear scale, as similar temporal pattern can be seen irrespective of time series data length. Right side graph shows distribution of wavelets in heartbeat series of different length. Pattern similarity is clearly seen between both epochs (From [107]).

The value of  $\beta$  exponent is around  $-1$  in healthy subjects (● Fig. 35.19). An altered  $\beta$  exponent was reported in patients after MI [126] and with CHF [127].

In contrast to a relatively stationary long time series (thousands of heartbeats) used for a reliable power-law behavior assessment, a model based on  $HRI$  calculation over a short time series (5 min) has been proposed [106]. Accordingly, the squared deviation from the mean heart rate is plotted on a 20-bin histogram with a bin size that equals  $1/20$  of the largest squared difference from the mean HR. A frequency distribution calculated from the histogram is plotted in the decimal log–log space. A regression line is fitted to the 20 data points and  $r^2$ , slope and intercept are derived. Although interesting results can be obtained in a selected population [128], this method is susceptible to the presence of non-stationarities or artifacts. In addition, a relatively long ECG recording is necessary for its reliable calculation.

#### Rescaled Range (R/S)

Fractal properties of data series can be measured by characterizing the divergence of data defined as the range ( $R$ ) of the sum of deviations from the mean divided by sample standard deviation ( $S$ ). For some processes that exhibit a long-range dependence (*persistence*), the  $R/S$  is proportional to a power of  $T$  (duration of the data sample) (see 35.17):

$$\frac{R}{S} = T^H. \quad (35.17)$$

The exponent  $H$  is called *Hurst exponent* [108, 109, 123, 124].

Given a time series  $x(n)$ ,  $n = 1, \dots, N$ ,  $H$  can be estimated by taking the slope of the plot of  $(R/S)$  vs.  $n$  on a log–log scale.  $H$  is related to the fractal dimension  $D_{(h)}$ . For 1D signals,  $H = 2D_{(h)}$  [123].

Figure 35.18

$1/f$  scaling behavior of HRV spectrum. The slope of a plot of power against frequency is almost straight in the range of  $10^{-2}$  and  $10^{-4}$  Hz. Two measures can be taken from  $1/f$  relationship: intercept and slope of this line (referred to as scaling index  $\beta$ ) (From [A32]).

Figure 35.19

Scaling properties of power spectrum. Fractal scaling analyses for two 24-h inter-beat interval time series. The solid black circles represent data from a healthy subject, whereas the open red circles are for the artificial time series generated by randomizing the sequential order of data points in the original time series. Exponent  $\beta$  in healthy indicates for the presence of long-range correlation ( $1/f$  noise). Loss of correlation properties is consistent with uncorrelated random time series (white noise) and  $\beta$ -exponent equals zero (From [107]).

### Detrended Fluctuation Analysis

A distinction between a local variation generated by external stimuli and intrinsic fluctuations from a complex system has been proposed to be feasible with *detrended fluctuation analysis (DFA)* [124]. These intrinsic fluctuations are presumed to exhibit a long-range scale-invariant (i.e., fractal) relationship. The DFA is a robust method for studying

fractal (or self-similar) behaviors of systems from which the originating signal exhibits an absence of characteristic temporal and/or spatial scale.

The calculation of DFA includes several steps. At first, heartbeat signals are represented as an integrated time series, following the equation (35.18):

$$y(k) = \sum_{i=1}^N (NN_i - NN_{ave}), \quad (35.18)$$

where  $y(k)$  represents an evaluation of trends,  $NN_i$  is the difference between individual inter-beat intervals, and  $NN_{ave}$  is the average interval of the total number of heartbeats  $N$ . The trend function  $y(k)$  is then separated into equal nonoverlapping boxes of length  $n$ , where  $n = N/(\text{total number of boxes})$ . In each box, the local trend  $y_n(k)$  is calculated using the least square method (Fig. 35.20). By subtracting the local trend  $y_n(k)$  from the trend function  $y(k)$  (“detrending”) for all possible length of boxes  $n$ , the function  $F(n)$  is calculated as the root mean square of the integrated and detrended series (35.19):

$$F(n) = \sqrt{(1/N) \sum_{k=1}^N [y(k)^2 - y_n(k)^2]} \quad (35.19)$$

Graphic presentation of the relationship between  $F(n)$  and  $n$  on a bi-logarithmic scale provides a regression line (Fig. 35.21). The slope of this line is termed the *scaling exponent*  $\alpha$ . It may vary from 0.5 (uncorrelated random data or white noise) to 1.5 (random walk or Brownian noise). If the signal obeys the power-law behavior, that is, corresponds to the  $1/f$  noise, the  $\alpha$  exponent equals 1 (Fig. 35.16) [124]. The exponent  $\alpha$  of this power relation defines

Figure 35.20

Illustration of the DFA algorithm to test for scale-invariance and long-range correlations. (a) Interbeat interval (IBI) time series from a healthy young adult. (b) The solid black curve is the integrated time series,  $y(k)$ . The vertical dotted lines indicate boxes of size  $n$  100 beats. The red straight line segments represent the “trend” estimated in each box by a linear least squares fit. The blue straight line segments represent linear fits for box size  $n$  200. Note that the typical deviation from the  $y(k)$  curve to the red lines is smaller than the deviation to the blue lines (From [107], Nat Acad Sci USA, with permission).

■ Figure 35.21

Bi-logarithmic presentation of the relationship between  $F(n)$  and  $n$ . The slope of the line is referred to as  $\alpha$ -exponent and in healthy subjects varies around 1 ( $1/f$  noise). For white noise or uncorrelated random data  $\alpha$ -exponent equals 0.5 (From [107]).

a pertinent parameter called the *self-similarity parameter* (when applicable it is related to the *Hurst exponent*  $H$  by  $\alpha = H + 1$ ).

Applying this analysis to real-life data-series, the scaling exponent shows two distinct linear segments that depend on  $n$  values. Depending on a crossover phenomenon, arbitrary cutoffs for the  $n$ -values are initially proposed ( $n = 4-16$  and  $n = 16-64$ ) [122–127]. This yields two scaling exponents,  $\alpha_1$  and  $\alpha_2$ , referred to as the short and intermediate-term exponents, respectively. However, in the most commonly applied variant of DFA, the  $n$ -values for  $\alpha_1$  and  $\alpha_2$  exponents range between 4–11 and 12–400, respectively [103, 110]. Thus, in contrast to  $1/f$  scaling methods, the DFA allows the determination of a scale-invariant property over a relatively short data-series (~8,000 heartbeats). A loss of fractal-like HR dynamics has been shown to characterize patients with cardiovascular disease [112].

DFA is a mono-fractal technique, assuming that the scaling properties of the system are the same throughout the entire signal. In addition, only normal-to-normal heartbeats are included. As all of these assumptions may be flawed, another technique has been developed, namely multi-fractal analysis [129–132]. Multi-fractal DFA may help to detect changes of scaling behavior with time, providing the multiple scaling exponent  $D(h)$  (► Fig. 35.22).

Multi-fractality in heartbeat dynamics raises the possibility that many nonlinear control mechanisms are actually involved with coupled cascades of feedback loops in a system operating far from equilibrium. A loss of such dynamics was reported in patients with heart failure [132].

### Correlation Dimension

Correlation dimension is an alternative procedure for the calculation of the fractal dimension (although it is not strictly the same) [133, 134]. It is also considered as a measure of degrees of freedom stimulated by a system, thus expressing the complexity of a system. From a defined data vector ( $y_i, i = 1, \dots, N$ ) with  $N$  points, an  $m$ -dimensional phase-space of dimension  $p$  (*embedding dimension* (Number of axes of a return map sufficient to describe the properties of the corresponding phase space)) is constructed according to *Takens theorem* (A delay embedding theorem gives the

Figure 35.22

Multifractal properties of heartbeat variation (From [107]).

conditions under which a chaotic dynamic system can be reconstructed from a sequence of observations of the state of a dynamic system.) [113], obtaining (35.20):

$$\vec{x}_t \equiv (y_t, y_{t+\tau}, y_{t+2\tau}, \dots, y_{t+(m-1)\tau}), \quad (35.20)$$

for  $t = 1, \dots, N - (m - 1)\tau$ , where  $\tau$  is the time delay or lag. Grassberger and Procaccia [136] have developed the basic algorithm which consists of computing the fraction of pairs of points in the *embedded space* that lie within a distance  $\epsilon$  of each other with the dimension  $d$  (also referred to as  $D_2$ ) (35.21):

$$d = \lim_{\epsilon \rightarrow 0} \left[ \frac{\log_2(C_m(\epsilon))}{\log_2(\epsilon)} \right], \quad (35.21)$$

where  $C_m(\epsilon)$  is the correlation integral which measures the number of points  $x_j$  that are correlated with each other in a sphere of radius  $\epsilon$  around the points  $x_t$ . This algorithm is also known as *sphere (box) counting method*. Thus, in the phase-space, the correlation integral  $C_m(\epsilon)$  is defined (35.22):

$$C_m(\epsilon) = \frac{1}{N \cdot (N - 1)} \cdot \sum_{i \neq j} \Theta(\epsilon - |Z_i - Z_j|), \quad (35.22)$$

where  $\Theta(z)$  is the Heaviside function:  $\Theta(z) = 0$ , if  $z \leq 0$  and  $\Theta(z) = 1$ , if  $z > 0$ , and  $|z_i - z_j|$  is the distance between a pair of points within the *attractor* (Attractor – an object to which the time series in a phase space is attracted.).

When  $\log_2 C_m(\epsilon)$  is plotted versus  $\log_2(\epsilon)$ , the slope of the resulting straight line, determined by linear regression at lower  $\epsilon$ , yields the dimension  $D_2$ . Several  $C_m(\epsilon)$  are computed for increasing values of the embedding dimensions  $m$ , and the slopes are determined from a *scaling region* of the log–log plot, as shown in Fig. 35.23a, obtaining a sequence of  $d(m)$ . As  $m$  is increased,  $d(m)$  tends to a constant value of saturation (the  $D_2$  value) shown in Fig. 35.23b [137]. The  $D_2$  value is obtained by considering the points where  $d(m)$  values remain constant (high values of  $m$ ). A variance of the  $D_2$  calculation, the point estimate of the heartbeat  $D_2$ , has also been proposed [138].

### 35.3.4.2 Entropy Analysis

Entropy  $H$ , as a physical term, is an energy that dissipates with time, as embodied by the Second Law of Thermodynamics. The concept of entropy was introduced into the theory of information by Shannon [139]. Applying entropy analysis to

■ Figure 35.23

(a) Correlation integral as a function of the sphere radius ( $r$ ) for each embedding dimension showing the scaling region. (b). Correlation dimension ( $D_2$ , here CD) as a function of the embedding dimension  $m$  with a fitted exponential curve .

a real time series is based on its ability to measure order (regularity) and disorder (irregularity/randomness) and the probability  $p$  of these states.

#### Approximate Entropy (ApEn)

Approximate entropy analysis exhibits the rate of generation of new information within a biological signal (similar to the classic Kolmogorov-Sinai entropy).

To calculate *ApEn* [140], a data series is evaluated for the presence of recurrent patterns. First, a length  $m$  of data sequences is defined and the likelihood of similarity with other sequences of length  $m$  with a *tolerance*  $r$  is determined. Vector sequences  $x(i)$  of consecutive data-points  $u(i)_{(i=1,2,3\dots N)}$  of length  $m$  are derived. Then, the distance  $d(x(i), x(j))$  is defined, as the maximum difference between two vector components  $x(i)$  and  $x[j]$ . If this difference is within tolerance  $r$ , the vectors are considered similar.

The frequency ( $C_i^m(r)$ ) of occurrence of similar vectors  $N_j$  of sequences with length  $m$  and tolerance  $r$  throughout the data set is calculated (35.23):

$$C_i^m(r) = N_j \in d(x[i], x[j]) \leq r / (N - m - 1), \quad (35.23)$$

where  $j \leq (N - m - 1)$ . Then, the relative occurrence of repetitive patterns  $\Phi_{m(r)}$  of length  $m$  within the tolerance  $r$  is obtained (35.24):

$$\Phi_m(r) = \sum_i \ln C_i^m(r) / (N - m - 1), \quad (35.24)$$

where  $\sum_i$  is a sum from  $i = 1$  to  $(N - m - 1)$ . Finally, the approximate entropy ApEn is calculated, following the equation (35.25):

$$\text{ApEn}(m, r, N) = \Phi_{m(r)} - \Phi_{m+1(r)}, \quad (35.25)$$

Thus, the  $\text{ApEn}(m, r, N)$  measures the logarithmic frequency (probability) that runs of patterns (within the tolerance  $r$ ) of length  $m$  remain similar when the length  $m$  of the run is increased by 1. Small values of the ApEn indicate regularity, given that increasing the data sequence of a length  $m$  by 1 does not decrease the value of  $\Phi_m(r)$  significantly (i.e., regularity connotes that  $\Phi_{m(r)} \approx \Phi_{m+1(r)}$ ). The value of  $\text{ApEn}(m, r, N)$  is expressed as a difference, but in essence it represents a ratio, as the  $\Phi_{m(r)}$  is a logarithm of the averaged  $C_i^m(r)$  and the ratio of logarithms is equivalent to their difference. Although the ApEn can be calculated from relatively short data-series, the length of ECG recordings influences the value of ApEn (similarly to the SDNN). In healthy subjects, the ApEn is found to be slightly over or around 1 [141]. In pathological conditions, ApEn was found to be higher [112, 142] indicating the existence of more unpredictable patterns.

As with many other HRV measures, the ApEn requires data to be stationary and noise-free (without artifacts). In addition, relatively long ECG recordings are required for the ApEn to be measured reliably. Also, ApEn includes a spurious contribution from “self-matching”.

A variant of ApEn in which self-matching is not included, referred to as the *sample entropy* (*SampEn*) has been proposed [143]. *SampEn* describes the conditional probability that two sequences for  $m$  data points (with a tolerance  $r$ ) remain within  $r$  of each other (similar) at the next point. The *SampEn* converges to a consistent value for a considerably lower  $r$  and  $N$  than the ApEn [143]. A reduced *SampEn* was described in neonates prior to the clinical diagnosis of sepsis [144] and before the onset of atrial fibrillation [145].

As biological systems are structured on multiple spatial-temporal scales, a description of their dynamics using the ApEn or *SampEn*, which evaluate regularity on one scale only, might provide conflicting results. Thus, the so-called *multi-scale entropy* (*MSE*) evaluation has been proposed in which the *SampEn* is calculated for the coarse-grained data for a range of scales (e.g.,  $\tau = 1$  to  $\tau = 20$  [146]). The MSE is applicable to a data-series of finite length ( $\sim 30,000$ ). Increased regularity irrespective of variability (decreased or increased) was found to characterize pathological states. A reduced MSE, depending on the scale of reduction, distinguishes patients with CHF, AF, or diabetes from healthy subjects [146, 147].

Another variant is *compression entropy* (*CE*). It quantifies the extent to which the data-series can be compressed, depending on the occurrence of repeated sequences [148]. CE reduction was documented in patients with CHF and malignant ventricular arrhythmia [149]. The reliability of this method depends on sampling rate, the window length, buffer size, and integer numbers [148].

### Symbolic Dynamics

The absolute value of parameters is seldom of importance for diagnostic (classification) purposes, while the relative orders or qualitative values (above or below a threshold) are significant. In such instances, a great simplification in the form of *symbolic dynamics* (*SDyn*) can be applied [150–152]. *SDyn* is based on coarse graining and involves the transformation of the original time series into a series of a limited amount of discretized symbols that are processed to extract important information about the system generating the process.

■ **Figure 35.24**

Illustration of symbolic analysis method. R – R interval series is uniformly spread on pre-determined levels. Each level is described by symbol (number) and 3-symbols patterns (words) are constructed (From [A37]).

A variant of the SDyn approach has been proposed to describe short-term HRV dynamics [151]. First, the data series is transformed into a sequence of symbols. These symbols are simply the alphabet  $A = (0,1,2,3, \dots)$  and permit the classifying of various patterns and monitoring of their occurrence and changes with time (► Fig. 35.24). At least three symbols (*strings*) are necessary to characterize short-time dynamics. The resulting data are expressed as the probability of distribution of each single word (3 symbols) within a word sequence. A modified procedure of SDyn that permits a shortened data series (~300 heartbeats) to be analyzed has been proposed [151]. This method naturally results in a considerable compression of the data with a subsequent loss of detailed information. It also improves the sensitivity to noise. However, the presence of artifact influences the symbol strings.

To quantify low-variability data epochs, a parameter called *POLVAR10* has been proposed [152]. It is calculated on the basis of the most simplified transformation of differences of 10 ms or more (symbol:1) or less (symbol:0) between successive heartbeats. Only words of six unique symbols (all 1 or all 0) are counted. The *POLVAR10* represents the probability of occurrence of the word “000000,” which indicates severely depressed variability [152].

The *acceleration change index (ACI)*, an index that can be obtained from the sign (1 for HR deceleration, 0 for acceleration) of the beat-to-beat difference, which characterizes the dynamics of zero-crossing, has been proposed [141].

A series of sign changes (SC) is generated. Then, the differentiation of SC (*DSC*) is calculated and the ACI is defined as (35.26):

$$ACI = \frac{k}{M}, \quad (35.26)$$

where  $k$  is the number of times that the *DSC* time series equals 1, and  $M$  is the total number of samples in the *DSC* series. Therefore, the ACI is the proportion of times that a local maximum (or minimum) is followed immediately by a local minimum (or maximum) by the total number of local maxima and minima. Despite the method being simple and robust, the ACI quantifies similar changes of a different length (increase or decrease by 20 or 40 ms for example, and so on). Arif and Aziz have proposed the *threshold-based* (indicating the necessary change to be signed) *acceleration index* (TACI). The TACI allows better classification of patients with specific diseases [154]. However, its clinical applicability is not proven and the threshold value has to be chosen empirically.

### Information Entropy

The entropy of a random variable is defined in terms of its probability distribution and can be considered as a good measure of randomness (or uncertainty). This is the basis of the so-called *Shannon entropy* (or *measure of uncertainty*) [155].

Consider a stationary time series  $\{x(n)\}_{n=1}^N$  that is characterized by the discrete probability distribution  $\{S_i\}_{i=1}^K$  with the marginal distribution  $p_i = \sum_i S_i$ . Then, for the discrete probability distribution  $\{p_i\}$ , the Shannon information measure is defined (35.27) as:

$$H_x = - \sum_i p_i \log_2 p_i \quad (35.27)$$

For HRV complexity measurements, the Shannon entropy can be applied for time series transformed into symbol sequences (see symbolic dynamics). Thus, having the  $W^k$  set of all words  $\omega$  of length  $k$ , the  $H_k$  calculated from the distribution of probability of words  $p(\omega)$  is given by (35.28):

$$H_k = - \sum_{\omega \in W^k, p(\omega) > 0} p_\omega \log p_\omega \quad (35.28)$$

Larger values of *Shannon's entropy*  $H_k$  indicate a higher complexity. Among various “words” there are some that never or only seldom occur. These “words” are called “forbidden”. Counting the forbidden words in the distribution of words (of length 3 symbols), regular or irregular behavior in the data series can be distinguished (with a high or low number, respectively).

If the data series contains negative values, one informative measure, which allows negative values in the distribution is *Renyi's entropy* described as (35.29):

$$H_\alpha = \frac{1}{1-\alpha} \log_2 \left\{ \sum_{k=1}^N p_k^\alpha \right\} \quad (35.29)$$

where  $\alpha$  is order ( $\alpha > 0, \alpha \neq 1$ ). The result produced by this measure is expressed in *bits*: if one elementary signal yields zero bits of information, then two well-separated elementary singles will yield one bit of information, four well-separated elementary singles will yield two bits of information, and so on. Thus, for different cardiac signals, Renyi's entropy in the time–frequency domain is different [155].

*Mutual information function* (MIF) is an informative approach analogous to the cross-correlation or the auto-correlation function. For two stationary data series  $x(n)$  and  $y(n)$  the Shannon  $H_k$  can be calculated ( $H_x$  and  $H_y$ , respectively). Then, the MIF is given by (35.30):

$$MI_{xy} = H_x + H_y - H_{xy} = \sum_{ij} S_{ij} \log_2 \frac{S_{ij}}{p_i q_j} \quad (35.30)$$

■ Figure 35.25

Scheme of Autonomic Information Flow (AIF) as function of the time scale  $\tau$ . The AIF value at  $\tau = 1$  heartbeat quantifies the information flow to the successive heartbeat. The respective loss of the signal inherent information (AIF normalised to 1 at  $\tau = 0$ ) is quantified by the AIF decay measure BD (beat decay at  $\tau = 1$  heart beat). Correspondingly, the loss of information over a longer time scale  $\tau$ , such as the vagal or respiratory sinus arrhythmia rhythms, which can appear as peak in AIF (full line), can be assessed as PD (peak decay). In cases of nonappearing peaks, the decay with regard to the mean AIF of appropriate time scale range ( $PD^m$ , dashed lines) are used as robust measure. The lower boundary  $\tau_l$  and the upper boundary  $\tau_u$  of the time scale range is chosen according to the corresponding frequency band boundaries  $f$  by  $\tau = 1/(2f)$  (From [A 36]).

The MIF measures the average information in  $x(n)$  on  $y(n)$  in units of “bit”. MIF is symmetrical ( $MI_{xy} = MI_{yx}$ ), non-negative, and bounded from above by  $\min\{H_x, H_y\}$ . MIF vanishes if the time series are statistically independent. Thus, the  $x(n)$  (almost surely) determines  $y(n)$  only if  $MI_{xy} \geq H_y$ .

On the basis of the MIF, the *autonomic information flow* (AIF) has been proposed by Hoyer et al. [156]. In this method, all statistical dependencies are considered as *information flow* within the time series. AIF is independent of signal amplitudes and allows the predictability and regularity of a signal to be quantified.

A typical AIF is sketched in Fig. 35.25. The amplitude at  $\tau = 0$  (normalized to 1) represents the entire information of a time series. The decay of this function over a prediction time  $\tau$  (which is considered as a time scale) represents the loss of information (here, over one heartbeat interval). In the case of a highly complex interval series, the next RRI is poorly predictable and consequently the decay of the AIF curve (information loss) is high (large BD, beat decay). In the opposite case of a confidently predictable heartbeat series, the AIF decay is low and consequently the BD is small. Predominant rhythms (such as vagal oscillations) can be assessed by the information loss over respective prediction time horizons (= time scales) corresponding to the well-known autonomic rhythms. The resulting measure is called *peak decay* [156]. Various time scales of AIF can improve prognostication in patients with multiple organ dysfunction syndrome and after cardiac arrest.

### 35.3.4.3 Methods for Chaos and Determinism Analysis

(Chaos – a property of a system that looks random being in fact deterministic (albeit irreversible and unpredictable). Determinism–this means that points close to each other in phase space at a time  $t$  will probably be close to each other at a time  $t + \Delta t$ . Thus, determinism implies that evolving from time  $t_0$  to  $t_1$ , and then from  $t_1$  to  $t_2$ , is the same as evolving from  $t_0$  to  $t_2$  (known as *Chapman-Kolmogorov law*.)

Many biological phenomena which look like a random (stochastic) process (atrial fibrillation, ventricular fibrillation) are in fact related to many factors (the number of degrees of freedom (Mathematically, the number of degrees of freedom (or the dimension of state space) equals the number of first-order differential equations necessary to describe the system.), usually not known exactly) that determine their nonlinear dynamics (behavior) [108, 109, 111]. Dynamical

Figure 35.26

Bifurcation diagram of logistic map (From [108]).

(biological) systems (continuous) usually consist of phase space ( $M$ ) and map (evolution, flow,  $F$ ). Typically, there are at best *differential equations* (Differential equation is a mathematical equation for an unknown function of one or several variables that relates the values of the function itself and its derivatives of various orders.) to express the evolution of the system. For exploratory reasons, the continuous system behavior is evaluated after discretization (i.e., “time” is given as a set of points  $1, 2, 3, \dots, F$ ). For a 1D system, a nonlinear behavior can be characterized by means of a so-called *logistic map* (Logistic map – a polynomial mapping of chaotic behavior can arise from very simple nonlinear dynamic equations.) (35.31):

$$x_{n+1} = ax_n(1 - x_n), \quad (35.31)$$

where  $x_{n+1}$  is the point (state) after time 1,  $x_n$  is the initial point (state), and  $a$  is the bifurcation parameter. When  $a$  increases, the system switches to higher periodicities (so-called *period-doubling bifurcations*) until at a certain value of  $a$  the system exhibits chaotic behavior (period-doubling route to chaos) (Fig. 35.26) [108, 109]. The transition from regular (periodic) to chaotic behavior takes place via a quasi-periodicity, sub-criticality, or intermittency. All possible dynamics have been observed with respect to cardiac arrhythmias (i.e., ventricular fibrillation [116–120]).

Consider two initial states of  $x(t)$  and  $y(t)$  at time  $t = 0$ . If the tendency is to diverge at an exponential rate with time ( $\gamma > 0$ ), then the system exhibits chaotic dynamics (35.32)

$$|x(t) - y(t)| \approx |x(0) - y(0)| e^{\gamma t}, \quad (35.32)$$

which define a property of chaotic dynamics, that is, the sensitivity of the evolution of the system to the initial condition [157].

### Largest Lyapunov Exponent

The Lyapunov exponent ( $\lambda$ ) is a quantitative measure of the sensitive dependence on initial conditions [109, 157]. It defines the average rate of divergence of two neighboring trajectories. An exponential divergence of infinitesimally close trajectories in phase space, coupled with a folding of trajectories to ensure that the solutions will remain finite, is the general mechanism for generating deterministic randomness and unpredictability. A negative exponent implies that the orbits approach a common fixed point. A zero exponent means that the orbits maintain their relative positions – they are on a stable attractor. Finally, a positive  $\lambda$  implies that the orbits are on a chaotic attractor. Thus, Lyapunov exponents allow the discrimination between periodicity and chaotic dynamics. Amongst all possible  $\lambda$ , the largest Lyapunov exponent (LLE) is of particular interest. Its positivity is presumed to be a “gold standard” for chaos in “deterministic” time series.

Wolf et al. [158] have proposed the algorithm for LLE calculation from time series. For a given time series  $x(t)$  and the nearest to initial point  $x(t_0)$ , the average exponential rate of divergence is characterized by (35.33):

$$\lambda = \frac{1}{t_M - t_0} \sum_{k=1}^M \log_2 \frac{L(t_k)}{L(t_{k+1})}, \quad (35.33)$$

where  $L$  indicates the distance between these two points. To calculate the LLE, the following set of parameters must be chosen:  $m$  – the embedding dimension,  $\tau$  – the delay, evaluation time  $t_{k-1}$ ,  $t_{k+1}$ , as well as separation points and maximum orientation error. For LLE calculation for ECG data series, an  $m$  between 5–20 and a time delay of 1 is indicated. However, a reliable calculation of LLE requires a relatively long and uncorrupted data series. In addition, it remains controversial whether LLE per se allows sufficient proof of chaos or provides a quantitative measure of chaos intensity.

### Poincaré Sections

This is a way of obtaining a discrete  $(n - 1)$  dimensional dynamic from an  $n$ -dimensional continuous space-phase. For a 3D orbit, it is possible to intersect the orbit in a discrete set of points  $x(t_k)$  with a suitably oriented plane  $P$  (*Poincaré section*). Then, the points where the orbit intersects the plane from the same side (from behind) can be chosen. Therefore, a two-dimensional discrete dynamics  $x_{k+1} = G(x_k)$  in the plane  $P$  can be determined [108, 116, 117].

### Noise Limit Titration

The presence of noise in real (experimental) data series is the main factor that limits the reliability of various methods that are proposed for the detection of deterministic chaos. Poon and Barahona [159] have proposed an analytical technique called *noise titration*. Instead of removing or separating noise from the data, artificially generated random noise is added to the quantitatively titrate chaos. White (or linearly correlated) noise of increasing standard deviation ( $\delta$ ) is added to the data until its nonlinearity goes undetected by a particular *indicator* at a limiting value of  $\delta = \text{noise limit (NL)}$  (noise ceiling of the signal) and at a limiting condition (equivalence point). An NL value  $> 0$  indicates chaos, and its given value estimates its relative intensity. If  $NL = 0$ , the data-series can be considered either nonchaotic or the background noise (so-called noise floor) neutralizes the chaotic component. The power of the numerical titration technique depends critically on the choice of a suitable *nonlinear indicator*, which has to be specific (to nonlinear dynamics) and tolerant (to measurement noise). One verified method is the *Volterra-Wiener algorithm* [159]. The titration procedure is highly sensitive and specific to chaos, immune to noise, relatively simple and robust. Its ability to distinguish healthy young and elderly people from CHF-patients has recently been reported [160]. However, its clinical significance still remains unexplored.

## 35.3.4.4 Nonlinear Prediction (Forecasting)

A characteristic feature of a dynamic system with deterministic chaos is that the prediction of its behavior is possible with some degree of confidence only in the short term. Thus, with some knowledge about a part of system dynamics (so-called *library*), it is possible to try to predict its behavior several steps into the future. These assumptions provide a basis for the development of methods for HRV predictability (forecasting) [161, 162].

### Correlation Coefficients

Sugihara and May [161] have arbitrarily proposed dividing a given time series into two equal parts, using the first half as a library, from which the behavior of the second half can be predicted. By constructing an  $m$ -dimensional vector (called *the predictee*)  $X_t = (x_t, x_{t+1} \dots x_{t-(m-1)})$  from the first half of the time series, it is then possible to make a numerical prediction for the parts immediately following the elements of the predictee. Denoting these predicted values by  $x_{t+p}$  for  $p = 1, 2, \dots, p_{\max}$ , it is then possible to plot the  $x_{t+p}$  against the values  $x_{t+p}$  actually occurring in the time series. By repeating this procedure for many  $m$ -dimensional vectors drawn from the second half of the series, it is feasible to compute the correlation coefficient  $\rho$  for the predicted and actual values as a function of  $p$ , the number of time-steps into the future.

### S-map (Sequential Locally weighted Global Linear Maps)

A locally weighted map can provide a simple test for nonlinearity in a time series [156]. Suppose there is an embedding of the actual time series  $X_t \in R^{m+1}$  where  $X(t) \equiv 0$ , and the time step  $Tp$  forward is  $X_{t+Tp}(1)$ , then the forecast at  $Tp$  is given by (35.34):

$$\widehat{Y}_t = \sum_{j=0}^m C_t(j) X_t(j). \quad (35.34)$$

#### 35.3.4.5 Irreversibility/Asymmetry Analysis

Time irreversibility analysis is a nonlinear dynamics technique that produces temporal *asymmetries* in statistical properties that are different when the series are observed after time reversal. Thus, if a stationary time series is considered to be time reversible, then the probability of the vector  $(z_n, \dots, z_{n+k-1})$  is equal to the probability of the vector  $(z_{n+k-1}, \dots, z_n)$  for all  $k$  and  $n$  [163]. For a time-reversible segment, it follows that the return map  $R - R_{n+1}$  versus  $R - R_n$  is symmetrical with respect to the line of identity. Thus, the irreversibility is defined by the asymmetry of the distribution of the difference of consecutive intervals with respect to zero. The simplest test statistic used for detection of deviations from time reversibility is the *skewness of the differences of R-R intervals* [163].

Costa et al. [164] have proposed a so-called multi-scale time asymmetry index  $A_I$  that is based on methods derived from basic physics assumptions. First, data-series are transformed into binary sequences of HR accelerations and decelerations. Then, a set of coarse-graining time series  $y_\tau$  is constructed by taking the average inside the moving window with a different scale factor  $\tau$ . The difference between the probability of energy distribution for HR accelerations and decelerations provides the estimator of time reversal asymmetry  $\widehat{A}(\tau)$  (35.35):

$$\widehat{A}(\tau) = \frac{\sum_{y_\tau > 0} P(y_\tau) \ln[P(y_\tau)]}{\sum_{y_\tau} P(y_\tau) \ln[P(y_\tau)]} - \frac{\sum_{y_\tau < 0} P(y_\tau) \ln[P(y_\tau)]}{\sum_{y_\tau} P(y_\tau) \ln[P(y_\tau)]}, \quad (35.35)$$

where  $P(y)$  denotes the probability of  $y_\tau$ . For a range of time scales  $\tau$ , the *multi-scale time asymmetry index* ( $A_I$ ) is calculated as the summation of the asymmetry values  $\widehat{A}(\tau)$  obtained for each time scale (35.36):

$$A_I = \sum_{\tau=1}^L \widehat{A}(\tau). \quad (35.36)$$

The  $A_I$  values are significantly higher for young healthy adults than for the elderly and subjects with CHF or AF. Interestingly, highly irregular time series of AF and less variable (compared to healthy subjects) time series of patients with CHF tend to be more symmetric [164]. Thus,  $A_I$  can be considered as a measure that can be applied irrespective of heart rhythm.

Many simple tests for time-irreversibility that are based on return map evaluation have been proposed by Ehlers et al. [165], Guzik et al. [166], and Porta et al. [167]. The distribution of R-R intervals (or differences) with respect to the main diagonal of the return map is quantified as the number of points (or distances) below or above the diagonal.

The clinical significance of time-irreversibility remains unresolved. However, evidence of a link between autonomic control and the asymmetry index has been found [168]. Recently, Porta et al. have described a method for distinguishing various types of nonlinearities over different temporal scales [169].

#### 35.3.4.6 Phase-Rectified Signal Averaging Method

Periodicities in HR signals are usually contaminated by the presence of noise and artifacts, which may cause a reset of the periodicities (quasi-periodicities). These “new” quasi-periodicities can be determined by means of a phase-rectified

averaging method (● Fig. 35.27) [170]. First, the so-called anchor points (Anchor points correspond to increases (or decreases) of the signal.) in the phase of deceleration or acceleration are determined (● Fig. 35.27). The averages over anchor points are calculated within a segment (window) containing signals close to them (usually two intervals for each side). Differences in PRSA over increasing and decreasing parts of the signal indicate a loss of time-reversal symmetry. The derived index called *deceleration capacity* (DC) has been shown to be helpful in risk stratification in post-MI patients [171], especially in those with preserved left ventricular function [172].

### 35.3.4.7 Recurrence Quantification Analysis

Recurrence quantification analysis (RCA) is a method for quantification of determinism in a time series [173]. This method is especially useful for transient behavior far from equilibrium (RQA software (Webber & Zbilut), can be downloaded from the following URL: <http://homepages.luc.edu/~cwebber/>). Basically, the difference in the embedding dimension  $z_n - z_m$ , which constitute the *recurrence matrix*  $R_{n,m}$  can be calculated. Points of the recurrence matrix are designated “recurrent” if the difference between paired vectors is below a cut-off value. Recurrent points are plotted as darkened pixels at corresponding  $n, m$  coordinates (● Fig. 35.28) [174]. If the signal is regular, its deterministic nature will show regular patterns. A quantitative description is given by the parameter percent of determinism (%DET) (among others proposed), which is about zero for the stochastic process and approximately 100 for a deterministic signal. %DET provides information about the intrinsic structure of the signal [174]. Although the RCA also allows for the determination of the LLE and Shannon entropy, this method has been found to be of limited clinical interest [175].

### 35.3.4.8 Stochastic Resonance

The presence of noise might not necessarily be considered harmful. In fact, under certain circumstances, an “extra dose” of noise can help the performance of the system [176]. The noise component can be calculated by means of several methods, with the most popular being the *signal-to-noise ratio* (SNR) [176]. The geometric mean of the average distribution values below and above the signal bandwidth has been proposed for its calculation. The SNR of the RRIs (SNR<sub>RR1</sub>) can be calculated as a ratio of  $(D_{S+N} - D_S)/D_N$ , where  $D_{S+N}$  is a distribution of the recorded signal (signal  $[s]$  + noise  $[n]$ ), and  $D_S$  is a distribution of the true signal over a prespecified bandwidth. For transient changes to be examined, a robust locally weighted regression can be used to smooth varying SNR temporally [177].

## 35.3.5 Methods for Qualifying and Quantifying HRV Relationship with Other Biological Signals

Important information provided by HRV analysis extracted from a single time series cannot enhance other time series. Therefore, the interaction between two (or more) physiological (sub)systems might be necessary. Sometimes, a single ECG time series can provide data regarding breathing rate though the respiratory function is not recorded [177, 178]. In addition, other ECG-derived parameters that might be related to heart rate control can be obtained, estimated, and correlated with the HRV signal [179].

Usually, simultaneously recorded time series for each system are required. Hence, many bivariate or multivariate techniques have been developed that aim to quantify the imprint of the physiological interaction between the two or more systems. Apart from the detection of interrelations, some of these techniques are designed to assess causal relationships between the signals.

### 35.3.5.1 Time-Domain Method

Time-domain approaches for quantifying a relationship between any two signals (HR and respiration or SBP or other) are based on the simultaneous measurement of changes of the two parameters and the calculation of the correlation of their

Figure 35.27

Calculation of Deceleration Capacity index by phase-rectified signal averaging. For explanation see [170, 171].

■ Figure 35.28

Recurrence plot. The various colors reflect different Euclidean distances between trajectories and are analogous to geographical relief maps. Five RQA variables are computed (%recurrence, %determinism, information entropy, maximum diagonal line length, state trend) which have relevancy as nonlinear markers of changes in dynamical systems and physiological states. If the signal is regular, its deterministic nature will show regular patterns (From <http://homepages.luc.edu/~cwebber/withpermission>).

linear regression. Accordingly, the change of a signal  $x(t) - x(t + i)$  is plotted against the change of a signal  $y(t) - y(t + i)$ . The slope of a linear regression describes the magnitude of the relation. This relatively simple approach forms the basis of some clinical tests, like the RSA deep breathing test, Valsalva or Muller test, tilt test, and BRS evaluation.

Time-dependent occurrence of the signal changes with another signal may help to investigate coordination and synchronization. The simplest example is the relation of the P-wave to the QRS complex. If the relation is given by the number 2, it simply indicates the presence of a II° A-V block Mobitz I with a 2:1 pattern. A similar approach can be applied in studying coordination of HRV and respiration or blood pressure changes. In addition, nonlinear phenomena that can mimic AV block patterns (i.e., bifurcations) cycle-multiplying (i.e., periodicities including alternans) can also be examined.

### 35.3.5.2 Cross-Spectrum

The *coherence* is a complex function of the frequency and estimates a degree of linear correlation between two signals [180–187]. If  $S_{xx}(f)$  and  $S_{yy}(f)$  are spectra of  $xx$  and  $yy$  signals, and  $S_{xy}(f)$  is a cross-spectrum of the signal  $x(t)$  and  $y(t)$ , then the coherence  $K(f)$  is given as:

$$K(f) = \frac{S_{xy}[f]}{\sqrt{S_{xx}[f] * S_{yy}[f]}} \quad (35.37)$$

Figure 35.29

Bivariate analysis of BP-HR variation in a healthy subject. Thick line – squared coherence spectrum, thin line – phase spectrum (From [185]).

Figure 35.30

Example of a coordination diagram. The coordination diagram indicates changes in the relative number of coordinated R-peaks as a respective  $m:n$  ratio (see text). In this example the cardiorespiratory coordination is oscillating with the 4:1 pattern's predomination. The absolute maximum of 68% of coordinated R-peaks (left y axis) is reached at midnight. Amount of coordination regardless of  $m:n$  ratio is depicted by the line of the %coordination (right y axis) (From [195]).

The coherence is commonly represented as the squared modulus  $K^2(f)$ , which at any frequency band is an index between 0 and 1 of the amount of squared correlation. Values above 0.5 are considered significant (Fig. 35.29).

Availability of the cross-spectrum allows also the calculation of the phase relationship in the range of  $-180^\circ$  and  $+180^\circ$  or  $-\pi$  rad to  $+\pi$  rad, with a positive angle for a leading  $x(t)$ , and a negative angle for a leading  $y(t)$ . The phase relationship is commonly represented as the *phase spectrum* ( $\varphi(f)$ ).

The relationship between two signals, which are the input and output of the system, can also be described by the *transfer function*, which is given as:

$$H(f) = \frac{S_{xy}[f]}{S_{xx}[f]} \quad (35.38)$$

The cross-spectrum can be calculated from spectra obtained by means of parametric or nonparametric methods, including the Fourier Transform, autoregressive modeling, wavelet transform and others [185, 186].

### 35.3.5.3 Nonlinear Methods

#### Phase Coordination and Synchronization

The term *coordination* means that there is some kind of temporal or phase incidence between HRV (the time of the R-wave) and another signal (e.g., onset of respiration, maximum blood pressure). The term *synchronization* means that there is a real physiological coupling between signals [187, 188].

In order to obtain coordination and synchronization indexes, signals  $(x, y)$  have to be recorded simultaneously and continuously and presented as time series  $x(i)$  ( $i = 1, \dots, m(x)$ ) and  $y(j)$  ( $j = 1, \dots, n(y)$ ). The absolute ( $t$ ) or relative ( $\varphi$ ) distance between the  $y(j)$  and the preceding  $x(i)$  or successive  $x(i)$  can be calculated. This allows for presentation of the so-called synchrogram (or post-event time series) that illustrates variety in how the  $m$ th  $x(t)$  corresponds with the  $n$ th  $y(t)$  (i.e., *m:n coupling*) [187].

Hildebrandt et al. and Kenner et al. have provided the first description of methods for continuous measurement of the phase relation between HR and respiration [189, 190]. They found an intermittent coordination between the onset of inspiration and the preceding R-wave. In addition, the ratio of HR and respiratory rate has been suggested as a simple measure of cardiorespiratory coordination [191]. Many advanced approaches to cardio-respiratory coordination have been proposed (e.g., state-space correspondence, phase synchronization  $\lambda$ , phase recurrence, information flow, distribution) [192–194]. The performance of these methods depends on the time-window used. Cysarz and coworkers have recently shown (🔗 Fig. 35.30) that the largest number of coordinated R-peaks and coordinated sequences was detected by the phase recurrence approach [195]. As the clinical usefulness of these methods has not been thoroughly validated [196], all the proposed methods seem to be valid for research purposes only.

#### Nonlinear Prediction

Nonlinear predictability of one  $x(n)$  of two series given from samples of another series  $y(n)$  is used to define directional coupling. This approach is suitable for short and noisy data, frequently present in physiological series (artefacts, transitions etc.), which contains local constants, local linear parts and nonlinearities. The predictability can be quantified by using the cross-predictability and the predictability improvement calculation. The degree of predictability can be calculated as the squared coherence between the original and predicted values. Nonlinear prediction methods are especially useful for investigating HRV-BPV causal relationships in many clinical states [192].

#### Stochastic Resonance

The stochastic resonance analysis might be more helpful for the analysis of interactions between various systems (e.g., heart rate and blood pressure) [197]. Its analysis might open new possibilities for the understanding of physiological and pathological phenomena associated with HR control [198]. At present, data accumulated for its application is limited, being anecdotal for clinical use [199].

### 35.3.5.4 Baroreflex Sensitivity

Analysis of baroreflex sensitivity (BRS) enables the quantification of the reflex circulatory effects of arterial baroreceptor activation or deactivation at the sinus node level through changes in vagal and sympathetic activity [77, 82, 182, 183, 186, 200, 201]. It has to be borne in mind that HR changes are only a part of the complex circulatory response to short (sensitivity) and long-term (resetting) blood pressure fluctuations, in which the systemic vascular resistance control seems to be the main target. Various methods can be used for BRS assessment [202]. All of them are based on the measurement of the extent of R–R interval change (ms) per unit (mmHg) change in systolic blood pressure. Assuming that the relationship between SBP and R–R interval in response to a rapid BP change is linear, the quantitative measure of BRS is provided by the slope of the regression line fitting changes in SBP against the second succeeding R–R interval (one-beat delay) [186, 201]. Usually, a significant relationship is required to accept the BRS value obtained. However, the BRS value calculated on a linear fit with a lack of a significant correlation is allowed if an adequate increase in SBP (>20 mmHg) is obtained [186].

### Invasive Approach (External Stimuli)

Vasoconstrictor agents are normally used to explore the vagal component of the baroreflex sensitivity. Phenylephrine, a pure  $\alpha$ -adrenergic agonist, is administered intravenously during the continuous recording of ECG (R–R interval) and BP (beat-to-beat arterial pressure) [203]. The latter can be performed either invasively, mainly in experiments on animals, or noninvasively, by using the finger-cuff method, which provides overestimation of BP variability [204], largely within the lower frequency bands [205]. After a bolus dose of 1–2  $\mu\text{g}/\text{kg}$ , incremental doses of 25–50  $\mu\text{g}$  are given until a SBP increase of 20–30 mmHg is reached. In normal subjects, the average values of 15 ms/mmHg have been reported [186]. In certain clinical settings, the BRS values close to zero, or even a negative BRS, can be observed [206]. Vasodilating agents are normally used to explore the sympathetic component of the BRS [207]. Nitroglycerine, a direct vasodilator, is given via the injection of 100–200  $\mu\text{g}$  to obtain a rapid and progressive fall in SBP of 20 mmHg. The BRS values after administration of vasodilators are lower, indicating that the use of both vasoactive agents allows for a more comprehensive assessment of BRS. Alongside, a “steady-state” method for estimating BRS has been proposed [208], in which either phenylephrine or nitroglycerine is administered in order to obtain the step-wise increase or reduction of blood pressure.

Methods that use vasoactive agents are criticized because of their nonselective actions leading to the introduction of changes that alter the baroreceptor reflex at various levels (e.g., central effects, direct action on sinus node). On the other hand, these methods allow the initiation of an integral response, irrespective of the mechanisms contributing to the reflex.

Mechanical maneuvers, like the neck chamber technique or lower body negative pressure, represent other approaches to studying BRS. In the neck chamber technique, either positive or negative pressure is applied to the neck region inducing a decrease or increase in SBP with corresponding changes in R–R intervals [209]. The negative pressure ranges from –7 to –40 mmHg and HR response is observed over three heartbeats following the maneuver. The BRS is defined as a slope of R–R interval over neck pressure. A modified method of the neck chamber method has been proposed that allows both for activation or for deactivation of carotid baroreceptors [210]. The lower body negative pressure that imitates a reduction in circulating blood volume can be helpful in an evaluation of sympathetic activation and HR response [211]. However, in contrast to direct carotid baroreceptor stimulation/inhibition, this method provides information regarding cardiopulmonary reflexes [211]. Methods based on mechanical manipulations should be used in a specifically designed research laboratory and for particular pathophysiological purposes [212, 213].

### Noninvasive Approach (Internal Stimuli)

Noninvasive methods of BRS analysis represent alternatives to invasive techniques in that they use internal stimuli that can be simply induced (e.g., Valsalva or Muller maneuver, head-up, or downward tilt) or that they occur spontaneously (Fig. 35.26).

#### (a) The Valsalva maneuver

The Valsalva maneuver is a forced expiratory effort against a closed airway. The Muller maneuver is the reverse. There are four phases of these tests, and among them, phase IV is commonly used for the BRS assessment purposes. The BRS

Figure 35.31

The relation between the changes in systolic blood pressure increase and corresponding RR interval lengthening during downward tilting (From [216], Elsevier, with permission).

is calculated using linear regression of instantaneous R–R intervals and corresponding SBP values. Kautzner et al. have proposed calculating the BRS index, which is the ratio of the differences between maximum and minimum R–R interval and SBP during the so-called overshoot period of the maneuver [214]. Unfortunately, reliable measurements cannot be obtained in a large proportion of normal and post-infarction patients [215]. In addition, the correlation coefficients with invasive methods vary between 0.27 and 0.91 [214].

(b) Tilt testing

A body movement introduces changes in blood pool compartments and venous return, with corresponding BP and HR changes. Takahashi et al. have proposed a method for BRS evaluation during a rapid downward tilting from an upright to a supine position, which provides values comparable to the phenylephrine test [216].

(c) Time-domain (sequence) method

The sequence method is based on the spontaneous presence of concurrent R–R interval and systolic blood pressure changes (increase or decrease) over at least three consecutive heartbeats (sequence) [217]. For each sequence, the linear correlation between R–R intervals and SBP values is fitted. The average of individual slopes of sequences that are significant ( $r > 0.8$ ) and reach predefined minimum change (1 mmHg and 4–6 ms for SBP and interbeat duration respectively) is taken as the BRS measure. Usually, lower BRS values have been observed in comparison with the phenylephrine test [78]. Simplified variants of the sequence method have been proposed. Among them, the measurement of R–R interval variation over a 5-min period of controlled breathing at 0.1 Hz, that allows SBP changes to be ignored, has been documented as useful for distinguishing normal subjects (77 ms) from patients with heart failure (31 ms) [218].

(d) Spectral ratio (alpha-index)

Spectral ratio (gain, alpha-index) provides an estimate of the sensitivity of the baroreceptor-heart rate reflex based on frequency-domain analysis of the spontaneous variability of SBP and HR [77, 78, 82, 203]. The method is based on a high degree of linear correlation between systolic blood pressure and heart rate at the respiratory frequency and at 0.1 Hz in normal subjects, and on the assumption that that correlation is due to the baroreflex coupling [82].

First, the spectra of systolic blood pressure and RR-interval series, and their squared-coherence modulus, are computed. If the coherence at 0.1 Hz and at the respiratory frequency is sufficiently high (i.e., greater than a threshold usually set at 0.5), the spectra of systolic blood pressure and RR-interval are integrated over the 0.1 Hz peak, giving the  $SBP_{LF}$  and  $RR_{LF}$  powers, and over the respiratory peak, giving the  $SBP_{HF}$  and  $RR_{HF}$  powers. Then the square-root ratio of RR and SBP powers at low and high frequencies is computed:

$$\alpha_{LF} = \sqrt{\frac{RR_{LF}}{SBP_{LF}}} \quad \text{and} \quad \alpha_{HF} = \sqrt{\frac{RR_{HF}}{SBP_{HF}}} \quad (35.39)$$

A close correlation of  $\alpha$ -coefficients with the phenylephrine methods has been reported in a small-number of initial studies. Larger studies have revealed a moderate linear association between the two techniques with a relatively high limit of agreement ( $\sim 5$  ms/mmHg in normal subjects and hypertensives and  $\sim 13$  mmHg in post-infarct patients) [218–221]. These observations indicate limitations of the BRS assessment using frequency-domain methods. Despite these limitations, a noninvasive approach provides BRS estimation of a short-term liability coming from complex and redundant reflexes with no procedural (apart from laboratory conditions) requirements.

### 35.3.5.5 Heart Rate Turbulence

A short-term fluctuation in sinus cycle duration after a ventricular premature beat forms the basis for introducing another noninvasive method that is related to the baroreflex control of HR, and is referred to as heart rate turbulence (HRT) [222–226] for explanation see text and ref. [294] (► Fig. 35.27). Interestingly, the description of this method has been forced by

■ Figure 35.32

Normal (left) and abnormal (right) ventricular premature contractions tachograms used for the heart rate turbulence.

simultaneous evidence of its usefulness in risk stratification after myocardial infarction [222], while the pathophysiological background that might help to explain the strength of HRV as a risk stratifier [112, 222, 226, 227] using this method is not known.

The HRT is quantified by two measures termed turbulence onset (TO) and turbulence slope (TS). The turbulence onset is a measure of immediate initial R–R interval shortening following a ventricular premature beat and is calculated using the equation (35.40):

$$\text{TO} [\%] = \frac{(RR_1 + RR_2) - (RR_{-2} + RR_{-1})}{(RR_{-2} + RR_{-1})} * 100 \quad (35.40)$$

where  $RR_{-2}$  and  $RR_{-1}$  are sinus cycles preceding a ventricular premature beat, and  $RR_1$  and  $RR_2$  are the two intervals following the compensatory pause. TO is calculated for each single premature beats and then averaged.  $\text{TO} > 0$  means deceleration,  $\text{TO} < 0$  means acceleration of the sinus rhythm.

The turbulence slope (ms/beat) is a measure of subsequent deceleration phase and is calculated as the maximum slope of a regression line assessed over any sequence of five subsequent sinus-rhythm RR intervals within the first 20 (15) sinus-rhythm intervals after a ventricular premature beat and is assessed in the average HRT tachogram.

HRT cannot be calculated in the presence of interpolated ventricular premature beats without compensatory pauses. Also, a minimum number of five premature beats is necessary to obtain a reliable pattern. However, a recommendation for TO and TS calculation in the presence of only a single premature beat can be found [226, 228]. The HRT measure depends on heart rate itself, and the coupling interval (prematurity) of ventricular beats [226, 229]. Considering HRT as a specific noninvasive measure of BRS, it is necessary to keep in mind that the sinus rate response to premature ventricular beats depends also on intact SAN function and the post-extrasystolic potentiation phenomenon [226, 230].

## 35.4 Methodological Considerations

### 35.4.1 Ideal HRV Method and Index

The complexity of heart rate fluctuation *a priori* excludes an ideal HRV method or index to be identified. However, such an attempt can be made for a particular purpose of HRV assessment. The requirements and characteristics of the index or method that can meet the purposes of an HRV study are presented in Table 35.5 and discussed below.

Criteria for an ideal HRV index that have to be met for the index to be applicable for the assessment of cardiac autonomic control in physiological and pathophysiological studies, proposed by Goldberger et al. [231], are listed as follows:

1. The ideal index should behave in a comparable manner in various subjects in response to stimulating or inhibiting maneuvers that lead to changes in cardiac autonomic balance or in its main components
2. Between-subject variability of the index at the same conditions should be minimal
3. The ideal HRV index should be explicable on the basis of physiological or pathophysiological mechanisms contributing to vagal-sympathetic interactions

For the reasons above, only short-term HRV analysis (and derived indices) seems to be applicable if cardiac autonomic control is to be explored (▶ Table 35.6).

From a clinical point of view, an ideal HRV index should possess quite different features, while the association between HRV and cardiac autonomic control might not necessarily be so tight. Considering these issues, the criteria for a clinically useful HRV index might be proposed as follows:

1. The ideal HRV index should be an independent prognostic measure of the risk of death, especially if sudden (unexpected)
2. The ideal HRV index should have the potential to be applied in a wide population (without exception for cardiac rhythm disturbances)
3. Common applicability in clinical practice requires the ideal HRV index to be as simple as possible in order to be understandable to physicians
4. The ideal HRV method should be implemented in available analytical systems, allowing for its practical use in large populations
5. Normal limits defined as limits of agreement (LOA) should be established in a local (geographically or race-homogenous) population.

For these reasons, long-term HRV analysis (and derived indices) can be considered more suitable, as they cover most mechanisms related to the HRV phenomenon (▶ Table 35.7). However, the interpretation of the meaning of these indices on the basis of cardiac autonomic control does not seem to be appropriate.

The common HRV measures also suffer from other limitations, including the non-normal distribution that requires mathematical transformation (usually natural logarithm), and a lack of standardization.

There is still a place for an ideal method and index from the mathematical, physical and technical point of view. The implementation of ideas that come from other areas or phenomena might prove to be fruitful. However, their physiological (Goldberger criteria) or clinical (clinical criteria) meaning should be tested each time. This requires close cooperation between inventors and clinicians. Otherwise, methods can proliferate without solving any important physiological or clinical issues, and simply add “scientific-like” noise.

## 35.4.2 Data Acquisition

### 35.4.2.1 Integration of the Signal

The basic cardiac signal, generally in the form of the electrocardiogram, is required to be digitized by a computer in order to obtain a series of R–R intervals. However, sometimes the R–R-interval series can be derived from analog systems. Also, a use of plethysmography or blood pressure recordings can provide the opportunity to derive pulse intervals.

Ideally, a raw ECG record should be preserved to check for the integrity of the signal, the presence of non-sinus beats and for editing artefacts [4, 5]. Accurate on- and off-line analysis depends primarily on the integrity of the signal. However, for HRV analysis purposes, the digitization rate (sampling frequency) is crucial for the detection of small variations of cardiac rhythm. Several types of errors and their solutions are presented in ▶ Table 35.8.

### 35.4.2.2 Errors Relating to Digitization Rate

A sampling frequency of 250–500 Hz has been recommended [4, 5]. However, in many studies the sampling frequency is not reported. Others considered a digitization rate of 500–1000 Hz, which would provide a basic resolution of 1–2 ms

**Table 35.5**  
**Characteristics of HRV index/method used in various kinds of studies (purpose-oriented)**

Purpose/ Requirements	Index or method	Universality (no exclusions)	Availability (common)	Robustness (high)	Reproducibility	Inter-subjects variation	Physiological meaning	Diagnostic value
Epidemiological studies Fundamental requirements: HRV index calculable from short time series (routine ECG?) Controlled study conditions	Mean RRI (or HR)	Yes	Yes	Yes	High	Small	Sympatho-vagal balance	Prognostic value proven in many studies
	SDRR CV RMSSD CIPA	No	Yes	No	Relatively high	Large	Respiratory/vagally related	Screening for DAN Screening for early atherosclerosis? Outcome prediction

[232–237]. A higher sampling frequency might be necessary to gain small variations in the amplitude of cardiac rhythm, especially in pre-term newborns and after heart transplantation. Most of the studies of HRV have gathered data using 24-h ECG systems with a nonoptimal sampling frequency of 128 Hz (~ 8 ms resolution), despite a resolution of at least 4 ms (250 Hz) suggested for adequate RSA quantification [4, 5, 235]. The noise introduced by an insufficient sampling rate can be overcome by the use of template matching or an interpolation algorithm. A digitization rate below 100 Hz is not considered acceptable [4, 5].

A low sampling frequency can cause a jitter in the determination of the fiducial points of the QRS complex, thus creating an error in the RR interval measurements [237]. The jitter-error is a source of additional high frequency content, and thereby affects the reliable determination of short-term variation.

Conventional Holter systems influence parameters estimating short-term, high frequency variation (RMSSD, NN50, pNN50). The R wave detection error using conventional systems can make spectral HRV analysis inaccurate and too low

Table 35.8  
Errors in ECG data (unedited and edited)

Type of R-R interval distortion	QRS pattern	Mechanisms	Influence on HRV assessment	Solution	Limitation
True Premature ectopic beats (PEBs)	Supraventricular normal pattern	Abnormal automaticity or delayed potentials	Significant error in short-term statistical descriptors, spectral analysis unreliable	Rejection of epochs with beats which duration differ from neighbor by more than 20%	Inappropriate in the presence of long-coupled (late) PEBs
	Ventricular abnormal pattern			Rejection if frequent, interpolation procedures if sporadic	Ignores effects of PEBs on the autonomic milieu, introduces a sort of technical error
Parasytolic (allorhythmic) ectopic beats	Normal or abnormal	Constant coupling between repetitive PEBs	Presence of a separate oscillation	Unsolved, usually treated as PEBs	Introduces a sort of technical error
Normal sinus beats with abnormal connotation	Abnormal pattern	Abnormal intraventricular conduction (i.e., BBB)	"Jitter" error, may influence short-term spectral measures	Unsolved, usually treated and managed as ventricular PEBs	Introduces a sort of technical error
Spurious premature beats	Normal or abnormal	External noise, baseline shifting	None if recognised	Correct skin-electrode contact	Sometimes impossible due to sweating, body motion
		Low sampling rate		Appropriate sampling rate	Less possible in commercial long-term ECG recordings
		Large P- or T-wave amplitude		Appropriate threshold for QRS detection	Not always possible in commercial systems
Missed beats	None, RRI is doubled or a multiple of the preceding average	External noise, baseline shifting	Significant error in short-term statistical descriptors, spectral analysis unreliable	Correct skin-electrode contact, manual correction, splitting into equivalent R-R intervals, interpolation algorithms	Sometimes impossible due to sweating, body motion, introduces a sort of technical bias
		Low R-wave amplitude		Appropriate threshold for QRS detection, manual correction	Not always possible in commercial systems
Pauses	None, RRI is doubled or a multiple of the preceding average	Post-ectopic beats	Significant error in short-term statistical descriptors, spectral analysis unreliable	Rejection if frequent, interpolation algorithms if sporadic, splitting into equivalent R-R intervals	Ignores effects of or on the autonomic milieu, introduces a sort of technical bias
		Sinus arrest/high grade sino-atrial block			
		A-V block			

a sampling rate can influence high-frequency components irrespective of the spectral analysis methods used [236–238]. An error of up to 4% in the RMSSD and HF power has been reported when systems with conventional (8 ms) and high resolution (1 ms) timing accuracy have been compared [237]. These errors have been even greater in patients after MI, reaching 71% and 8%, respectively. A higher sampling rate leads to a reduction in the HF power. As a result, significant error is introduced with a sampling rate of 128 Hz not only to the HF power, but also to the LF/HF ratio with an error of up to 14%. Tapanainen et al. observed a large error in post-MI patients reaching 22.6% in those with low HRV and 17.5% in those with normal HRV. A 5% error of short-term components of the return map (SD1) has been shown to be due to a low sampling rate. Voss et al. reported a 2% error in the nonlinear symbolic RR interval dynamics in normal subjects, when a conventional system had been compared to a high resolution system with a sampling frequency of 2 kHz [235]. A similar range of error has been observed in the short-term scaling exponent  $\alpha 1$  (DFA) in subjects with normal HRV. However, the error increased to 5% in post-MI patients with a reduced HRV. A marked difference (11%) between low (~8 ms) and high (1 ms) resolution has been observed for the approximate entropy (ApEn). The error was more pronounced in post-MI patients with low HRV or faster HR (17.6% and 15.0%, respectively) [237]. The magnitude of all these differences grew proportionately when the overall heart HRV diminished. Thus, *the measurement of the nonlinear dynamics parameters should preferably be done with a sampling frequency higher than the conventional 128 Hz.*

The sampling frequency does not seem to affect long-term (RRI, SDNN, SDANN) or low-frequency HRV components (VLF, LF).

Sampling frequency is more important in the accurate detection of IBI short-term fluctuations if the RR interval series are shorter or smaller in amplitude [235]. Most prognostic studies on post-AMI patient populations, however, are based on the SDNN calculation. It is unlikely that the results of these studies would change with a higher sampling rate. However, *for experimental studies in physiology, psychophysiology and pathophysiology, the minimum sampling rate of 250 Hz should be mandatory.*

### 35.4.2.3 Errors Introduced by Noise

A rigorous recording method should be used in order to minimize noise, which usually interferes with the signal and results in an overlapping with the true R-wave amplitude [34, 239–242]. This can lead to *spurious R-wave* timing due to variation in peak amplitude and makes the use of simple maxima-based peak-finding algorithms unreliable. However, smoothing or filtering of the digitized signal, template or derivate matching and interpolation procedures can help to solve this problem. If the heartbeat signal is obtained from continuous BP recordings, where the fiducial point detection is more problematic due to a lack of clearly defined peaks, a template-matching approach is considered most appropriate.

Another consequence of noisy recordings is the identification of artifactual waves as *spurious R-waves*. Such erroneous R-waves might be harder to eliminate through the above mentioned algorithms. A careful visual investigation of a series of data is necessary. It is quite easy for short-term ECG recordings. However, for a 24-h recording it can be achieved through an automatic class (template) ascertainment of accuracy, by the visual checking of R–R interval (or differential) distribution histograms' tails, or step-by-step correction using a full disclosure option available in commercial systems. These procedures are time-consuming and may require up to 45 min for thorough analysis, labeling and editing.

### 35.4.2.4 Errors Related to the QRS-Wave Detectors

Another set of *spurious R-waves* results from an inappropriate threshold for R-wave detection. If the threshold is too low, an R–R interval would be subdivided into additional inter-event intervals due to the detection of T-waves (usually peaked with a relatively high amplitude, not infrequently in normal subjects), or more rarely, due to P-waves (usually when the amplitude of the R-waves is small, a frequent feature in patients with an advanced heart failure). If the threshold is set too high, R-waves of smaller amplitudes would be undetected and an exceptionally long IBI that merges two or more normal R–R interval would be recorded. These undetected beats are referred to as *missing beats* [239–242]. Their presence introduces sizeable and dramatic biases in estimates of HRV that can result in errors of up to 80% for SDNN, 25% for HF power and above 200% within lower frequencies [242].

Table 35.9

Steps to avoid non-stationarity in ECG recordings

1	Minimize non-stationarities in data through conditions control
2	Use filtering procedures for the removal of slow trends
3	Avoid unnecessarily long analytical epochs
4	Test for non-stationarities if appropriate
5	Omit (or remove) highly non-stationarity data segments
6	Use approaches explicitly designed for non-stationarity data evaluation

Another type of error is related to the identification of abnormal (either ectopic or artifactual) beats as normal. As the data-series containing abnormal heartbeats could be rejected from further analysis, leaving *mistakenly labeled R-waves* introducing a significant error especially in spectral estimates, particularly within the HF bands [34, 239–242].

Instabilities of the isoelectric line (baseline) with extreme upwards or downwards shifts due to a poor electrode-skin contact, and following rapid changes in impedance, would result in *missing beats* even if the technical requirements are fulfilled. Some aspects of these sources of errors are discussed in other chapters (Ambulatory ECG, Signal averaging etc.).

### 35.4.2.5 Errors Relating to the Presence of True Ectopic Beats

The presence of a few premature ectopic beats (PEBs) is a normal feature of long-term ECG recording in healthy subjects. The number of ectopic beats increases with age and in patients with CVD. In such cases, they can also appear in a short-time series. Irrespective of data length, their presence introduces an error that is related to a sudden shortening of the sinus fulfill cycle preceding the PEB (coupling interval) and a compensatory prolongation of the subsequent cycle (compensatory pause). As a result, a significant error in time-domain and especially in frequency domain measures is introduced [34, 238, 240–242]. In an excellent paper, Berntson and Stowell showed that the presence of only one ectopic PEB in a 2-min recording introduced an error in the SDNN of up to 50%, in the HF of around 10% and in the LF of approximately 80% [242]. Interpolation procedures for the replacement of PEBs with interpolation-derived heartbeats do not necessarily prevent these errors. The use of a filter function to interpolate for heartbeats preceding and following PEBs can help to solve this problem. However, it may lead to a disruption of the continuity of data.

### 35.4.2.6 Non-Stationarity as a Source of Errors

Stationarity is defined as the invariance of distributional characteristics of data-series in all moments over time. In a controlled laboratory setting, when short-time data series are subjected to evaluation, ECG signal non-stationarity might reflect the physiological properties of complex heart rate control. If long-term ECG recordings are used for HRV assessment, occurrence of sudden changes in sinus cycles related to internal or external stimuli is frequent. Also, sustained trends can reflect physiological control mechanisms. They may distort spectral frequencies and usually are subject to detrending procedures [243]. These procedures provide technically valid data-series, but at the cost of a loss of information. Another way to fit stationarity of data is the use of linear or polynomial trend removal or bandpass filters to isolate the periodicities of interests and minimize the effects of non-stationarities. For the stationarity of the time series to fit, the simplest way is to maintain test and subject conditions stable throughout the recording period and to minimize the length of recordings. If non-stationary epochs cannot be removed or extracted from prolonged data-series, multiple short-epochs, in which stationarity is satisfied, should be analyzed to examine the dynamics of the signal over time. Otherwise, *the analysis of relatively stable short-time series with appropriate methods (e.g., discrete FFT, time-frequency analysis) seems to be more advisable than the use of detrending algorithms*. Steps necessary to solve the stationarity issue are listed in Table 35.9.

### 35.4.2.7 Management with Errors Relating to the Presence of Ectopic, Spurious and Missed Beats

In acute studies, when the ECG signal recorded is of only a few minutes duration, continuous visual inspection is required. *Only data that does not contain any abnormal beats should be extracted for further analysis.* For short-term recordings, it seems advisable to acquire time series somewhat longer than the period assumed for further analysis as it increases the probability for taking undisturbed portions of a required length from the entire recordings. In any other cases, the studies have to be repeated or rejected [4, 5, 34, 242, 243].

Less strict approaches are proposed for 24-h ECG recordings [4, 5, 34, 242, 243]. For time-domain methods, data can be passed through various filters that eliminate annotated heartbeats other than the normal (dominant) beat. Additional logical conditions are imposed to eliminate the preceding and post-ectopic heartbeats. If the sequence of heartbeats is required to be sustained (e.g., for spectral analysis), various solutions are proposed. However, there are no specific recommendations regarding the cut-off of absolute or relative frequency of abnormal heartbeats. Many authors use different criteria.

If the number of abnormal heartbeats is considered insignificant, algorithms that allow the correction (substitute) of abnormal (usually ectopic) heartbeats could be applied. A variety of algorithms have been proposed and reviewed in depth elsewhere.

The duration of the compensatory pause depends in a complex manner on the coupling interval and the mean IBI before PEBs. Thus, PEBs can occur as interposed, compensated or phase-shifted extrasystoles, so simple replacement using interpolation procedures is not reliable. Also, the annotated PEBs may in fact represent either true physiological phenomena, especially in healthy young people, or true pathological phenomena related to SAN dysfunction. Most algorithms ignore the fact that ventricular PEB occurrence is associated with changes in the autonomic milieu.

All errors in QRS detection and IBI measurements are of special significance in individuals with low HRV, where the same level of error is associated with much greater influence upon a true signal. These errors are more likely to be found in persons with PEBs as well as intraventricular conduction disturbances. Guidelines indicate the necessity for a clear description of the specific procedures for interpolation or data rejection and for a discussion of their contribution to the results [4, 5, 242]. Even so, *if the data is corrupted, the analysis should be limited to more robust time domain statistics.*

### 35.4.3 Data Length

The duration of the R–R interval recording for HRV analysis is not a priori limited. However, for comparison between different studies, the data is required to be of similar length. The total variance of IBI increases with the length of recordings. From a physiological point of view, a fundamental issue is the duration of the cycle of a certain phenomenon (wavelength) considered for analysis, assuming a relative selectivity of various periodicities (spectral analysis). It is required that the R–R interval recording time be ten times longer than the wavelength of certain oscillatory phenomena. A recording of at least 1 min is necessary to assess reliably short-term vagally mediated respiratory-related HR variation, and of 2 min for longer-term variation attributed in part to sympathetic control. For cycles recognized as VLF ( $\sim 0.0033$  Hz), it is necessary to prolong recording time periods to approximately 1 h.

A standard recording period of 5 min is recommended for clinical purposes [4, 5]. However, it has been shown that very short ECG recordings of 8–10 s duration covering no more than two to three respiratory cycles, can efficiently estimate the vagal tone (i.e., CIPA) [28, 29]. In addition, for certain purposes (e.g., psychological, exercise studies), a 5-min period may be too long to meet stationarity requirements. It would be ideal to use time-frequency approaches if shorter data-length is required to be analyzed.

With the use of a nonlinear dynamics approach, nonlinearities in time series are apparently the true subject of analysis. For the calculation of nonlinear measures, more prolonged time series is advised. However, attempts have been made to calculate these measures from short-term recordings.

For long-term recording, it is necessary to present data regarding a true period of analysis since there are some methodical differences in data selection. These differences are related to the definition of prematurity of non-sinus heartbeats ( $>30\%$  or  $>20\%$  deviation from the previous heartbeat interval or  $>10\%$  of an interpolated beat interval), pause detection (usually  $>125\%$  of averaged local means or  $120\%$  of running time), minimum duration of recordings (from 12 h including 6 night hours, to 22 h) and at least 50–90% normal (sinus) heartbeats. Also, data substitution varies

with different equipment where non-sinus beats, together with the neighboring one to two heartbeats, are either eliminated or interpolated with a range of algorithms. The differences in these procedures influence time-domain HRV measurements by no more than 10%, while for spectral-measures, it can be expected to be even higher. However, this has not yet been calculated.

#### 35.4.4 Data Presentation

Although IBI is usually employed for HRV analysis, heart rate and counts are also used as a basic metric in studies of cardiac rhythm. It is important, as a distinct relationship exists between vagal activation and HR or IBI, whereas the relationship between sympathetic activation and HR or IBI seems to be nonlinear. As the range of vagal control is considerably greater than that of the sympathetic branch and fundamentally influences the latter itself, IBI presentation has advantages over HR for the analysis of cardiac rhythms. However, if HR is employed on a beat-to-beat manner and referred to as an instantaneous HR (iHR), analyses based on iHR may not necessarily produce a similar pattern of results as for heart period analyses. Janssen et al. showed that various data presentations influenced the magnitude of HF power and LF/HF ratio, which could differ up to 37% depending on the method used [244]. Normalization procedure (dividing of observed values by their corresponding average values) has recently been proposed [245].

The HRV signal can be presented as a function of beat number. Such a presentation is referred to as the R–R *interval tachogram*. Interpolating and resampling the heartbeat series allow HRV to be expressed in a common time scale [4, 5, 77].

Successive R–R intervals are spaced unevenly in time. However, time series analyses require the data to be sampled at equal time intervals. Resampling procedures are necessary to derive the R–R series suitable for spectral analyses. Various methods have been proposed and discussed in the literature [4, 5, 77, 79].

As indicated by the guidelines, it is preferable to use a sampling approach in which the value at a given point represents a weighted average of the beats that fall within the sample interval [4, 5]. The resampling rate seems to be crucial in order to avoid aliasing. The sampling rate is recommended to be at least twice the lowest resolvable frequency. A sampling rate of 4 times the target frequency is considered most appropriate. Thus, the higher the mean heart rate, the higher is the sampling frequency required. For studies in adult humans, it is at least 2 Hz, whereas in children or individuals with higher heart rates it would be more prudent to use 4 Hz. For animal studies, a higher sampling frequency is needed [246].

#### 35.4.5 Universality of HRV Analysis

Ideally, HRV measurement should be applied to all subjects. This requirement is referred to as *universality*. Current recommendations necessitate the presence of sinus rhythm in order to evaluate HRV qualitatively (high, normal, low or normal/abnormal pattern) and quantitatively. For this reason, heartbeats are labeled as normal (N) and IBIs as normal-to-normal (N-N or NN-intervals) [4, 5]. In fact, the American Heart Association/American College of Cardiology Task Force for Ambulatory Monitoring listed the presence of *sinus rhythm as an a priori inclusion criterion for standard HRV analysis* [247]. Such a statement excludes a substantial proportion of more severely diseased patients with a higher risk of an unfavorable outcome from studies on the clinical use of HRV, especially HF and older patients in whom the presence of frequent ectopic PEBs or atrial fibrillation is not uncommon.

A detailed analysis of the methodological descriptions of the most important studies indicates that standard HRV methods cannot be applied to 6–55% of study populations (▶ Table 35.10). In addition, newer proposed measures based on spectral analysis or nonlinear techniques, including HRT, cannot be used in 17–35% of patients (▶ Tables 35.10 and ▶ 35.11). The reasons for rejecting patients from HRV studies are varied and only rarely reported. In a small number of studies in which the reasons for exclusion are listed, the presence of artefact or insufficient data length accounts for 10–65% of exclusions, while the presence of cardiac arrhythmias/pacemakers is the reason for 10–100% of exclusions.

The clinical consequences of these assumptions and recommendations are critical in a high risk population with frequent ventricular premature beats and atrial flutter/fibrillation, in whom the opportunity for HRV analysis is abandoned (▶ Table 35.10). Farrel et al. reported a significantly higher total mortality rate (19.7%) and arrhythmic events rate (12.3%) in acute MI patients excluded from the HRV study, compared to 11.3% and 5.7% in those who entered the study [248]. The clinical course of acute MI in the rejected group was worse, with higher Killip classes and a higher proportion of

Table 35.10  
Applicability of HRV analysis in clinical outcome studies

patients with previous MI. In an epidemiological study (The ARIC Study), excluded subjects were older, more frequently females and obese, and their outcome was worse with a higher MI/fatal CHD rate compared to HRV study participants [249]. Observations from the DEFINITE trial indicate that patients excluded due to the presence of frequent ventricular PEBs or atrial fibrillation have a lower survival rate than patients in whom HRV analysis is possible [250].

A new promising index of HRV, i.e., *deceleration capacity* (DC), has been shown to be applicable to almost all patients in sinus rhythm. However, the presence of atrial fibrillation still limits its applicability to the entire spectrum of patients [171].

The index that possesses the potential for HRV global description in patients either in sinus rhythm or in atrial fibrillation is the HRV Fraction [65]. A uniquely low exclusion rate (less than 1%) with HRVF use has been observed in the post-MI population [66]. Unfortunately, this index has not achieved wider interest. The HRVF can be applied extensively but not to ECG recordings with long periods of atrial flutter/tachycardia or very frequent PEBs (>25% of all heartbeats) or with a pacemaker-driven rhythm. Interestingly, the author's investigations indicate very similar properties for the SDANN (*unpublished*). However, systematic studies are necessary to justify its usefulness in nonselected populations of patients with and without arrhythmias. Nevertheless, documented data on risk prediction with the use of the SDANN, indicates its superiority compared to the SDNN [252–254], as does our own data. More intensive use of the SDANN in clinical outcome studies is awaited.

### 35.4.6 Robustness

Robustness is one of the most important properties of indices of HRV methods, mainly because the necessity for time-consuming manual editing of the data-series can be minimized [4, 5, 34]. Results of HRV analysis with the use of a robust index/method are similar irrespective of the presence of noisy data (artefacts, non-stationarities, PEBs, AF). The use of a less robust index/method requires noisy data to be eliminated. The latter procedure, however, might lead to a loss of significant information. From data provided in [Table 35.10](#), it can be concluded that the standard time- and spectral HRV indices are sensitive to artefacts and sudden IBI changes of either physiological or pathological origins. The robustness of nonlinear indices is rather moderate and strongly depends on the method used. However, for most such indices, their robustness is unknown. The HRV index (St. George's index) was the first introduced to improve robustness. However, the HRVI is critically sensitive to the distribution of data and cannot be reliably determined in the presence of a bimodal distribution [38]. HRVF and DC are indices with high robustness, which are also independent of the distribution of IBIs [65, 171].

### 35.4.7 Biological Variations

Variation in HR reflects the adjustment to changeable metabolic demands of key vital organs in response to internal and external stimuli in a specific neuro-humoral milieu, and any of the HRV measures obtained at a given time varies accordingly. In a controlled environment (the same time of recording, mental and physical activity, drugs and so on), this variation is still present in an individual subject and between individuals. This variation is referred to as *biological variation*. The biological variation is always present as most of the factors (genetics, race, age, gender etc.) that determine HRV cannot be controlled in any way. Biological variation differs from other sources of HR variation which are related to investigator biases (intra- and inter-observer errors) and technical precision of measurements ([Fig. 35.28](#)). However, it has to be stressed that in an individual subject or a population sample, the biological variation can be much greater than reported as the average. The study population (healthy subjects, patients with certain diseases), conditions of examinations, like breathing (spontaneous, controlled, deep breathing, Valsalva maneuver), body position (supine, standing), exercise (treadmill, bicycle) or other testing (head-up or head-down tilting, mental stressing, cold pressor test, and so on) might be an important determinant of intra- and inter-individual reproducibility. Importantly, errors due to the foregoing might have a different contribution on the overall measurements in patients with an already reduced HRV. Lastly, use of various periods of ECG recordings (second, minutes, hours) or different algorithms for traditional spectral HRV measures (AR, FFT) might be in part responsible for differences in quantification of the degree of such errors. Thus, a purpose-specific use of different HRV methods requires the determination of predictable errors (possibly drawn from

Figure 35.33

Measurement errors of common HRV measures: components by length of short-term recordings. The main source of HRV errors can attribute to inter-individual variation, except for spectral HRV measures, where between- and within-visit changes may play a significant role (i.e., lnLF, lnHF). Importantly, readers' errors are entirely negligible. However, there is a space for within-visit errors if spectral HRV is aimed to be measured (According to data provided by Schroder et al. [255]).

former validation studies) and a proper calculation of the sample in order to detect a significant change of a particular HRV measure [255].

### 35.4.7.1 Intra-Individual Variation

The determination of intra-individual variation of HRV indices requires the definition of their range in the setting of controlled conditions in the same subject. Within the same visit, variation attributed to intra-individual short-term variation accounted for 5–14% for SDRR, 2–7% for RMSSD, 8–28% for HF power and 14–41% for LF power [256]. The contribution of intra-individual variation decreases with prolongation of recording length (Table 35.12). Also, between-measurement period duration influences the contribution of intra-individual variation on the measurements (Table 35.12). If more repeated measurements on different visits are performed, the contribution of intra-individual variation between visits appears to be even lower. It accounted for 0.5–7% for SDRR, 2–7% for RMSSD, 3–8% for HF power and 4–6% for LF power [256]. In contrast, the contribution of intra-individual variation increases with prolongation of recording length and can reach 30% for a certain HRV measures. Intra-individual variations might be of importance for studies in which the effects of internal or external stimuli are to be examined. The intra-individual variation can be in part a source of measurement error of HRV indices calculated from long-term recordings. However, strict estimates of these errors have not yet been provided.

Intra-individual variation range provides limits beyond which HRV changes can be considered significant and interpreted as a true effect of interventions or changes in study conditions. It is of importance since intra-individual variation might be even greater than inter-individual variation [256].

### 35.4.7.2 Inter-Individual Variation

Inter-individual variation defines the range of HRV in a population. The determination of between-subject variation is necessary when population (or subpopulation) studies are going to be undertaken in order to detect effects of various interventions. Awareness of inter-individual variations is necessary with the interpretation of changes of the mean

Table 35.12  
Intra-individual variability of HRV measures in healthy subjects (Coefficient of variation)

Author[s] Source/Year	Subjects	Condition[s]	RRV [or HR]	SDRR	RMSSD	LF	HF	Comments

			5.0%[HR]	NR	NR	21.2%	19.5%	
			4.7%	NR	NR	23%	20.1%	

or median values. This is also an ultimate condition for the determination of normal limits and the definition of abnormal HRV.

Between-subject variation is the main source of measurement error. For time-domain HRV indices, it contributes 86 to 91% of the entire error and was shown to be independent of data length [256] (► Table 35.13). For spectral HRV indices (HF and LF power), its contribution ranges from 69 to 81% and 55 to 79%, respectively, being greater for a longer data-length [256].

### 35.4.7.3 Intra and Inter-Observer Errors

Measurement errors define the range of subjective assessment of data-series. Intuitively, this depends on the robustness of the HRV method or index. If manual editing and visual inspection is necessary, the differences both between measurements performed by the same investigator (intra-observer error) and by two investigators within the same data-series (inter-observer error) can be assumed to be greater compared to a robust method/index, which is calculated automatically without any investigator's management of the data-series [34, 256].

Intra-observer errors for HRV short-term recordings have been shown to account for less than 0.1% of total measurements errors. Inter-observer errors for short-term HRV were estimated to account for less than 0.1% of the measurement error for time-domain indices and less than 3% for spectral indices [256]. In the ARIC study, the intra- and inter-observer variance of 2-min SDNN has been reported to reach  $0.04 \text{ ms}^2$  (0.6%) and  $3.24 \text{ ms}^2$  (5.3%) [258]. The inter-observer error relates also to the condition of analysis (manual, automatic, pre-defined fixed frequency) [259], being lower in the latter setting. The inter-observer error has been reported to be greater in a study on patients with chronic stable CAD, where the respective data for 5-min and 40-min recordings ranged between 0.2–6.0% and 0.1–1.2% [260]. The longer the data-series analyzed, the greater the errors on the part of the observers. Kroll et al. noticed the inter-observer errors reaching 8% as a result of inaccurate labeling of heartbeats, especially PEBs, in intentionally selected patients with aortic regurgitation [261]. The SDANN index proved to be least sensitive to the inter-observer error [261, 262].

Only one study addressed this issue in children [263]. In the Bogalusa Heart Study, in which 20 children aged 10–16 years old had been included, the inter-observer errors in the estimation of time-domain and frequency-domain measures did not exceed 1% and 4%, respectively [263].

The intra- and inter-observer errors depend in part on technical characteristics of available instruments. The use of different devices influences the level of agreement for either short-time frequency-domain or long-term time-domain indices [257, 263, 264].

### 35.4.7.4 Reproducibility

Reproducibility characterizes the summarized effect of intra-individual, inter-individual, intra-observer and inter-observer errors, as well as precision accuracy, assuming similar length and conditions of HRV recordings. In addition, the use of different devices influences the comparisons of different interventions and their reproducibility. A high reproducibility can be defined by various measures, like the coefficient of variation (as being <10%), intra-class coefficient (>0.79), limits of agreement (LOA, 75–125%) and others [256]. Values of CV, ICC and LOA that indicate acceptable (minimum) reproducibility are <30% and >0.60 and 60–140%, respectively.

► Tables 35.14 and ► 35.15 provide results of selected studies that addressed this issue in healthy subjects. The results of reproducibility in patients with specific CV diseases are presented in ► Tables 35.16 and ► 35.17.

Murray et al. showed a poor to moderate reproducibility of 5-min HRV measurements repeated 2–3 min apart with LOA between 61% and 157% for SDNN in a wide age-range sample (21–77 years) [265]. Similarly, minute-to-minute reproducibility of spectral HRV indices was found to be moderate in young subjects in a study of Højgaard et al. [266]. The CV was lowest for HF and LF/HF (27–28%). However, a great inter-individual variability range was noticed (2–75%). On the contrary, in middle-aged subjects, Pikkujämsä et al. found the SDNN very highly reproducible if evaluated by means of a CV of 2% [141].

Moderate or poor day-to-day reproducibility of short-term HRV measures has been reported for various spectral indices (mean CV between 27–39%) in young adults [266] and even poorer in children with a CV range of 35–97% [267].

The evidence for reproducibility of nonlinear HRV measures is sparse. In a study by Maestri et al. [268], only a ratio of SD1 to SD2 from a return map has been shown to be reproducible (Table 35.14). The DFA and SampEn were shown to be moderately reproducible. Reproducibility of other nonlinear HRV measures has been reported to be rather poor [268].

In several studies, measurement errors were quantified for a longer period between repeated investigations. It was found that the long-term reproducibility of short-term HRV indices appears better than that of the shorter term reproducibility. Sinnreich et al. found the CV values of logarithmically transformed HRV indices to be between 6–12.1% [269]. In their study, the SDNN, RMSSD, total and VLF power were highly reproducible while the HF and LF power were only moderately reproducible. Interestingly, controlled breathing did not improve their reproducibility. Reported ICC values for LF vary from 0.66 to 0.87 with FFT and 0.70–0.86 with AR. Similarly, for HF, the ICC values are between 0.48–0.96 (FFT) and 0.15–0.86 (AR). The largest differences of the ICC related to LF/HF with the worst reported being 0.06 (sic)(AR) and the best being 0.85 (AR). For very short registrations (10 s), the ICC values ranged between 0.41 and 0.57 [255]. Increasing the number of repeated measurements seems to improve reproducibility of short-term HRV measures (Table 35.14).

Thus, 5-min recordings provide most (moderate in fact) of the reproducible data for standard indices. However, in healthy subjects, their relative changes between examinations can reach 30% (overall), which should be considered as independent of biological and measurement variation.

Many studies have addressed the issue of reproducibility of HRV indices from 24-h ECGs in healthy subjects (Table 35.15). In the largest one, 165 healthy adults were included [65]. For the time-domain HRV indices the ICC was found to be good or high (>0.7) if compared from day-to-day. However, individual subjects showed a high range of variation explored by means of LOA. Thus, if significant changes of HRV indices are defined as lying beyond LOA, significant (independent from biological and measurement variation) changes of SDNN

Table 35.17

Reproducibility of HRV measures from long-term ECG recordings in patients

Author[s], Source/Year	Subjects	Between-measurements period	HRV measures	Statistics	Results

Burger et al. 1997 [A24]	23 DM1-type patients 8F, 15M Aged 37 ± 10	3, 6, 9, and 12 months	Time-domain Spectral-domain	Pearson's correlation coefficient	0.35–0.98 0.47–0.93

would be considered if its value was reduced by 41 ms or increased by 35 ms (for the mean SDNN of 140 ms changes need to be less than 99 ms or greater than 175 ms) in an individual subject. This corresponds to a change of 25–30% from the initial value. Similarly, a change of at least 25% is necessary to consider significant difference for time-domain indices, including HRVI and HRVF. This finding is consistent with observations made by others for short-term recordings.

The reported CV of SDNN from 24-h ECG recordings in healthy subjects varies from 4.2 to 10.3% on a day-to-day basis, and 9.6% for a 6-month period between repeated measurements. Thus, *the difference of approximately 10% from the initial SDNN value can be considered statistically significant if the time-distance from repeated measurements is longer than 6 months*. The pNN50 was found to be least reproducible in some studies and highly reproducible in others (▶ Table 35.15).

Reproducibility of the HRV indexes may play a greater role in patients with a reduced HRV, in whom a similar range of absolute differences between measurements makes the relative differences even greater. However, a simple comparison between data from healthy subjects and patients with certain diseases cannot be conclusive, as various data-length and reproducibility measures have been used.

Studies in which a comparison between normal subjects and patients has been performed are scarce. Short-term HRV reproducibility has been found to be poorer in hypertensive patients with OSAS in a study of Salo et al. [270] (▶ Tables 35.14 and ▶ 35.16). In another study in patients after heart transplantation, the coefficient of variation of the LF component reached 76%, being greater than in healthy controls [45%] [271]. According to the dots-data (from the figure) provided in a report by Haas et al. in post-MI patients [272], the mean value of short-term (5-min) SDNN of around 20 ms was associated with the LOA of measurement being –14 to 12 ms, accounting for –70 to 160%, indicating rather a poor reproducibility. In a comparable study of Sinnreich et al. in healthy subjects, the recalculated mean value of 5-min SDNN of 37 ms has been associated with a 6% coefficient of variation (i.e., ± 17% range) [269].

A poor or moderate reproducibility of short-term HRV measures has been reported in patients with CHF (▶ Table 35.16) with the CV range between 25 and 139% for time-domain, and 45–115% for frequency domain HRV indices in a study of Ponikowski et al. with a between-measurement period of 7–56 days [273]. In contrast, Freed et al. found a good short-term variability between two adjacent 10-min periods in CHF [274] with the CV range between 9–12% for LF and HF (FFT). Much better reproducibility of short-term HRV has been reported in the largest study in patients with stable CAD [260] with the CV range being between 11.3–29.9% for all measured indices, except for RMSSD with a CV value of 48.9%. Also in patients with diabetes mellitus, the day-to-day reproducibility has been moderate or high for SDNN (mean bias 17%) and moderate for FFT-derived spectral measures (mean bias 2–39%), while reproducibility for AR-derived spectral measures has been poor (27–102%) [275].

Thus, short-term HRV reproducibility seems to be lower in patients than in healthy subjects. Accordingly, a greater change of particular HRV measures is necessary to detect the true effect of interventions in patients with autonomic neuropathies or certain diseases. As yet, there are no indications from standards, statements or reviews. A magnitude of necessary change (absolute or relative) considered to be significant should be pre-defined taking into account the age of the population examined and the methods used.

There are independent studies in which normal subjects and patients with a certain disease have been compared simultaneously to evaluate reproducibility of 24-h HRV measures (▶ Table 35.17). Nolan et al. analyzed the NN50+ index in 67 patients with CAD [276]. The ICC reached 0.94 (similar to 0.97 in healthy subjects). However, there was a much poorer CR (0.41) than in healthy subjects (0.21). In a sample of 87 diabetic patients in the same study, the ICC values have varied between 0.80–0.91 depending on between-measurement interval whereas the CR values were unacceptably large (0.61–0.98) [276]. Day-to-day variation of 24-h HRV has been found to be moderate in patients with CHF in a study of van Hoogenhuyze et al. [277]. The mean values of differences ranged from 8.5–13.8% (SDNNI and SDANN). However, individual variations have been observed of up to 50.6% and 28.2%, respectively [277]. Recalculated ICC values ranged from 0.87–0.95 (▶ Table 35.17). Also, a high reproducibility for all 24-h spectral measures with an ICC > 0.79 has been reported by Bigger's group [278] in post-AMI patients. Time-domain (SDNN, SDANN and SDNNI, geometric) measures have been found reproducible in a sample of post-AMI patients [279] and in HF studies [280–282]. However, reproducibility of the pNN50 has been shown to be poor in these studies (▶ Table 35.17).

In the largest study on long-term HRV reproducibility in CAD patients, Weber et al. reported a maximum change of ~36 ms for SDNN in stable angina (~25% of the average) [283]. Comparing this value with the corresponding values reported by Hohnloser et al. [281] and Sosnowski et al. [65], the range of variation between examinations in cardiac patients appeared to be similar to that in healthy subjects (~30%).

Thus, whereas the reproducibility in patients with cardiac disease can be seen to be significantly lower with short-term HRV (~ twice than that in healthy subjects), in long-term recordings a similar reproducibility with long-term HRV examination can be assumed both in normal subjects and in patients with known cardio-vascular disease.

There is little data on the stability of diurnal variation of HRV measures. Huikuri et al. found the diurnal variation of HRV indices to be very stable in 20 normal persons on two consecutive days and then at 1-week intervals. However, neither results of rhythm analysis nor its reproducibility was reported [284]. A more detailed cosinor-based analysis [87] in patients with stable CAD has been provided by Hayano et al. [285], who repeated 48-h ECG recordings in 40 patients aged 58 years (38–72). The mesor (corresponding to the median values) of SDNN, LF (ms), HF (ms) and LF/HF were shown to be highly reproducible with ICC values ranging between 0.8–0.89. The values of the amplitude (the magnitude of change from the mesor) varied between 0.63–0.73, and of the acrophase (the time of maximum amplitude) varied between 0.76–0.95 [285]. These results may indicate that the use of a highly reproducible, understandable and robust cosinor-based circadian rhythm analysis may offer more than other statistical analyses to evaluate the effects of interventions. However, one has to bear in mind that the period of recording has to be longer than one day.

Noninvasive baroreflex sensitivity (BRS) reproducibility has been reported as being moderate to poor with a range of CVs of about 8–40% if the BRS is calculated using spontaneous approaches [266, 286–290]. However, some studies indicate a high reproducibility [291, 292]. The reproducibility of BRS is affected by the specific methodological features [289, 291, 293], age, health status, mean arterial pressure and period between measurements and the failure rate [287, 290, 291, 293]. The 95% limit of agreement varies between 1.7 ms/mmHg up to 10.6 ms/mmHg [287, 291] depending on the mean BRS value in the sample examined. Transfer function BRS and cross-spectral BRS appear to be applicable to most subjects, and calculated sample size to detect a change of 15% varies between 20 and 80 subjects [291, 292]. Within-subject variability seems to be responsible for a substantial proportion of reproducibility [287, 293]. The use of logarithmically-transformed HRV measures might improve the reproducibility [293]. However, the net results are similar. As pharmacologic and mechanical intervention-based methods are rarely used and restricted to highly specialized laboratory centres, the issue of the reproducibility of these methods is of marginal importance. However, in any laboratory study, the validity of the method of study still remains a fundamental requirement.

Heart rate turbulence (HRT) reproducibility (i.e., turbulence onset, turbulence slope, turbulence dynamics) has never been explored despite significant support in some investigators' teams for their superiority over traditional HRV measures (SDNN and HRVI only) [222, 226, 227]. A lack of reproducibility studies on HRT has been observed in recently published standards [294].

### 35.4.7.5 Reclassification Rate

Reproducibility of a specific HRV measure influences the categorization of its value as normal or abnormal depending on the cut-off values defined *a priori* (from the literature or guidelines) or *a posteriori* (from the distribution of values in the studied sample, i.e., mean or median, 10th, 25th, or 33rd percentile).

For the SDANN cut-off of 90 ms, the day-to-day variation in the SDANN calculation in data from van Hoogenhuyze et al. [277] caused a change in classification from normal to abnormal in 4 out of 22 CHF-patients (18%) and from abnormal to normal in 2 (9%). The overall reclassification rate achieved was 27% (6/22). Similar values for a cut-off of 100 ms resulted in a lower rate of reclassification (overall 2/22, 9%, from normal to abnormal 2/6, 30%), while with a cut-off value of 50 ms, only 1 out of 4 cases with SDANN<50 ms moved into the normal category (5% overall, 25% of abnormal). In 33 normal middle-aged (35 years) subjects, the reclassification rate from normal to abnormal (cut-off <100 ms) was 3 out of 29 (10%) and from abnormal to normal was 1 out of 4 (25%). Overall, there was a 6/33 (18%) rate of change in category for SDANN<120 ms, 4/33 (12%) for SDANN<100 ms and 3/33 (10%) for SDANN<90 ms.

From data of Haas et al. [272], the reclassification rate of 10.2% (4 out of 39 AMI-patients) can be calculated for 5-min SDRR with cut-off defined as values below 20 ms, and of 8 (9.6%) out of 83 for VR < 10 bpm. A detailed analysis of figures (1 and 2) from the paper of Stein et al. [280] on the stability of HRV indexes in CHF patients indicates that despite a high ICC of 24h-SDNN (= 0.91), the reclassification rate dichotomized at 70 ms regarding 6/17 patients (35%), including 3 out of 5 with an abnormal value in the first recording and normal in the second visit. The SDANN categorization changes within two visits appeared similar (1 out of 3 (33%) changed from abnormal to normal).

Reclassification rate might be of importance in some clinical syndromes, which use an HRV analysis for their diagnosis, for example, diabetic autonomic neuropathy, sinus node dysfunction and obstructive sleep apnea syndrome. As yet, studies that address this issue are lacking.

### 35.4.8 Selection of Method for HRV Analysis

The choice of HRV method to be applied in a specific study is dictated by the purposes and conditions of the study. From a clinical point of view, it is important that the HRV measure is normally distributed (like LV ejection fraction), thereby providing results which can be easily expressed and understood as raw values rather than log-transformed measures (► Fig. 35.34). If the distribution is not normal, data should be transformed for statistical calculation. However, the presentation of results requires re-transformation.

A fraction of abnormality, i.e., the proportion of abnormal range and total range, would also be informative (► Fig. 35.35). Within a restricted limit of abnormality (98%CI) that is based on distribution of the results, there was nobody (neither healthy nor post-MI-patients) with the SDNN value <20 ms, whereas 13% of CAD patients were recognized on the basis of HRVF evaluation. For less restricted limits, there was still a significant difference in the proportion of CAD-patients with abnormal results (i.e., 5. % for SDNN vs 36.7%), albeit the cut-off points lay below the 2.5th percentile. This indicates that the definition of abnormal values is strongly affected by the normality of distribution of an HRV measure.

The duration of HRV recordings seems to play a crucial role in the applicability of HRV analysis. Studies on clinical outcome and risk factor association with HRV, in which HR had been used as an independent measure of the autonomic balance, were undertaken in tens of thousands of people. Meanwhile, in other studies in which short- or median-time HRV analysis was used, smaller populations, around a tenth of the size, were gathered. While 24-h HRV analysis was applied, the number of subjects studied was reduced by a further factor of 10 (► Fig. 35.36).

If the HRV analysis is going to be performed in a large sample population, as in epidemiological studies and registries, the use of simple statistical methods from short-term recordings seems to be most appropriate (► Fig. 35.37). HRV from routine ECG recordings lasting 8–10 s can be applied taking into account that each index derived from routine ECG strips (VR, SDRR, CIPA, CV) reflects vagally-mediated respiratory HR modulation. As short epochs are characterized by a relatively great biological variation, the reproducibility of individual measures should be assessed or simple HR used as an index of sympathovagal balance of greatest reproducibility. Otherwise, the duration of ECG recordings should last 5 min, because there is a relatively large experience with the use of HRV from 5-min epochs. However, as there is an inverse relationship between the statistical power of a study and the reliability of an HRV measure for a given sample size, it is necessary to calculate sample size on the basis of *a priori* defined change of an HRV index to be detected and of *a priori* or *a posteriori* defined reproducibility [285].

■ Figure 35.34

Frequency distribution and estimated skewness (S) of the commonly used HRV measures. Data from 1,070 healthy subjects. The SDNN (Var) and spectral HRV measures are characterized by a nonnormal distribution, so the logarithmic transformation is necessary. Normal distribution is present for the RRI, HF [N.U.] and LF [N.U.], however the latter two (HF, LF expressed as %) do not have an explanation on physiological or pathophysiological basis (From [324]).

Figure 35.35

Comparison of the distribution of normal and abnormal SDNN and HRVF in respect to health status. Median values of the 24-h mean R – R interval (RRI = 830 ms), SDNN (119 ms) and HRVF (47%) in the entire cohort (805 subjects) are depicted by the vertical or horizontal lines (respectively). These values constitute approximately 30% and 60% of the total ranges, respectively. If one considers abnormally low HRV values on basis of a population distribution, only few normal subjects have SDNN and HRVF below the lower normal limit (here: 89 ms and 35%), however these values constitute various percentile of the total range (here: 23% and 46%). The open boxes indicate the 98% CI of prediction of the normal/abnormal result. Each value of RRI, SDNN and HRV that lies outside the boxes are definitively abnormal. Interestingly, there are none subjects (normal or post-MI) with SDNN < 98% CI (22 ms), whereas 67 patients (13%) (exclusively from the postMI-cohort) had abnormal value (i.e., HRVF < 20%). If we turn into established cut-off of SDNN (< 50 ms) and HRVF (< 30%), the respective proportions reach 27/515 (5.2%) for SDNN and 187/515 (36.7%) for HRVF again exclusively form the CAD cohort. Open squares indicate healthy subjects (n = 290) and circles indicate patients after myocardial infarction (with/without sinus rhythm, n = 515) (Author's data).

Figure 35.36

An exponential relationship between simplicity of available indices of cardiac autonomic tone and examined population. Data from 94 studies in normal population (either selectively healthy or random sample). A magnitude of 10 is a scaling factor for this relationship. Thus, HR as a crude sympathovagal balance index can be employed in largest population, whereas spectral analysis seems to be applicable to 100 times lower samples (Author's data).

■ Figure 35.37

Reportable size of population samples as a function of HRV indices and length of ECG recordings chosen. Data from 94 studies that employed HR and/or different time- and spectral HRV measures for clinical outcomes, HR and HRV associations with risk factors and HRV determinants evaluation. (Author's data).

If HRV analysis is to be used for physiological, psychological, and pathophysiological reasons, either short-time or long-term time series could be appropriate. However, a prolongation of HRV recordings for these purposes reduces the number of factors that can be controlled during a study.

Cumulated experience indicates that long-term HRV analysis appears to be a useful tool for clinical outcome studies. It is necessary to be aware of the contribution of the autonomic control of HR to the entire HRV over a 24-h period, which is less than 10% of total variance [80]. Thus, in clinical outcome studies, it is not advisable to search for an association between clinical events and sympathetic and vagal activity as well as their balance. However, most global HRV measures certainly require the autonomic system to mediate their influences. The uses of various HRV methods/indices for different purposes are summarized in ▶ Table 35.18.

### 35.4.8.1 Reliability

Homogeneity in the evaluation of the effects of interventions and in agreement with other methods determines the reliability of various HRV indices as noninvasive measures of cardiac autonomic control. There are several methods that allow the determination of HRV reliability.

For short-term HRV reliability assessment, simple maneuvers are used (controlled breathing, body position change from supine to standing, head-up tilt, exercise, mental stress) for which changes in cardiac autonomic control are well established. ▶ Tables 35.19–35.21 summarize the results of selected studies that have addressed this issue.

The reproducibility of 5-min SDNN and spectral HRV indices in response to a head-up tilt has been shown to be poor or moderate [266, 295, 296]. Data are conflicting regarding the reproducibility of HRV in response to active standing.

Table 35.18

HRV methods used in population studies depending on their type and objectives

Authors, acronym of the study (if exists)	Year	Total sample (% men)	Age (range)	Length of recording	HRV method/index	Specific purposes

Salo et al. [270] reported an unacceptably high CV for RMSSD and all spectral measures (42–83%), while Lobing et al. observed low ICC of LF and HF (0.57 and 0.33, respectively) using a very complicated protocol [297]. On the contrary, an excellent reproducibility has been reported by others (Table 35.19). In a study in children, Dietrich et al. observed good reproducibility of standing LF and HF (natural logarithms). However, differences in these measures have been found to be highly unpredictable (Table 35.19) [298].

In a head-to-head comparison of FFT and AR spectral HRV indices in analysis of controlled breathing, Pitzalis et al. showed a moderate ICC for the LF and HF, and a poor reproducibility (ICC<0.6) for TP and LF/HF in 20 young healthy subjects [296], while a moderate reproducibility was found for SDNN and RMSSD. Limitations of the reliability of spectral HRV measures for evaluation of the effect of controlled respiration have been confirmed in many studies (Table 35.20). On the other hand, positive studies confirming good reliability of HRV in the examination of the effects of respiration do exist (Table 35.20) [256, 269, 297, 299, 300]. Tarkiainen et al. reported that logarithmic transformation of the standard HRV measures (RMSSD, TP, LF, HF) improved the reliability of evaluation of HRV response to

controlled breathing [260]. The reliability of HRV in response to other maneuvers is shown in Table 35.21 [270, 300–302]. In general, the reliability of HRV measures in evaluating the effects of the aforementioned interventions seems to be unsatisfactory [256].

Other methods of reliability evaluation are related to the pharmacological action of agents that exert either direct or indirect stimulatory or inhibitory effects upon the vagus or sympathetic branch or both. Unfortunately, data on reliability of HRV analysis in such settings are extremely rare. Cloarec-Blanchard et al. examined the effects of nitroglycerin infusion on LF components in ten healthy volunteers 1 week apart and found it to be reproducible [303]. Moderate to good reproducibility (CV between 4 to 30%) of HRV has been reported by Piepoli et al. in heart failure patients under dobutamine infusion [304].

For long-term HRV reliability assessment, quite different approaches are in use. Physical training or body mass changes are assumed to be associated with HRV changes, but unfortunately, studies addressing HRV reliability in this area are lacking.

### 35.4.8.2 Explicitness

Ideally, the HRV index changes should be caused by a specific alteration in cardiac autonomic control. Effects of an intervention, like vagus nerve intersection, which results in almost total reduction of IBI variation [305], should be universally observed. Similar effects should be observed by a muscarinic receptor blockade in any examined subject [23]. Data from studies by the Goldberger group [231] indicates that cholinergic blockade with a high dose of atropine results in elimination of RSA and HRV in almost every subject examined. However, parasympathetic stimulation does not necessarily result in uniform HRV changes [231]. As indicated by an early study of Anrep et al. in dogs, blood pressure increment beyond a certain level (associated with a reflex parasympathetic excitement) results in a reduction of VR of HR [3]. A suppression of HRV (SDNN, LF and HF) as a result of the phenylephrine-induced activation of parasympathetic branch of the ANS has been found in normal humans [231]. However, changes of certain HRV spectral measures in response to parasympathetic baroreflex-related stimulation have been observed to depend on the initial level of HRV, because a reduction in those with a high basal HRV and an increase in those with a low basal HRV, despite slowing of HR, was found in each case [231]. A possible explanation for such a discrepancy is the phenomenon of saturation (see part 35.5), where the effects of inspiration and expiration-induced vagal activity can be rather diminished [231].

The situation is even more complicated if the effects of sympathetic inhibition or stimulation are considered. Alpha-adrenergic stimulation with phenylephrine in a setting of a so-called total autonomic blockade (atropine 0.04/kg + propranolol 0.2/kg [306]) has not been found to have an effect on either time or spectral HRV indices in healthy subjects, while a significant reduction of HRV has been observed in subjects with an intact activity of both branches of the ANS [231]. It indicates that inhibition of  $\beta_1$ -adrenergic and M1-muscarinic receptors prevents the effect of action of  $\alpha$ -adrenergic-mediated stimulation, or that these effects are truly negligible [231].

The effects of beta-adrenergic stimulation or inhibition on HRV strongly relate to the choice of stimulus/inhibitor. For instance, a large increase of LF power in response to up-right body movement is accompanied by a significant reduction in total HRV [307]. Such an LF power increase has been observed to be lower in a setting of parasympathetic blockade [231]. In addition, the use of different sympathomimetics elicits various effects. Exogenous epinephrine has been shown to reduce HRV (SDNN) with variable changes (increase, no change or a decrease) in the LF power in healthy subjects, while isoproterenol infusion has exerted more of an inhibitory effect on LF power. Interestingly, the HF power has been simultaneously reduced with isoproterenol, in contrast to epinephrine [307].

Such experimental circumstances are rather unique in clinical settings. Changes in a specific physiologically explainable R–R variation (e.g., RSA, LF power) need not follow changes in the entire HRV [308]. Thus, *a reduction or an increase of heartbeat variation cannot definitively indicate its cause.*

For instance, in a patient with an acute MI, a reduction of HRV can be attributed to various mechanisms, which can depend on factors such as age of the MI, its location and size, LV function, drugs, interventions, coexisting diseases (e.g., diabetes, respiratory system disease, depression), and finally complications and adverse events such as malignant ventricular arrhythmia, stroke, cardiac tamponade, loss of blood, etc. In addition, the magnitude of HRV reduction is pre-determined by the pre-event level of cardiac autonomic control (age, sex, coexisting diseases).

For such a complex clinical entity, the detection of a specific alteration in the cardiac autonomic control is *a priori* impossible.

However, if an effect of a specific intervention with known patho-mechanism(s) contributing to a certain HRV measure is to be studied, a link between them can be explored. Again, the control of many factors is necessary to draw an explicit interpretation. The more sophisticated and mathematically complex the method used for HRV assessment, the less likely is its unequivocal explanation.

Actually, none of the currently used HRV measures can help to explain what specific alteration (in terms of level and location) is responsible for HRV changes in any physical condition or in cardiac and noncardiac diseases.

### 35.4.8.3 Redundancy and Inter-Changeability Among Different Methods and Measures

The variety of HRV measures determined in different domains has, in fact, a similar complex physiological and pathological background. Current guidelines indicate that some HRV measures are most useful, but actually only very few are commonly applied in clinical settings [309]. A plethora of methods and derived indices have been proposed for which the advantages over standard HRV measures have been justified in terms of a better description of underlying physiological and pathological processes and in prediction of hard end-points or their surrogates [310]. As a result, researchers and physicians are faced with a dilemma of choosing the most appropriate method and indices that would help to meet the purpose of their studies. From this point of view, it is important to know the meaning of particular HRV measures, but also their redundancy and inter-changeability, as well as differences between the methods used for obtaining their measurements. Simple comparisons of techniques for HRV analysis are given in [Table 35.22](#) [after 310].

There are relationships between HRV indices from the same or different domains (time, spectral, nonlinear) that permit them to be used as a substitute for one another, or to interpret (within a limited credibility) simple time-domain or complex nonlinear measurements on the basis of the known background of spectral components. The higher the correlation between different indices, the higher is their inter-changeability. The most significant relationships among HRV indices in various domains are shown in [Table 35.23](#). [4, 11, 311, 312].

Time-domain measures are least dependent on the algorithms used for their determination and the main differences between means are related to the duration of recording. However, spectral estimates are not necessarily similar if obtained using the two most popular methods, namely FFT and AR modeling.

In a comparative study of FFT and AR spectral techniques for LF and HF components of the HRV power spectrum, Pichon et al. found a significant bias between these two methods meaning that they are not interchangeable. For the 265 s ECG registrations, the bias calculated from FFT and AR [16th order] has been measured and reached  $-132 \text{ ms}^2$  for LF and  $-111 \text{ ms}^2$  for HF with the lower LOA of  $-1442$  and  $-469 \text{ ms}^2$  for LF and HF respectively and the upper LOA of  $1176$  and  $246 \text{ ms}^2$ , respectively [313]. Even greater bias was found after body position movement, where LOA (lower and upper) lie far from the mean values [313]. Similar observations have been reported by Chemla et al. [275]. They found that the fast Fourier transform and AR analysis provided quite different estimates of spectral HRV in diabetic patients. Moreover, they stated that these methods are not interchangeable at all and in this specific patient population, the FFT method provided spectral estimates of TP, HF and LF in all patients contrary to the AR method which was unable to produce spectral peaks in almost half of the diabetic patients [275]! They observed that in subjects in whom spectral peaks could be detected by means of either method, spectral estimates within frequency bands were similar. Also, the FFT appeared less dependent on the minor changes (5%) in the timing of the onset of the analysis. In a former head-to-head study of Pitzalis et al., the power spectrum of LF and HF was 20–30% lower if assessed by means of AR [12th order] than that obtained by means of FFT [296]. Also, in a study of Sinnreich et al. in 398 healthy subjects [269], the AR [16th order] LF and HF spectral powers [mean of LF of 221 and HF of 151  $\text{ms}^2$  in males and 126 and 128  $\text{ms}^2$  in females, respectively] were clearly lower than those reported by Pikkujämsä et al. in 50 healthy subjects of similar age [mean LF of 520 and mean HF of 375  $\text{ms}^2$ ] calculated by using 5-min AR [20th order]. They were even lower than in diabetic patients (5-min) [275] and similar (with respect to LF components) to the mean 24-h value estimated in patients in the early phase of acute MI by means of AR [10th order] modeling (299 and 270  $\text{ms}^2$  respectively) [316]. A comparison of the corresponding means of AR-spectral indices

Table 35.22

Comparison of techniques of HRV analysis (Modified after [310] and [111])

HRV analysis	Description	Advantages	Limitations	Universality
Time-domain	Statistical	Simple, easy to calculate, proven clinical utility, gross distinction of high and low frequency variation	Sensitive to artefact; requires stationarity, fails to discriminate distinct signals	SDNN most widely used, SDANN most widely applicable (also in AF)
	Frequency distribution	Visual representation of data, can fit to normal or log-normal distribution	Lacks widespread clinical application, arbitrary number of bins	Undetermined
	Geometric	Visual representation of data, does not requires stationarity, relatively robust, can be also used for nonlinear analysis	Fails to discriminate distinct signals, requires relatively large datasets	HRVI most widely used HRVF most widely applicable (also in AF)
Frequency-domain	Frequency spectrum representation	Visual and quantitative representation of frequency contribution to waveform, useful to evaluate relationship to mechanisms, widespread HRV evaluation	Requires stationarity and periodicity for validity, sensitive to artifacts, altered by posture, sleep, activity	Only in subjects with sinus rhythm
Fractal analysis	Power law	Ubiquitous biologic application, characterization of signal with single linear relationship, enables prognostication	Requires stationarity and periodicity, requires large datasets, vulnerable to artifacts	1/f slope of power law most widely applicable (also in AF)
	Detrended fluctuation analysis	Identifies intrinsic variations to system (versus external stimuli), does not required stationarity, enables prognostication	Requires large datasets (>8000 data points), dependence on artifacts	Undetermined (only in sinus rhythm?)
Entropy	Measures the degree of disorder (information or complexity)	Unique representation of data, requires fewest data points	Needs to be complemented by other techniques, stationarity is required	Undetermined (only in sinus rhythm?)

Abbreviations see [Table 35.2](#) and [Sect. 35.1](#)

reported in a study of 50 age-comparable healthy subjects (LF of 520 ms<sup>2</sup> and HF of 375 ms<sup>2</sup>) [141] and in those with diabetes (similar age range) (LF and HF of 222 ms<sup>2</sup> and 485 ms<sup>2</sup>) in a study by Chemla et al. [275] might indicate that there is either a problem with the determination of a proper order for AR modeling or that it might not be [empirically] a reliable method for HRV spectral assessment.

There are also data indicating that the so-called sympatho-vagal balance, indicated by means of the LF/HF power ratio, is not interchangeable while using either FFT or AR for estimation. Apart from controversies regarding the rationale and background of the use of this index, the comparability of the LF/HF ratio is low either in normal subjects, namely 3.84 in AR[12] modeling in normal young subjects, 4.11 in AR[16] modeling in middle-aged subjects and around 5 in AR[20] modeling in a similar sample [269, 275, 313].

Abbreviations as in Sect. 35.1. On basis of data provided by HRV Standards [4], Voss A et al. [111], Stein KM et al. [311], Cygankiewicz I et al. [312].

\* short-term

The accumulated data also indicates that cut-off values of prognostic values of spectral HRV estimates stated in the Standards [4] should not be applied in studies in which AR modeling is to be applied. This might also imply that the use of the fast Fourier transform, despite its limitations [see 35.4], should be preferred for short-term HRV assessment in laboratory settings. If the AR modeling is to be used, referencing of previous studies should be limited and should include studies in which other methods (FFT in particular) had been applied.

### 35.4.9 Normal Limits and Abnormal HRV

The successful application of HRV analysis to clinical medicine is critically dependent on the definition of normal limits and abnormal values. Guidelines [4] provide standard HRV measurements in a healthy population. However, they might be useful only as a reference for comparison with population samples with known characteristics (e.g., prevalence of CAD, mean age, mean RRI, etc.). HRV analysis, like other diagnostic methods, should take into account the prevalence of the disease and its influence on the performance of a particular HRV index. As yet, in almost all studies, the positive predictive value of HRV indices has been reported ignoring the prevalence of a disease in a population (if normal persons had been comparators). The author's studies, confirmed by others, clearly indicates that examination of a sample of a population is necessary to determine normal limits and to define abnormal values [64, 65]. As there are significant age-, gender-, race-, HR-, respiration-, and distribution-related differences among various populations, normal limits as well as abnormal and risk-predictive values should therefore be determined in a sample of a "regional" population rather than be drawn from the literature [315, 316]. Also, even if they can be controlled for the constitutional factors, a skewed distribution of most standard HRV measures (Fig. 35.34) prevents use of their standard deviation value for setting normal limits. Thus, the use of data provided by the Standards [4] does not seem to be justified at present. It should be remembered that there have been specific technical limitations (>12 h with at least 6 night hours and >50% sinus heartbeats) for HRV analysis in the study of Bigger et al. [317] from which data cited in the Standards [4] have had been drawn. Currently, these data cannot be used further in terms of the same Standards, which indicates requirement for at least 18 h of acceptable data. Nevertheless, researchers might need to compare results of their studies to the corresponding data of others. Also, if population sample characteristics cannot be established accurately, the use of published normative values might be helpful.

Thus, reported values of traditional long-term and short-term HRV indices are provided (Tables 35.24 and 35.25). In addition, if nonlinear HRV measures are to be more commonly used, then reported values (not references) of either short-term or long-term HRV studies need to be provided as has been done (Table 35.26.). Strong dependence of HRV

on age indicates that reference values require either age-adjustment or that age-related references need to be considered ([Table 35.27](#)). Separate data on HRV measures (not references) in children is presented in [Table 35.28](#).

A multitude of factors influencing HRV prevents the determination of normal limits for short-term measures. Lower normal limits (2.5 percentile) of 5-min spectral indexes have been published ([Table 35.29](#)) [335]. However, these values can be considered as reference only if a similar method (FFT, 1 kHz sampling rate) is used. Thus, the use of other techniques or algorithms requires data from a control group with comparable characteristics and recordings made under similar examination conditions.

An apparently abnormal result from any HRV measurement has to be interpreted in the light of the known statistical performance (i.e., sensitivity, specificity, predictive value, likelihood etc.) of the measure. For HRV measures, a relative paucity of well defined normal limits excludes a wider use of values <2.5 percentile and >97.5 percentile in practice. Therefore, it is necessary to be aware of whether an apparently abnormal value is defined as population-driven or as an arbitrarily set cut-off value based on statistical performance ([Table 35.30](#)).

In fact, there are only a few studies in which the HRV value, thought to be abnormal on the basis of its distribution in a healthy sample, has been used in diagnosing patients with diabetic autonomic neuropathy (DAN) [336], sinus node dysfunction (SND) [337] or in risk-prognostication in patients after a myocardial infarction [64, 315]. By using a range of 2.5%–97.5% of the normal values, the specificity of the selected HRV index is 97.5% both for abnormally low and high results. The respective sensitivities of such a defined abnormal result have reached 88% [336], 70% [337] and 25% [64, 315]. Some authors have proposed defining three categories of results, i.e., abnormal, borderline, and normal for DAN detection [339–341] or in patients with diagnosed cardiovascular disease [342]. This message has already come from Standards [4], which have cited HRV values indicating severe (SDNN<50 ms, HRVI<15a.u.) and moderate (SDNN<100, HRVI<20s.u.) abnormality. It has also been proposed that for HRV indices with normal distributions, the values lower or higher than 2SD from the mean could be considered as pathologic, those between -1 SD and -2 SD or +1 SD and +2 SD as moderately changed and those within the mean ± 1 SD as normal [342]. For HRV indices with other than normal distribution, it has been suggested that the values lower than 2.3 percentile or higher than 97.7 percentile could be considered to be pathologic, those between 2.3–15.9 percentiles and 84.1–97.7 percentiles to be moderately changed and those between 15.9–84.1 percentiles to be normal [32]. An almost similar categorization of HRV data has been used in the ATRAMI study [343].

In another proposal, a categorical distinction of a low, moderate and high HRV has been made on the basis of a calculation of the mean and 1 SD value. Therefore, a low HRV is defined as < mean -1 SD, a high HRV as > mean +1 SD, and moderate HRV as a result in between [283]. In patients with stable angina pectoris, the corresponding 24-h SDNN values were <106 ms, >178 ms and 106–178 ms, for the SDANN, they were <94, >164 and 94–164 ms, and for RMSSD they were <15, >41 and 15–41 ms [283]. However, the use of standard deviation as a determinant of limits should be cautioned

Data from Agelink et al. 2001 [335]. Spectral analysis using a Fast Fourier Transform (5 min, 1,000 Hz, discrete signal of 1,024 datapoints)

as its value is influenced by outliers (from a statistical point of view) and by the age range of the sample (important for HRV indices). On the other hand, use of percentiles requires a relatively larger number of subjects in order to be reliably calculated. Also, a wide or narrow range of age may produce different 2.5 and 97.5 percentile values.

In most studies on HRV, the abnormal results indicating optimal statistical performance are drawn from the distribution of a particular index, with either median, tercile or quartile values defining a cut-off point. Such an attempt is commonly justified by the need to find the cut-off value of a particular index with the highest positive predictive power [338]. Actually, these values should not be considered “pure abnormal” since they do not necessarily correspond to an HRV index distribution in a population and might show a significant variation (▶ Table 35.30). It might be suggested that the term “risk predictive value” (RPV) should be used.

It is necessary to be even more prudent when an index like the HRT-derived turbulence slope (TS) or onset (TO) is in use, as it is difficult (*a priori*) to determine normal limits and abnormal values in a sample of population since this requires either ventricular PEBs to be present or induced in persons without diagnosed cardiac disease. Even so, normal limits have been calculated in healthy volunteers with mean TO values ranging from  $-2.7\%$  to  $-2.3\%$  and mean TS from  $11.0$ – $19.2$  ms/RR1 [294]. Grimm et al. found the 95% percentile range for HRT slope to be  $11.78$ – $17.69$  and HRT onset of  $-0.033$  to  $-0.009$  [366]. A bias regarding the presence of atrial PEBs conducted with intra-ventricular aberration should be noted, as many Holter systems detect abnormal ventricular PEBs only on the basis of the QRS duration [367].

In most clinical studies,  $TS < 0\%$  and  $TS > 2.5$  ms/RR1 are considered normal. However, it should be noted that despite these values not being close to normal limits in normal persons cited above (of whatever calculation method), there is still a significant proportion of subjects with abnormal HRT results, especially for the HRT onset, reaching almost 20% [366]. Both descriptors of the HRT are in use for categorical classification, where an HRT category of 0 means that both TO and TS are normal, 1 means that either TO or TS is abnormal, while 2 is used if both TO and TS are abnormal. Importantly, those with no or too few suitable VES are considered to have an HRT category of 0 [294].

As the baroreflex sensitivity examination is limited to laboratory centers, normal and abnormal data are not provided, despite some efforts to define normal limits having been undertaken [368–371]. Various methods for the BRS (analogous to the frequency-domain HRV) exclude an indication of unified normal data. It would be helpful if definitive normal values could be agreed by the laboratories working in this field.

### 35.4.10 Physicians' Compliance with HRV Measures

The familiarity of physicians with HRV phenomena and currently available methods for its evaluation is generally poor. Such a statement seems to be justified by reviewing, in depth, the details from most of the so-called evidence-based studies in internal medicine and cardiology in particular. As a result, it can be stated that a fundamental clinical sign such as heart rate is frequently missed. Thus, it should not be expected that its variation (HRV) would attract greater attention. A simplified comparison of the proportion of real-life and scientific-life awareness of the importance of HRV and related phenomena (▶ Table 35.31) indicates that the HRV contribution to knowledge regarding such important

MI – myocardial infarction, HF – heart failure, HRV – heart rate variability, EF – ejection fraction. Terms present in titles, abstracts or keywords. ? HRT

fields like myocardial infarction (past epidemic) or heart failure (future epidemic) is between 0.5–2.0%. Meanwhile, the contribution of studies, in which ventricular function is investigated, reaches 10% on average (range 5–25%).

Some reasons for a such situation are related to the multiplicity of methods, variety of algorithms within the same method, different number of confounding factors, use of complicated measures sometimes (or commonly) completely unintelligible for physicians, and inconsistency of data.

It would greatly improve matters if members of the next Task Force setting new Standards could unequivocally establish a basic protocol for HRV analysis. In addition, recommendations for minimum requirements for investigation reports would be helpful.

Some methodological suggestions that present an opportunity for a wider use of HRV in clinical practice are listed in Table 35.32. As the investigators' and clinicians' interests might not appear to converge, a close cooperation between clinicians and technicians or physicists would seem to be mandatory.

## 35.5 Physiological Basis of Heart Rate Fluctuations

Changes in heart rate have to be considered in the context of changes in the entire cardiovascular system, as well as in extra-cardiac body compartments, mainly within key vital organs. Hence, the physiological and pathophysiological interpretation of HR variation cannot be restricted to HR control itself. For clinical use, it would be necessary to separate HR changes that are functional (reflex or compensatory) from those which are related to true neuropathies.

The primary assumption usually taken is that the function of the sino-atrial node (SAN) is intact. Really, this holds true mainly in physiological states. In certain settings, it might not be unusual that heartbeat formation is compromised. The common clinical syndrome of heart failure may serve as an example [306], according to the early observation of

■ Table 35.32

**Methodological guide for clinical HRV studies**

1	Use a method explicable to physicians not familiar with HRV phenomenon
2	For global HRV estimates it is required (not obligatory) to: <ol style="list-style-type: none"> <li>1. Calculate the number of subjects necessary to be examined on basis of reproducibility of the HRV measure going to be used</li> <li>2. Look on data regarding reproducibility of chosen HRV measures in previous studies or provide results of a separate pilot-study</li> <li>3. Be familiar with the prevalence of abnormal HRV within an examined sample (as it influences sensitivity of detection of abnormal HRV in a planned study)</li> <li>4. Not rely on references' data that come from a limited (usually unsatisfactory) number of examined subjects</li> <li>5. Be aware that there may be a substantial number of subjects (10–25%) with other than normal HRV indexes behavior</li> <li>6. Do not rely on data obtained from a healthy population if the examined subjects suffer from any disease that is associated with HRV abnormality</li> <li>7. Be sure that changes in HRV measures are really a result of an intervention and not contaminated by errors</li> <li>8. Use devices with the lowest possible technical-related errors</li> <li>9. Be familiar with the errors relating to characteristics of devices used</li> <li>10. Balance gender proportion</li> </ol>
3	For HRV estimates of certain [patho]physiological explanation (i.e., respiratory-related (=cardiac vagal tone), arterial pressure-related (= baroreflex (LF, HRT), vasomotor-tone related (VLF), day–night difference, activity (ULF, TP), baroreflex sensitivity, heart rate turbulence, it is required (not obligatory) to: <ol style="list-style-type: none"> <li>1. Be sure that chosen method truly complies with an examined phenomenon</li> <li>2. Be aware of reproducibility of chosen method or provide coefficient of variation in a sample of examined population</li> <li>3. Carefully observe conditions of study for all examined persons (i.e., the same time of study for short-term HRV, similar diurnal activity for long-term HRV)</li> <li>4. Balance gender proportion or perform separate investigation in females and males</li> <li>5. Perform investigation in a few groups of different ages instead of a single study in large age-range group</li> <li>6. Use a control group (nested-study design)</li> <li>7. Comprehensively check for outliers</li> <li>8. Include individual data if a small number of subjects is examined</li> <li>9. Use a reference method (if exists) if a new method or a modification of an established method is introduced</li> <li>10. Provide data regarding other significant determinants of HRV phenomenon (age, gender, race, HR, BP, respiratory rate, usual physical activity)</li> <li>11. Provide data regarding important clinical entities (for example in AMI-patients: time-to-reperfusion (successful or failed), door-to-balloon time, infarct extension (CKMB mass, cardiac troponins), functional status (Killip class), hemodynamic data LVEF), use of drugs that interfere with HRV, etc.)</li> <li>12. Avoid inclusion of subjects with various ANS derangement (i.e., diabetics, post-CABG) or with other confounding factors into a single group with subjects with a presumed intact ANS (no neuropathy), instead perform an investigation in separate groups</li> </ol>
4.	Carefully follow the HRV Standards or the other Statements' requirements (if applicable)

Wollenberger in 1939. In this syndrome, pacemaker function is compromised and the responsiveness of the SAN to sympathetic over-activity is attenuated (so-called *chronotropic incompetence* (A term indicating inadequacy between heart rate and requirements, i.e. impaired HR adjustment for functional needs (usually metabolic))) [372], despite the resting HR being accelerated and the HRV reduced. Moreover, changes in intrinsic SAN properties appear before the overt HF syndrome [306]. The importance of intrinsic SAN should also be considered in such syndromes like hyperthyroidism, inappropriate sinus tachycardia, postural orthostatic tachycardia, and also in subjects with a high-vagal tone (endurance athletes) [306, 373, 374]. Also, in the model of high renin systemic arterial hypertension, an increased intrinsic firing of the SAN has been observed [374].

One the other hand, SAN abnormalities may be responsible for the inadequate response to proper neural stimuli leading to pacemaker desynchronization and irregular heart rate fluctuation. This can be observed experimentally in transgenic knock-in mice without the expression of cardiac connexin Cx40<sup>-/-</sup> and in the clinical setting in patients with sinus node disease [375, 376].

The second assumption usually taken is that heart period changes reliably reflect changes in sinus node firing. As parallel changes are normally seen in physiology and pathophysiology, sporadically this assumption is false. Overdrive stimulation of the SAN may lead to the so-called exit block [377, 378]. In such settings, the surface ECG shows a prolongation of heart period, while a series of SAN depolarization can actually be recorded from intra-cardiac electrodes.

The examples mentioned are given to emphasize the fact that heart period variation should be interpreted with caution when making conclusions about cardiac autonomic control of SAN activity. In fact, significant progress in the understanding of mechanisms of heartbeat formation, briefly described below, makes a detailed evaluation of the contribution of the autonomic nervous system and other modulators to heart period variation even more difficult.

### 35.5.1 Ionic Mechanisms of Heart Beat Formation

The self-excitability of specialized cardiac cells is related to the function of ionic channels that carry ionic currents responsible for *spontaneous diastolic depolarization* (The fourth phase of action potential of specialised cardiac myocytes involved in the impulse propagation.). The most important currents in this phase of the action potential are inward calcium currents ( $I_{CaL}$ ,  $I_{CaT}$ ), outward potassium currents ( $I_{Kr}$ ,  $I_{Ks}$ ,  $I_{K[ACH]}$ ,  $I_{K[Ca]}$ ) and inward hyperpolarization-activated cyclic nucleotide-gated (HCN) current  $I_f$  (*funny current* (Funny current means a current having a combined property aimed at distinct ion transportation)) [379, 380]. The latter current plays a major role in the generation and control of pacemaker activity (*pacemaker current* (An ionic current specific to self-excitabile cardiomyocytes, not present in other working myocardial cells)) [380]. The  $I_f$  activation range varies largely from cell to cell, being more negative at peripheral areas. The  $I_f$  channels are uniquely activated by a direct binding of cyclic AMP (cAMP) molecules to the intracellular aspect of the channels. This property means that a funny-channel can be voltage-gated, as well as being a cyclic-nucleotide-gated (CNG) channel – part of a superfamily of CNG channels of sensory neurons (for review see [380]). Four isoforms of molecular components of  $f$ -channels have been cloned forming a family of HCN channels. In the heart, HCN4 is the major component in the pacemaker region. Accumulated data suggests that HCN2 prevents the diastolic membrane potential from becoming too negative and HCN4 is the major channel mediating sympathetic stimulation of the pacemaker activity. Recent studies indicate that a manipulation in HCN components was able to modify the spontaneous rate of pacemaker cells, thus opening an area for a clinical application of the so-called “biological” pacemakers [380].

Experimental studies have shown that  $I_f$  is a common effector of muscarinic and  $\beta$ -adrenergic activation through an allosteric conformation of the  $\alpha$ -subunit of G-protein, a trimer protein coupled with a membrane GTP-ase [380]. It is suggested that this interaction depends on a lipid composition of the P-cells plasma membrane [381]. Experimental data also indicates an involvement of the sodium channel in the generation of sinus arrhythmia. A low concentration of tetrodotoxine reduces sinus rate and increases its variability [382]. The accumulated experimental and clinical data strengthen the role of the  $I_f$  current in heartbeat formation and opens an area for the clinical use of drugs that inhibits  $I_f$  currents (so-called HR-lowering drugs) [383].

### 35.5.2 Cellular Mechanisms

#### 35.5.2.1 Pacemaker Cells

Sinus beat formation is the result of a *synchronisation* (Forced rate by a dominant pacemaker over neighboring P-cells, which generate diverse rates of spontaneous depolarisation while uncoupled.) of a group of spontaneously depolarizing cells, referred to as pacemaker cells (P-cells, pale, pacemaker, primitive) [384]. The highest density of P cells is to be found in the central region. However, they are also sparsely scattered in the right atrium. Each isolated P-cell possesses a similar self-excitabile property. However, the frequency of beating is varied, even among neighboring P-cells due to the stochastic nature of channels opening and closing. A synchronized rate of firing is possible thanks to the between-cell

communication related to the presence of gap junctions [384]. The common rate of a group of P-cells (synchronization) is based on a phenomenon called *phase resetting* (Changes in the frequency of depolarisation usually through recruitment of a new dominant pacemaker or alteration of the dominant pacemaker's rate.) due to mutual entrainment [385].

### 35.5.2.2 Sino-Atrial Node and Sino-Atrial Pacemaker Complex

That cardiac beats have their origin within the heart's own "substance" was initially proposed by Galen centuries ago. This "substance" had been discovered by Keith and Flack in 1907 as a fine subendocardial structure lying within the anterolateral part of the right atrium near the superior vena cava orifice (sino-atrial node, SAN). The proof of its role in heartbeat formation was provided by Lewis in 1910 [after 386]. However, electrophysiological studies in humans with the use of multisite mapping demonstrated that consecutive sinus beats of various lengths could appear in different sites that functionally might lie well beyond the anatomically defined SAN. This functional region, referred to as the *sino-atrial pacemaker complex*, spreads from the upper portion of the right atrium to the orifice of the inferior vena cava [387]. Pacemaker recruitment (a group of P-cells) with shortening cycle length appears more cranially, while when it moves caudally, a cycle length prolongation is observed due to the different sensitivity of P-cells to norepinephrine and acetylcholine depending on their location within the SAN and right atrium [388]. This phenomenon is referred to as *pacemaker shift* (A movement of a dominant pacemaker.) [381]. Apart from the different sensitivity of the P-cells to NA and ACh, a nonuniform autonomic innervation is thought to constitute an anatomical basis for the pacemaker shift, as evidenced by pharmacological interventions and SAN-specific autonomic nerve stimulation [389]. The pacemaker shift phenomenon is basically responsible for changeable sinus cycle length through variation in *sino-atrial conduction time* (Electrophysiological term (SACT, ms), indicates the time between the first depolarisation within the pacemaker complex (usually SAN) and the first depolarisation within atrial tissue (usually onset of the P-wave).). Changes in the chemical and physical environment could modulate this phenomenon, as happens with temperature changes, hypoxia, acidosis or hyperkalemia [390, 391].

## 35.5.3 Neuromediators and Hormones

### 35.5.3.1 Acetylcholine

Acetylcholine (ACh) is a key neurotransmitter of the parasympathetic branch of the autonomic nervous system [389]. ACh acts through the activation of ligand-gated ion channels (nicotinic receptors) or G-protein-coupled receptors (muscarinic receptors). With respect to heart rate autonomic control, nicotinic  $\alpha$ -7 subunits mediate fast synaptic transmission in ganglia supplying the heart and muscarinic  $M_2$  receptors mediate vagal stimulation in the SAN [389]. In addition, ACh modulates central pre-motor vagal activity [392].

ACh concentration at the SAN neuroeffector junction depends primarily on its kinetics. Tonic [DC] and phasic [AC] "net" vagal activity modulates ACh release from efferent cardiac vagal motorneurons endings [389]. In addition, ACh release is controlled by other mechanisms, including automodulation (pre-synaptic inhibition by ACh), transneuronal (pre-synaptic inhibition by NE through  $\alpha$ 1-adrenoceptor and NPY) and trans-synaptic (via prostaglandin PGE1 and adenosine) modulations [393]. Pre-synaptic automodulation is discussed as a possible mechanism involved in paradoxical HR slowing after low doses of atropine, an  $M_2$ -receptor antagonist [394].

The ionic mechanisms of ACh action depends on its local concentration. Small amounts of ACh inhibit  $I_f$  current, while larger (20-fold) amounts inhibit  $I_{CaL}$  and stimulates  $I_{K[ACh]}$ . The  $I_f$  inhibition is achieved through the stimulation of  $M_2$ -cholinergic receptor-coupled inhibitory G-protein  $G_i$ , that results in cAMP levels reduction and a negative shift of the  $I_f$  activation curve, thereby modulating its gating properties. It was also shown that a reduction of intracellular cAMP leads to a reduction of L-type  $Ca^{2+}$  current. The latter requires  $M_2$ -receptor coupling to  $G_{\alpha 0}$  subunit and seems necessary to opposite effects of  $\beta$ -adrenergic stimulation [395].

Clearance properties depend on the rate of ACh hydrolysis by acetylcholinesterase. Its washout from the junction determines the actual local *effective concentration* of ACh [389]. Other factors, like the size of the release store terminal and diffusion to distant receptors, also influence the effective ACh concentration. ACh action on the P-cells is related

to the number of  $M_2$ -receptors and their *saturation* (Lack of changes in sinus cycle duration in response to a certain increment or reduction in stimulation frequency above or below breakpoints. In a clinical setting, saturation denotes a lack of changes in heart beat variation with alteration in heart period duration. Such a phenomenon may be observed either in an extreme heart period prolongation or shortening.). The binding of ACh to  $M_2$ -receptors is necessary for its inhibitory effect on P-cell activity. This action modulates the intrinsic diastolic depolarization rate and antagonizes simultaneous sympathetic effects. In an *in vitro* study on isolated rabbit pacemaker cells, a superfusion with ACh increases cycle length and its variation exponentially and interdependently [396]. However, in earlier experiments with vagal stimulation, a linear relationship has been observed [397]. Within a physiological (and pathophysiological) range of sinus cycle length, a linear relationship with vagal stimulation can also be seen in studies that advocate nonlinear relationships (▶ Fig. 35.38) [398]. Saturation at a longer sinus cycle length does not allow further prolongation to be linearly related, as an increase in stimulation frequency of the vagus does not result in a further substantial increase in ACh concentration (▶ Fig. 35.38 inset) [398]. A clinical study supporting such experimental data has been published [399]. Thus, two parts of a relationship can be observed, one within the usual range of the sinus cycle, where such a relationship is linear and a second within prolonged sinus cycles, where such a relationship is also linear but flat. In an extreme case, further increase in the frequency of vagal stimulation would result in significant sinus cycle prolongation. However, nonlinearities in the SAN response to stimulation of the vagus may, sporadically, result in sudden cycle shortening [377, 378]. Experimental studies have shown that under normal physiological conditions maximal diastolic potential and threshold potential are actually not affected by neural activation. However, this may not hold true in a pathological setting [396].

■ Figure 35.38

Dependency of pacemaker cycle length on the rate of vagal neural activity. Nonlinear relationship between the frequency of vagal stimulation and sinus cycle length in a rabbit pacemaker cells. Note, within physiological rate the relationship is linear. Inset: a plot of ACh concentration against the frequency of vagal stimulation indicating a phenomenon of saturation (From [396]).

### 35.5.3.2 Norepinephrine and Epinephrine

Norepinephrine (NE) is a catecholamine released from sympathetic nerve terminals, while epinephrine (Epi) is a circulating hormone synthesized in and released from the suprarenal medulla. These substances accelerate the spontaneous diastolic depolarization of the pacemaker cells via stimulation of the  $\beta$ -adrenergic receptors ( $\beta$ AR) coupled to the stimulatory G-protein  $G_s$ , with activation of adenylate cyclase and increase in cAMP levels [393, 398]. Subsequently, a shift of the  $I_f$  activation curve to a more positive voltage occurs and heart rate accelerates. In certain conditions, activation of  $I_{CA}$  and  $I_K$  channels mediates NE effects on pacemaker cells [400]. Although NE and Epi act mainly through activation of  $\beta$ AR, their effects depend on the specific properties and pathways of various types of  $\beta$ AR, as well as on the action on  $\alpha$ -adrenergic receptors ( $\alpha$ AR) [401, 402].

### 35.5.3.3 Neuropeptide Y

Neuropeptide Y (NPY) represents one of various neuropeptides that act in addition to the “classical” neurotransmitters. NPY coexists with NE in cardiac sympathetic nerve terminals. Dense population of NPY-immunoreactive nerves is found in the SAN region [403]. The NPY-nerves also form synapses on the soma and dendrites of vagal preganglionic neurons within NA [404]. Upon a direct sympathetic stimulation, NPY is co-released with NE within the  $\alpha$ -adrenoceptor [404]. Some data suggests that NPY inhibits ACh release from pre- and postganglionic parasympathetic neurons, thereby attenuating cardiac vagal action [404–407].

### 35.5.3.4 Nitric Oxide

Nitric oxide (NO) is a signaling molecule that mediates vasomotor tone, ATP production and cardiac contractility. Recently, its role as a mediator of the peripheral autonomic control of the heart has been extensively studied [408–418]. The presence of endothelial NO synthase (eNOS) in human cardiomyocytes [413] and neuronal NO synthase (nNOS) in cholinergic and sympathetic nerve terminals, as well as NO-sensitive neurons in the stellate and intrinsic cardiac ganglia argues for a role for NO in heartbeat control [408, 409, 411, 412]. Neuronal NOS is present in the central nervous system nuclei contributing to vasomotor and cardiac control, like the solitary tract nucleus (STN), nucleus ambiguus, dorsal nucleus of vagus, ventrolateral zona reticularis in the medulla oblongata, and in the periphery in carotid bodies [409, 410].

NOS inhibition has been shown to block the negative chronotropic effects of cholinergic agonists and prevent cholinergic inhibition of  $I_{CaL}$  in sympathetically activated pacemaker cells *in vitro* [414]. In a study with a nNOS inhibitor, a dose-dependent profound bradycardia has been found in parallel with a large increase in heart rate variability and, at larger doses, vasoconstriction [415]. The effects of NO donors and inhibitors on HR control are thought to be indirect, consistent with a presynaptic modulation of vagal neurotransmission and ACh release during vagal activation. A significant post-synaptic action via ACh- $M_2$  receptor coupling to eNOS has also been reported. The post-synaptic action of NO (HR acceleration via  $I_f$  activation) has been shown to be opposite to that of pre-synaptic action (HR slowing via a facilitation of the ACh release). However, data are not consistent. The importance of NO action seems to be more pronounced with age and adrenergic activation [408, 410–412].

Nitric oxide can also interfere with  $\beta$ -adrenergic signaling. This action can be mediated through cAMP degradation (either via activation of phosphodiesterase activity or inhibition of Ca channels) and the inhibition of NE release (via NO-cGMP and, independently,  $K_{ATP}$ -channel mechanisms) [408]. Additionally, NO contributes to the metabolic breakdown of NE and provides a barrier for diffusion of the NE into the bloodstream. NO can also inhibit central sympathetic neurotransmission [411, 412]. The central part of NO contribution to CV control includes the modulation of aortic and carotid mechanoreceptor reflexes, reduction in the sensitivity of cardiac baroreflex and augmentation of tonic vagal activity [410].

Recent studies indicate that NO action on the cardiac vagus might have a clinical perspective [416, 418]. In an experimental study, targeted nNOS gene transfer enhancing nNOS expression resulted in a rapid increase in parasympathetic

activity. In a study in patients with heart failure, those who were homozygous for the T/C polymorphism of the e-NOS promoter had a more advanced imbalance of the autonomic cardiac control [421] in spite of better left ventricular function.

As vagal stimulation is thought to be cardioprotective [419] and might increase the probability of survival after myocardial infarction [420], the importance of vagal modulation through NO donors [418] or NOS expression manipulations [416] awaits clinical verification.

### 35.5.3.5 Serotonin (5-Hydroxytryptamine)

All central brain nuclei that are involved in cardiovascular control are innervated by fibers containing serotonin and have direct or indirect synaptic contact with cardiac vagal preganglionic fibers that are likely to originate from within the brainstem [422]. Some vagal afferents also contain 5-HT. In addition, these regions express a wide range of 5-HT receptors. The blockade of 5-HT<sub>1A</sub> receptors attenuates the bradycardic response evoked by baroreceptor and cardiopulmonary receptor afferents stimulation. However, the number of 5-HT receptors and variable effects of their activation/inhibition limits understanding of their functional roles [422].

### 35.5.3.6 Neuregulins

Neuregulins are growth factors that are required for the maintenance of ACh receptor-inducing activity of nicotinic receptors. A recent observation in an experimental study in mice with neuregulin-1 gene deletion supports a role for neuregulins in maintaining normal parasympathetic modulation of excess  $\beta$ -adrenergic stimulation of the heart [423]. It might be of clinical importance in patients treated with cardiotoxic drugs that are known to suppress neuregulins signaling. Such drugs, i.e., doxorubicine, can lead to the development of cardiac impairment that is accompanied by a reduction in parasympathetic activity that may even precede the occurrence of overt heart failure [424].

## 35.5.4 Local Tissue Factors

---

Locally released mediators, mainly neuropeptides, may generally act as neurotransmitters, neuromodulators or neurohormones. Substances, like vasoactive intestinal peptide, somatostatin, substance P, neurotensin, phenyl-histidin-isoleucine, dynorphine or melatonin-stimulating hormone are released from neuronal endings within the SA node or from interconnecting neurons in peri-nodal ganglia. Peptides synthesized locally in the endothelium of coronary microcirculation or in the SA node, atrial or ventricular myocytes, can modulate sinus beat formation [425, 426]. Positive chronotropic action was observed after stimulation with adreno-medulline, angiotensin II (via AT<sub>1</sub> receptor), atrial natriuretic peptide C and endothelin (via ET<sub>A</sub> receptor), while a negative chronotropic effect was observed in response to bradykinin, somatostatin and endothelin (via ET<sub>B</sub> receptor) [425, 426]. Other peptides (ANP, BNP, substance P) are considered as cardiac rhythm modulators. However, evidence for their direct actions are conflicting [427]. Cholinergic and sympathetic neuron activity can also be modulated by several amino acids, purine derivatives, and free radicals [428]. A role for all of these local factors is probably limited in a normal physiological state.

## 35.5.5 Mechanical-Electrical Feedback

---

Active and passive changes in the mechanical load of the heart, either physiological or pathological, can influence the initiation and propagation of cardiac electrical excitation via pathways that are intrinsic to the heart itself. This cross-talk between mechanical and electrical activity is referred to as contraction-excitation or mechanical-electrical feedback (MEF) [429]. Processes involved in the MEF include stretch-activated ion channels in cardiomyocytes, changes in calcium handling, interaction with other mechano-sensitive non-myocyte cells, or stimulation of protein expression, local

peptides secretion, and biochemical changes [430, 431]. Mechanical factors are believed to be involved in heartbeat triggering during the early stages in embryogenesis [432]. The mechanical contribution to HRV can be observed in heart transplant patients, in whom a small (2–8% of normal) RSA has been recorded [433]. Similar findings have been reported in individuals after brain death [434].

### 35.5.6 Vascular Factors (Endothelium)

---

In general, the ANS and endothelium play opposite roles in controlling vascular tone through their action on the vascular smooth muscle layer, which lies between the two [435]. There is evidence that the ANS directly influences the endothelial cell function due to the presence of  $\alpha_2$ - and  $\beta$ -adrenoceptors and muscarinic receptors. The activation of  $\alpha_2$ -adrenergic and muscarinic receptors results in eNO release and subsequent vasodilation. In addition, sympathetic activation can stimulate the release of endothelium-derived contracting factors. The effect of ANS stimulation can be observed despite the presence of major conduit vessels that do not receive direct innervation. On the other hand, the endothelium may affect the extent of ANS-mediated vascular tone mainly through the changes in NO production and release [435]. The role of the endothelium in mediating ANS effects increases in clinical entities, in which endothelial dysfunction is a common feature (e.g., diabetes mellitus, hypertension).

### 35.5.7 Hormonal, Inflammatory and Other Humoral Factors

---

#### 35.5.7.1 Renin–Angiotensin–Aldosterone System

The renin-angiotensin-aldosterone system (RAAS) interacts with the autonomic control of the heart at both central and peripheral levels [425]. Angiotensin II (AngII), a key hormone of RAAS, enhances central sympathetic tone and facilitates the NE release from sympathetic nerve terminals [436]. The net effect of RAAS activation is related to the entire circulatory response (circulating AngII level), cardiac local AngII action, and central local interaction within cardiovascular and respiratory centers [425, 437]. The magnitude of RAAS-ANS interactions depends on genetic variations (polymorphisms) within RAAS [438, 439]. In addition, the response of the RAAS blockade (with either ACEI or ARBs) varies, as different agents of these classes have been shown to exhibit divergent effects on autonomic function [440–442]. In addition, these effects depend on the initial status (before treatment) of the autonomic balance, with negligible changes in healthy persons or significant, albeit not uniform, changes in patients with hypertension or heart failure [440–442]. Sympathoexcitatory action of aldosterone (central or peripheral) both directly or via an inhibition of nitric oxide synthesis [443], together with the involvement of bradykinin, with its direct chronotropic effects [444, 445], further complicate explanation of the effects of RAAS activation or inhibition on cardiovascular autonomic control.

#### 35.5.7.2 Hypothalamic–Pituitary–Adrenal System

Corticotropin-releasing hormone (CRH) is the principal regulatory neuropeptide that mediates stress-related biological responses as a physiologic regulator of adrenal epinephrine secretion [425, 446]. Neuroanatomical studies show a projection of CRH-fibers linked directly to autonomic regulatory nuclei in the brainstem [447, 448]. There is little experimental evidence of its sympathotonic effect. This action depends on a heterogeneous distribution of CRH-receptor subtypes between ANS brain centres and the heart and vasculature [447–449]. Recent studies have shown the presence of endogenous agonist for CRH2-receptor, referred to as urocortin, which mediates many actions previously attributed to CRH [450]. Interestingly, the results of a study in CRH2-receptor-deficient rodents suggest that CRH may act on a long time scale, i.e., h, thereby influencing the circadian rhythm of HR and its variation [451]. Adrenocorticotropin and cortisol actions are very complex and diverse, depending on the magnitude and length of stressful conditions [452]. Although they are involved in circadian and ultradian (12-h, 90-min) circulatory oscillations, short-term fluctuations (3-min) have been observed [453]. An increased vagal HR control has been reported in a clinical setting such as hypercortisolemia [454].

### 35.5.7.3 Insulin-Leptin-Adiponectin and Inflammatory Cytokines

Insulin leads to an acute hyperpolarization of the plasma membranes. With respect to excitable cardiac conduction tissue, this may result in an attenuation of the firing response to stimulation and desensitization of HRV during euglycemic hyperinsulinemia in subjects with intact autonomic control [455–459]. Insulin also affects the sensitivity of arterial baroreceptors. Insulin exerts its action indirectly through adrenergic activation that is expressed as a centrally-mediated stress reaction, an increase in the firing rate of adrenergic nerves and a shift in the sympathovagal balance in the HRV power spectrum [456–459]. These effects are age-dependent [460].

Insulin action, like other trophic factors (growth hormone, tumor necrosis factor  $\alpha$ , transforming growth factor  $\beta$ ), might be also related to the modification of  $M_2R$  expression via transcriptional regulation and  $M_2R$  downregulation. These changes may lead to parasympathetic withdrawal [459, 461]. Clinical studies suggest that parasympathetic modifications can occur early on in the development of obesity and diabetes and are concomitant with a greater variation in plasma insulin levels [460, 461] and insulin sensitivity or resistance [462, 463].

Leptin, the adipose tissue hormone, plays a crucial role in body weight control. A release of leptin is under tonic feedback control by the sympathetic nervous system. Adrenergic neurotransmitters exert an inhibitory effect on leptin release and synthesis [464]. Actually, leptin itself might influence the sympathetic neural drive and either acutely or chronically increase HR. This action can be completely reversed by a combined adrenergic blockade [465]. The significance of leptin-sympathetic activity in normal subjects is not clear, as a greater correlation with HR alone than with sympathetic nerve traffic has been reported. However, gender differences have been observed [466]. Recently, an association of leptin circadian and ultradian rhythms with a very-low oscillation of HR has been reported [467]. Also, the G/A polymorphism in the human leptin receptor gene influences sympathovagal balance.

Adiponectin is an adipocyte derived hormone which acts on the CNS to control autonomic function, energy and cardiovascular homeostasis [468, 469]. It acts as an insulin-sensitizing hormone and its circulating concentration is inversely related to adipose tissue mass [468]. Adiponectin receptors have been found in brain nuclei, playing a central role in the integration of cardiac autonomic control where it interacts with neuropeptide-Y neurons [470, 471]. Low serum adiponectin has been shown to negatively correlate with a sympathovagal index in patients with type-2 diabetes [472]. Hypoadiponectinemia has also been reported to be associated with sympathetic overactivity in obstructive sleep apnea syndrome [473].

Inflammatory cytokines are normally produced by the immune system. However, their excessive expression can in some circumstances lead to damage of various tissues, as they are involved in chronic inflammatory diseases, including atherosclerosis among others [474]. Experimental and clinical evidence indicates that stimulation of parasympathetic activity (via the nicotinic receptor) can result in anti-inflammatory action via inhibition of the production of some cytokines, like tumor necrosis factor  $\alpha$ , interleukin-1, interleukin-6 and interleukin-8 [475]. Activated macrophages and lymphocytes also express specific receptors for other neurotransmitters released by the autonomic and central nervous system, including those mentioned above [475].

On the other hand, there are many clinical reports on the association of noninvasive measures of cardiac autonomic control (on the basis of HRV analysis) with the most commonly examined inflammatory substances, like C-reactive protein, interleukin-6 and TNF- $\alpha$ . However, negative observations also exist [370, 476, 477].

### 35.5.7.4 Gonadal Hormones

Accumulating evidence suggests that gonadal hormones, especially oestrogen, have significant effects on the brain, peripheral efferent nerves and signaling pathways of effector organ/cells that respond to neurotransmitters [478]. Gonadal hormone signals are mediated through binding of steroids to cytoplasmic/nuclear receptors (genomic actions) and membrane receptors (non-genomic actions). Nuclear oestrogen receptor and membrane binding sites for oestrogen, progesterone and testosterone have been identified in brain nuclei involved in the regulation of cardiovascular function [478].

The central action of oestrogen includes increased vagal tone via stimulation of choline uptake and ACh synthesis and suppressed sympathetic efferent activity via the stimulation of catalytic activity of catechol-0-methyltransferase and monoamine oxidase. On the contrary, testosterone increases sympathetic activity via the stimulation of the synthesis of

NE and neuropeptide Y and the inhibition of NE clearance. Oestrogen increases the density and affinity of muscarinic receptors. In the periphery, the actions of gonadal hormones are similar to those acting centrally. Under experimental conditions, exogenous oestrogen and progesterone increases the density of  $\beta$ -adrenergic and muscarinic receptors in the heart, while testosterone stimulates choline uptake and tyrosine hydroxylase (catecholamine synthetase). Some effects of gonadal hormones are mediated through nitric oxide [478].

There are differences in the parasympathetic and sympathetic responsiveness in females and males - the parasympathetic response is greater in females and the sympathetic response greater in males. There is more pronounced bradycardia after vagal stimulation. Apart from experimental data, there are concordant data indicating the positive correlation between oestrogen level and cardiac vagal activity that can be observed during either the menstrual cycle or the menopausal period [479–482]. Some of these changes can be related to the action of endogenous progesterone-related steroids, which inhibits muscarinic receptors probably via their allosteric conformation and increases central NE release [478]. The attenuation of HRV has also been observed during progestogen-containing replacement therapy [483]. However, in a randomized trial on hormone replacement therapy in postmenopausal women, multiple 24-h HRV indices remained unchanged [484]. However, it has to be noted that the approach used in this trial is too crude to explore cardiac autonomic control.

### 35.5.8 Thermoregulation

---

Heart rate (or pulse rate) changes with hyper- or hypothermia are easy to detect. In some disease states (e.g., typhoid fever), a lack of heart rate acceleration, or even HR slowing in spite of increasing body temperature, has been considered to be an ominous sign by attending physicians.

Thermoregulation is a complex integrative process generating patterns of autonomic, motor, endocrine and behavioral changes in response to endogenous and environmental challenges. By considering the impact of thermoregulation on cardiac autonomic control, both circadian variation of body temperature balancing over a core temperature “set-point” and reactivity to cold or heat exposure can be investigated.

Circadian variation of body temperature is related to the central pacemaker located in suprachiasmatic nuclei, acting upon hypothalamic centres modulating the set point, and altering the thresholds for cutaneous vasodilatation and sweating [485, 486]. This circadian rhythm is involved in the regulation of the sleep–wake cycle together with pineal melatonin rhythm, and the responsiveness of the circadian pacemaker to light. From this point of view, thermoregulation is associated with the circadian rhythm of heart rate and its variation, being similar to sympathetic rhythm and opposite to cardiac vagal rhythm. There is neuroanatomical and neurochemical evidence linking central sympathetic activity with the sleep-wake clock and temperature rhythm [487].

The potentiation of cardiac vagal action in response to cold and vagal inhibitory effects during heat stress has been reported [488–490]. Also, thermogenic-related changes within cardiac autonomic control have been studied in response to various meals [491]. Variations in the frequency of the thermal component of HRV has been shown to arise from variations in the time delay in response to a periodic thermal stimulus and has been referred to as thermal entrainment [492].

### 35.5.9 Architecture of Cardiac Autonomic Control

---

#### 35.5.9.1 Anatomical Basis for Cardiac Autonomic Control

##### Efferent Limb of Cardiac Vagal Control

Inhibitory vagal motorneurons originate in the dorsal vagal nucleus (DVN) and nucleus ambiguus (NA). The preganglionic motor neurons in the DVN and NA may exert preferential control over separate populations of neurons within the intrinsic cardiac ganglionated nervous system [493]. Their activity is characterized by tonic discharges modulated in phase with respiration. However, they are not able to generate spontaneous activity. Instead, their action potential generation rate follows the impulsation of glutaminergic neurones from the solitary tract nucleus (STN) in the dorsal medulla, where all afferent autonomic fibers are terminated. The importance of diverse cardiac vagal efferents may lie in

the fact that an intact DVN is not necessary for an efficient baroreceptor reflex, while other cardiopulmonary reflexes are critically-dependent on an intact DVN [494, 495].

Vagal efferent motoneurons sprouting to the mediastinum form the anterior and posterior cardiac plexus. Aside from presynaptic parasympathetic fibers, these plexi also contain presynaptic sympathetic fibers, intermediate purinergic neurons and autonomic ganglia [496]. Postsynaptic fibers of the vagi preferentially innervate SAN and AVN regions and atrial muscles [497]. Parasympathetic innervation of the ventricle is rather sparse and, accordingly, the ACh concentration in ventricular tissue is lower, achieving approximately  $\frac{1}{4}$  of its concentration in the atria. Although a weak inhibitory action of parasympathetic stimulation on LV hemodynamics can be observed in experiments, especially when the sympathetic drive is augmented (*accentuated antagonism*), such an effect seems to be negligible in physiology [498].

The main effect of vagal stimulation is a reduction of sinus node rate. The magnitude of sinus cycle prolongation is greater after stimulation of the right vagus nerve, while the left vagus nerve exerts a stronger inhibitory action on the impulse conduction through the AV junction. A negative chronotropic action of vagal stimulation is phase and frequency-dependent. The SAN response to vagal stimulation is rapid, with a latency period less than 400 ms, and is sustained for less than 5 s after cessation of stimulation [396, 498]. Since the relationship between the frequency of vagal stimulation and slowing HR is nonlinear, changes in the heart period (sinus cycle) seem to be a better indicator of vagal influences [396]. However, it has to be remembered that the time-delay of the vagally-mediated response can vary significantly not only in healthy people, but even more so in patients with cardiac disease [499].

#### Efferent Limb of Cardiac Sympathetic Control

Pre-motor sympathetic neurons are located in clusters in four topographically defined nuclei in the intermediate gray matter on either side of the spinal cord (mainly intermediolateralis thoraco-lumbalis pars funiculus) [500]. Presynaptic sympathetic stimulating fibers spread like the sympathetic nerves into the thoracic sympathetic ganglia. Postsynaptic fibers from these ganglia travel by two pathways: firstly as sympathetic nerves directly to intrathoracic extra- and intra-cardiac plexi, further innervating atrial and myocardial muscle, and secondly, as sympathetic fibers of the stellate ganglions joining the vagi, traveling to specialized cardiac self-excitabile and conducting tissue [500]. The sympathetic fibers traveling with the vagus nerve may contribute to the axo-axonal synapses that have been observed to lie between these nerves, providing a morphological basis for the observed vagal-sympathetic interaction [501].

#### Afferent Limb of Cardiac Autonomic Control

In general, cardiovascular afferent neurons are divided as those that are sensible to mechanical deformation in the region of their sensory endings (mechanosensors) and those that detect alteration in chemical milieu surrounding their sensory neurites (chemosensors) [397]. Anatomical and functional data indicate that most of afferent neurons can simultaneously transmit mechanical and chemical signals [502]. Also, the distribution of neural somata of different sensors is similar throughout nodose, dorsal root, intrathoracic and cardiac ganglia.

Mechanosensors localized in the right ventricular papillary muscle transmit RV loading or pressure in a linear and reciprocal manner. Those distributed throughout the outflow tract of the right and left ventricles sense development of chamber pressure, but their exponential activation patterns vary. Significant populations of mechanosensors along the adventitia of the inner arch of the thoracic aorta and the base of both venae cavae precisely detect phasic mechanical changes that are undergone during each systolic and diastolic event.

There is a limited population of chemosensors, which are activated when exposed to an altered concentration of a variety of local chemicals. Most local mechanical and chemical stimuli sensed by the neuronal endings are transmitted to adjacent neurons that form local circuit interconnections at cardiac and intrathoracic ganglia. These functional linkages are relevant to short-loop cardio-cardiac and vascular-cardiac reflexes. Sensory information arising from the heart and major vessels initiate central and peripheral reflexes that control the activity of extracardiac (long- and short-loop) and intrinsic cardiac motoneurons (ultra short-loop) [496, 503].

The direct measurement of vagal nerve activity is usually employed in experimental settings. However, the invasive nature, need for anesthesia and limited functional and behavioral contexts restrict the utility of the direct approach. Occasionally, direct recordings can be made from cervical vagal afferents and their stimulation can be applied to humans [504].

### 35.5.9.2 Local Cardiovascular-Cardiac Reflexes

Cardiac mechanosensory reflexes characterize short-term latency due to a relatively short distance to the first synapse. The short-term scaling properties are responsible for the cardiac motorneurons' differential activation at any phases of the cardiac cycle [505]. Cardiac mechanosensitivity seems to be related to an expression of titin [506]. Some intrathoracic efferent neurons display activation reflecting initiation of the aortic and carotid baroreflex. In addition, the stretching of vena cava mechanosensors (which can be found with venous congestion) trigger intrathoracic reflexes.

Cardiac chemosensory reflexes modulate large numbers of cardiac motorneurons over longer timescales and multiple cardiac cycles. They also lead to the resetting of cardiac motorneuron activity for a period considered to be long enough to indicate the retention of information (*memory* (Biological phenomenon of determinism in which future events are causally set by past events)) [507].

### 35.5.9.3 Accentuated Antagonism

The nonlinear nature of autonomic interactions within the sino-atrial pacemaker complex is emphasized when both arms of autonomic cardiac control are activated. Levy et al. found that the cardiac pacemaker response to the vagus nerve stimulation is greater with a rise in sympathetic activity (*accentuation*) in spite of their opposite action (*antagonism*) [15, 498] (● Fig. 35.39). Such a phenomenon, referred to as *accentuated antagonism*, can be seen in very fit humans. In older people, and in certain clinical pathophysiological settings, this phenomenon cannot be observed easily, as the vagal activity or inhibitory effects of its stimulation are usually depressed. Pyetan et al. [508] found an increase in power at respiratory frequency in a healthy young adult with a high level of cardiac vagal tone subjected to a relatively large

■ Figure 35.39

Sympathetic-parasympathetic accentuated antagonism. Changes in HR in response to various vagal and sympathetic stimulation. Vagal inhibition is greater when sympathetic activity increases, sympathetic stimulation is much less when vagi are active. The formed exemplifies synergism, the latter antagonism (From [A31]).

cumulative dose of atropine. They interpreted such a response as a feature of the reduction of sympathetic influence accompanying vagal effector inhibition.

### 35.5.10 Nonregulatory Reflexes Involving Co-Activation of ANS

Classic reciprocal action between sympathetic and parasympathetic outflows represents a highly simplified description of cardiac autonomic control. The presence of the accentuated antagonism between two branches of the ANS in physiologic and pathophysiologic settings can find further support in some protective reflexes that are accompanied by excitation of both autonomic outflows [509].

Among reflexes that are accompanied by the co-activation of both ANS branches, the peripheral chemoreflex, diving response, oculocardiac reflex, defense response, and somatic nociception response are considered [509]. The common functional significance of these reflexes/responses is considered to coordinate the relationship between ventricular contractility and heart rate with sympathetic and vagal activation targeting the ventricular myocardium and SAN, respectively. This may be of special importance during a prolonged and deep hypoxia (diving response), when the bradycardic response causes a substantial fall in ventricular function via a nonneural mechanism (So-called Bowdich effect.) and sympathetic co-activation may serve as a compensatory response to maintain stroke volume, as well as blood flow and oxygen delivery to the heart through action upon coronary arterioles via  $\beta$ -adrenoceptor stimulation. Another possible significance is related to vagally-mediated tachycardia, when both branches of the ANS act synergistically. It is suggested that this paradoxical feature is related to ACh release in the intrinsic cardiac ganglia neurons along with activation of chromaffin cells to release catecholamines. Alternative explanations include the muscarinic receptor mediated release of neurotransmitters co-localizing cardiac vagal fibers, which may have the same effect as NE of increasing HR.

#### 35.5.10.1 Peripheral Chemoreceptor Reflex

In experimental settings, activation of carotid body chemosensors resulted in the transient increase in cardiac vagal and sympathetic activity reflected by a profound bradycardic response. Co-activation of branches of the ANS can also be elicited by a mild prolonged hypercapnia and mild hypoxia, whereas a co-inhibition occurs in response to hypocapnia.

#### 35.5.10.2 Diving Reflex

Vagally-mediated bradycardia is a major feature of the diving response in humans and other mammals. It is suggested that facial or nasopharyngeal stimulation is responsible for this reflex. Coincidence of sympathetic activation during the diving reflex is expressed as the occurrence of ventricular arrhythmias, including polymorphic VT, and shortening of the QT interval, that can be prevented by  $\beta$ -adrenoceptor blockade with propranolol.

#### 35.5.10.3 Oculocardiac Reflex

The stimulation of trigeminal nerve endings triggers a reflex that produces vagally-mediated bradycardia and which in extreme cases may lead to cardiac arrest. Historically, this reflex has been used as a manual procedure for the termination of paroxysmal tachycardia (Aschner) by putting pressure on the ocular bulbs (more precisely on the corneal surface). A sympathetic component of this reflex is expressed as increased outflow to the ventricles and, subsequently the occurrence of ventricular ectopic beats.

#### 35.5.10.4 Defence Responses

Experimental stimulation of different discrete hypothalamic areas evokes various possible patterns of ANS activation (sympathetic activation/vagal inhibition or co-activation or co-inhibition). In the case of centrally-mediated ANS co-activation, HR follows vagal changes. The defence-like response may also occur in the response to alerting-eliciting acoustic stimuli (startle reflex). Despite these stimuli provoking a small transient tachycardia, a pronounced negative chronotropic effect of sympathetic blockade suggests a role of vagal co-activation. Interestingly, the vagal response rapidly habituates with repeated stimuli, while sympathetic activation persists.

#### 35.5.10.5 Somatic Nociception Response

Stimulation of somatic nociceptors typically leads to tachycardia, increase in blood pressure and hyperpnea in animals and humans. Direct cardiac vagal nerve recording has shown that the nociception response involves augmentation in the activity of cardiac vagal outputs. It is postulated that this complex response is centrally-mediated and modulated by central respiratory activity. Nociception-evoked tachycardia seems to be vagally-mediated and can be attenuated by atropine. However, a combined blockade is necessary to abolish this chronotropic response completely.

#### 35.5.11 Brain–Heart Interactions

---

It is well recognized that sympathetic and parasympathetic neurons play a regulatory role in modulating cardiac dynamics. This regulatory role is achieved through a very complex structural and functional interplay between afferent neurons localized in different cardiac regions and within vascular beds (mainly intrathoracic and cervical) and efferent neurons localized in the cerebral cortex, brain stem nuclei, medulla oblongata, spinal cord, paravertebral cervical, and thoracic ganglia, as well as pericardial and intrinsic cardiac ganglia. Spatially overlapping afferent neurons differentially transduce regional cardiac and vascular events throughout each cardiac cycle directly or indirectly (via interconnecting neurons) allowing for temporally organized reflexes. All constitutive parts are redundant and stabilize the whole cardiac behavior [507].

In pathological settings, overactivity of the autonomic nervous system plays a critical role in myocardial damage and mortality [13, 510]. Therefore, abnormal cardiac rhythm oscillations can be seen in patients with stroke, subarachnoid hemorrhage, epilepsy, and head trauma [510–513]. Brain-heart interactions are also important in the pathogenesis of (a) sudden unexpected death in adults and infants, in specific circumstances (for example status asthmaticus, alcohol-withdrawal, drug abuse) [56, 510], and (b) cardiac dysfunction in tako-tsubo cardiomyopathy and pheochromocytoma, in which altered fluctuations of heart rate can be detected [514–516].

### 35.6 Determinants of HRV

---

#### 35.6.1 Genetic Factors

---

There is accumulating data confirming the role of genetic factors in HR and HRV control. Early data suggested that genetic variance can determine the arrhythmia index, the measure of RSA introduced by Schlomka, which has been reported by Fuller in 1951 in purebred dogs [517]. Kreutz et al. were the first group to identify HR-determining gene location on the rat chromosome 3 [518]. Since that time, other genes which contribute to heart rate have been described [519–523].

Martin et al. [519] performed the variance decomposition linkage analysis for genomic screening in 2209 individuals and found that the heritability of the resting HR was around 26%. In their study, HR linkage on chromosome 4 (4q28.2) was observed. Interestingly, in this region, linkages have also been found for insulin, blood pressure, abdominal subcutaneous fat, as well as for type 4 long QT syndrome, associated with bradycardia [after 519]. Similar heritability (24–27%), as well as HR linkage to chromosome 4 has been reported among hypertensives [520]. A heritability of 36% for HR and 20% for BP responses to exercise training has been found in another set of patients with high blood pressure [521] and

various candidate genes have been proposed [522]. A recent meta-analysis of genome wide scans indicates the location of a gene influencing HR on chromosome 5p13–14 [523].

The attempts that explore the HR genetic basis do not necessarily explain the genetic background of HRV. The results of the Copenhagen Holter Study indicate a significant association of a reduced HRV with the familial predisposition to premature heart attack [524]. Using a genome-wide scan in participants from the Framingham Heart Study, Singh et al. have provided evidence of linkage of the LF power to chromosome 2 and of the VLF power to chromosome 15, although the linkage odds scores have not exceeded the threshold for significant linkage on a genome-wide level [525]. Interestingly, around the region of interest (chromosome 2), a candidate gene for *KCNJ3*, a human gene encoding the G-protein activated inwardly rectifying potassium channel, known to be involved in HR regulation [526], has been identified. Also, candidate genes for human neuronal nicotinic cholinergic receptors have been reported on chromosome 15 [527].

The combined results of the Framingham Heart Study and Framingham Off-Spring Study (1151 subjects) indicate the presence of a significant correlation among standard HRV parameters in siblings (between 0.21 and 0.26), compared to spouses (0.01–0.19) [528]. Genetic factors seem to be responsible for substantial inter-individual variations in HRV that reached 23% in the Framingham cohort. However, after the adjustment for HR, this proportion is reduced to 9–22%, suggesting an involvement of similar genetic factors that determine both the HR and HRV [528]. Genes account for 13–23% of the variation among spectral HRV measures in this population [529]. Heritability estimates of 0.41–0.45 for SDNN and of 0.39–0.45 for RMSSD from 5-min ECG recordings have been reported to be independent of breathing mode (spontaneous vs controlled) [530].

Associations between HRV and genetics are frequently explored in twins [531–539]. In a small sample of twins, Piha et al. found that both ANS branches were strongly related to genetic factors independently of body mass [531]. In a larger sample of 160 twins, the RSA appeared to be determined by stable genetic factors and variable environmental components [532]. Snieder et al. have estimated a genetic contribution to RSA of 31% at rest and between 28% and 43% at four different stress task conditions [533], independently of respiratory rate. A genetic contribution to the mean ambulatory SDNN index (ranging from 35% to 47%) and the mean ambulatory RMSSD (ranging from 40% to 48%) has been reported [534]. Short-term vagally-related HRV measures (RMSSD and HV power) at rest and under stress have been found to be largely influenced by the same gene [535]. An association of reduced HRV and depression has been found to be genetically-predetermined [536]. Also, the dipper-pattern of the blood pressure has been found to be heritable [537]. Importantly, HRV-related familiarity can be detected already in newborns. However, environmental influences seem to play a greater role than genetic factors early in life [538].

In a recent study, an association of parasympathetic activity with the variation in the choline transporter, a component of ACh neurotransmission, has been reported. Subjects having any T-allele (TT or GT genotype) had greater HF power and lower LF power and LF/HF ratio, compared to subjects with GG genotype [539]. Studies that compared HRV in relation to known genetic polymorphisms (ACEI, angiotensinogen, uncoupling proteins) complement evidence for a genetic background of HRV [540, 541]. Furthermore, an experimental investigation has confirmed the importance of G-protein heritability for HR autonomic control [542].

## 35.6.2 Constitutional Factors

### 35.6.2.1 Age

Heart rate and its variation is critically dependent on age, especially if one considers the period of the entire lifespan [322]. Within the lifespan, two distinct phases are present with distinct HRV behavior. The first phase is a period of development and maturation, and the second starts early in adulthood and is related to aging and senescence. Therefore, in studies in which the age-range is limited (e.g., a young adult cohort or middle-aged subjects) the possibility of detection of significant HRV changes with age is *a priori* reduced. Also, data on the age-dependence of HRV is generally obtained from cross-sectional studies. To evaluate within-person age-related changes, longitudinal observations seem to be more appropriate.

### Autonomic Control Changes During Development

Detectable variation in heart rate can already be observed in fetuses [543]. Mechanisms underlying these variations are largely unknown. An intrinsic rhythmicity of the SAN seems to determine HR changes early in gestation (9–15 weeks), albeit cholinesterase activity can be detected at the eighth gestational week. With the advance of gestation, parasympathetic effects become evident [543]. More data is available regarding maturation of cardiac autonomic control from infancy to adolescence. A dominating role of maturation of central parasympathetic signal processing has been suggested [544].

### HRV Changes During Development

The main component of HRV is attributed to RSA, which is detectable at around 33 weeks gestational age, and remains a predominant component of HRV in neonates [330–332, 545]. An earlier occurrence of HR fluctuation in the LF range (<20 week of gestational age) has been documented. However, it seems to be secondary to maternal HR and BP variation [546]. A clear dependency of all time- and frequency domain measures on gestational age has been shown [547, 548]. It has to be pointed out that, in fetuses and neonates, the spectral HRV component may have different ranges, i.e., 0.025–0.07 Hz for VLF, 0.07–0.13 Hz for LF and 0.13–1.0 Hz for HF [549]. Global HRV changes from 3 h to 7 days of post-natal life have not been consistently observed [550]. It might also be difficult to assess spectral HRV indices in this period of life, since the influence of various factors may lead to misinterpretation of HRV data [551]. A significant increase in SDNN (+20%) and MSSD (+42%) between the first and third month, with a prominent increase in SDNN following awakening (+72%) in spite of a shortening of mean RR interval, has been reported [552]. In a study by Massin and von Bernuth in 210 healthy children aged 3 days to 14 years, 24-h SDNN values were found to have almost doubled between 1 month and 1 year, and tripled at 5–6 years (tab.35.28) [331]. Further increases of SDNN and SDANN from long-term ECG recordings with maxima at a late adolescence period have been reported [332, 334]. Meanwhile, RMSSD has been found to reach a maximum value already in early childhood [332]. This is in accordance with the findings of Finley and Nugent, who have observed maxima of both short- and long-term spectral HRV indices at about 5–6 year of age [553, 554]. The maxima of short-term HF and LF power have been observed at late adolescence in another study [555]. The difference between both studies might be as a result of different data presentation (instantaneous HR vs RR), length of ECG recordings and the use of different algorithms (FFT vs AR). The significance of data presentation and length as well as choice of algorithm for HRV power spectrum estimation is discussed in 35.4.

### 35.6.2.2 Cardiac Autonomic Control Changes Related to Aging

Aging is associated with complex and diverse changes in cardiovascular structure and changes [556]. The most important variations are listed in [Table 35.33](#).

Some of these changes gain a special importance when HRV is considered. A reduced responsiveness of the SAN to adrenergic stimuli and an increased responsiveness to vagal stimulation is the most relevant [397, 556–560]. As intrinsic properties of the SAN are altered, leading to the partial uncoupling of P-cells [561], an increase in the level of sympatho-excitatory hormones is detected (increasing plasma NE) as well as central sympathetic discharge (increasing efferent sympathetic nerve activity in microneurographic studies) [562]. This is accompanied by a reduction in a high affinity state  $\beta_1$ -adrenergic receptor density, with changes in the proportion of  $\beta_1$ AR to  $\beta_2$ AR from 4:1 to 2.5:1, mimicking that observed in heart failure [558]. A 30% reduction in the amount of activated adenylyl cyclase in response to Gs-mediated  $\beta_2$ AR stimulation has been reported [557, 558]. As a net result, although aging is associated with sympathetic over-activity, HR and age has not been correlated in the majority of studies.

On the other hand, muscarinic receptor density is increased in older subjects in spite of a surprisingly increased responsiveness to vagal stimulation [556, 564]. This seems to indicate that a reduced central vagal outflow can play a greater role in tonic cardiac parasympathetic control changes with age than SAN responsiveness to ACh itself [556, 564]. However, these changes are not consistently observed, and even the opposite has been reported [557, 558]. In terms of  $M_2$ -R mRNA concentration and muscarinic/ $\beta$ -adrenergic mRNA proportion, the heart does not age as a unit: age-related changes are focused on the SA node area [564]. Among possible mechanisms leading to a reduced vagal tone in elderly people, a reduced baroreflex sensitivity mainly due to increased arterial wall thickening and stiffness, and a reduced arterial wall distensibility together with endothelial dysfunction (mainly a reduction in NO) are of greatest importance

Table 35.33

Factors affecting ANS control and HRV measures associated with aging (Modified after Ferrari et al. [550, 556])

Level of integration	Morphological changes	Functional changes	Consequences (regarding HRV)
Cellular/subcellular			
<i>cardiomyocytes</i> <i>non-muscle cells</i> <i>adrenergic receptors</i> <i>muscarinic receptors</i>	Increased dimension/number Increase in collagen cross-linking Altered $\beta_1/\beta_2$ density ratio Up-regulation	Reduced responsiveness to stimuli Increased responsiveness to stimuli	Altered SAN responsiveness
Cardiac tissue			
<i>Sino-atrial node</i>	Reduced P cells: all cells ratio P-cells uncoupling	Altered pacemaker shifting Reduced SAN-respiratory coupling	Altered SAN responsiveness
Organ			
<i>Heart</i>	Increase in heart weight, LV hypertrophy/ fibrosis Decreased sympathetic innervation	Reduced lusitropic properties/ diastolic function	Altered mechano-electrical coupling/reflexes
Circulation			
<i>Endothelium</i>	Reduced NO synthesis/release Reduced SOD activity VSMC migration	Endothelial dysfunction Increased oxidative stress Increased total peripheral resistance	Reduced baroreflex sensitivity
<i>Arteries</i>	Increased subendothelial collagen Increased intima-media thickness VSMC proliferation Reduced elastin Increased elastin fragmentation	Increased total peripheral resistance Decreased arterial distensibility Increased pulse wave velocity Reduced cardioacceleration after baroreceptor deactivation (delayed response)	Reduced baroreflex sensitivity
<i>Hormones/ mediators</i>	Increased level of vasoconstrictive peptides Increased ANP/BNP synthesis/release Increased inflammatory mediators level	Endothelial dysfunction Increased oxidative stress	Reduced baroreflex sensitivity
Brain			
ANS	Loss of neurons Pigments accumulation Neurotransmitters activity changes	Altered responsiveness to afferent inputs	Central control alteration

[556, 565]. Only a few studies systematically addressed the issue of cardiopulmonary reflexes in aging and the evidence is in favor of a blunting of the hemodynamic and humoral components of cardiopulmonary responses. However, evidence to the contrary does exist [556].

Consistently observed age-related reduction in vagal tone measures should not simply be interpreted as signs of vagal neuropathy or an impaired parasympathetic control. Instead, reduced afferent signals coming from peripheral sensors may lead to a reduced central vagal outflow, irrespective of an altered SAN responsiveness. Moreover, age related autonomic innervation changes can appear relatively early in adulthood (>35 years of age) [557] mainly as a reduction in sympathetic nerve endings [566]. Generally, aging is associated with alterations in cardiac autonomic control that, not surprisingly, lead to consistent observations on a reduction of HRV with age. However, other factors not necessarily directly connected to autonomic modulation, are also changed in ways that actually are associated with a reduced HRV, especially over a 24-h period.

#### HRV Changes Related to Aging

An age-dependent reduction in the RSA from short-term ECG tracings has been reported as early as 1940 by Schlomka et al. [after 8]. Further studies in adults consistently reported a reduction in time-domain HRV measures with aging

■ Figure 35.40

Age-dependence of the SDNN from 24-h ECG in healthy subjects. A combined data from 18 studies in children and adults. HRV reaches its maximum in late adolescence or early adulthood. Thereafter HRV reduces gradually. Confidence limits (1.96 SD) shown do not mean the normal limits (Author's data).

[567–570]. Interestingly, the RSA assessment over five heartbeats has originally been proposed to estimate “cardiac age” [570]. Similarly, the estimation of “cardiac age” has been proposed by others, though, by using a more sophisticated approach [571]. Actually, there is only one alternative method for “cardiac age” estimation, namely coronary artery calcium scoring on cardiac computed tomography [572].

The rates of HRV decline at different stages in the life course vary with different traditional HRV measures and the times of recordings. For the HRV indices that are acknowledged to strongly relate to vagal tone (RMSSD or pNN50 from 24-h recording and almost all statistical descriptors from short-term recordings) the decline is exponential and occurs early in adulthood, beginning usually well before the fourth decade of age [321, 322]. At the sixth decade of life, pNN50 and RMSSD reach values that are 25% and 50% of that observed in young adults. Over the following decades, these indices do not change significantly. In 4% to 12% of people after 65 years of age, these values can be as low as cut-off values indicating an increased risk of CV mortality [322].

The 24-h SDNN and SDANN decline more gradually. According to the accumulated data from 18 Holter-based studies, SDNN is reduced by approximately 25% in middle-aged persons (compared to young persons), and by ~40–50% in the elderly (>75 years of age) (► Fig. 35.40) [64, 320–322]. There is still a small reduction of SDNN in senescence [322] (► Table 35.27). Importantly, the lowest SDNN and SDANN values in subjects  $\geq 65$  years old sporadically achieve the level indicating an increased risk for all-cause or CV death. Reported 24-h SDNN values decline almost linearly from their maximum at 20–30 years of age achieving a 25% reduction in the elderly compared to young adults with a significant proportion (25%) below the cut-off value for being at risk [322].

Data from studies on HRV analysis from shorter ECG recordings show a similar trend. In the Framingham Heart Study in 2,722 subjects with an age range of 21–93 years, the 2-h SDNN has been reported to decline by 25% in

middle-aged persons and by 40% in subjects older than 70 years as compared to young persons [573]. In another cross-sectional study in subjects aged between 35 and 65 years, the reduction of the median values of 5-min SDRR and RMSSD has reached 17% to 25% from the fourth to fifth decade of age and 7% to 11% from fifth to sixth decade, respectively [269]. In another cross-sectional study in 373 healthy Japanese (16–67 years old), the rate of short-term SDRR decrease from the third to fifth decade was greater in females (–35%) than in males (–17%), and was similar from the fifth to seventh decade (17% and 15%, respectively) [574]. Agelink et al. reported a smaller rate of the 5-min RMSSD of 33% and 22% over 3 decades in men and women, respectively [335]. In a large prospective within-persons study (1,999 participants, 29% females, mean age  $55.6 \pm 6.0$  years) over the 5-year follow-up period, the mean 5-min SDRR decrease of 2.3% after 55 years of age was observed only in males, in contrast to a mean increase of 3.9% in females [575].

The power of the HF component declines exponentially from the maximum value usually between the age of 16–20 with almost 50% reduction over next 2 decades [555]. In a longitudinal investigation of 1,780 young Finnish children re-examined at the ages of 24–39 years, the short-term (3 min) lower 2.5% reference limit of HF power decreased by more than 50% from young adulthood to middle-age consistently for three heart rate strata [576]. Thereafter, the 24 h-HF power reduced at a rate of 10–15% per decade [317, 577]. After 65 years of age, variations of HF power are smaller or insignificant [317, 577]. In a longitudinal within-persons study the power of 24-h HF was unchanged over 15 years in a small sample of elderly persons [578]. In another longitudinal study, a 6% reduction of the short-term HF power over 5 years of follow-up has been observed only in males [579]. At the same time, the lower normal limit of the 24-h HF power diminishes with age, being highest in subjects who are 20 years old, decreasing by 50% at 40 years of age, with a further reduction to 20% of the maximum values at 65 years of age [580].

The power of the LF component decreases more gradually from the LF maximum value at 20–30 years of age, with a rate of ~20% per decade [317, 320]. A similar rate of LF power decrease with age has been reported in a cross-sectional study on short-term HRV [335]. A steeper decline of ~30–35% per decade was found in the Framingham Heart Study population [573]. Biphasic changes with 50% reduction between the fourth and fifth decade and 10% between the fifth and sixth decade [269], as well as oppositely directed changes with a rate of 20% reduction between 35 and 55 and of ~50% from 55 to 65 years of age have been reported [574]. In a longitudinal study in young adults, the LF power diminished by 50% between 24- and 39-year-old persons [576], while in another longitudinal study in the elderly followed over 16 years, a continuous decrement of the LF power was noted [578]. A significant reduction of 11.3% in older males and an increase of 4.1% in older females has been reported over a 5-year period of follow-up [575]. There is also a report in which the LF power in subjects  $\geq 60$  years was comparable to that of younger people (<35 years old) despite a significant 40% reduction in cardiac NE turnover and peripheral MSNA over 2 decades [581].

The VLF and ULF power are almost linearly age-related. A rate of VLF power reduction of 12% per decade from the base value at age 40 years has been observed [317, 320]. A decrease of ULF power is less distinct and in persons  $\geq 60$  years of age, the ULF power represents ~90% of initial values [320].

Geometrical HRV measures are also age-dependent [64, 321, 580]. The highest value of HRVI is observed in young adults, and then it declines exponentially, reaching values of ~60% of maximum (overall 40% over 4 decades) in the seventh decade [321]. The mean HRVF decreases more gradually, from 55% at age 25 years to 45% at age 60 (overall decrease of 20% over 4 decades). Interestingly, there are distinct rates of reduction of the lower and the higher normal limits. They change from the third to sixth decade by 33% and 15%, respectively [64].

Results of investigations on age-dependence of nonlinear HRV measures are far from consistent. The DFA  $\alpha 1$  index has been shown to increase with age in several studies [320, 584, 585], decrease [327, 583], or remain unchanged [582, 586]. However, in longitudinal studies in young and elderly persons, DFA  $\alpha 1$  has been consistently found to decrease with age [578, 579]. In various reports, the DFA  $\alpha 2$  index increases [320, 583, 584], decreases [327] or remains stable over various age ranges [582, 586]. The beta-coefficient (slope of  $1/f$  power) becomes steeper with age [574, 578, 579], although in the elderly it remains stable [579]. Two distinct behaviors of the beta-coefficient have been reported depending on the frequency break-point [587]. There are other inconsistent data regarding other scale-invariant measures [583, 586].

Results of cross-sectional studies indicate a gradual decrease of the approximate entropy [320, 327, 583]. However, in a longitudinal observation, no change of ApEn has been seen [578]. Investigations on other entropy measures provide inconclusive data [582, 588]. In addition, aging-related alteration of the largest Lyapunov exponent has been found to differ in magnitude and direction in cross-sectional studies [327, 582, 583, 586, 588].

Multilevel influences of aging on cardiac autonomic control are reflected by changes in the baroreflex sensitivity (Table 35.33). An inverse effect of the aging process on BRS has been reported in several cross-sectional studies [589–594]. This age-association reduction has been confirmed in a number of investigations using various experimental techniques providing information on separate aspects of the BRS [595]. In a cross-sectional study, the BRS assessed by means of the Valsalva maneuver decreases by ~33% in middle-aged subjects (from  $17.8 \pm 1.8$  to  $11.9 \pm 1.3$  ms/mmHg), and by ~60% in older subjects ( $7.1 \pm 0.6$ ) [592]. A similar reduction has been found for the phenylephrine method ( $19.5 \pm 1.4$ ,  $10.7 \pm 1.2$  and  $6.0 \pm 0.6$  ms/mmHg, respectively) [593].

The vagally-related arm of the BRS loop declines by a rate of 10% per decade, while sympathetic-related BRS reduces at a rate of 5% per decade [594]. The  $\alpha$ -index of high- and low-frequency has been shown to reduce by ~33% and ~45% over 3 decades, respectively, as estimated by means of the spectral method and by 50% as estimated by means of the phenylephrine method [595]. Reduction in the BRS with age resulted in the occurrence of abnormal risk-predictive values in a significant proportion of elderly persons (30–50%). However, the proportion of abnormal BRS depends on the technique used for its assessment, with the mean BRS of 4.5 ms/mmHg with the Valsalva method (50% abnormal), 7.8 ms/mmHg with a vasopressor agent (phenylephrine, 37% abnormal) and 5.6 ms/mmHg with vasodilator (sodium nitroprusside, 30% abnormal) based techniques [596]. Cumulative data indicates that in subjects older than 50 years, it is almost impossible to differentiate whether the reduction of BRS is related to the aging process or the presence of other risk-factors, with systemic hypertension being amongst the most important [590, 597, 598]. However, spontaneous BRS during controlled breathing has been shown to linearly decrease from 50 to 75 years of age [599]. In one reported longitudinal study, the aging effect on spectral BRS has been evaluated in 205 men ( $36 \pm 10$  years at entry) over a mean 5-year period [600]. The rate of BRS decrease of 3.6% per year until 45 years of age has been observed. In the oldest group (46–50 years at baseline), no significant change over the 5-year follow-up was observed.

Age-associated changes of cardiac autonomic control are also reflected by the effect of age on heart rate turbulence. The TO increases with age, while the TS appears to remain stable [601]. These relationships strongly depend on the duration of the preceding sinus cycle at younger ages, and the influence of the basic HR attenuation as age increases [601]. On the contrary, in another study, an inverse relation of TS with age and no relation between age and TO has been reported [366]. In a study of healthy children, lower TS has been found in those with pre-pubertal status compared to those during puberty, while TO has been found to be age-independent [602]. Thus, conclusive statements on the age-relationship cannot be established as yet.

### 35.6.2.3 Gender

Gender differences in cardiac autonomic control are multi-factorial and originate not only from differences in hormonal status, but also from distinctive heart rate, blood pressure and respiratory control, constitutional and demographic factors, life-style and psycho-behavioral factors, as well as intrinsic central and peripheral nervous system features. Some of these factors with their possible influences upon HRV are presented in Table 35.34. These factors may have a different role to play at various points throughout life, between women and men actually disappear.

Gender related differences in the time and frequency domain variables are the subject of diverse opinions. In most studies, some HRV measures are reported to be gender-related whereas others are not. Age and race (where applicable) are only rarely added as the covariate [248, 269, 315, 615, 616]. In a small number of studies, heart rate has been analyzed as a covariate or a separate analysis for various heart rate strata has been performed [319, 573, 576]. A combination of reported relationships between HRV and gender is schematically presented in Table 35.35. More detailed data from short-term and long-term HRV studies are shown in Tables 35.36 and 35.37.

Clearly, these results indicate that global HRV measures and LF power are either comparable or lower in females, while the respiratory-related HRV measures are either similar or higher. Interestingly, time-domain short-term variation measures (RMSSD, pNN50) from 24-h ECG recordings, which are known to be closely correlated with HF power, have been found to be either similar [65, 316, 319, 321, 332], higher [619], or lower [319, 322] in women. Some authors prefer using the relative powers of LF and HF for their superiority in detecting the effect of gender [323, 324]. However, these relative spectral indices have the least well defined or even no physiological background. Evidence for lower values of HRV measures in females might be of clinical importance, although in some instances, normal limits remain to be established. For example, Gerritsen et al. proposed separate reference values of 3-min LF power for women and men, while proposing HF power and SDRR normal limits for the entire population [599].

■ **Table 35.34**

Factors associated with gender differences in HRV. See ▶ **Table 33.2** for list of abbreviations

Factor[s]	Difference	Mechanisms	Effect on HRV
Blood pressure	Lower	Baroreflex gain changes	Reduction
HR	Faster	Closer HRV-HR relationship	Reduction
Intrinsic HR	Faster	Intrinsic SAN properties	Reduction
Respiratory pattern	Thoracic	Greater intra-thoracic pressure changes	Increase (RSA)
Breathing frequency	Faster	Smaller intra-thoracic pressure changes	Reduction (RSA)
Physical fitness	Usually lower	Lower cardiac autonomic tone	Reduction
Smoking habits	Less frequent	Lower sympathetic activation	Reduction (LF)
Alcohol abuse	Less frequent	Greater cardiac vagal activity	Increase (RSA)
Psycho-behavioral factors	Multiple	Greater sympathetic activation, lower vagal sympatho-inhibitory actions	Reduction
Personality type	More complex	Multiple	Reduction
Nor/epinephrine level	Lower	Lower response to sympathetic activation Lower adrenal medullary content of Epi Higher epinephrine clearance rate Lower neuronal/extraneuronal uptakes	Reduction
Central control	Multiple	Less sensitive to excitatory stimuli and more sensitive to inhibitory stimuli, varies with oestral and menstrual cycles	Not studied
Noradrenergic neurotransmission	Higher	Increased presynaptic $\alpha_2$ -adrenoceptors number/activity varies with oestral and menstrual cycles	Not studied

■ **Table 35.35**

Patterns of HR and HRV differences in females (versus males) from short-term ECG recordings

HR	SDRR (or TP)	HF power	LF power
↑	↔	↔	↓
		↑	↓
	↓	↔	↓
↔	↔	↑	↔
			↓
	↓	↔	↔

Variability in patterns depends on age, race, algorithms used, and statistical adjustment.

Differences between women and men have also been studied in terms of nonlinear dynamics. Gender differences of fractal dynamics measures vary depending on methods and duration of registration. In short-term HRV studies, the  $\beta$ -exponent has been found to be less steep in women than in men [481, 574], contrary to long-term study findings, where a steeper  $\beta$ -exponent or no difference has been observed in females [320, 583]. Short-term and long-term DFA  $\alpha_1$  coefficients have been found to be lower in females, with no differences in DFA  $\alpha_2$  [141, 320, 583]. Higher approximate entropy in women has been observed in some HRV studies [141, 328, 583], but not confirmed by others [320]. Other indices have only rarely been studied (▶ **Tables 35.36** and ▶ **35.37**).

Actually, accumulated data indicates that gender-related differences should be taken into account or a proper statistical method should be applied for a valid interpretation to be drawn, irrespective of the duration of HRV recordings.

The influence of gender on baroreceptor reflex control of heart rate in humans is controversial. Baroreceptor sensitivity has been found to be gender-related in some studies, being lower in women compared to men [323, 593, 621–624], whereas other studies have indicated similar BRS in females and males [625–627]. The discrepancy of BRS-dependence on gender is related to various methods used, age-difference, number of examined subjects (usually small, except for [323, 593, 623]) and training status. In a study of Adbel-Rahman et al. the gender-related differences in BRS were found to depend on the pattern of the rise in blood pressure, being significant with a brief increase (53% lower BRS in females) and undetectable with sustained BP [621]. Women have been found to exhibit greater inter-individual variation [593, 626], to have a shift of the BRS with lower blood pressure [626], and to require a lower infusion rate of phenylephrine in order to increase SBP by 20 mmHg from baseline [625]. Also, the age-dependence of BRS has not been found in females in some studies [623, 627], while it has been observed in others [593]. Interestingly, many of these findings come from studies which had a negative result in assessing gender-BRS interaction [625, 626].

Effect of gender on heart rate turbulence is poorly recognized. Only one study aimed at examining HRT differences between women and men [601]. In women, a greater age-dependence of TO and a lower age-dependence of TS along with a weaker TS relationship with preceding R–R interval was found [601].

#### 35.6.2.4 Ethnicity

Ethnic differences in heart rate response to heat were reported more than half of century ago [628]. Since then, epidemiological, physiological and clinical evidence has been accumulated confirming the importance of ethnicity in the mortality and morbidity from certain cardiovascular causes [629–631]. Ethnic-related variations in the resting ECG have been reported, but with negligible clinical relevance [632].

The evidence of ethnic differences in HRV is sparse and inconclusive. Lower long-term and similar short-term heart rate variations have been reported in the fetuses of African American or Caribbean women when compared to the fetuses of white women of European-ethnic origin [633]. A smaller post-stimulus deceleration of R–R interval and smaller acceleration following four cycles has already been found in black newborns compared to white newborns [634].

Deep-breathing RSA changes in response to atropine have been found to be similar in two ethnic groups [635]. Blunting sympathetic neural modulation as indicated by a lower 24-h LF normalized power and LF/HF ratio in Afro-Caribbean American hypertensives compared to CA hypertensives has been suggested [636]. In the same study, the 1/f power  $\beta$ -coefficient was found to be similar in both ethnic groups [636]. African Americans (AA) have been found to have a lower LF and higher HF compared to Caucasian Americans (CA) in an epidemiological study by Liao et al. [248]. Also, the I/D polymorphism of the ACE genotype may play a greater role in parasympathetic cardiac control in AA hypertensives [637]. In a study in American- and European American youth, a greater age- and HR-adjusted short-term RMSSD and HF power indicates an increased parasympathetic influence on the heart in blacks [638]. AA have around a 3.5 times greater probability of having depressed ULF power, compared to CA [639]. It has also been suggested that higher HRV may buffer AA from the deleterious effects of ethnic-related stress [640]. The HF power and BRS have been found to be lower in young AA males compared to age-matched non-AA males. However, the latter was a heterogeneous group (55% CA, 31% Asian, 15% Hispanic) [641]. In addition, spontaneous BRS assessed by means of sequence method has been found to be lower in AA than in non AA [641]. In another study, resting spontaneous BRS and its change in response to lower body negative pressure were comparable in AA and CA [642].

Results accumulated from cross-sectional comparisons suggest that there is a more parasympathetic predominance in young AA, a similar autonomic balance in middle-aged AA and CA, and greater sympathetic influences in older AA than CA.

Some ethnic HRV differences can result from environmental influences. Data from a study on Caucasian lowlanders and Himalayan Sherpas show higher values of respiratory-related indices (HF and VLF) in CA lowlanders, interpreted as a lower stability in breathing control in Caucasians compared to Sherpas [643].

In general, ethnicity should be taken into account if an HRV study is going to be undertaken in a multiethnic population.

#### 35.6.2.5 Body Mass

There are no consistent data regarding the relationship or causality between body mass and HRV, despite a basic study indicating that dietary-induced weight gain is accompanied with a reduction in  $M_2$ -muscarinic gene expression, signaling modifications and density [644]. Moreover, the importance of circulating insulin, leptin and free fatty acids, known to interact with cardiac autonomic control in obesity, have been acknowledged [458, 462, 465–467, 645].

The differences in reported correlations are related to the various HRV measures used and the lack of adjustment for the variety of co-factors (age, gender, ethnics and others). Population size and characteristics examined vary in different studies (healthy volunteers, sample of general population, hypertensives, diabetics and others). Additionally, in a seminal study on HRV determinants, BMI was not included among potentially significant co-factors [573].

In a study of healthy children/adolescents, a significant correlation between BMI and age and gender adjusted 24-h pNN50 and RMSSD has been reported [332]. A similar observation has been reported in normotensive obese school children [646]. In healthy adolescents and young adults (15–31 years), neither BMI nor waist circumference was found to impact significantly on a statistical model of determinants of short-term HRV (30 sec) [647]. In a small sample of young women, BMI was graded as the second factor, after age, influencing overall HRV, but not pNN50 or RMSSD [608]. An approximate 5% contribution of BMI to the total HRV spectral power has recently been reported in a large sample of young adults [576].

In a population-based study, a significant correlation of BMI with age and HR adjusted short-term spectral HRV measures was found in middle-aged males, whereas a similar relationship was not present in females [648]. The contribution of BMI was found to be marginal (5% in males), although in certain conditions it clearly surpasses the effects of age and heart rate [315]. In the ARIC studies on a large cohort of middle-aged subjects, the BMI relationship with short-term HRV was not observed [649]. In a prospective HRV study in middle-aged adults, a higher BMI has been found to increase the probability of being at the worst quartile of age and gender adjusted 5-min HR and HRV over a 5-year follow-up period [575]. In contrast, in middle-aged normal persons, the BMI coefficient of determination relating to the age and gender adjusted total power of spectral HRV was found to be less than 5% [615].

There are conflicting data regarding the relationship of BMI with HRV in the elderly. The lowest short-term SDNN quartile has been found to be associated with a higher BMI in a large population-based cohort of the Rotterdam Study [650]. In a study across four European populations, a higher BMI was found to be associated with a lower HF and higher LF in one population, whereas no association was present in the other countries [651]. Also, in wide age range samples of population, insignificant or negligible contributions of BMI to HRV metrics were reported [580, 619, 652–655]. In the SAPALDIA study, the time and frequency domain HRV indices adjusted for many variables have been shown to correlate negatively with BMI in subjects >50 years old [609]. Also, in the CARLA study, the waist–hip ratio was inversely associated with HRV [655]. In contrast, observations from a longitudinal study in a small sample of the elderly did not produce evidence of a relationship between BMI change and standard HRV measures, while a significant correlation was found for the DFA  $\alpha_1$  coefficient [578].

Despite the majority of data indicating that body mass contributes only marginally to HRV, in an individual case, the influence of weight gain or loss might be of importance as indicated by the more concordant data that come from studies in obesity. Both weight gain and its reduction have been found to be associated with a significant change of certain HRV indices [656–661]. Longitudinal studies also provide some evidence regarding the influence of body mass changes on HRV [647]. An impressive amount of data has come from a study in obese patients who were treated surgically for extreme obesity. In these patients with a mean weight loss of 32 kg (28%) over a 1-year follow-up, the mean NNI decreased by 8%, while SDANN and SDNNI increased by 5% and 24%, respectively [658]. Spectral HRV measures also increased by 21% (LF, HF), but a relative increase of 35% for LF and 43% for HF was observed only for daytime, with no changes during night-time. Data on changes in lower frequency components were not reported in that study [658]. In another study in a group of morbidly obese patients treated with bariatric surgery, the average 17% BMI reduction and 13.5 kg fat mass loss 3 months after surgery was associated with 39–49% increase of 24-h SDNN, RMSSD, HRVI and TINN, while the pNN50 values doubled. Further weight loss over the next 9 months (–33% BMI and –28.7 kg fat mass at 12 months after surgery) were not found to be associated with further increase in HRV. On the contrary, a small decrease of 5–16% (SDNN, HRVI, pNN50 and RMSSD) was observed, while the TINN remained unchanged [661]. Changes in HRV have been found to be independent of improvement in insulin resistance [661]. Even a small weight loss (~10%) after dietary restrictions has been found to result in an increase of 24-h HRV in the time and frequency domains [659]. Conversely, a 10% increase in body weight has been associated with HR acceleration and a reduction of short-term respiratory-related HR power [656].

A lower baroreflex sensitivity resulting from increasing body mass and visceral fat in resting conditions and under stress challenges [662–664] was reported to be related in part to sympathetic overactivity in obese subjects [657]. Body weight reduction was found to be associated with a restoration of BRS [665]. This effect has been observed both in young and old obese subjects [666].

In the only study that addresses HRT changes in obese normotensive subjects without co-morbidities, no difference was observed between normal and obese subjects. However, there were limitations in the methods, e.g., allowing calculation of HRT from one ventricular PEB [667].

In general, body mass influences HRV and BRS, but in large-sample studies, its contribution to measured indices is marginal, albeit sometimes significant, and can usually be neglected. However, in an individual, gain or loss in body mass contributes substantially to changes of heart rate and its variation that can surpass the effects of established factors (age, gender).

### 35.6.2.6 Heart Rate

Heart rate is one of the main factors that always has to be considered for the understanding and interpretation of HRV. Consequently, a lack of knowledge about HR (or RR interval) *a priori* excludes a reliable assessment of its variation. Although HR would be expected to be considered, this fundamental requirement has not necessarily been met in many clinical studies [e.g., 314, 343, 346, 350, 351, 352]

Coumel et al. listed reasons for which HR itself cannot be ignored: (1) HR is probably the best and simplest measure of the ANS balance, (2) HRV indices are influenced by HR itself, and (3) the HR and HRV relationship does have a physiological significance and this perfect harmony between HR and HRV should not be overlooked [668]. This harmony is related to the so called sympathovagal balance, and can be derived from the classical Rosenblueth-Simeone model, describing the net effect of combined vagal and sympathetic stimulation upon SAN [669]. In their model, an actual HR is a function of intrinsic HR and sympathetic and parasympathetic influence:

$$aHR = IHR * m * n, \quad (35.41)$$

where *aHR* is actual (resting) HR, *IHR* is an intrinsic HR, *m* is a sympathetic factor, and *n* is a parasympathetic factor [669]. This multiplicative relationship (*m* \* *n*) is in concordance with the phenomenon of accentuated antagonism [15]. The *m* \* *n* product may be regarded as the sympatho-vagal balance [670]. Simply, *m* \* *n* > 1 indicates a predominance of sympathetic activity (net HR acceleratory influence), while with *m* \* *n* < 1 there is vagal predominance (net inhibitory effect). Since *IHR* cannot be simply measured, and there is no HRV index that explicitly describes “*m*” or “*n*” factor, the measurement of actual HR remains still the most useful crude estimate of ANS balance. Corroborative observations can be found in a series of studies by investigators in Chicago [671–675], who proposed to replace the *m* \* *n* product by the term VSE (vagal-sympathetic effect): VSE = RR interval/intrinsic RR interval [231] or simply *aHR*/*IHR* [676].

#### Intrinsic Heart Rate

A spontaneous firing of the cardiac pacemaker can be easily seen in the heart removed from a body of an experimental animal, when central and circulatory factors controlling heartbeat formation are disrupted. The rate of this spontaneous heartbeat activity is referred to as *intrinsic heart rate* (IHR) [677]. In humans, the IHR can be assessed after pharmacological denervation by means of a combined M<sub>2</sub> and β<sub>1</sub>AR (double blockade), with the use of weight-adjusted doses of atropine (0.04 mg/kg) and propranolol (0.2 mg/kg) [677–679]. Despite some limitations owing to the use of a high dose of atropine (nicotine-receptor partial blockade with a subsequent inhibition of the NE release, antagonism with 5-HT and histamine) and propranolol (nonspecific membrane action, negative inotropic effects) and actually incomplete autonomic blockade (with no effects on α-adrenoceptor or humoral factors) [393, 676], this approach is the only one available in physiological and clinical studies.

In healthy subjects the mean IHR is approximately 80–125 bpm [306, 679, 680]. The mean IHR of 128 ± 24 bpm has been reported in seven healthy children [681]. The IHR does not seem to be dependent on gender [306, 680, 682]. The importance of IHR for understanding heartbeat variation is related to its age, ventricular function and autonomic tone dependencies. Age-dependence on IHR is recognized by the inclusion of age into the regression equation (*r*<sup>2</sup> = 0.42) proposed by Jose and Collison 4 decades ago [306]:

$$IHR = 118.1 - 0.56 * \text{age} \pm k \quad (35.42)$$

where the constant *k* is 14% for subjects aged <45 and 18% for subjects aged ≥45 years.

Figure 35.41

Scatterplot of reported means of the intrinsic heart rate against means of age of examined group in various studies. Data from studies in which IHR has been assessed by means of double autonomic blockade using muscarinic antagonist + beta2-adrenergic agents.

In a study of Alboni et al., the mean IHR of  $103 \pm 13$  bpm in subjects 45 years of age or younger and of  $93 \pm 8$  in subjects > 45 years was observed [680]. Their data indicate that IHR is additionally related to aHR (resting baseline). Thus, the recalculated equation ( $r^2 = 0.61$ ) would be:

$$\text{IHR} = 90 - 0.57^* \text{age} + 0.41^* \text{aHR} \pm 7 \text{ bpm.} \quad (35.43)$$

Figure 35.37 shows a plot summarizing age-effect on the IHR in several studies that examined this relationship [306, 679–684].

A dependence of IHR on ventricular function was firstly reported by Wollenberger and Jehl in a model of cardiopulmonary function [685]. This relationship has been corroborated by others, indicating also that a reduction of IHR precedes the occurrence of overt heart failure [306, 678, 679]. An intact innervation of the SAN is a key factor for IHR, as indicated by experimental studies with extrinsic or SAN selective parasympathectomy and pericardial effusion [686, 687]. In clinical settings, it might play a role in patients after open heart surgery [688, 689], coronary artery by-pass surgery [690–692] pericarditis and myocarditis, including chronic Chagas' disease [693, 694], as well as after ablation procedures [695, 696]. In patients, following mitral valve replacement, a reduced HRV with an erratic spectrum can be detected [689], comparable to that seen in SAN dysfunction (Fig. 35.42) [697] and in patients after heart transplantation [433, 698]. An increase in IHR can be observed in patients with hyperthyroidism [306], inappropriate sinus tachycardia and postural orthostatic tachycardia [373]. There is also evidence that increased parasympathetic tone may result in a compensatory increase of IHR in renal hypertension [374]. In addition, temperature changes and atrial stretching might influence the intrinsic SAN firing [676, 699]. Thus, *the presence of changes in IHR in a number of settings indicates that RR interval may vary irrespective of cardiac autonomic tone.*

The change in mean RR interval (or ratio between the longest and shortest RRI) after parasympathetic blockade with atropine is used as an index of the relative basal vagal tone ( $\bar{V}$ ), while the difference in mean RR interval (or ratio between

■ Figure 35.42

Patterns of abnormal HRV power spectra in patients with sinus node disease. Tachograms (*upper panel*) in two patients after double autonomic blockade (atropine+propranolol), power spectra (*lower panel*) show residual contents with abnormal distribution which are resemble harmonics or erratic variation over mean value (From [697]).

longest and shortest RRI) after sympathetic withdrawal and subsequent vagal blockade with atropine, can serve as an index of the absolute vagal tone [700, 701]. Similarly, an index of the relative and absolute sympathetic influences can be derived from RRI after adrenergic blockade and after atropine and subsequent propranolol administration, respectively. An alternative approach of autonomic control of the heart based on the analysis of HR recovery from exercise has been reported [702].

#### Actual Heart Rate (Resting)

Heart rate and HRV can be considered as factors that limit their ranges. Accordingly, at a certain actual HR, the HRV varies within some limits (depending mainly on age). However, a reverse relationship is possible, that is, ANS and other influences reflected by an actual HRV establishes HR limits. This can be easily seen when the circadian variation of heart rate and HRV is examined [284, 318, 321, 703]. Indices of short-term variation (RMSSD and pNN50) follow an RRI circadian pattern, while the index of long-term HRV (SDANN) behaves in a reciprocal manner [321]. Accordingly, circadian rhythm of 24-h HF power mimics the rhythm of RRI, while circadian rhythm of 24-h LF power shows the reciprocal reflection of RRI [703]. A significant negative correlation ( $r^2 = 0.74$ ) of SDNN on day-night RRI difference described in healthy subjects emphasizes the importance of HR itself [318]. In older healthy subjects, similar relationships might not be observed because of a reduction of most time and frequency domain HRV indices, despite sustenance of circadian rhythm of RRI [321]. Interestingly, circadian rhythm of the SDANN index has been shown to be least affected by aging [321]. It has also been found that at in extreme conditions, both HRV decrease or increase cannot further follow changes in R – R interval (saturation areas) [399, 675]. In healthy persons, two distinct patterns of the HF power changes with RRI interval increment can be detected, i.e., saturated or linear [399]. Despite the authors having described a low-correlated pattern in their healthy subjects, detailed analysis of data provided indicates that these subjects had in fact been hypertensive [399].

In an experimental study on dogs with myocardial infarction, a low-correlated response to a beta-blockade with atenolol was observed in animals susceptible to sudden death, in contrast to resistant and sham-operated dogs, in which a parallel HR reduction and SDRR increase was found [704]. Actually, a close negative exponential relationship between HR and HRV (▶ Fig. 35.43) and clearly VF-prone experimental dogs is characterized by a simultaneous reduction in HRV and acceleration of the HR, as expected from the HR-HRV relationship (▶ Fig. 35.43 inset). Thus, the same data might bring different conclusions depending on the type of analysis adopted.

A significant relationship between RRI and HRVI on Holter recording has been found for risk prognostication after myocardial infarction [347]. For a wide range of statistical performance (sensitivity and positive predictive accuracy) results from the lower quartile of mean RRI and mean HRVI were comparable. All-cause mortality reached 24.3% and

■ Figure 35.43

Relationship between HR and SDRR in experimental AMI in dogs. Distinct HR-SDRR relationship is shown in dogs with experimental AMI prone to sudden cardiac death (SUCS) before and after beta-blockade (SUCS-BB) as compared to dogs resistant (RESIST) and (RESIST-BB) or sham-operated (SHAM, SHAM-BB). However, an analysis on entire group (inset) indicate that susceptible dogs HR-HRV are simple representing reduced HRV in accordance with a reduced HRV. Plots on basis of data from Adamson et al. [704]).

22.2% over a mean 2-year follow-up, respectively. Post-AMI patients with simultaneous low HRVI ( $\leq 20$  U) and shorter RRI ( $\leq 736$  ms) had the highest all-cause mortality (28.7% over a mean 2-year follow-up). On the contrary, in those in the lowest quartile for HRVI and the highest for RRI, the survival rate was excellent (no deaths) [347]. However, the mortality rate in those with HRVI in the highest quartile and RRI in the lowest quartile was still substantial (16.7%). The impact of a beta-blockade (40% of patients) that might prolong RRI without significant alteration of HRVI was not discussed. It might also be speculated whether a good prognosis in patients with low HRVI and longer RRI overall reflects better survival in patients with sinus node disease [705]. Another outcome of a separate study in patients with acute MI has found evidence that HRV indices do not provide additional prognostic power over that of RRI itself, clearly because of the significant mutual relationship ( $r^2 = 0.37$ ) [706].

The significance of basic RRI for HRV evaluation has been reflected in some investigations that addressed the issue of HRV normal limits [573, 576, 707]. In a recent study, the influence of RRI duration on HRV indices was underlined again [585]. In a short-term HRV study, the most common tests revealed a distinct behavior in RRI and HRV (► Fig. 35.44) in healthy subjects and post-MI patients [708].

In certain pathological states (heart failure, sinus node dysfunction) the actual heart rate is different than expected from a concomitant HRV change [709]. As a reduced HRV represents parasympathetic withdrawal in HF patients (with/without sympathetic over-excitation) [710], an R-R interval shortening (faster HR) can be expected. In such cases, an impaired IHR prevents heart rate adjustment. Therefore, a relatively slow HR and a reduced HRV can be observed. The author referred to this feature as the *metronome-like bradycardia* (Metronome-like bradycardia – a specific feature of chronotropic impairment in which slow HR is associated with a significantly reduced HRV.) and found it to be a specific

■ Figure 35.44

A distinct behavior of HR and HRV in response to various stimuli. Example shows that changes in HRV do not necessarily follow RRI alteration. Also, differences between healthy and post myocardial infarction patients are clearly seen (On basis of data from [708]).

sign of an organic sinus node impairment (in patients not treated with agents that may interfere with SAN function) [711]. In heart failure, circadian HRV measures have not been found to vary correspondingly to HR changes [712]. Also, in a third of post-AMI patients, a poorly correlated pattern of HF-RRI relationship has been reported [399]. Abnormal HR–HRV relationship can be ascribed to an increased HRV in spite of HR acceleration. Such behavior is seldom observed in heavily trained healthy subjects [709]. More commonly, such behavior can be seen in patients after heart transplantation and with obstructive sleep apnea syndrome [212, 433, 698, 713, 714]. Under these conditions, HRV may be increased due to the rising contribution of mechanical respiratory influences unrelated to cardiac autonomic tone (that is actually shifted towards a sympathetic predominance). A similar feature can be observed in patients with sinus node dysfunction after double autonomic blockade [697]. Therefore, an increase in short-term HRV in patients after heart transplantation cannot be simply interpreted as a sign of re-innervation or increased mechanical load unless sinus node function is reassessed [715, 716]. A higher HRV than expected from actual HR is a frequent feature of SAN dysfunction [337, 697, 711]. Interestingly, a prognostic value of increased HRV has recently been confirmed [53].

Baroreflex sensitivity does not seem to depend on heart rate. Despite a weak negative correlation ( $r^2 = 0.06$ ) between BRS and HR having been found in healthy subjects, the significance of the relationship was lost in multivariate analysis [593]. The BRS–HR relationship was not found in persons  $\geq 60$  years old even in a univariate analysis [593]. Another study indicated that there might be a gender difference in BRS–HR correlation. However, the small number of subjects examined does not allow a conclusive opinion to be drawn [621]. A lack of correlation between HR and BRS has been reported in most studies in which the BRS had been estimated by means of various methods [595, 600, 627, 629].

Heart rate turbulence parameters are dependent on heart rate in healthy subjects. Turbulence onset and turbulence slope decreases with HR increase [601]. A need for adjustment of the turbulence slope for heart rate was concluded from

a study in patients with coronary heart disease [312]. However, the accumulated data is relatively sparse, so a general statement cannot be given.

In summary, heart rate is of the utmost importance in the analysis of HRV. Actually, an interpretation of HRV data without information regarding actual (or mean) HR or RR interval might be inappropriate, diminishing conclusions drawn from such an investigation. Even in a case of seemingly insignificant HR (RRI) differences in comparative studies, HRV measures should be adjusted not only for age, gender and ethnicity, but also for HR (RRI).

### 35.6.2.7 Respiration

Respiration is one of the most important determinants of short-term heartbeat variation, which is clearly evidenced by a phenomenon referred to as *respiratory sinus arrhythmia* (RSA, Carl Ludwig 1847) [1, 4–6, 9, 20, 23, 717–725]. During normal breathing, the raw (unadjusted) RSA contributes to 30–80% of the total short-term HRV. Respiratory-related short-term HR variation is frequently interpreted as an index of tonic cardiac vagal modulation of heart rate [68, 69, 700, 720, 721]. However, respiratory influences on HRV do extend beyond high frequencies, and in certain settings can affect HRV within low- and very-low frequencies (► Fig. 35.45) [296, 717, 722].

The RSA magnitude is significantly related to respiratory parameters both in laboratory conditions and during daily life [6, 9, 718–720]. In an early investigation, Eckberg found that a 50% increase in tidal volume led to only a 15% increase of RSA estimated by means of the peak-valley method [720]. In a study of Grossman et al. with similarly determined RSA, the amount of variance accounted for by frequency of breathing and tidal volume has reached 64% (58–69%) [723]. By dividing RSA by tidal volume ( $RSA_{TF}$  [ms/ml]), the greater proportion of HR variance was explained. Additionally, a correction for breathing frequency has been shown to be unnecessary [723]. A need for additional adjustment for arterial partial pressure of  $CO_2$  has also been pointed out, especially while central autonomic drive is affected, i.e., hyperventilation, sleep-related breathing disorders, heart failure [724]. The respiratory HR variation is accentuated during slow ( $\sim 0.1$  Hz) deep breathing [18, 718, 720]. This relationship constitutes the basis for a clinical test [18, 725]. Interestingly, an evolution of this method can still be seen [726].

Respiratory parameters should be obligatorily controlled for in laboratory studies [727]. In clinical settings, some information about respiration (breathing rate) might be extracted from the mean (or median) frequency of HF component of the short-term HRV power spectrum. Unfortunately, respiration parameters are only rarely taken into account in clinical studies both in normal subjects and those with various clinical entities. Meanwhile, the respiratory rate (defined as the frequency of maximum HF power) has been identified as a factor explaining HRV differences between CAD-patients

■ Figure 35.45

Spontaneous slow respiration effect on HRV spectral components. In an example, the power spectrum (AR) shows only one peak that cannot be considered either a LF or HF power (From [296], Oxford Univ Press, with permission).

with preserved and depressed LV systolic function [728]. As respiration influences frequencies lower than that of the HF component [184, 717, 722, 729], its contribution for VLF and LF components should also be considered. It could be of the utmost importance in patients with heart failure and sleep-related breathing disorders in whom chemoreceptor-reflex or centrally-driven changes contribute significantly to HRV [730–734]. Recently, it has been observed that the frequency of respiration influences fractal measures of HRV [735].

The contribution of nonneural influences to short-term HR variation due to lung volume oscillation is usually small under normal conditions (~3%). However, it can be responsible for up to 30% of the HF power in healthy middle-aged persons [730]. It has been shown that a slow deep breathing can provoke R – R interval oscillations of ~120 ms after complete autonomic blockade [717]. In addition, the proportion of nonneural components of RSA has been observed to increase during exercise [736]. The relative contribution of nonneural RSA mechanisms increases even in mild heart failure, and accounts for 15% of the HF power. Importantly, in an individual patient, this mechanical contribution can reach 77% of the HF component [730]. Abnormal breathing patterns that can occur in patients with heart failure during exercise influence lower frequencies [737].

Another form of respiratory contribution to HRV is related to so-called cardio-ventilatory coupling [188, 190, 193–196] and seems to be independent of cardiac autonomic tone, blood pressure variability, and baroreflex sensitivity [738]. The cardioventilatory coupling has been observed in two third of healthy subjects, being most apparent at low breathing rates and associated with high HRV [738]. As reduced cardiorespiratory interactions have been found in patients with a myocardial infarction [196] and is associated with low HRV [738], it might be another mechanism that should be taken into account while interpreting reduced HRV in a number of clinical conditions.

In general, respiratory parameters should be measured and reported in studies on HRV, especially in patients in whom breathing and related disorders play a significant role in pathophysiology and clinical presentation.

Figure 35.46

Examples of diurnal fluctuation of long-wave (SD) and short-term (dif 6%) measures of HRV in a healthy subject. (From [318], with permission).

### 35.6.2.8 Day–Night Rhythm

Diurnal variation of HR and HRV are well recognized [739]. They are related to the circadian rhythm of sleep and activity. Measurement of the global 24-h HRV indices (SDNN, SDANN, HRVI, or HRVF) provides a crude description of the level of circadian rhythm, since the sleep–wake cycle is the strongest determinant of overall HRV (► Fig. 35.40). More detailed analysis requires a partitioning of 24-h recordings into day and night periods, or even hourly intervals. In healthy subjects, HRV measures of high frequency variation (pNN50, RMSSD, HF power) reach their maximum early in the morning before awakening (usually about 5 AM) independently of gender and activity [321, 618, 739, 740]. However, a lack of diurnal variation has been reported [318] as has attenuation of cardiac vagal modulation with age [321]. Sleep-related increase in HRV short-term indices has been confirmed in shift workers [741]. Also, cardiorespiratory coupling has been found to exhibit day–night differences [195]. Sleep deprivation has been shown to result in attenuation of parasympathetic and augmentation of sympathetic-related HRV indices [742]. Diminished LF/(LF+HF) ratio during non-REM sleep that mimics sleep deprivation has been found in subjects homozygous for the PER3<sup>5/5</sup> allele, in contrast to other polymorphisms in this gene encoding circadian clock [743]. Apart from the sleep–wake cycle, there is a role for light–dark rhythm intrinsically coupled with HRV changes over 24-h [744].

In a recent study, Hu et al. investigated intrinsic circadian cardiac dynamics in healthy subjects by adjusting the sleep–wake behavior cycle to 28 h [745]. They found significant circadian changes of DFA scaling exponent  $\alpha$  with the average maximum value at ~9–11 am and the average minimum value at ~1 pm. The protocol used in this study forcing a lack of synchrony allowed the detection of the influence of the circadian pacemaker on cardiac dynamics independent of HR circadian rhythm [745].

Early HRV abnormalities can easily be detected in diabetic patients without autonomic test abnormalities and in patients with uncomplicated coronary artery disease in the form of a reduction of night-time (sleep) HF power, whereas daytime values can still be comparable [746, 747]. In diabetic patients with autonomic neuropathy, the HRV diurnal pattern is reduced or even lost, thereby making both daytime and night-time HF and LF power lower compared to healthy subjects [747]. Similar findings have been reported in heart failure patients [277]. Increased night-time SDNN, in spite of a smaller HF increase, has been observed in post acute MI patients [748]. Also, higher pNN50 values during sleep have been reported in hypertensive patients with left ventricular hypertrophy [749]. The absence or reversal of circadian rhythm of a particular HRV measure has been shown to be of prognostic significance in post-MI patients and in survivors of sudden death [750–752]. Last, but not least, the pharmacodynamic effects of certain agents can be tracked by means of circadian HR and HRV analysis [753].

Baroreflex sensitivity also undergoes clear day–night rhythmicity with minimum values during the day [754].

In general, evaluation of HR and HRV circadian rhythms may add information beyond their mean values that may be useful in risk-prognostication. Additionally, diurnal changes of certain HRV measures indicate that measurements of short-term HRV should be performed at similar specific times in the day.

## 35.6.3 Behavioral Factors

### 35.6.3.1 Physical Activity

The autonomic nervous system is involved in the complex adjustment of circulatory control to altered demand in response to physical activity. Thus, the effects of short-term exercise or prolonged training can be easily recognized by means of HRV analysis. The autonomic response to exercise or training depends on the type of physical activity (tonic or phasic), its frequency, intensity, and duration. Also, initial physical status should be taken into account. On the contrary, spells of physical inactivity can be studied in the setting of prolonged bed rest.

Physical activity has been listed among the most important determinants of 24-h HRV [318]. Subjects with good fitness levels have a higher power of both HF and LF components [577]. However, conflicting data exists in general population studies. Vigorous self-reported physical activity has been found to be associated with short-term HRV in males. Those men in the highest category of vigorous activity had an 8% higher SDNN, 19% higher LF power, and 23% higher HF power than those men who reported no vigorous activity, after adjustment for age and for light and moderate activity [755]. Similar observations have been reported in healthy adolescents [756] and in middle-aged subjects [757].

Interestingly, in the latter study, moderate and vigorous physical activity has been associated with a higher LF power [757]. In the SAPALDIA study, each hour of heavy physical exercise has been associated with a 2.0% increase in SDNN, a 3.6% increase in the high frequency (HF) range power and a 4.2% increase in LF power [609]. A lower LF power but not HF power has been found in women with a sedentary lifestyle [758]. In contrast, in a large cross-sectional study in an elderly population, no association between physical activity and HRV measures has been reported [655]. In addition, in a cross-sectional study of Byrne et al., physical fitness has not been identified as an independent predictor of HRV, despite univariate associations having been observed [652]. Cumulated data indicate that preserved age-dependent HRV measures can be found in those humans who are physically active over years or decades [759, 760].

Basic physical fitness can be improved by various exercise protocols. However, the effects of training depend on its intensity and duration. Light or moderate physical training that can improve peak  $\text{VO}_2$  does not necessarily alter HRV measures [761–763]. More vigorous training has been found to increase parasympathetically-mediated HRV indices irrespective of age [755, 759, 764–766]. Aerobic training at 50% of maximum  $\text{VO}_2$  exerts evident influences on HRV in post-menopausal women [767, 768]. An extreme physical loading may exert harmful effects upon HRV [769]. A distinct effect of physical training on various measures of autonomic control (HRV, HR recovery, and HRT) has been discovered recently in patients with heart failure [770].

Increased HF power response to exercise and increased RMSSD during recovery have been associated with a worse prognosis in one study (mainly males) [771], whereas no evidence of prognostic value has been found in another [772]. Differences might result from exercise testing (treadmill test vs bicycle ergometer), gender-differences or intensity of workload. Heavy exercise above the ventilatory threshold has been shown to determine occurrence of increased HF power [773].

The effects of physical fitness and training on baroreflex function are more difficult to evaluate since exercise simultaneously exerts influence on central command, the exercise pressor reflex and the arterial baroreflex. Some harmony between these three components of an integrative response to exercise is required to produce a normal response to exercise [774]. The use of various methods for BRS assessment, different parameters for its description (usually only maximum gain), different intensity, protocols and duration of exercise or training is one reason for data inconsistency. Exercise capacity parameters, like maximum or peak  $\text{VO}_2$ , have been found not to correlate with BRS changes or their lack of change [593, 624].

Too short a period of physical training, as well as BRS examination by means of baroreceptor unloading, are more frequently reported in studies in which the BRS has been found reduced or unchanged [775–778]. Also, the use of semi-invasive maneuvers results in inconsistent observations, including those usually with unchanged BRS following exercise [779]. In studies with spontaneous BRS estimation, an increase of BRS in response to exercise can be observed more consistently [780–782]. More regular exercise of moderate intensity has been reported to attenuate age-related reduction in BRS [592]. Multi-phasic response to prolonged exercise training has been described with an initial BRS improvement after 3 months, which is sustained for the next few months and followed by a decline after a 1-year period despite markedly increased training [783]. This might be an effect of baroreceptor resetting. However, more detailed analysis of baroreflex function curve and its operative parameters would help to explain the changes described [774].

### 35.6.3.2 Mental Stress

Mental stressors (anger, mental arithmetic, presentation with/without audience participation, and others) are frequently used in acute psychophysiological studies in which short-term spectral HRV analysis is preferentially employed [5, 6, 10, 784, 785]. Others have investigated more chronic traits, like depression, anxiety disorders, panic disorder, personality types, hostility, mistrust, and work stress, as well as the white-coat effect and post-traumatic stress [785–790]. Also, the effects of anti-stressor behavior (mental distraction, yoga, relaxation training) have been investigated [791]. For the effects of chronic mental stress evaluation, either short-term or long-term HRV analysis is in use [785].

Cardiac vagal withdrawal is evoked by a wide range of stressful states [791]. However, acute stressors induce various effects on HRV sympathetic and parasympathetic-related components that are related to mutual influence on respiration [786]. Anger has been found to induce an increase in both LF and HF components, while anticipation of giving a presentation has been associated with an increase in LF power although HF power has remained unchanged [793, 794]. An increase of LF power and a shift of HF power towards higher frequencies in response to the reaction time task have been

associated with a shift of the respiratory spectrum in healthy subjects [784]. Meanwhile, a mental arithmetic test has been shown to induce a large increase in LF power with a reduction of HF power into almost undetectable values, broadening and flattening of the respiratory spectrum and a reduction of the alfa-index of BRS gain [784]. Unfortunately, the changes described have not been adjusted for accompanying HR acceleration and SBP increment. Delaney and Brodie found a shift of the HRV power spectrum towards low frequencies in response to defence-arousal reaction [795]. Decreases in HRV in response to random number generation have allowed the detection of anxiety and depression in apparently healthy subjects, even though basal HRV remained similar in all those in the study [796].

Anxiety traits and disorders are associated with changes in HRV [792]. In phobic disorder, decreased vagal and increased sympathetic cardiac function, have been revealed in a study of HRV by Yeragani et al. [797]. A phobic anxiety self-rating score has been inversely related with age-adjusted SDNN in the Normative Aging Study [798]. In a small case-control study, both 24-h HF and LF powers were found to be lower among subjects with panic disorder as compared to those without [799]. Also, a negative relationship between cardiac vagal indices and anxiety trait has been reported in many studies [see 792 for review], but contradictory data has appeared [800, 801]. Encouraging data on the potential of HRV analysis for evaluation of treatment of anxiety has been reported. These and other studies are reviewed elsewhere [785, 792]. Depression has been found to be another entity in which HRV can be seen as abnormal. Agelink et al. compared short-term HRV in depressive and normal subjects and found a faster HR in moderately and severely depressed subjects, while HF power was lower only in patients with a high Hamilton Depression Score [802].

Some difficulties in interpretation of the cumulated data arise from the lack of information about such fundamental physiological parameters as heart rate or respiration in the majority of studies. In the most frequently cited study of Carney et al., an association between depression and low 24-h HRV in patients with acute MI (the Enhancing Recovery in Coronary Heart Disease (ENRICHED) trial), the average HR in the groups compared has neither been adjusted for nor compared. In addition, more important clinical data have been missed [803]. Interestingly, in a few studies in which HR has been accounted for, the differences in HRV have not been seen. O'Connor et al. found significant differences in HR, but not in RSA, in bereaved and depressed subjects [804]. Similar results have been obtained by others [805]. A significant correlation of anxiety state with HR has been observed in a study by Watkins et al., while RSA and anxiety state were not found to be correlated [806]. These authors also reported that respiratory control did not change this relationship. However, in their multivariate analysis, they did not include heart rate and respiratory rate (despite being measured) into the final model [805]. In addition, respiratory rate and arterial pressure variability have been the most consistently changeable parameters among all those measured in an acute sleep deprivation study. However, conclusions have been drawn on the basis of unadjusted HRV parameters [807].

Generally, accumulated data document the role of mental stressors (acute and chronic) for cardiac autonomic control. However, the effects of heart rate and respiration are required to be considered or at least adjusted for in further investigations in order to draw clinically valid conclusions.

### 35.6.3.3 Smoking

Smoking is one of the most important determinants of HRV because of the direct effects of nicotine on the autonomic nervous system and the indirect consequences related to the role of smoking on the processes of atherosclerosis, thrombosis and chronic pulmonary diseases.

The association of smoking and increased heart rate is consistent across many reports. Gillum et al. quantified the HR increase of 2.9 bpm and 1.4 bpm in current male and female smokers, as compared to ex-smokers and those who had never smoked [808]. Acute nicotine administration increases HR by 10–25 bpm [809].

The acute effects of smoking in young persons was not reflected in the 5-min SDRR, although RSA was reduced [810]. Heavy chronic smoking (>25 cigarettes per day) can be associated with RSA being reduced to a level observed in sedentary nonsmoking subjects [810, 811]. However, in one study, differences in RSA were not detected in subjects older than 31 years of age [810]. In the ARIC study, a greater reduction of 2-min adjusted SDRR and HF power during active postural changes was noticed in smokers compared to nonsmokers [812]. Blunted changes of unadjusted short-term HRV measures in response to controlled breathing have also been reported [813]. Lower amplitudes of LF and HF components of 24-h HRV have been found in smokers [577]. A diverse influence upon circadian HRV measures has been described,

with significant differences between smokers and nonsmokers only within daytime HF power, while LF power has been reduced both during daytime and nighttime in smokers [577]. In another study, the 24-h SDNN and SDANN were found to be lower in smokers only during daytime, while RMSSD was comparable to that of nonsmokers over the whole ECG recording [814]. Also, tobacco use was found to be an independent determinant of global time-domain, but not short-term HRV measures in patients referred for coronary angiography [815].

There are also negative studies in which the relationship between smoking and HRV was not confirmed [816, 817]. The minimal significance of smoking as an HRV determinant has been observed as a lack of influence of smoking as a covariate on the predictive value of reduced SDNN in the Framingham Heart Study and in the ARIC Study [251, 649]. Also, in a study by Kuch et al., smoking was associated with short-term HF power only in women. However, the significance of association was weak and smoking as a determinant of HRV was rejected from the final multivariate models both for the resting state and controlled breathing [648]. The contribution of smoking to the total variance of HF and LF has been accounted for as approximately 3.5% [654]. In a number of studies, smoking habits have not been considered [141, 269, 322, 555, 583, 599]. Also, in the majority of clinical studies, smoking has not been listed among sample characteristics.

### 35.6.3.4 Other Factors

There are a plethora of reports accounting for the association between HRV and other factors, like anthropometrics (height), biochemical (lipids and glucose, insulin, leptin, adiponectin, uric acid, anemia), inflammatory measures (white blood cell counts, CPR, interleukins), habits (caffeine and alcohol consumption), social status and others [4–6, 521, 609, 655, 785, 816–821]. However, none of these factors has been evaluated reliably without taking into account contributions of all of the more important determinants. It is reasonable to consider the impact of a single factor that might influence HRV measures in certain circumstances. However, in general, the contribution of other factors to HRV seems to be negligible.

### 35.6.4 General Comments

In any subject, at a certain point of the life-course, HRV seems to be dependent on nonmodifiable determinants, such as heritability, age, gender and ethnicity. These factors should always be considered in any statistical analysis (if an examined population is heterogeneous). However, as indicated by studies in twins, these factors have accounted for less than 60% of explained variation in the HRV [521, 528, 533, 534, 638]. So, there is still a place for the role of other factors.

If short-term HRV examination is to be performed, the significance of *heart rate, respiration, body position and physical fitness* might be of importance, and so these determinants should be controlled apart from nonmodifiable factors. However, these factors have been found to account for no more than 8–15% of explained HRV variation.

If long-term HRV is to be examined, *median HR, day–night difference and sleep–wake cycle*, as well as *diurnal activity*, including work pattern, are of greater importance. Therefore, it seems necessary to check for these determinants in every study in addition to nonmodifiable factors.

Importantly, in longitudinal studies, a change in factor that is known to have only a marginal effect on HRV in the population might be of special interest, as changes in modifiable determinants can influence actual HRV by a factor of at least 10, as compared to their impact in population studies. Thus, if body mass influences HRV by 1–2%, an individual decrease of 10 kg affects HRV by at least 10%. Probably, a similar rule can influence changes in other factors, including physical training, smoking cessation, stress controlling approaches (i.e., yoga), and others. However, it is important to keep in mind that HRV error estimation is necessary to account for differences. As mentioned earlier, changes of at least 25–30% in HRV can be considered significant.

## 36.1 Introduction

Exercise testing is a widely used method for diagnosis in patients with suspected ischemic heart disease and for functional evaluation of patients with known heart disease. Throughout the years, most attention has been given to the information obtained from the electrocardiogram during exercise. However, other information that can be obtained during the test is of equal importance. Such information, as listed in [Table 36.1](#), can be obtained by observation of the patient, measurement of the heart rate and blood pressure responses, measurement or estimation of total body oxygen consumption, and from other noninvasive investigations such as myocardial-perfusion scintigraphy and evaluation of left ventricular function by radionuclide angiography or echocardiography. This chapter focuses on exercise electrocardiography.

Compared with the noninvasive stress imaging tests such as stress echocardiography and myocardial perfusion scintigraphy, exercise testing can be performed at a much lower cost. However, the noninvasive imaging modalities have been increasingly more used in the last decade and have been shown to outperform the standard exercise test in terms of diagnostic accuracy. This does not mean, however, that exercise electrocardiography should be replaced by these imaging modalities. The standard exercise test remains the initial test of choice in many clinical circumstances. However, new technical improvements in the field of the stress imaging tests are expected to further increase their performance and clinical use. Furthermore, new techniques are being developed that permit direct, noninvasive imaging of the coronary arteries (e.g., multislice computed tomography). These developments will require a continuous reassessment of the relative role of all commonly used diagnostic tests and procedures.

The report of an exercise test should contain a summary of the previous history of the patient, his present symptoms, medication, and an interpretation of the ECG at rest. The exercise protocol should be described with the expected performance of a normal subject of the same age, sex, and body size. The reasons for termination of the test should be stated and symptoms which occur during the test should be described, including the workload at which symptoms began, the type of symptoms, their severity, and the duration of the symptoms after exercise has ceased. Heart rate and blood pressure should be reported at rest, at the onset of symptoms, at peak exercise, and after approximately 6 min into the recovery period. A description of the ECG should contain any arrhythmias which may have occurred and changes in the QRS complex and ST segment. Finally, a conclusion should be drawn which answers the clinical questions that were posed before the test. The report should not be limited to words like “positive” or “negative.”

## 36.2 Safety of Exercise Testing, Precautions, and Contraindications

Exercise testing is a well-established procedure that has been in widespread clinical use for many decades. Although exercise testing is generally a safe procedure, both myocardial infarction and death have been reported. A large survey reported

**Table 36.1**

Information obtained by exercise testing in patients with (suspected) heart disease

17 deaths among 712,285 patients tested in three German-speaking countries [1]. In addition, nonfatal ventricular fibrillation occurred at a rate of 1/7,000 tests and nonfatal myocardial infarction at a rate of 1/70,000 tests. Since these risks are not negligible, all stress testing should be done in a setting where emergencies can be treated efficiently and expeditiously. A defibrillator and an emergency kit of appropriate drugs should be immediately available, and the staff of the exercise laboratory should be trained in cardiopulmonary resuscitation [2]. In addition, exercise testing should be supervised by an appropriately trained physician, who should be in the immediate vicinity and available for emergencies [3]. However, the most important safety factors in stress testing are patient selection and good clinical judgment, deciding which patient should undergo exercise testing and knowing when not to start and when to stop a test are essential in reducing the risk of stress testing. Absolute and relative contraindications to exercise stress testing are listed in [Table 36.2](#) [4].

### 36.3 Exercise Protocols

Exercise should be performed on a treadmill or a calibrated bicycle ergometer [5, 6]. Other modalities may be used in special situations; for example, in sports medicine a rowing ergometer or a canoe ergometer might be used. The various forms of step tests are outdated, since these do not permit quantification of the work performed. The choice between a bicycle ergometer and a treadmill can be made on the basis of personal preferences or local custom. In general, normal subjects can reach higher heart rates and a higher level of oxygen consumption on a treadmill [7]. Furthermore, virtually all subjects can be exercised on a treadmill, while riding a bicycle requires some skill. On the other hand, the body position is more stable on a bicycle ergometer, resulting in less motion artifacts on the ECG. For studies of left ventricular function during exercise or studies with indwelling catheters, only bicycles can be used, usually with the patient in the supine position. Guidelines for the design of a clinical exercise testing laboratory have been published by the American Heart Association [2].

Exercise should start at a low workload and increment stepwise or continuously, according to a fixed protocol. A large number of treadmill protocols has been described ([Fig. 36.1](#)). Probably the most widely used protocol has been described by Bruce [8]. In this protocol, both the grade (slope) of the treadmill and its speed are altered at the end of

<sup>a</sup>Systolic blood pressure of >200 mmHg and/or diastolic blood pressure of >110 mmHg, as suggested by the ACC/AHA Committee on Exercise Testing

Figure 36.1

Summary of five treadmill protocols and three bicycle protocols. The figures above the lines of the treadmill protocols represent treadmill speed in kilometers per hour, and the figures below the lines represent the slope. Some treadmill protocols use steps of 3 min each (Bruce, USAFSAM, Weld), while others use steps of 1 min (Balke) or alternating steps of 3 and 2 min (Ellestad). The figures above the lines of the bicycle protocols correspond to workload in Watts. Either 1-min steps or steps of 3 min are used. The value of the divisions marked on these lines is indicated on the left.

■ Figure 36.2

Comparison of oxygen requirements over time for two bicycle protocols (steps of 20 W/min or 10 W/min) and two treadmill protocols (Bruce and Weld) in a 75 kg male subject. The horizontal axis represents time in minutes and the vertical axis represents average oxygen uptake ( $l/\text{min}$ ), which can be equated to metabolic equivalents (METs). It should be noted that the actual oxygen consumption of a given patient at a certain level of exercise varies widely and depends on their level of physical condition. Furthermore, oxygen consumption on the treadmill is dependent on body weight.

each 3-min stage. In the Ellestad protocol [9], the slope is constant during the first four stages, while the speed increases. At stage five, speed is kept constant while the slope is altered; for stage six, speed is again increased. The Balke protocol and its derivatives maintain a constant speed in the range of 4.8–6.4 km/h with changes of treadmill slope every minute or every 3 min [10]. Modifications of these protocols have been developed for the evaluation of patients prior to discharge from hospital after myocardial infarction. For example, the protocol used by Weld employs two stages with a low treadmill slope prior to the first stage of the Bruce protocol [11].

Workload on a treadmill is dependent on body weight. Accordingly, the workload performed using various protocols can be expressed as  $\text{ml}/\text{kg}/\text{min}$  oxygen consumption. In the literature, workload has frequently been expressed in metabolic equivalents (METs) [12, 13]. One MET equals  $3.5 \text{ ml}/\text{kg}/\text{min}$  oxygen consumption, which corresponds to the average resting oxygen consumption. In [Fig. 36.2](#), mean oxygen consumption is given for various protocols and the corresponding METs have been indicated. Oxygen consumption rises more rapidly with the Bruce protocol or the Ellestad protocol than with the USAFSAM modification of the Balke protocol, which uses a speed of 5.3 km/h [14, 15]. The work on a bicycle ergometer is independent of body weight. Frequently used protocols on a bicycle ergometer in the sitting position increase the workload by 10 W/min or 20 W/min. For adult male subjects with average body weight, the metabolic requirement (total body oxygen consumption) of a protocol with 20 W/min workload increments is comparable to the Bruce protocol ([Fig. 36.2](#)). Similarly, a protocol with 10 W/min steps is comparable to the Weld protocol for submaximal pre-discharge tests after myocardial infarction. Predicted normal values for the peak workload for a protocol with steps of 20 W/min are presented in [Table 36.3](#). In the supine position, lower workload increments are normally used; for example, 20 or 30 W every 3–5 min.

It should be realized that the hemodynamic response to exercise in the supine position differs considerably from the response in the sitting position. In patients with coronary artery disease (CAD), the peak level of exercise in the supine position is approximately 70% of the peak level in the sitting position. Peak heart rate and peak systolic blood pressure are

■ **Table 36.3**

**Predicted normal exercise tolerance (in Watts) using a bicycle ergometer protocol for exercise testing**

Age (years)	Exercise tolerance in women					Exercise tolerance in men				
	Height (cm)					Height (cm)				
	160	170	180	190	200	160	170	180	190	200
20	176	192	208	225	241	220	240	261	281	301
25	167	183	199	215	232	209	229	249	269	290
30	158	174	190	206	222	197	217	238	258	278
35	149	165	181	197	213	186	206	226	246	267

65	94	110	126	142	158	117	137	157	178	198
70	84	101	117	133	149	106	126	146	166	186

Predicted normal exercise tolerance (in Watts) for women (left) and men (right). These normal values are applicable when a protocol with steps of 20 W/min is used on a bicycle ergometer. The normal range is between 85% and 115% of these values. For example, a 45-year old man with a height of 190 cm has a predicted normal exercise tolerance of 223 W, ranging from 190 to 256 W.

approximately 10% lower. On the other hand, pulmonary capillary wedge pressure during exercise is higher in the supine position owing to the greater venous return [16–18]. In order to obtain reproducible results, each hospital and laboratory should select one or two protocols which can be applied to all subjects. Reference values for such protocols are readily available as shown in ▶ Fig. 36.3 and ▶ Table 36.3. Nevertheless, each laboratory should verify whether these values are indeed applicable to the local population. Measurement of oxygen consumption is not very useful in a laboratory for exercise electrocardiography. If necessary, oxygen consumption can be estimated from the workload as shown in ▶ Fig. 36.2. The standard deviation of this estimation is between 5% and 10%.

## 36.4 Exercise Endpoints

For most purposes, exercise can be continued until symptoms occur. It is a fallacy to terminate exercise at an arbitrary percentage (70 or 85%) of the age-adjusted maximum predicted heart rate for a number of reasons. First, the heart-rate response in normal subjects is highly variable [13]. The mean value at each age may be predicted as 220 minus age, or 200 minus age/2. These mean values apply both to men and women up to 70 years of age. However, the standard deviation is large, approximately 10 beats/min. Thus, the 95% confidence interval is between 20 beats below and 20 beats above the predicted mean value [12]. Second, the maximum heart rate reached by patients with severe disease is considerably lower than the heart rate reached by normal subjects. Thus, when heart rate is used as an endpoint for terminating exercise, patients with severe disease may be stressed beyond their limits, while other patients will be unnecessarily prevented from exercising to their true capacity. Finally, the target heart rate approach has additional limitations in patients with heart rate impairment, those with excessive heart rate response, and those receiving medication such as beta-blockers, some calcium antagonists, and specific sinus-node inhibitors [20–23].

Therefore, other endpoints for terminating exercise testing, as summarized in ▶ Table 36.4, are strongly preferred. It should be noted that ST segment elevation developing in leads (other than aVR or V<sub>1</sub>) without diagnostic Q-waves of a previous myocardial infarction usually indicates transmural ischemia rather than just a subendocardial problem. It is almost always associated with a high-grade obstruction proximal in the respective coronary artery. If exercise continues, myocardial infarction may be imminent, so that it is necessary to terminate the test and direct the patient to immediate follow-up care including coronary angiography.

■ Figure 36.3

Nomogram for assessment of functional aerobic impairment of men and women according to age, duration of exercise by the Bruce multistage procedure, and habitual physical activity status. In order to find functional aerobic impairment (C), apply a straight-edge to age (A) and duration (B) and read intercepts of diagonal (Adapted from Bruce [19]).

It is advisable to express symptoms which occur during exercise on a semiquantitative scale, such as the Borg scale (Table 36.5) [24]. The use of rating of perceived exertion scales is often useful in assessment of patient fatigue. Symptom-limited testing with the Borg scale as an aid is very important when the test is used to assess functional capacity. It also permits a comparison of the degree of a patient's symptoms over time.

It has previously been recommended that all medication be stopped one or more days before an exercise test is done. Although this may be useful for some scientific applications, this principle is not generally followed in clinical practice. In patients with stable angina, a period of instability may develop if beta-blockers, nitrates, or calcium antagonists are withdrawn. If the interpretation of the test is significantly hampered by medication, for example, a normal response is obtained in a patient with angina using beta-blockers, the medication may be gradually withdrawn and the test repeated. However, most patients with angina will develop symptoms and ischemic ECG changes in spite of the use of antianginal drugs, albeit at a higher workload than without such drugs [21, 22, 25, 26]. Despite the effect of beta-blockers on maximal exercise heart rate, no differences in test performance were found in a consecutive group of men being evaluated for possible CAD when they were subgrouped according to beta-blocker administration initiated by their referring physician [4, 27]. Therefore, for routine exercise testing, it appears unnecessary for physicians to accept the risk of stopping beta-blockers before testing when a patient exhibits possible symptoms of myocardial ischemia.

## 36.5 Recording and Computer Processing of the Electrocardiogram

### 36.5.1 Recording of the Electrocardiogram

It is essential to record a high-quality ECG. Proper ECG quality can be achieved in virtually all patients if skin preparation is meticulous. The skin should be abraded with sandpaper or a special, commercially available, drill. Special electrodes

Table 36.4

Indications for terminating exercise testing (Adapted from ACC/AHA 2002 Guideline Update for Exercise Testing [4])

Sensations felt by patient	Observations made by physician
Absolute indications	
<ul style="list-style-type: none"> <li>Moderate to severe (progressive) angina</li> <li>Increasing nervous system symptoms (e.g., ataxia, dizziness, or near-syncope)</li> <li>Subject's desire to stop</li> </ul>	<ul style="list-style-type: none"> <li>ST-elevation (<math>\geq 1.0</math> mm) in leads without diagnostic Q-waves (other than V<sub>1</sub> or aVR)</li> <li>Technical difficulties in monitoring ECG or systolic blood pressure</li> <li>Sustained ventricular tachycardia</li> <li>Drop in systolic BP of &gt;10 mmHg from baseline despite an increase in workload, when accompanied by other evidence of ischemia</li> <li>Signs of poor perfusion (cyanosis or pallor)</li> </ul>
Relative indications	
<ul style="list-style-type: none"> <li>Fatigue, shortness of breath, wheezing, leg cramps, or claudication</li> <li>Increasing chest pain</li> </ul>	<ul style="list-style-type: none"> <li>Drop in systolic BP of &gt;10 mmHg from baseline despite an increase in workload, in the absence of other evidence of ischemia</li> <li>ST- or QRS-changes such as excessive ST-depression (&gt;2 mm of horizontal or down-sloping ST segment depression, especially when the magnitude of the ST-depression is increasing rapidly at low workloads) or marked axis shift</li> <li>Arrhythmias other than sustained ventricular tachycardia, including multifocal PVCs, triplets of PVCs, supraventricular tachycardia, heart block, or bradyarrhythmias</li> <li>Development of bundle-branch block or IVCD that cannot be distinguished from ventricular tachycardia</li> <li>Hypertensive response (systolic blood pressure of &gt;250 mmHg and/or diastolic blood pressure of &gt;115 mmHg)<sup>a</sup></li> </ul>

BP, blood pressure; ECG, electrocardiogram; PVCs, premature ventricular contractions; and IVCD, intraventricular conduction delay

<sup>a</sup>As suggested by the ACC/AHA Committee on Exercise Testing

should be used to prevent motion artifacts. Furthermore, the ECG cables should be of special design to prevent artifacts owing to cable motion. As stated, cycle ergometers produce less motion of the upper body resulting in less motion artifacts on the ECG. Finally, ECG amplifiers which meet the American Heart Association standards, and have high input impedance, should be used [2]. If a proper combination of skin preparation, electrodes, cables, and amplifiers is used, a stable baseline can be achieved throughout the test in most subjects.

### 36.5.2 Computer Processing of the Electrocardiogram

Computerized exercise stress test systems have become the method of choice in most stress testing laboratories. The principles of computer-assisted interpretation of exercise ECGs have been described [28–32] and a review of methods for computer-based resting electrocardiography is also presented elsewhere in this textbook (▶ Chap. 37). A summary of methods for analysis of exercise ECGs is presented here in brief.

Table 36.5

Borg scale

Grade	Symptoms
0	Nothing at all
0.5	Extremely weak (just noticeable)
1	Very weak
2	Weak (light)
3	Moderate
4	Somewhat strong
5	Strong (heavy)
6	
7	Very strong
8	
9	Extremely strong (almost maximal)
10	Maximal

The Borg scale for rating of perceptual intensities constructed as a category scale with ratio properties [24]. This can be used for quantitative evaluation of symptoms, for example chest pain

Computer systems for exercise testing regulate the workload of the bicycle or treadmill ergometer according to one of several predefined protocols. The computer systems also maintain a record of time, heart rate, and workload, and display these data on a computer screen together with baseline ECG waveforms [33]. The continuous stream of ECG waveforms, data, and computer measurements are stored and processed online in the system. ECG waveforms are acquired by a process termed analog–digital conversion. Most current digital processing ECG and exercise test systems sample the analog waveforms at the rate of 250 samples/s. A representation of the original analog signal can be obtained by digital–analog reconstruction of the digitized waveform. The computer system subsequently processes the ECG waveforms online to minimize noise and artifactual effects. Especially, at the higher workloads and heart rates, the recorded basic ECG tracings may show so much noise and artifacts from exercising skeletal muscles and respiratory variability that measurements from the original ECG waveforms are unreliable.

The processing involves the steps of QRS-detection, temporal alignment, and signal averaging. The QRS complexes are detected with the aid of a combination of the derivatives of multiple ECG leads. Thus, the characteristic feature used for detection of the QRS complex is the large voltage changes that occur in all leads simultaneously during ventricular activation. The QRS complexes are then classified as normal or abnormal. Abnormal beats may be a result of premature ventricular or supraventricular complexes, or they may be normal beats distorted by excessive noise or baseline drift. The normal beats are then combined into a single representative complex by computation of an average (mean) or median beat. Signal averaging can be performed at preselected intervals, for example, during 20 s of each minute, or continuously. The latter is the method of choice because it permits continuous display of the updated ECG waveform. Since the averaging procedure might be subject to errors in some of the patients, the user should compare the shape of the averaged signal with the original ECG tracings.

From the representative complexes, measurements can be obtained. Since the noise level during exercise is rather high in comparison with resting ECGs, it is not appropriate to take measurements from individual beats as is the case in some resting ECG programs. In commercially available systems, the baseline and ST segment are defined at fixed intervals before and after a single fiducial point in the QRS complex. Therefore, it is necessary to define the proper onset and end of the QRS complex. Such precise definition of QRS-onset and end is only possible if a combination of multiple leads is used [29, 30]. Computerized algorithms for QRS-detection and time alignment are, therefore, more reliable and robust in multichannel recording. Additionally, algorithms are applied that reduce the effect of baseline drift during exercise caused by temperature changes, respiration, and body motion, especially at higher workloads and if there is poor skin–electrode contact.

The processed, online cleaned data allow more accurate measurements of the exercise ECG, especially the low-amplitude signals such as the P-wave, the PR-segment, the junction of the QRS complex and ST segment (J-point), and the ST segment itself [33]. The digital measurements are generally more accurate and reproducible than manual measurements. However, careful overreading to provide quality control for automated choice of onset–offset waveform fiducial markers on the signal-processed data is required to avoid error in interpretation resulting in false-positive test results [4, 33]. Therefore, ECG recordings of the raw, unprocessed ECG data should be available at each stage of the exercise protocol for comparison with the averages that the exercise test monitor generates. Recommendations and standards for the degree of filtering and processing of data have been published [2, 4].

### 36.5.3 Lead Systems for Exercise Electrocardiography

---

Various types of lead systems have been developed, studied, and used in the last decades. Bipolar precordial lead systems have been used for a number of years and have produced satisfactory results in patients with suspected CAD and a normal ECG at rest. The two optimal leads for detection of ST segment depression during exercise are the bipolar lead from the right infraclavicular region to the V5 position (CS5 bipolar lead system) and that from the manubrium of the sternum to the V5 position (CM5 bipolar lead system). They have been reported to detect up to 90% of all ST segment depression identified by multiple-lead systems [34–36]. In patients with a previous myocardial infarction, a single-lead system is inadequate and such patients should be tested with a multiple-lead system. Multiple-lead systems that have been evaluated include the pseudo-orthogonal lead system, the corrected orthogonal lead system (with computer-processed Frank leads), the precordial map, the conventional 12-lead ECG system, and systems using a combination of bipolar leads and the standard 12 leads [33–35, 38–41]. The arrival of powerful high-speed microcomputers has allowed the development of systems for continuous online recording and analysis of the standard 12 ECG leads, which has become the norm in most testing facilities today [33]. It should, however, be noted that lead V5 remains by far the most sensitive electrode position that outperforms the inferior leads and the combination of lead V5 with II, because the latter has a relatively high false-positive rate. Therefore, in patients without prior myocardial infarction and with normal resting ECGs, the precordial leads alone are a reliable marker for CAD, and monitoring of inferior limb leads adds little additional diagnostic information. In these patients, exercise-induced ST segment depression confined to the inferior leads is of little value for detection of CAD [4, 42].

#### 36.5.3.1 Right-Sided Chest Leads

In a study of 245 patients, it was shown that the diagnostic accuracy of exercise testing was increased when right ventricular leads were added to the standard 12 ECG leads [43]. By using right-sided chest leads, the sensitivity for the detection of CAD by angiography was comparable to that of myocardial perfusion scintigraphy (92 versus 93%). However, it is important to realize that these data were obtained in a population with a very high prevalence of CAD and might well be less reliable if the prevalence of CAD were to be substantially lower. Therefore, routine clinical use of right-sided chest leads awaits confirmation of these results in differing populations [4].

## 36.6 Interpretation of the Electrocardiogram

---

### 36.6.1 Changes of the ECG During Exercise in Normal Subjects

---

Normal ECG changes during exercise have been studied in standard chest leads [44], in corrected orthogonal leads [45] and by body-surface mapping [46, 47]. It has been shown that such changes occur gradually in relation to heart-rate changes during stress.

The amplitude of the P-wave increases, without major changes in the waveform. At heart rates over approximately 120 beats/min, this is enhanced by the superposition of the T-wave and the P-wave. At peak exercise with heart rates over 160 beats/min, the P-wave amplitude is on average twice, but in some patients up to five times the amplitude at rest.

Obviously, the PQ-interval shortens, owing to increased sympathetic activity during stress. With the P-wave becoming taller and the Ta-wave (atrial repolarization) increasing, there is a downward displacement of the PQ-junction below the isoelectric line in the resting ECG. This point is considered to be the baseline for terms of measuring ST segment change [33]. Exaggerated atrial repolarization waves during exercise may extend into the ST segment and T-wave and can cause downsloping ST-depression in the absence of ischemia at high peak exercise heart rates [48, 49]. Patients with false-positive exercise tests based on this finding have a high peak exercise heart rate, absence of exercised-induced angina, and markedly downsloping PQ-segments in the inferior leads [4, 48, 49].

QRS-duration does not change significantly during exercise. In one specially designed study, a systematic reduction of QRS-duration of only a few milliseconds was observed [50]. Prolongation of QRS-duration, however, is certainly abnormal. Changes in QRS-morphology have been discussed extensively. At peak exercise, QRS-forces shift toward the right and superiorly. Accordingly, Q-waves in the left precordial leads deepen, R-waves in the left precordial leads decrease, and S-waves become wider and deeper. However, intra-individual variability is large. In standard precordial leads, R-wave amplitude increases frequently at intermediate workloads, with heart rates between 120 and 160 beats/min [44]. This is precisely the heart rate reached by most patients with CAD. At higher heart rates, R-wave amplitude decreases. The situation is even more complex when body-surface maps are analyzed [46, 51]. The position of the maximum amplitude on the chest wall during ventricular depolarization remains located in the left anterior region, but the precise location of the maximum shifted one electrode position or more in seven out of 25 normal subjects studied by Block [46]. No consistent pattern was observed in the changes of the maximum QRS-forces in body-surface maps in normal subjects exercised up to a heart rate of 150 beats/min during maximum exercise. The mechanism of the QRS-changes during exercise is still unclear. It has been claimed that these are related to reduction of end-diastolic volume, which would diminish the effect of the radially oriented depolarization fronts in the left ventricular wall traveling from endocardium to epicardium. However, no reduction in end-diastolic volume was seen in patients studied in the supine position with radionuclide ventriculography [52]. Furthermore, R-wave amplitude variations appeared not to be related to changes in left ventricular volume during experimental myocardial ischemia [53].

The QT-interval shortens during exercise, although it cannot be measured accurately when the T-wave and P-wave overlap at higher heart rates. Usually, there is depression of the J-point followed by an upsloping ST segment. However, the ST segment slope may vary considerably. The T-wave amplitude varies greatly during exercise but increases considerably in most normal subjects immediately after exercise. Generally, the ST segment amplitude 80 ms after the end of the QRS complex remains positive in normal subjects at heart rates around 140 beats/min in the left precordial area, while a minimum develops below the right clavicle. During exercise, depression of the J-point and ST segment are prominent in leads with a lateral and vertical orientation [54]. These changes are far less significant in anterior–posterior and transverse leads. This explains in part the relatively high incidence of so-called false-positive ST segment depressions in these leads. ECG changes in healthy female volunteers are similar to those in males, with the exception of ST segment measurements. Flat or even slightly negative ST segments are present in some of the females at rest. This contributes in part to the false-positive ST segment changes in females [55]. Accordingly, separate criteria were developed for quantitative interpretation of the ECG changes during exercise in females [56].

## 36.6.2 Changes of the ECG During Exercise in Patients with Coronary Artery Disease

The most prominent electrocardiographic findings associated with CAD are a depression or elevation of the ST segment in the left precordial leads.

### 36.6.2.1 ST Segment Depression

The probability that a given subject has CAD is higher if the ST segment depression adheres to the following pattern: it develops early during exercise at a low heart rate, is deeper and has a more horizontal, or even downsloping pattern. However, it should be appreciated that, in subjects with a normal ECG at rest, there remains a considerable overlap between ST segment measurements in normal subjects and in patients with CAD. Also, as mentioned, ST segment waveforms in females during exercise differ from males and show a greater tendency towards ST segment depression, particularly in

**Figure 36.4**

Bicycle exercise stress test in 56-year old male who underwent percutaneous coronary intervention of the left anterior descending artery 10 years earlier for stable angina. He was referred for screening before entering a fitness program. Upon request, he admitted that he had chest pain on exertion. The degree of functional impairment was difficult to assess because of an inactive lifestyle. The patient reached 120 W, whereas the predicted normal value for the peak workload was 174 W. He discontinued the test because of shortness of breath and chest pain. With increasing workload, there is a slow-up sloping ST segment depression up to 1 mm (0.1 mV) in the inferior and left precordial leads, evolving to a downsloping pattern in the recovery phase. The patient was referred for coronary angiography, which revealed a significant stenosis in the left circumflex artery that was subsequently treated by percutaneous coronary intervention.

the vertically-oriented leads [54]. In combination with the lower incidence of CAD in females, this results in an increased fraction of false-positive exercise test results in women, as reported in the literature [55, 57–59]. Nevertheless, exercise testing can be used in females when these factors are taken into account [57, 58]. Accordingly, the likelihood of CAD in females is lower than in males for most combinations of age, history, and ST segment depression, as will be discussed later.

#### Upsloping ST Segment Depression

The significance of upsloping ST segment depression has been studied extensively in the past decades and has generated much controversy. Clearly, downsloping ST segment depression is a stronger predictor of CAD than horizontal depression, and both are more predictive than upsloping depression. However, slowly-upsloping ST segment depression, for example, when the slope is less than 1 mV/s or when the degree of depression at 60–80 ms from the J-point is 1.5 mm (0.15 mV) or more below the baseline level of the PQ-junction, is associated with an increased probability of CAD (Figs. 36.4 and 36.5) [33, 60–62]. In a study of 70 patients with these ST segment changes, 57% had either two- or three-vessel CAD [33, 61]. On the other hand, junctional depression with a very steep upsloping ST segment is probably not pathological. From this it follows that, if slowly-upsloping ST-depression is considered an abnormal finding, sensitivity of exercise testing is increased, albeit at the cost of decreased specificity resulting in more false-positive test results. In the most recent ACC/AHA guidelines on exercise testing, the use of the more commonly-used definition for a positive test of  $\geq 1$  mm (0.1 mV) of horizontal or downsloping ST segment depression is favored [4].

#### Horizontal and Downsloping ST Segment Depression

The most commonly-used definition for visual interpretation of a positive exercise test result from an electrocardiographic standpoint is  $\geq 1$  mm (0.1 mV) of horizontal or downsloping ST segment depression for at least 60–80 ms after the end of the QRS complex (Fig. 36.6 (Continued)) [4]. As stated, downsloping ST segment depression is a stronger predictor of CAD than horizontal depression.

■ **Figure 36.5**

A 60-year old male treated for hypercholesterolemia by his general practitioner underwent exercise testing at the request of the specialist in allergy and immunology. He was suspected to have had a severe allergic reaction to the (rare) combination of wheat and exercise. Before planning an exercise test after ingestion of wheat to assess whether an allergic reaction could be provoked, a standard bicycle exercise test was performed as baseline. In daily life, the patient had a good exercise tolerance without any angina-like complaints. He reached 180 W (predicted peak workload 167 W) and discontinued because of fatigue. There were no angina-like symptoms or dyspnea. The baseline ECG was normal. Up to 160 W, there were no significant ST segment changes indicative of myocardial ischemia. From 160 W onward, minimal slow-up-sloping ST segment depression developed in the left precordial leads, which got a more horizontal pattern and increased up to 2 mm (0.2 mV) at peak workload. The ST segment depression resolved directly following the discontinuation of exercise. This ECG pattern in which the ST segment becomes abnormal only at high workloads and returns to baseline in the immediate recovery phase may indicate a false-positive test in an asymptomatic subject. A nuclear perfusion scintigraphy using dipyridamole was subsequently performed which showed no signs of myocardial ischemia.

#### Magnitude of ST Segment Depression and Probability of Coronary Artery Disease

► Table 36.6 summarizes data from various studies that related the magnitude of ST segment depression at peak exercise to the probability of CAD at coronary angiography [64–67]. It is evident that, for example, horizontal ST segment depression of  $\geq 2$  mm (0.2 mV) is highly specific (if only such results were considered abnormal, the specificity would be 99%), but occurs in the minority of patients with CAD (sensitivity would be only 28%). On the other hand, ST segment depression of 0.5 mm (0.05 mV) is nonspecific (sensitivity is 68%, but specificity only 80%), and should, therefore, not be used as a criterion for abnormality. A superior approach is to compute, from the data in ► Table 36.6, the ratio of

(a) Bicycle exercise stress test in 54-year old male with no history of cardiovascular disease who visited the outpatient clinic for angina-like chest pain complaints, class III according to the Canadian Cardiovascular Society [63]. The predicted maximum workload was 175 W. The patient discontinued the test at 120 W because of severe chest pain. Slow-upsloping to horizontal ST segment depression already developed at low workload (80 W) and increased to a maximum of 3.5 mm (0.35 mV) in the left precordial lead  $V_5$  at maximal exertion. The ST segment depression evolved to a downsloping pattern in the recovery phase. Coronary angiography revealed a severe stenosis at the bifurcation of the left anterior descending artery and first diagonal branch, which was subsequently treated by percutaneous coronary intervention with bifurcation stenting according to the culotte technique. (b) Overview of ST segment trends and hemodynamic data of the same exercise test, showing the development of progressive ST segment depression in the inferior and precordial leads with increasing workload.

### ■ Figure 36.6 (Continued)

(c) The same patient visited the outpatient clinic approximately 1 year after the percutaneous coronary intervention. He indicated that he suffered again from chest pain similar to the complaints he had prior to the revascularization procedure. The only difference was that the chest pain now occurred with more strenuous exertion as compared to the complaints 1 year earlier (functional class II according to the Canadian Cardiovascular Society [63]). The patient reached the predicted workload of 171 W and discontinued the test because of tiredness and shortness of breath. The exercise electrocardiogram again showed marked ST segment depression up to 6 mm (0.6 mV) with a horizontal to downsloping pattern at maximal exertion. Coronary angiography revealed severe in-stent restenosis in the treated segments in the left anterior descending artery and first diagonal. The patient was subsequently successfully treated by repeat percutaneous coronary intervention.

the likelihood that a given range of ST segment depression is related to the presence or absence of CAD. This likelihood ratio is 0.4 for ST segment depression up to 0.9 mm (0.09 mV). Only ST segment depression greater than 1 mm (0.1 mV) is clearly associated with CAD. It is apparent that this likelihood increases when the ST segment depression is more pronounced.

### Magnitude of ST Segment Depression and the Degree of Anatomical Coronary Artery Disease

Many investigators have attempted to correlate the magnitude of ST segment depression with the degree of anatomical CAD. Initial studies reported that an increased magnitude of ST-depression was associated with an increased degree of ischemia [33, 68]. Later studies have been unable to correlate the ischemia estimated from the magnitude of the ST segment depression in any lead or from the sum of the ST-changes in all leads with either the number of diseased coronary

arteries or the size of the area of reversible ischemia observed on myocardial perfusion scintigraphy [33, 69, 70]. As the development of ST segment depression as an electrophysiological phenomenon results from many influences, including those caused by electrolytes, hormones, and hemodynamic, metabolic, as well as anatomical changes, it is unlikely that the magnitude of ST segment depression would correlate well with the coronary anatomy in patients with CAD. Furthermore, the degree of ST-depression at higher workloads also depends on what is used as an indication to terminate exercise. For example, if patients with single vessel disease are encouraged to exercise strenuously or if they have some degree of left

■ **Figure 36.7**

**Bicycle exercise test (10 W/min protocol) in a 77-year old male with angina pectoris complaints, classified as II–III according to the Canadian Cardiovascular Society [63]. His medical history was unremarkable except for poorly controlled arterial hypertension. The resting ECG showed signs of an old inferior myocardial infarction (Q-waves in leads II, III, and aVF), as well as left ventricular hypertrophy with repolarization abnormalities in the left precordial leads (downsloping ST segment with inverted T-wave). With increasing workload, the preexistent ST segment depression increased progressively up to 4 mm (0.4 mV), persisting in the recovery period. Coronary angiography revealed three-vessel coronary artery disease and ventriculography showed a moderately impaired left ventricular systolic function. The patient subsequently underwent coronary artery bypass grafting.**

ventricular hypertrophy, they may have severe ST-depression (see also ▶ Figs. 36.6 (Continued) and ▶ 36.7). Therefore, the magnitude of ST segment depression at maximum workload may not indicate the severity of CAD.

#### Time Course of ST Segment Depression

ST segment depression that comes on early during exercise at low workloads is associated with more severe disease and impaired prognosis [33, 68, 71–73]. In a study on the predictive value of the time course of ST segment depression during exercise testing in patients referred for coronary angiography, a direct relationship between the time of onset and offset of ST-depression and the number of diseased coronary arteries was demonstrated [33, 73]. Severe three-vessel CAD was found in 33% of patients with early onset and late offset of the ST-depression, while this increased up to 50% in those with resting ST-depression that increased with exercise [73]. Even ST segment depression occurring at high workloads and with

rapid resolution during recovery may be associated with significant CAD, although it may also indicate a false-positive response in an asymptomatic subject (► Fig. 36.5).

Furthermore, although ST segment depression during exercise often persists into the recovery phase, it sometimes may not develop until exercise has been terminated (► Fig. 36.4). Whereas this phenomenon is still not completely understood, several studies have demonstrated that ST segment depression occurring only during recovery has the same significance as exercise-induced ST-depression in predicting CAD [33, 74, 75].

#### Adjustment of ST Segment Depression

Subjects with tall R-waves exhibit a greater amount of ST segment depression than those with smaller R-wave amplitude [76]. Accordingly, when the R-wave in the lateral precordial leads is less than 10 mm, the sensitivity of ST-depression for the detection of CAD is low if 1 mm (0.1 mV) of ST-depression is required for a positive test result [77]. Correcting ST-depression for R-wave amplitude has been proposed by dividing the amount of ST segment depression by the R-wave height (both expressed in mm) [78]. The ST/R-ratio may then be used as an alternative to the amount of ST segment depression per se, with 0.1 as a cutoff value for an abnormal test result [33]. In studies, however, adjustment of the amount of ST segment depression by the R-wave height has not been shown to consistently improve the diagnostic value of exercise-induced ST-depression [4].

Several methods of heart rate adjustment have been proposed to increase the diagnostic accuracy of the exercise ECG. The first technique is to derive the maximal slope of the ST segment relative to heart rate (ST/HR slope). The second method, termed the ST/HR index, divides the difference between ST-depression at peak exercise by the delta heart rate (difference between resting and maximum heart rate) [4, 33, 79–82]. The value of ST/HR adjustment in improving diagnostic accuracy has been evaluated in several studies [4, 83–87]. Most studies, however, were limited by work-up bias and enrollment of relatively healthy patients, which presents a limited challenge to the ST/HR index [4, 85–87]. In a large multicenter study without these limitations, the ST/HR slope or index was not found to be more accurate than simple measurement of the ST segment depression [88]. The most recent guidelines on exercise testing take the perspective that the ST/HR adjustment approach in symptomatic patients has at least equivalent accuracy to the standard approach [4]. Although the ST/HR approach might be useful in assessing certain borderline or equivocal ST segment responses during exercise (e.g., ST segment depression associated with a very high exercise heart rate), further validation is required.

#### ST Segment Depression and the Location of Coronary Artery Disease

In several studies, an attempt has been made to relate the location of ST segment depression during exercise to coronary anatomy. As stated, extensive CAD (three-vessel disease) is more likely to be present in a patient who develops major ST segment depression in multiple leads at low workloads. However, even in patients with single-vessel disease, there is no clear separation between the leads in which ST segment depression develops when either the right coronary artery or the left anterior descending coronary artery is involved [67]. Studies using body-surface mapping indicate that the ST segment depression is most prominent in the precordium. The actual position where the largest ST segment depression occurs varies widely, from the level of the third intercostal space to the tenth intercostal space [46]. However, even analysis of precordial surface maps has not permitted an accurate prediction of the location of CAD [40, 89], although this has previously been claimed [40]. Furthermore, in another study, no relation was found between the spatial orientation of the ST segment vectors during exercise and the location of myocardial ischemia as detected by myocardial perfusion scintigraphy [90].

#### ST Segment Depression and/or Exercise-Induced Angina

The occurrence of chest pain during stress testing is of equal diagnostic value as the development of ST segment depression [91–93]. Symptoms that cannot be clearly understood during an outpatient clinic visit may be clarified if they occur during the actual exercise procedure and disappear rapidly in the recovery phase. In order to permit optimal comparison between the history of the patient and the observations during the stress test, it is recommended that either the test is performed by the patient's own physician, or that the physician supervising the test reports in detail all the complaints that occur during the test and notes whether these are similar to the complaints that led the patient to the outpatient clinic. In ► Fig. 36.8, the incidence of CAD and the number of diseased vessels are presented for ST segment depression with and without angina [92].

■ Figure 36.8

Incidence of normal coronary arteries (zero-) and one-, two-, or three-vessel disease in 311 patients without a history of transmural myocardial infarction. It should be noted that the incidence of CAD was similar in 30 patients with ST segment depression without symptoms (30%) and in 68 patients with exercise-induced angina without significant ECG changes (36%). ST-depression represents 0.1 mV or greater of ST segment depression in at least one precordial lead (Adapted from Roskamm [92]).

### 36.6.2.2 ST Segment Elevation

ST segment elevation during exercise is observed most frequently in leads with Q-waves in patients with a history of myocardial infarction (● Fig. 36.9). The significance of ST segment elevation in areas of Q-waves of an old myocardial infarction is controversial. Some studies have suggested that this ST segment elevation is caused by an area with abnormal wall motion (ventricular akinesia or dyskinesia) [64, 94–97]. However, other studies have shown that in some patients such ST-elevation disappears after coronary bypass surgery, which suggests that the ST-elevation was a result of myocardial ischemia [98]. More recent studies using myocardial perfusion scintigraphy have found such ST-elevation to be a marker of residual viability in the infarcted area [99–101]. Therefore, it seems advisable to consider additional tests such as myocardial perfusion scintigraphy in patients with chest pain complaints after myocardial infarction and ST segment elevation during exercise stress testing.

Exercise-induced ST segment elevation in leads without Q-waves on a normal ECG (other than in aVR or V<sub>1</sub>) is very rare and represents severe transmural myocardial ischemia (whereas ST segment depression represents subendocardial ischemia) [94, 102–109]. It is caused by a coronary artery spasm that completely obliterates antegrade flow through the epicardial artery, or a high-grade proximal stenosis in a coronary artery (● Fig. 36.10). In patients with variant or Prinzmetal's angina, coronary spasm is most commonly seen at rest, but very occasionally it occurs with exercise, probably indicating the presence of hemodynamically significant coronary atherosclerosis [33, 110, 111]. In contrast to ST segment depression, exercise-induced ST segment elevation is very arrhythmogenic and localizes the ischemic area. When ST segment elevation occurs in leads V<sub>2</sub> through V<sub>4</sub>, there is severe anterior wall ischemia with a high-grade stenosis in the proximal left anterior descending coronary artery (● Fig. 36.10); in leads II, III, and aVF, there is severe inferior wall ischemia with involvement of a proximal stenosis in a large right coronary artery; and in the lateral leads, the left circumflex or diagonals are involved [4]. As stated previously, this rare finding warrants immediate discontinuation of the stress test and prompt referral for coronary angiography.

Bicycle ergometer

Protocol: steps of 20 Watts (W) per minute

ST segment: measured at J-point plus 60 msec ( $\mu\text{V}$ ); ST-slope in mV/sec

Figure 36.9

Bicycle exercise stress test in a 62-year-old male approximately 1 year after he underwent a primary coronary intervention with recanalization of the occluded left anterior descending coronary artery for an acute anterior myocardial infarction. The result of the intervention was suboptimal because there was no reflow in the infarct-related artery. No intervention was performed on a 50–70% stenosis in the left circumflex coronary artery. Echocardiography showed an impaired systolic left ventricular function with akinesia of the interventricular septum and hypokinesia of the anterior wall and apex. The baseline ECG showed sinus rhythm, a left anterior fascicular block, and a QRS-pattern compatible with an old antero-septal-apical myocardial infarction with QS-complexes in  $V_1$  and  $V_2$ , a small R-wave in  $V_3$ , as well as a Q-wave in aVL. The patient reached 160 W and discontinued the test because of fatigue. The patient did not experience any anginal complaints or dyspnea during the test. With an increase in workload, there is an increasing level of ST segment elevation in the right precordial leads ( $V_1$ – $V_3$ ), representing either wall motion abnormalities or residual viability in the infarcted area. Furthermore, the duration of the QRS complex increased. In the recovery phase, minimal 0.5 mm (0.05 mV) downsloping ST segment depression developed in the inferior and left precordial leads.

### 36.6.2.3 Changes of the QRS Complex

#### R-Wave Amplitude

It has previously been reported that an increase in R-wave amplitude during exercise is a useful indicator of CAD [112]. The first reports on this phenomenon were based on an unusual series of patients with known false-positive or false-negative ST-changes during exercise. Although some studies supported these observations, others found that the R-wave amplitude changes were variable both in patients with CAD and in normal subjects [52–54, 113]. It is possible that the observed differences in R-waves between patients with CAD and normal subjects result in part from differences in heart rate, since most patients stop exercising at heart rates between 120 and 150 beats/min which is the rate at which normal subjects frequently exhibit increased R-wave amplitudes [44]. The mechanisms of these changes also remain unclear. In particular, the hypothesis that the increase in R-wave amplitude would be related to an increase in ventricular volume owing to

Bicycle ergometer

Protocol: steps of 20 Watts (W) per minute

ST segment: measured at J-point plus 60 msec ( $\mu\text{V}$ ); ST-slope in mV/sec

■ Figure 36.10

Bicycle exercise test in a 59-year-old male with no history of cardiovascular disease who underwent stress testing because of complaints of chest pain on exertion suspected for angina pectoris. The predicted maximum workload was 163 W. The test was discontinued at 200 W by the attending physician because of shortness of breath, as well as failure of the blood pressure to rise in the presence of ST segment depression. Starting at 180 W, up to 1.0–1.5 mm (0.1–0.15 mV) of slow-up-sloping to horizontal ST segment depression developed in the inferior and left precordial leads, indicating subendocardial ischemia. Directly following discontinuation of exercise, the patient experienced angina-like chest pain. This was attended on the ECG by ST segment elevation and a marked increase in T-wave amplitude in the right precordial leads, suggesting transmural ischemia due to a high-grade stenosis in the proximal left anterior descending artery. Later on in the recovery phase, biphasic T-waves developed in the right precordial leads. At the end of the recovery period, the ECG had returned to normal. The patient was subsequently admitted to hospital. Coronary angiography was performed the same day and revealed, as expected, a severe stenosis in the proximal left anterior descending artery which was treated with stent implantation.

myocardial ischemia [114] was not supported by studies in which the volume changes were actually measured [52, 53, 115]. As exercise-induced changes in R-wave amplitude have provided very little, if any, discrimination for myocardial ischemia, the R-wave measurements are not routinely applied in clinical practice.

#### QRS-Duration

As stated, the duration of the QRS complex during exercise does not increase but may be reduced slightly because conduction velocity is increased by catecholamine release [50, 116]. Although a number of studies have shown that conduction

velocity is decreased by myocardial ischemia [61, 117], QRS-duration measurements are not routinely used for the diagnosis of CAD as studies on this phenomenon have had equivocal results [61]. Prolongation of the QRS-duration during exercise was found to be associated with CAD in 330 patients who underwent exercise testing and coronary angiography [118]. The greatest prolongation was found in patients with three-vessel disease. However, the observations could not be used in individual patients to determine the presence or absence of myocardial ischemia as the variations around the mean value were too large [118].

#### Bundle-Branch Block

Rate-dependent bundle-branch block may become apparent during exercise and the interpretation of such a finding is the same as in rate-dependent bundle-branch block occurring under other circumstances. Rate-dependent left bundle-branch block, right bundle-branch block or left anterior fascicular block may be related to CAD [33, 119]. However, they have also been observed in healthy subjects without myocardial or coronary pathology [33]. The isolated finding of a rate-dependent bundle-branch block should, therefore, not be used as a proof of significant heart disease. On the other hand, the occurrence of a bundle-branch block during exercise should be viewed in light of the other clinical findings in each patient in order to assess the probability that CAD is present. Leftward rotation of the frontal axis with development of a left anterior fascicular block during exercise in a patient *with* CAD usually signifies involvement of the proximal left anterior descending coronary artery or three-vessel CAD [120, 121]. The axis shift associated with left anterior fascicular block may mask the ischemic ST segment changes in the frontal plane and to a lesser extent in the precordial leads.

The significance of ST segment depression as a predictor of ischemia in the presence of right bundle-branch block has been the subject of debate. Exercise-induced ST-depression usually occurs with right bundle-branch block in the anterior chest leads  $V_1$  through  $V_3$ , probably because of secondary repolarization changes, and is not associated with ischemia [4, 122]. However, ST segment depression in the left precordial leads ( $V_5$  and  $V_6$ ) or inferior leads (II and aVF) has the same significance in predicting CAD as exercise-induced ST-depression in a normal resting ECG [123, 124].

Exercise-induced ST-depression usually occurs with left bundle-branch block and has no association with ischemia [125]. Even up to 10 mm of ST-depression occurs in healthy subjects. There is no level of ST-depression that confers diagnostic significance in left bundle-branch block. Therefore, there is a consensus, as stated in the guidelines, that exercise-induced ischemia cannot be diagnosed from the ECG in patients with left bundle-branch block [4].

#### 36.6.2.4 T-Wave Changes

As previously mentioned, the T-wave amplitude varies greatly during exercise but increases considerably in most normal subjects immediately after exercise as a result of an increased stroke volume, which makes up for the lingering metabolic debt after the heart rate has dropped very rapidly. Many patients with flat or inverted T-waves at rest will manifest upright T-waves at the time of exercise. This is particularly true in women. This phenomenon of normalization of inverted T-waves or pseudonormalization of the T-waves is not considered to indicate ischemia. In earlier studies, T-wave normalization was accompanied by significant ST segment depression in 90% of patients with CAD, but by a negative test result based on ST segment criteria in all patients without ischemic heart disease [33, 126]. Similarly, exercise-induced deep T-wave inversion is almost always accompanied by significant ST segment depression and is then associated with a more severe degree of CAD.

### 36.7 Exercise Testing to Diagnose Coronary Artery Disease

---

The vast majority of exercise testing is performed in adults with symptoms of known or suspected ischemic heart disease. There has been considerable discussion on the value and use of exercise testing for the diagnosis of CAD and the literature on this subject is extensive. Knowledge of terminology used in describing diagnostic test characteristics and test performance is required for understanding the exercise test literature (► Table 36.7).

■ **Table 36.7**

**Diagnostic test characteristics**

True-positive test result (TP)	Abnormal test result in subject <i>with</i> disease
False-positive test result (FP)	Abnormal test result in subject <i>without</i> disease
True-negative test result (TN)	Normal test result in subject <i>without</i> disease
False-negative test result (FN)	Normal test result in subject <i>with</i> disease
Specificity	Percentage of subjects <i>without</i> disease who have a normal test result = $TN/(TN + FP)$
Sensitivity	Percentage of subjects <i>with</i> disease who have an abnormal test result = $TP/(TP + FN)$
Test accuracy	Percentage of true test results = $(TP + TN)/\text{total number of tests performed}$
Predictive value of a positive test result	Percentage of subjects with abnormal test who have the disease = $TP/(TP + FP)$
Predictive value of a negative test result	Percentage of subjects with normal test and without disease = $TN/(TN + FN)$
<i>Formula for calculation of posttest probability (Bayes' theorem):</i>	
Posttest odds (disease present) = pretest odds (disease present) $\times$ likelihood ratio (LR) where, odds = probability/(1 – probability) LR = sensitivity/(1 – specificity) in case of an abnormal test result = (1 – sensitivity)/specificity in case of a normal test result	
Posttest odds (disease absent) = pretest odds (disease absent) $\times$ likelihood ratio (LR) where, odds = probability/(1 – probability) LR = (1 – specificity)/sensitivity in case of an abnormal test result = specificity/(1 – sensitivity) in case of a normal test result	
The better (very high or very low) the likelihood ratio of the test (determined by sensitivity and specificity), the more discriminant the test is.	

■ **Table 36.8**

**Pretest probability (%) of CAD in patients by age, sex, and chest pain characteristics (Adapted from Diamond and Forrester [127])**

Age (years)	Sex	Non-anginal chest pain	Atypical angina	Typical angina
30–39	M	5.2 $\pm$ 0.8	21.8 $\pm$ 2.4	69.7 $\pm$ 3.2
	F	0.8 $\pm$ 0.3	4.2 $\pm$ 1.3	25.8 $\pm$ 6.6
40–49	M	14.1 $\pm$ 1.3	46.1 $\pm$ 1.8	87.3 $\pm$ 1.0
	F	2.8 $\pm$ 0.7	13.3 $\pm$ 2.9	55.2 $\pm$ 6.5
50–59	M	21.5 $\pm$ 1.7	58.9 $\pm$ 1.5	92.0 $\pm$ 0.6
	F	8.4 $\pm$ 1.2	32.4 $\pm$ 3.0	79.4 $\pm$ 2.4
60–69	M	28.1 $\pm$ 1.9	67.1 $\pm$ 1.3	94.3 $\pm$ 0.4
	F	18.6 $\pm$ 1.9	54.4 $\pm$ 2.4	90.6 $\pm$ 1.0

CAD denotes coronary artery disease

### 36.7.1 Pretest Probability

The pretest probability of obstructive CAD can be estimated from factors such as age, gender, risk factors, and chest pain characteristics [127–129]. The pretest probabilities described in this way by Diamond and Forrester in a series of over 60,000 patients are shown in [▶ Table 36.8 \[127\]](#). From this table, it is apparent that exercise testing is not very useful for establishing the diagnosis CAD in a 64-year-old man with typical or definite angina. The pretest probability of CAD

Table 36.9

	0.05–0.09	94	90	65	52	26	17	11	7
	0.10–0.14	97	95	81	72	45	33	23	15
	0.15–0.19	99	98	89	83	62	49	37	25
	0.20–0.24	99	99	96	93	81	72	61	47
	>0.25	>99	>99	99	98	94	90	85	76

is so high that the test result does not substantially change this probability. As shown in Table 36.9, the likelihood of CAD is 79% if no ST segment depression occurs during the test, while it would be 99% if 2 mm (0.2 mV) of ST segment depression developed. However, the test may still be used to determine the functional impairment of that subject, to measure the blood-pressure and heart rate response, or to estimate the prognosis. Similarly, the diagnostic value of exercise electrocardiography is low in asymptomatic men and women (see also Fig. 36.11). The greatest diagnostic value of exercise testing is obtained in patients with an intermediate pretest probability of CAD, for example, between 20% and 80%, because the test result has the largest potential effect on diagnostic outcome. If the posttest likelihood is intermediate, another noninvasive (e.g., myocardial perfusion scintigraphy) or invasive test may be applied.

### 36.7.2 Diagnostic Characteristics and Test Performance

One of the problems with diagnostic tests for CAD is that there is a considerable overlap in the range of measurements for the normal population and those with CAD. Since the depth of exercise-induced ST segment depression and the extent of the myocardial ischemic response can be considered as continuous variables, a certain cutpoint or discriminant value (e.g., 1 mm (0.1 mV) of ST segment depression) cannot completely discriminate patients with CAD from those without

■ Figure 36.11

Illustration of the impact of the prevalence of CAD in the population studied on the fraction of false-positive test results and the predictive value of the exercise test. Each bar represents a population of 100 patients. In the left-most bar, 50 patients have CAD, while 50 do not have CAD. In the second bar, 40% has CAD, in the third 30%, in the fourth 20%, and in the right-most bar only 10%. In each theoretical example, the sensitivity for detection of CAD is 70%. Thus, 70% of patients with CAD do indeed have ischemic ST segment depression. On the other hand, the specificity is 90%. Thus, 10% of the patients without CAD exhibit false-positive ST segment depression (black area). In the population with a 50% prevalence of CAD (left-most bar), 40 abnormal tests are found, five of which are false-positive (12.5%). In the population with only a 10% prevalence of CAD (right-most bar), nine false-positive tests occur out of a total of 16 tests with ST segment depression (56.2%). In this latter population, which reflects the prevalence of CAD in many screening conditions, the number of false-positives is higher than the number of correct or true-positive test results. CAD, coronary artery disease; FP, false-positive; PV, predictive value; Pts, patients; and TP, true-positive.

disease. A higher discriminant value for ST segment depression improves specificity, but reduces the test's sensitivity. Therefore, sensitivity and specificity are inversely related and determined by the choice of a cutpoint or discriminant value. The positive predictive value (PPV) and negative predictive value (NPV) are also affected by the population tested. The PPV will be higher in a population with a higher prevalence of CAD. Accordingly, PPV is higher in patients with three-vessel CAD and lower in patients with one-vessel CAD. The NPV can be decreased if the test is used in patients in whom false-positive results are more likely such as those with ST segment depression on the resting ECG or left ventricular hypertrophy. ● Figure 36.11 illustrates these points.

### 36.7.3 Probability Analysis

The use of Bayes' theorem of conditional probability can assist in the interpretation of a test result and can also provide a meaningful estimate of the posttest probability in the individual patient. According to this theorem, posttest probability is a function of pretest probability, and the sensitivity and specificity (likelihood ratio) of the test [130].

Under the assumption of the independence of the exercise test result from the clinical (pretest) data, posttest probability can be calculated according to the formula listed in ▶ Table 36.7. Although this calculation is often made intuitively by the clinician, mathematical equations or scores have been developed from multivariate analysis of clinical and exercise test variables (including heart rate at peak exercise, ST segment response, the presence or absence of angina during the test, peak workload, and ST segment slope) that can provide a more accurate estimate of the probability that CAD is present, when compared with use of the ST segment measurements alone [4, 131–135]. However, the use of these statistical models remains limited. Nevertheless, they underline the importance of taking into account all relevant variables when estimating the probability of CAD in a given subject [136–138].

### 36.7.4 Diagnostic Accuracy of the Standard Exercise Test

A meta-analysis was performed on the diagnostic accuracy of the exercise test based on 147 consecutive published reports involving 24,074 patients who underwent both coronary angiography and exercise testing [139, 140]. There was a wide variability in the reported diagnostic accuracy of the standard exercise test among the studies (▶ Table 36.10). The mean sensitivity was 68% (range 23–100%) and mean specificity was 77% (range 17–100%). This large variability results from the fact that most studies do not fulfill two major criteria that are important when evaluating diagnostic tests [4]. The first concerns the fact that the population studied does not represent the diagnostic dilemma group in clinical practice. In particular, inclusion of patients who most certainly have the disease (e.g., post-myocardial infarction patients) in the test group presents a limited challenge to the diagnostic test. The second cause concerns the presence of work-up bias which refers to the fact that most reported studies were affected to some degree by clinical practice wherein the results of the exercise test were used to decide who would undergo coronary angiography and be included in the study [4]. The reported meta-analysis provides, however, the best estimate of the diagnostic accuracy of the exercise test. When only studies that excluded patients with a previous myocardial infarction were considered, mean sensitivity was 67% and mean specificity 72% (▶ Table 36.10). Only three studies avoided work-up bias and provide an estimate of the diagnostic accuracy of exercise testing in a more general population of patients presenting with chest pain [141–143]. The mean sensitivity and specificity in these studies were 50% and 90%, respectively (▶ Table 36.10).

### 36.7.5 Electrocardiographic Factors Influencing Sensitivity and Specificity

The influence of left ventricular hypertrophy, resting ST segment depression and use of digoxin on the exercise test characteristics are summarized in ▶ Table 36.10. Left ventricular hypertrophy with repolarization abnormalities is associated

■ Table 36.10

Meta-analysis of diagnostic performance of exercise test (Adapted from ACC/AHA Practice Guidelines on Exercise Testing [4] and from [139, 140])

(Sub-)Groups	Number of studies	Total number of patients	Sensitivity (%)	Specificity (%)	Predictive accuracy (%)
Meta-analysis of standard exercise test	147	24,047	68	77	73
Meta-analysis <i>without</i> prior MI	58	11,691	67	72	69
Meta-analysis <i>without</i> work-up bias	3	>1,000	50	90	69
Meta-analysis <i>with</i> ST-depression	22	9,153	69	70	69
Meta-analysis <i>without</i> ST-depression	3	840	67	84	75
Meta-analysis <i>with</i> digoxin	15	6,338	68	74	71
Meta-analysis <i>without</i> digoxin	9	3,548	72	69	70
Meta-analysis <i>with</i> LVH	15	8,016	68	69	68
Meta-analysis <i>without</i> LVH	10	1,977	72	77	74

LVH, left ventricular hypertrophy; MI, myocardial infarction

with a decreased specificity, but sensitivity is unaffected. If the test result is negative, the probability of CAD is substantially reduced, but additional tests are indicated in patients with an abnormal test result (▶ Fig. 36.7). Although not apparent from ▶ Table 36.10, studies have suggested that digoxin also lowers specificity by producing an abnormal ST segment response to exercise, which occurs in up to 40% of healthy individuals [144, 145]. Resting ST segment depression is associated with a higher prevalence of severe CAD and a higher incidence of adverse cardiac events [4, 146–151]. As shown in ▶ Table 36.10, resting ST-depression lowers specificity of the exercise test. The most recent guidelines on exercise testing state that, if the resting ST segment depression is less than 1 mm (0.1 mV), the standard exercise test may still be the first test because sensitivity is increased [4]. In a retrospective study of male patients with resting ST segment depression, but without prior myocardial infarction, undergoing exercise testing, 2 mm (0.2 mV) of additional exercise-induced ST segment depression, or downsloping ST segment depression of 1 mm (0.1 mV) or more in the recovery phase were found to be important markers for the diagnosis of CAD, with a sensitivity of 67%, a specificity of 80%, and a likelihood ratio of 3.4 [4, 151]. In patients with less than 1 mm (0.1 mV) of resting ST segment depression who are also taking digoxin or have left ventricular hypertrophy, as well as in those with more than 1 mm (0.1 mV) of resting ST segment depression (▶ Fig. 36.7), the diagnostic merits of the standard exercise test may be insufficient and imaging tests such as myocardial perfusion scintigraphy or stress echocardiography are preferred [4].

Finally, as stated, specificity was lowered and sensitivity increased when upsloping ST segment depression was classified as abnormal. Furthermore, the presence of right bundle-branch block does not appear to reduce the diagnostic accuracy of the exercise test for the diagnosis of CAD. On the contrary, exercise testing should not be used for the diagnosis of CAD in patients with complete left bundle-branch block, or in those with pre-excitation (Wolff-Parkinson-White) syndrome, or electronically paced ventricular rhythm [4].

### 36.7.6 Exercise Electrocardiography Versus Noninvasive Stress Imaging Studies

Although it is beyond the scope of this chapter to include a complete discussion on the comparison of exercise electrocardiography with the noninvasive stress imaging tests for the diagnosis of CAD, some features are presented here in brief. Studies that compared the diagnostic performance between exercise electrocardiography and the noninvasive imaging modalities using pharmacological stress (e.g., stress echocardiography or stress single-photon emission computed tomography (SPECT) myocardial perfusion scintigraphy) indicate that the latter are both more sensitive and more specific for the detection of CAD [152–155]. Furthermore, myocardial perfusion scintigraphy and stress echocardiography permit, to a certain extent, separation of patients with single and multiple vessel CAD and detection of the location of significant coronary artery stenosis [152–156]. This does not mean that exercise electrocardiography should be replaced by these imaging modalities. In many patients, CAD can be effectively ruled out, or diagnosed, by conventional exercise testing. Noninvasive imaging tests may provide additional information if the diagnosis is uncertain after conventional exercise testing, for example, if there is a posttest likelihood of intermediate probability. This likelihood is then considered as the pretest likelihood for the stress imaging test, as shown in ▶ Table 36.11 for myocardial perfusion scintigraphy; a 50% likelihood will reduce to 15% if the scintigram is normal, or increase to 93% if a reversible perfusion defect occurs. Myocardial perfusion scintigraphy and stress echocardiography using pharmacological stress agents can also be a useful alternative to exercise stress protocols in patients who are unable to exercise because of neurological, orthopedic, or peripheral vascular disease, as well as in those patients in whom interpretation of the ECG is hampered [152–158]. For a more complete and detailed overview of the noninvasive imaging modalities and their usefulness in the evaluation of CAD, the reader is referred to the relevant literature and guidelines [152–158].

## 36.8 Exercise Testing in Patients with Coronary Artery Disease

The value of exercise testing for risk or prognostic stratification must be considered in the light of what is added to that which is already known about the patient's risk status. Most studies on risk assessment in patients with CAD using exercise testing have focused on the relation between test parameters and future survival. The strongest predictor of survival in patients with CAD is the function of the left ventricle. Other important prognostic factors include the anatomic extent

**Table 36.11**

Calculation of posttest probability of CAD after myocardial perfusion scintigraphy. The pretest probability (after exercise testing) can be obtained from the appropriate data in [Table 36.9](#)

Pretest probability (%)	Posttest probability (after nuclear perfusion scintigraphy in %)		
	No defect	Nonreversible defect	Reversible defect
10	2	14	56
20	4	26	74
30	7	38	83
40	10	49	89
50	15	59	92
60	21	68	95
70	29	77	96
80	41	85	98
90	61	93	99

CAD denotes coronary artery disease

and severity of CAD, evidence of a recent acute coronary syndrome resulting from a coronary plaque rupture, and the propensity for the development of ventricular arrhythmias.

### 36.8.1 Risk Stratification and Assessment of Prognosis with Exercise Testing

In patients with suspected or known CAD and symptoms suggestive of myocardial ischemia, exercise testing is the standard initial test in those with a normal ECG for identification of ischemia and risk assessment [4, 159–161]. In patients with a non-interpretable ECG, exercise testing may still provide useful prognostic information, but cannot be used to identify ischemia. Studies on the prognostic value of the exercise test in symptomatic patients with non-acute CAD identify the maximum exercise capacity to be the strongest and most consistent prognostic factor [4, 162–168]. Maximum exercise capacity can be expressed as maximum exercise duration, maximum workload or MET level achieved, maximum blood pressure, or double (rate-pressure) product and represents at least in part left ventricular function. Markers of exercise-induced ischemia (electrocardiographic and/or clinical) represent the second group of variables that bear adverse prognostic information. In particular, electrocardiographic evidence of myocardial ischemia in patients with a low maximum exercise capacity represents a high-risk population [4, 162, 169].

Using data of 2,842 patients with known or suspected CAD, without prior revascularization or recent myocardial infarction, who underwent exercise testing before coronary angiography, the Duke treadmill score was created [163, 170]. This score is calculated using multiple variables of prognostic importance from the exercise test and can subsequently be converted into an average annual mortality rate [163, 170]. Based on the individual scores, patients can be classified in a high-risk group with a high average annual cardiovascular mortality, an intermediate risk group, or a low-risk group. The Duke treadmill score was shown to independently add prognostic information to the standard clinical data plus the data resulting from cardiac catheterization. The score can also be applied in women, although women have a lower overall risk for any score value than men [171]. Comparable prognostic scores have been developed by other groups [164].

Recently, several studies have identified other parameters from the exercise test to be important prognostic information. These include chronotropic incompetence, abnormal heart rate recovery, and delayed blood pressure response [172–179]. In one study of almost 10,000, mostly, asymptomatic patients, it was demonstrated that abnormal heart rate recovery and the Duke treadmill score were independent predictors of mortality [4, 177].

Exercise testing is a much stronger predictor of cardiovascular mortality than of nonfatal myocardial infarction. This may, in part, be a result of the fact that myocardial infarctions are mostly caused by rupture of relatively small, vulnerable atherosclerotic plaques that are difficult to detect by exercise testing because of their non-obstructive character, whereas exercise test results are correlated with the presence and severity of obstructive CAD [4, 163, 180].

### 36.8.2 Exercise Testing to Guide Patient Treatment

---

The results of exercise testing may be used to guide patient treatment. Patients with a low risk exercise test result and a low predicted average annual mortality rate can be treated medically, whereas patients at higher risk should be referred for additional testing or cardiac catheterization, especially in case of left ventricular dysfunction.

Patients with acute coronary syndromes without persistent ST segment elevation are stratified as low, intermediate, or high risk based on history, physical examination, 12-lead ECG, and cardiac markers of myocardial necrosis [181, 182]. High-risk patients will be scheduled to undergo coronary angiography and subsequent revascularization. In low or intermediate risk patients with unstable angina, exercise or pharmacologic stress testing plays an important part in risk stratification and identification of obstructive CAD. Exercise electrocardiography should be the standard mode of stress testing in patients with a normal resting ECG [4]. In general, stress testing can be performed as soon as the patient has stabilized clinically. Furthermore, studies have shown that exercise testing is safe when used in emergency department chest pain centers to provide risk stratification for chest pain patients believed to possibly have acute coronary disease [4, 183–185]. However, exercise testing in this setting should only be used in low, and intermediate risk patients on the basis of history, physical examination, 12-lead ECG, and markers of myocardial necrosis.

### 36.9 Exercise Testing after Acute Myocardial Infarction

---

Exercise testing after acute myocardial infarction can be used for patient management, risk stratification, and prognostic assessment. Treatment strategies for acute myocardial infarction have changed substantially over the past decades. In particular, the advent of reperfusion therapy involving the use of fibrinolytic agents or, more recently, direct or primary percutaneous coronary intervention has led to a marked improvement in the prognosis of patients after myocardial infarction. Contemporary medical treatment with beta-adrenergic blocking agents and angiotensin converting enzyme inhibitors has further improved prognosis. The patient population currently undergoing exercise testing after acute myocardial infarction is, therefore, far different from historical populations before the reperfusion era. The goals and basic principles of exercise testing have, however, not changed dramatically. Therefore, the role of exercise testing must be viewed in the context of the patients who present for exercise testing.

In patients following acute myocardial infarction, exercise testing is frequently performed before hospital discharge to establish the hemodynamic response and functional capacity for exercise prescriptions and cardiac rehabilitation, to detect serious ventricular arrhythmia, and to identify patients with inducible myocardial ischemia [186–191]. Furthermore, it is helpful in reestablishing patients' confidence in their ability to conduct their activities following discharge. Pre-discharge exercise testing in patients after acute myocardial infarction appears to be safe provided that the proper contraindications are observed [188, 192, 193]. Major contraindications in this patient population include manifest congestive heart failure and postinfarction angina. Pre-discharge exercise testing has historically been performed between 5 and 26 days following myocardial infarction [188, 192, 194, 196], although studies have suggested that exercise testing can also be performed safely within 3–4 days in patients with an uncomplicated myocardial infarction [196, 197]. Pre-discharge exercise testing following acute myocardial infarction has traditionally utilized a submaximal protocol that requires the patient to exercise until a target, predetermined workload (e.g., achievement of 5–6 METs or 70–80% of age-predicted maximum) has been reached [198]. However, it has been proposed that symptom-limited exercise testing prior to discharge may be safely performed in patients with an uncomplicated postinfarction course. As opposed to submaximal testing, performance of a symptom-limited test provides a better estimate of peak functional capacity and is associated with an increased detection rate of ischemic ST segment changes and angina pectoris [188, 193, 199].

#### 36.9.1 Exercise Testing in Patient Management

---

Both in patients treated with thrombolysis and in those who have not received reperfusion therapy, a pre-discharge standard exercise test remains the test of choice to identify myocardial ischemia and select patients who might benefit from coronary angiography and revascularization. Imaging studies may be helpful for risk stratification and detection

of myocardial ischemia in patients who have physical limitations that prevent them from exercising to an adequate workload, or in those with ECG abnormalities that preclude an accurate interpretation of ST segment changes. As expected, patients treated with thrombolytic therapy exhibit exercise-induced angina and ST segment depression less frequently than patients who have not received reperfusion therapy. In patients treated with direct or primary percutaneous coronary intervention, the coronary anatomy is known. If, besides the infarct-related artery, one or more of the other coronary arteries also shows a significant and important coronary obstruction at the time of angiography, additional coronary revascularization may be warranted. If the other coronary lesions found at the time of angiography are of intermediate or equivocal severity and significance, exercise testing or noninvasive stress imaging studies can be used to provoke residual ischemia and select patients who might benefit from additional revascularization, as well as those who can be managed conservatively.

### 36.9.2 Risk Stratification and Prognostic Assessment

---

As stated, the prognosis among patients after myocardial infarction has improved significantly, particularly in those who have received thrombolytic therapy or revascularization during hospitalization. Consequently, the low subsequent cardiac event rate associated with this improved treatment and survival substantially reduces the predictive accuracy of early exercise testing. Parameters derived from the exercise test following acute myocardial infarction that are associated with an increased risk of future death or recurrent nonfatal myocardial infarction include inability to perform the submaximal pre-discharge exercise test, poor exercise capacity, inability to increase - or a decrease in - systolic blood pressure, the development and magnitude of ST segment depression, especially at low workloads, and the development of angina [186, 194, 200–206].

Patients who have not undergone coronary revascularization and are unable to undergo exercise testing have the highest cardiac event rate. This was demonstrated both in trials in the thrombolytic era and in earlier studies in patients not receiving thrombolytic agents [194, 200–204]. In patients who are able to perform the test, exercise capacity is an important predictor of adverse cardiac events [189, 194, 195, 200, 203, 206–209]. Similarly, the hemodynamic response during the exercise test is of prognostic importance. Failure to increase systolic blood pressure by 10–30 mmHg or a decrease in blood pressure during exercise have been shown to be independent predictors of adverse outcome in patients after myocardial infarction [191, 195, 200, 203, 206, 209–211]. In a study in the prethrombolytic era, the degree of blood pressure rise during the exercise test was reported to be the single best predictive measurement [210]. The exercise capacity and the change in systolic blood pressure are, in fact, measures of left ventricular function which is the most important prognostic determinant of mortality following acute myocardial infarction. However, it was demonstrated that the maximum exercise capacity achieved during exercise testing provided an incremental prognostic value in patients with a low (less than 35%) left ventricular ejection fraction by gated radionuclide scintigraphy 1 month after acute myocardial infarction [212].

Exercise-induced ischemic ST segment depression in patients after myocardial infarction is an independent predictor of death or nonfatal myocardial infarction, particularly if the ST segment depression is accompanied by angina, occurs at a low level of exercise or in patients with controlled congestive heart failure [189, 203, 205, 206, 213, 214]. The predictive value of exercise-induced ischemia for adverse outcome is, however, limited by the fact that many patients who have an abnormal test result undergo coronary revascularization, which may alter the natural history of the disease process [193, 194, 201, 208, 215].

Finally, exercise testing can be used for activity counseling after hospital discharge and is an important tool in exercise training as part of a comprehensive cardiac rehabilitation program [4, 198].

## 36.10 Exercise Testing after Revascularization

---

### 36.10.1 Exercise Testing after Coronary Artery Bypass Grafting

---

The conversion of a positive exercise test result performed before coronary artery bypass grafting (CABG) to a negative postoperative test result is associated with successful revascularization [4, 216]. In patients with recurrent chest pain after

CABG, exercise testing may be used to demonstrate myocardial ischemia, although the exercise ECG is limited in this group of patients by the relatively high frequency of resting ECG abnormalities and the inability to document the site and extent of ischemia, as compared to stress imaging tests [4, 217, 218].

Exercise testing may be used for guiding exercise training as part of cardiac rehabilitation. It has been demonstrated that exercise testing in an asymptomatic individual, who has undergone successful CABG, is not predictive of outcome when the test is performed within the first few years after CABG [219, 220]. Therefore, routine periodic monitoring of asymptomatic patients after CABG is not indicated [4].

### 36.10.2 Exercise Testing after Percutaneous Coronary Intervention

---

Several studies that evaluated the diagnostic accuracy of exercise testing for identification of restenosis after percutaneous coronary intervention have shown that the exercise ECG is an insensitive predictor of restenosis [221–226], especially in asymptomatic patients, with sensitivities ranging from 40% to 50%, significantly less than those obtained by stress imaging tests [227, 228]. The insensitivity may be caused by the failure of moderate one-vessel stenoses to lead to significant ischemia on the exercise ECG. Routine, periodic exercise testing of asymptomatic patients after percutaneous coronary intervention without specific indications is therefore not recommended, especially since the prognostic benefit of controlling silent ischemia needs to be proved [4].

## 36.11 Exercise Testing and Heart Rhythm Disorders

---

Heart rhythm disorders occur frequently with exercise. The prevalence increases steadily with age, both in patients with heart disease and in normal individuals [229–231]. Increased sympathetic tone with withdrawal of much of the vagal tone, as well as myocardial ischemia may all play a role in the development of cardiac arrhythmias.

### 36.11.1 Sinus Node Dysfunction

---

Exercise testing may distinguish subjects with resting bradycardia with a normal increase in heart rate with exercise from those with sinus node dysfunction with a low resting heart rate that fails to accelerate normally with exercise, which is also labeled as chronotropic incompetence [4]. The definition of chronotropic incompetence has varied, the most common definition being failure to achieve 85% of (i.e., more than two standard deviations below) age-predicted maximum heart rate [4, 232]. The mechanisms involved are complex and not yet completely understood [233]. However, studies have confirmed the adverse prognostic implications of chronotropic incompetence [172, 233, 234]. Furthermore, a normal exercise test result does not negate the possibility of sinus node dysfunction.

### 36.11.2 Supraventricular Arrhythmias

---

The incidence of any supraventricular arrhythmia during exercise testing varies from 4% to 18% and increases with age. Atrial premature beats regularly occur at lower workloads, disappear as exercise increases and may return in the recovery period. They are considered to be of little clinical significance.

The majority of patients with atrial fibrillation demonstrate an abnormal heart rate response to exercise, which comprises an initial reduction of heart rate followed by delayed acceleration at lower workloads and a subsequent exaggerated increase in heart rate with tachycardia often persisting for a long period of time in the recovery phase [4, 235]. In patients with atrial fibrillation, exercise testing may help to evaluate the efficacy of drug regimens aimed at ventricular rate control. The ST segment changes associated with myocardial ischemia in atrial fibrillation are similar to those observed with sinus rhythm. However, in patients with atrial fibrillation and a very high ventricular response, the very short diastolic intervals may produce subendocardial ischemia because of the inadequate perfusion time in the absence of CAD. Atrial fibrillation initiated by exercise can be associated with CAD, rheumatic heart disease, or cardiomyopathy. However, it is

also seen in subjects with no apparent cardiac abnormalities, in whom it may be a prelude to the development of sustained atrial fibrillation at a later stage [33].

Patients with Wolff-Parkinson-White syndrome may exhibit ST segment depression during exercise testing in the absence of CAD. In patients with Wolff-Parkinson-White syndrome, exercise testing may be used to help evaluate the risk of developing rapid ventricular response during atrial arrhythmias. When the pre-excitation disappears during exercise, the antegrade refractory period in the accessory pathway is longer than that in the atrioventricular node and it is unlikely that a rapid ventricular response will occur [4].

### 36.11.3 Ventricular Arrhythmias

In normal subjects, there is an increase in the incidence of resting premature ventricular contractions (PVCs) of 2–15% with age [236]. It has been demonstrated that, in the absence of overt heart disease, these resting PVCs are usually benign [237]. PVCs are often induced by exercise and the incidence in clinically normal, middle-aged or older subjects during maximum stress testing is about 35%–45%, usually at high workloads [238–240]. In general, exercise-induced ventricular arrhythmias in a large group of subjects without symptoms followed for 5–10 years were found to have no influence on subsequent morbidity and mortality, and appear to be benign [239, 241]. These data are generally believed to apply to all asymptomatic individuals although one study on a large cohort of asymptomatic men suggests that exercise-induced PVCs may have more adverse prognostic implications than previously reported [242].

In patients with CAD, the reported incidence of ventricular arrhythmias during exercise ranges from 40% to 65% [238, 243, 244]. In general, patients with CAD manifest arrhythmias at a lower heart rate than normal subjects. Despite the fact that PVCs are more easily evoked in patients with CAD than in normal subjects, there is too much overlap between those with and without ischemia to allow such arrhythmias to have diagnostic value. Accordingly, the appearance of PVCs, including multiform or repetitive PVCs, should not be interpreted as a sign of myocardial ischemia in diagnostic stress testing [245].

The appearance of frequent, multiform, or repetitive PVCs during exercise is associated with an increased risk of mortality in patients with a previous myocardial infarction, especially apparent in patients with an impaired left ventricular function [246–252]. Most studies suggest that exercise-induced PVCs are also associated with an impaired survival in patients with CAD without a previous myocardial infarction, especially in cases of multiform, repetitive PVCs or (non-sustained) ventricular tachycardia [238, 244, 253–256]. Some reports have disputed such an association, however, at least in low-risk patients with demonstrable stable CAD [245, 257, 258]. Significant multivessel disease is likely to be present in patients with angina and exercise-induced ventricular arrhythmias, especially if ischemic ST segment changes are also present [238, 244, 245, 255, 256]. Although the induction of PVCs by exercise is well recognized, ventricular ectopic activity may also be abolished by exercise in patients with CAD, just as it may be in normal subjects. Therefore, this finding does not exclude the presence of CAD [33, 238, 255].

In general, more arrhythmias are seen on recovery than during exercise. In the recovery period, the imbalance between oxygen supply and demand induced during exercise may be augmented in patients with CAD; peripheral dilatation induced by exercise combined with a reduced venous return caused by cessation of muscular activity may result in reduced cardiac output and coronary flow at a time when myocardial oxygen demand is still high owing to tachycardia. Furthermore, catecholamine levels are considerably elevated [259]. These changes can be minimized by a gradual cool down.

#### 36.11.3.1 Exercise-Induced Sustained Ventricular Tachycardia

Sustained ventricular tachycardia during exercise testing is relatively rare and occurs most frequently in the group of patients with ventricular tachycardia or ventricular fibrillation as their primary complaint. As stated previously, because ventricular tachycardia can deteriorate into ventricular fibrillation, immediate termination of exercise is warranted. Sustained ventricular tachycardia or long runs of non-sustained ventricular tachycardia usually portray serious underlying diseases; either CAD with ischemia or some type of cardiomyopathy should be suspected. Ventricular tachycardia caused by ischemia almost never has a left bundle-branch block pattern.

### 36.11.3.2 Exercise Testing to Evaluate Spontaneous Ventricular Tachycardia

Exercise testing can play an important role in the workup of patients who survived sudden death, as well as in those with syncope and sustained ventricular tachycardia [4]. The usefulness of exercise-testing in patients with ventricular tachycardia is variable, according to the cause of the tachycardia. In patients with idiopathic right ventricular outflow tract tachycardia, the ventricular tachycardia can be reproducibly induced during stress testing as it is commonly provoked by exercise. During exercise testing, the patients also exhibit many PVCs and coupled PVCs. The ventricular tachycardia has a left bundle-branch block morphology and is more likely to be non-sustained [260].

In adrenergic-dependent ventricular tachycardia, including monomorphic ventricular tachycardia and polymorphic ventricular tachycardia related to long-QT syndromes, exercise testing may supply the circumstances necessary for induction of the ventricular tachycardia and is, therefore, a useful prelude to an electrophysiological study [4]. Furthermore, the occurrence and nature of exercise-induced ventricular ectopy is of prognostic value in these patients [4, 254, 261]. Even in patients at risk of ventricular tachycardia, maximal exercise testing can be conducted safely with the appropriate precautions [4, 262]. The main limitation of exercise testing in patients with ventricular arrhythmias is related to its limited reproducibility so that other testing modalities are also required in the evaluation of these patients [4, 263].

Exercise testing may also be used to unmask pro-arrhythmic responses with development of sustained ventricular tachycardia during exercise in patients receiving anti-arrhythmic therapy.

## 36.12 Exercise Testing in Valvular Heart Disease

---

The primary value of exercise testing in valvular heart disease is to objectively assess atypical symptoms, exercise tolerance, and extent of disability to guide decision making with regard to surgical treatment. This is particularly of importance when a patient is thought to be asymptomatic because of inactivity (e.g., as in the elderly) or when a discrepancy exists between the patient's symptom status and the echocardiographic severity of the valvular stenosis or regurgitation. Furthermore, exercise testing can be used in follow-up of asymptomatic patients with valvular heart disease to detect a reduction in exercise capacity over time [4]. Details regarding the uses of exercise testing in patients with valvular heart disease have also been described in the respective guideline for the management of patients with valvular heart disease [264].

### 36.12.1 Mitral Valve Stenosis and Regurgitation

---

Exercise testing in mitral valve stenosis is of most value when the patient's symptom status and mitral valve area show discrepancy. When exercise induces excessive heart rate responses to a relatively low level of exercise or hypotension as a sign of a reduction in cardiac output, a more aggressive therapeutic approach aimed at earlier surgery might be considered [264]. In a rare case, exercise may precipitate atrial fibrillation in a patient with mitral valve stenosis.

In patients with mitral valve regurgitation, exercise testing objectively determines the functional capacity of the patient. Patients with severe mitral valve regurgitation commonly demonstrate a reduction in exercise capacity and are usually limited by the development of dyspnea. In patients with moderately-severe mitral valve regurgitation, a combination of exercise testing and assessment of left ventricular function may be useful in documenting occult left ventricular dysfunction and provoking earlier surgery [4, 264, 265]. Furthermore, exercise testing can be used to monitor exercise tolerance over time in these patients.

### 36.12.2 Aortic Valve Stenosis and Regurgitation

---

Severe, symptomatic aortic valve stenosis is a contraindication to exercise testing. As aortic valve replacement is not indicated in asymptomatic patients [264], it is important to distinguish those who are truly asymptomatic from patients who are asymptomatic because they are inactive or have adjusted to their functional impairment. In these patients, exercise testing can be used to select a subpopulation of patients who are hemodynamically compromised by aortic valve

stenosis and in whom surgery should be considered. Studies in adults with moderate to severe aortic valve stenosis have demonstrated that, with the appropriate precautions, exercise testing can be safely performed in these patients [4, 264, 266, 267]. Adverse hemodynamic responses that advocate aortic valve replacement include profound functional limitation, hypotension during exercise or failure to augment systolic blood pressure with exercise, and a rapid increase in heart rate indicating a fixed stroke volume. In this way, exercise testing can be combined with echocardiography in the follow-up of patients with aortic valve stenosis to help in determining the time at which aortic valve replacement should be performed.

Exercise tolerance is preserved until late in the course of aortic valve regurgitation. Exercise testing is not routinely required to guide treatment as the decision to proceed to valve surgery in chronic aortic regurgitation is primarily based on symptom status, left ventricular systolic (dys)function, and left ventricular size [4, 268].

This chapter deals with the use of digital computers for the handling of the resting ECG. The reader is referred to other chapters of this book for a review of computer-assisted interpretation of the exercise electrocardiogram, for ambulatory monitoring, on-line arrhythmia detection in the coronary care unit, and for surface mapping and modeling applications.

## 37.1 Some History

It is a deep rooted fantasy of man, told in many stories, to be able to handcraft a creature in his own image and endow it with the breath of life: a “homunculus.” More often than not, the endeavor is initially successful but ends in disenchantment. The advent of the computer seemed to make it possible to equip such a creation with human intelligence. Electrocardiography appeared to be a field where the computer could be expected to deploy its intelligent capabilities to the best advantage.

The ECG was an attractive object for computerization for a number of reasons: (1) it is an electrical signal, easily recorded and easily digestible for a computer; (2) it is a rather simple, orderly and repetitive signal; (3) it carries important information about which a vast corpus of knowledge has been amassed to prime the computer program; (4) ECGs are produced in enormous quantities all over the world which makes it worthwhile to let a computer reduce human workload.

ECG diagnosis by computer would be an instance of artificial intelligence which might ultimately challenge the specific human faculty of diagnosis. When is artificial intelligence really intelligent? Turing devised a thought experiment to answer this question [1]. Suppose that a computer and a human being are sitting in separate closed chambers and that an outside investigator is questioning them. If the investigator cannot decide from the answers whether they are given by the computer or by man, then the computer has attained full human intelligence. This implies that the computer’s diagnosis of the ECG must exactly copy that of man in order to satisfy this requirement. Indeed, the agreement between computer classification and man-made diagnosis of the ECG has been extensively studied. But how intelligent is man? Disagreement between computer and man might even be due to a computer’s superior diagnostic power! A second approach in testing a diagnostic ECG program, therefore, had to be to gauge it against reality, the clinical diagnosis, and to compare its performance with the skills of the human reader in this respect. The outcomes of both approaches will be discussed later.

The first attempts to automate ECG analysis by computer were made as early as the late 1950s, but it took considerably more time to develop operational computer programs than had originally been anticipated. At that time, the analog electric computer dominated the field. Analog computers were being used in basic electrocardiographic research [2], but their impact on clinical electrocardiography remained insignificant and they soon disappeared from the scene [3]. To have an analog signal processed by a digital computer, it must be broken down into digital samples. However, analog-to-digital (A-D) conversion systems (see [Chap. 12](#)) were not available as they are today and a special purpose A-D conversion system for ECGs had to be developed first [4].

A very crude computer program for the separation of normal from abnormal records became operational in 1959 [5]. It was based on angles and magnitude of spatial ventricular gradients, calculated from the time integrals over one PQRST cycle in the three orthogonal leads. Cycle recognition was still obtained through analog circuitry. The beginning and end of P, QRS, and T were not identified in this simple screening program. The first automatic wave-recognition program became available in 1961, opening the way for more detailed analysis of ECG records [6]. This original program, as well as its successors developed by Pipberger and coworkers [7, 8], was based on the Frank XYZ leads for the main reason that three leads laid less claim to computer capacity, still very limited both in speed and in memory space, than 12 leads. Through the pioneering work of Caceres et al. [9] the first program for conventional 12-lead ECG analysis became available in 1962. It was supported by the US Public Health Service and intended to make expert ECG analysis immediately available to all who needed it, using the telephone system. The 12 ECG leads were transmitted sequentially and, therefore, had to be analyzed individually. The loss of context between the leads, together with inherent cable noise, caused considerable waveform recognition errors and the program came to an untimely end.

User satisfaction, indeed, was not won by these early accomplishments and the initial state of excitement was to give way to one of dogged perseverance. Fresh investigators were, according to their state of awareness, attracted by the seeming easiness or the proven difficulties of the subject. Commercial suppliers started to be active in this market [10]. Gradually, a number of operational systems came into being in North America, Europe, and Japan. In the bigger hospitals, main frame computers were installed, which received the ECG signals on tape from mobile carts and could store them in databases.

For the less well-equipped customers, ECG diagnosis via telephone was offered by all kinds of entrepreneurial services, which did a thriving business in the 1970s and 1980s, sometimes handling millions of ECGs a year [11, 12]. The scene changed completely with the advent of the microprocessor [13]. Microprocessor-based systems have made it possible to distribute computerized ECG analysis outside hospital and laboratory to even the smallest hospitals, to screening clinics and to practitioners of every kind. While it took minutes to process a single ECG on a main frame computer in the early years, a present-day simple PC takes a fraction of a second to do the analysis. Most of these electrocardiographs are “stand-alone,” that is, have a computer and printer on board. Some manufacturers offer separate front-end equipment (amplifiers and A-D converter) that can be interfaced with the computer standing in the doctor’s office.

With a widening choice of systems on the market, the consumer may wish to know how intelligent the system being considered for purchase is. But where can the consumer turn for an objective intelligence test? It is clear that objective assessment of the quality of computerized ECG systems is needed. We will return to this subject in later sections of this chapter.

## 37.2 ECG-Processing Computer Systems

---

### 37.2.1 Advantages

---

Although diagnostic accuracy and reliability are greatly desirable characteristics of an interpretation system, the program’s utility in a clinical environment is also determined by other factors. Reduction of the labor spent by the cardiologist and clerical staff has been a key determinant in moving toward computer-aided processing systems in hospitals [11, 14]; improvement of overall process quality has been another. Rigorous operational control, as imposed by a computer system, can substantially add to the recording quality and thus the reliability of interpretation. The quality of reporting is also improved through the use of standard terminology and formats.

Computer analysis abolishes the well-known subjective differences arising in visual interpretation, and through a quantitative approach may enhance correct classification. Pipberger et al. [15] have, since the early 1960s, pointed to improved accuracy of interpretation as the primary objective of computer ECG processing. Automatic storage and retrieval, with the possibility of comparing the new ECG with its predecessors (serial analysis) is another asset of computerized ECG processing.

Computerized analysis of the resting ECG has also increased the feasibility of large-scale cardiovascular screening and epidemiological studies. “Minnesota coding” of the ECG can nowadays be performed by computer, quickly and reliably (see [▶ Chap. 40](#)).

### 37.2.2 ECG Management Systems

---

An ECG management system can come in several forms and undertake multiple functions. In its simplest form, it effectively acts as a database for storage of ECGs and offers straightforward retrieval of ECGs for display or printing. It could be in the form of a small PC, to which an ECG machine might be directly attached as might be found in a small family medical practice.

At the other extreme, a large ECG management system could be used to centrally store all ECGs recorded within a large hospital or group of hospitals. Such systems generally have the capability to store multiple ECGs for a single patient and thereby facilitate serial comparison either through visual display of several ECGs on the same monitor screen or through automated techniques (see [▶ Sect. 37.16](#)). The large systems offer the user the ability to measure wave amplitudes, durations, and standard time intervals on an averaged ECG waveform, generally using digital calipers.

One of the major benefits of the larger systems is to allow editing, sometimes known as over-reading, of the automated interpretations. Generally, manufacturers provide facilities to assist with editing such as through acronyms to represent standard interpretative statements. In many environments, a physician will handwrite comments onto an automated report and a member of the administrative staff with appropriate knowledge can edit the changes on the ECG management system. A problem then arises if serial comparison is available on the system. In such a case, the original electronic copy

of the automated interpretation also has to be edited so that any subsequent serial comparison is made with the corrected report. This is actually quite a complex issue and one which can inhibit automated serial comparison.

Clearly, the ECG management system offers the facility for the provision of statistics on throughput of ECGs, number of edits made by each cardiologist, and so on. Nowadays, there is a trend toward manufacturers providing multiple databases for ECGs, echocardiograms, x-rays, etc., on a single server, but flexibility of editing and retrieving ECGs easily on an ECG management system still remains of significant importance in many healthcare environments.

### 37.3 Information Content of Lead Systems; Lead Transformations

---

In the analysis of biological signals in general, an enormous flow of information is channeled through a limited number of transducers. The often still redundant transducer output stream is then reduced and transformed to a manageable number of parameters. These in turn are harnessed into decision machinery, which finally summarizes the input information in a few standardized “diagnostic” terms that carry significance for the user and are the basis for further action. The ECG is such a biological signal.

The electrical activity of the heart gives rise to a three-dimensional time-varying distribution of currents and potentials. To obtain a full picture of this process, it is necessary to measure the complete course of potential distributions in and on the body. Only the body surface signals are readily available for measurement and even then the amount of information generated by the heart is so large that it is necessary to curtail the information stream for practical purposes. For the recording of a body surface potential map (BSPM), grids of 64–192 electrodes are being used (see [▶ Chap. 31](#)). In this way, in a single BSPM all ECG information of that moment may be considered to be present as to localization. However, in a sequence of BSPMs, it is not feasible to follow all these individual electrocardiograms in their time course. For practical reasons, global parameters like “isointegral maps” or “isochrone maps” have to be used, and for diagnostic purposes, “difference maps” and “departure maps” have also been used. All this manipulation of data has only become possible, thanks to the computer, but so far clinical acceptance of BSPM diagnostic systems has been poor.

The universally used standard 12-lead ECG system needs nine electrodes, the three original Einthoven electrodes and the six thoracic electrodes adapted from Wilson. With the use of nine electrodes, eight independent leads, as they are called, can be obtained. The four extra extremity leads, which complete the 12-lead system, are not independent as they are arithmetically derived from any two other extremity leads. Nine electrodes are a drastic reduction of the number of sampling sites used to create a BSPM; the diagnostic power retained in this reduced lead set is indeed amazing. The explanation lies in the large degree of redundancy present in the surface information. Even among the eight leads of the standard ECG there is much redundancy and the question arises how many leads are actually required to render all relevant information.

In the vectorcardiogram (VCG), all information is contained in only three orthogonal leads, the X, Y, and Z components of a single dipole vector that changes with time in direction and strength, but is assumed to be stationary in position. Clearly, the three leads of the VCG (composed from a set of selected primary leads by linear combination) carry less information than eight leads, but, in return, the vector depicts the temporal relation between leads, providing phase information that is largely neglected in the ECG. Vectorcardiography could properly be called “phase electrocardiography.” This feature makes up for the restriction on information input so that the diagnostic performances of the ECG and VCG are comparable, as will be discussed later on. Thus, each choice of data input, whether it be BSPM, standard ECG, or VCG, incurs the sacrifice of some information aspect: time resolution, phase coherence, or localization.

Presently, all ECG computer programs which are in clinical use will handle the conventional 12-lead system. Systems processing only the VCG have been driven from the market. The advantage that the VCG offers a data reduction of 8:3 has become insignificant considering the power of present-day computers. The clinical acceptance of the VCG has been hampered by the variety of different lead systems (from which the Frank lead system [16] emerged as the most commonly embraced), by a lack of understanding by clinicians of the physical principles, by the requirement of dorsal electrodes found to be cumbersome to apply, and finally by the absence, at the time, of proper recording equipment [17].

The question remains: how many leads are actually required to render all relevant information? It is of more than anecdotal value that Dower [18] let his ECG service only take vectorcardiograms. The ECGs that were then delivered to the hospital were derived from these VCGs by means of a mathematical transformation – apparently for many years to everybody’s satisfaction. The inverse transformation yields the VCG from the standard ECG [19, 20], or, for better

adjustment, from the standard ECG fitted out with some extra electrodes [21]. Kornreich [22, 23] demonstrated that the ECG and VCG leave some clinically useful spaces on the surface map not covered by their electrodes. With a set of electrodes also serving these areas, nine leads were determined that yielded better diagnostic classification (using multivariate analysis) than either the VCG or ECG [24, 25]. Kors et al. [26] proposed a system containing the standard electrodes of which two chest electrodes were moved to positions higher up and lower down on the chest. From the seven not-displaced electrodes (4 chest + 3 limb) the 12 leads could be reconstructed by linear transformation in very good approximation. In fact, it was possible to compose any set of ECG leads with electrode positions chosen for local information density and ease of placement, standard or nonstandard, and from these leads derive the standard ECG by a mathematical transformation [27]. Computer analysis of such a “derived” ECG should give all but the same result as that of its directly recorded counterpart. The nonstandard extra recorded leads might then be exploited for additional information – with the difficulty that no standard diagnostic criteria are available for such leads. Even an entire BSPM can be simulated from a limited number of measured ECG leads.

The EASI lead system designed by Dower uses only four electrodes to produce the 12 standard ECG leads by linear transformation [28]. Four electrodes will yield three independent leads; four was also the number of electrodes used originally by Burger to derive the three orthogonal vector components [29]. Linear transformations were also used to reduce signal noise [30] and to identify interchanged leads [31]. The first to use a linear transformation in electrocardiography were Burger et al. [32] to transform VCGs obtained from different lead systems into those from each other.

For practical purposes, this review will be further restricted to computer analysis of the resting standard 12-lead ECG with some reference to the orthogonal 3-lead ECG. Some ECG processing systems have an option to display and print vector loops, either directly recorded from the regular (Frank) electrode positions or computed through linear transformation from the ECG leads. The reader is referred to [Chap. 11](#) in this book for a review of other lead systems.

### 37.4 Computer Processing of the ECG

In teaching electrocardiography, and in order to start the novice reader on a career in electrocardiography, it suffices to say: “This is a QRS complex, this little wiggle in front is a P, and the hump following QRS is a T.” Some more detailed descriptions are absorbed with equal ease and the final touch is added by the recommendations and guidelines for nomenclature and measurements as issued by various committees and task forces [33–36]. Reading the electrocardiogram is in the first place a matter of visual observation, if necessary, aided by calipers and magnifying glass, and relies on the amazing deftness in pattern recognition of the human brain. The subsequent electrocardiographic diagnosis is a logic built on correct pattern recognition. The computer must do without human “eye balling” skills and needs to be instructed punctiliously about every detail of measurement down to the microvolt and millisecond level. Rules and definitions for visual ECG analysis may then appear imprecise and not consistent enough for computer application, and may even show gaps in their logic. New computer-compatible prescriptions for ECG signal measurements should, however, adhere as much as possible to accepted methods of visual measurement [34]. In the sections on waveform recognition (37.12) and parameter computation (37.13) we will go further into the matter.

As in visual ECG analysis, in an ECG data-processing system, the first of the two main parts that can be distinguished is that which contains program components to perform measurements. The second part includes the program components that derive the clinical significance of these measurements. This results in a final classification, or interpretation, of the ECG in terms familiar to the physician. The words “classification” or “interpretation” are preferred by some over “diagnosis,” which is then the term reserved for the human interpretative activity.

The principal components of the ECG measurement section are as follows:

1. Data acquisition
2. Preprocessing and signal conditioning
3. Detection of QRS complexes and of P waves
4. Typing of QRS complexes
5. Forming a representative (P)-QRS-T complex
6. Boundary recognition, that is, detection of points of onset and offset of waves
7. Parameter extraction

The principal components of the ECG interpretative section are:

1. Rhythm analysis
2. Diagnostic classification
3. Serial comparison

These separate program components will be discussed in detail in the following paragraphs. Many ECG processing systems implement these different tasks in separate modules, each of which has well-defined objectives [37]. The advantage of such a structured setup is its easy implementation, evaluation, and maintenance [38]. In addition, systems for clinical use will have to offer an over-reading facility, which allows manual correction of the computer output. A fixed set of codes, most commonly acronyms, takes care of producing the required text elements, thereby ensuring consistency of terminology. In addition, entries in free text are admissible.

To inform the consumer about the quality of a computerized ECG system, it is necessary to have access to reference standards for objective evaluation. A paragraph on reference databases will therefore precede the discussion of the various parts of computer processing mentioned above, since it will often be necessary to refer to these standards.

### 37.5 Reference Databases for Program Evaluation

---

“How to test the intelligence of the computer” was the question raised in the introduction of this chapter. The simple precept is to compare the computer statements with the objective “truth” embodied in the ECG readings of the human expert or the clinical findings. How to carry this out will be shown to be no simple matter.

Two qualities are to be considered separately in the operations of the computer program, namely, waveform recognition skill and diagnostic competence, with correct waveform recognition being a *sine qua non* for reliable interpretation. As to the first quality, large measurement differences may become apparent between programs while analyzing identical ECGs [39, 40]. As to the second aspect, where is it possible to obtain the diagnostic truth? Initially, a number of program designers compared the computer output with their own ECG interpretation [41]. Diagnostic criteria were identical for both. As could be expected, agreement between computer and human readers was excellent. It is obvious that not diagnostic accuracy but reliability of the wave-recognition and measurement parts of the programs was tested in these studies. For example, in the study by Crevasse and Ariet [42] a computer accuracy rate of 98% was reported for LVH. Both the computer and the human readers used the Romhilt-Estes point score. When this criterion was tested by the originators of this scoring system in 150 autopsy cases with LVH, they found a true accuracy of only 60% [43]. This is therefore the closest to “truth” that the computer could ever get on the strength of this criterion [8]. In other studies, computer results were compared to interpretations of human readers who used their own, individual diagnostic rules [44–47]. As had to be expected, percentages of disagreement rose sharply, reaching almost 50% in one early study [48].

Comparisons with ECG-independent clinical evidence were also carried out in due course [8, 49–53]. These investigations were mostly limited to one or two programs only. Moreover, they are difficult to compare since they utilized different databases, most of them collected within a single institute. More and more the need was felt for common, objective, impartial reference standards to test and improve different ECG computer programs [14, 54–58]. For this purpose, well-established test libraries are indispensable, together with well-defined measurement rules and evaluation procedures. On several occasions, this necessity was stressed, as at the first IFIP Working Conference on Computerized ECG Analysis [54] or in the editorial of Pipberger and Cornfield [15]. Detailed guidelines for program testing were presented at the 1977 Bethesda Conference on Optimal Electrocardiography [14].

In 1979, a concerted European action was started to develop “Common Standards for Quantitative Electrocardiography” (abbreviated: CSE). The CSE Working Party consisted of investigators from 25 institutes in Europe with the participation of investigators from six North-American and one Japanese center.

The CSE project was divided into two 5-year periods, the first dealing with measurements, the second with diagnostic interpretation [59]. The main objectives of the first part of the CSE project were, firstly, to establish standards for computer-derived ECG measurements, which implied agreement on definitions of waves and amplitude reference levels, and, secondly, to compare the results of measurements from different programs.

■ Figure 37.1

Example of wave boundary determination by five cardiologists (from Willems et al. [62]). The *short vertical lines* depict the individual, sometimes coinciding, referee estimates, the long ones the median results. The adjacent values denote the sample point locations relative to the onset of the recording window. The figures at the *bottom of the vertical lines* indicate the final reviewing round in which the estimates were obtained. Note that the onset of QRS in leads I and II is at a lower level than the onset of P, due to the presence of the atrial repolarization wave. In lead III the projection of this wave is isoelectric. Also, in lead III the T wave ends in an isoelectric segment. The observers disregarded this when they established T offset over the three leads simultaneously.

Thanks to this first CSE study, two reference databases came into being [60, 61]. They were composed of normal and a variety of abnormal cases. The first database [60] comprised 250 original and 310 so-called artificial ECGs. The recordings contain four lead groups of three simultaneously recorded leads each, as was common for most electrocardiographs at the time. From the original ECGs, companion artificial ECGs were constructed by concatenating one selected beat per lead group into strings of identical complexes. This artifice makes it possible to compare programs with different approaches for deriving a representative beat. To verify the effect of beat-to-beat variability, out of 30 original ECGs, two additional beats were selected to form an extra 60 artificial records. A group of five cardiologists determined the points of onset and offset of the various ECG waves (P, QRS, and T) on much enlarged tracings in an iterative, four-round, Delphi review process (● Fig. 37.1).

The second database [61] comprised 250 original and 250 artificial ECGs in which all 15 leads – the 12 standard ECG leads plus the Frank XYZ leads – were recorded simultaneously. In view of the work load involved, the visual analysis strategy could not be repeated. Instead, the median wave-recognition results of 11 ECG and six VCG programs participating in the CSE study were taken as the reference. The cardiologists reviewed a random set of about 20% of the cases in a two-round process, and it was shown that the median of the program results was almost identical to the median results of the referees [61].

Both for the three-lead and multilead database, the original and corresponding artificial ECGs were divided over two sets. The waveform reference results of one set have been released [63, 64]; the results of the other set remain under lock and key at the CSE coordinating center for independent testing.

Differing mathematical algorithms may lead to similar solutions in pattern recognition [34]. For that reason, it was not seen as fitting to propose any specific algorithm as the exclusive standard for ECG wave recognition. At the same time, the CSE reference databases are strongly recommended as a bench mark for ECG measurement programs. Comparison with the standard involves two quality measures: a program should approach the reference as closely as possible, and the standard deviation of the differences of its results with respect to the reference should not exceed certain limits. These limits have been described in detail in a paper with recommendations for measurement standards in quantitative electrocardiography [34].

The second part of the CSE project aimed at the assessment of the diagnostic performance of ECG computer programs. This study commenced in 1985 and finished in 1990. A database consisting of 1,220 multilead recordings was collected, comprising seven diagnostic groups: normal ( $n = 382$ ); left ( $n = 183$ ), right ( $n = 55$ ), and biventricular ( $n = 53$ ) hypertrophy; and anterior ( $n = 170$ ), inferior ( $n = 273$ ), and combined ( $n = 73$ ) myocardial infarction. Also some cases with both infarction and hypertrophy ( $n = 31$ ) were included, but ECGs showing major intraventricular conduction defects were not. The clinical diagnosis was documented by ECG-independent evidence, such as cardiac catheterization, coronary arteriography, echocardiography, cardiac enzymes, and patient history [65]. The ECGs and VCGs were analyzed by 15 computer programs and by nine cardiologists, from seven European countries [66]. Evaluation results will be discussed later.

The CSE reference libraries have become an international standard for the evaluation and improvement of ECG and VCG computer programs. A comprehensive overview of the CSE project appeared in 1990 [59].

## 37.6 Data Acquisition

Before the ECG signals are transmitted to a computer system for analysis, the operator has to enter patient identification data. The patient's name, sex, and date of birth together with an identification code are essential for proper automatic handling of the ECG data. Data like weight, height, blood pressure, and medication might be useful – if they are not based on guess-work by a lackadaisical technician! The system will also store the time and date of the recording, as well as, mostly, a technician and location code. For programs that perform serial ECG analysis, the unique patient identification code is indispensable for record linking.

In order to achieve optimal performance of an ECG-processing system it is essential that the data used in the analysis are of good quality. In practice, ECG records can be disturbed by power line interference, baseline wander caused by electrode polarization, electromagnetic muscle artifacts, spikes, sudden baseline shifts due to electrode contact interruption, and amplitude saturation. Although automated systems can achieve a great deal of signal conditioning (see the following paragraphs), it devolves upon the operator to correctly apply the electrodes and to detect and remedy signal errors and disturbances before entering them in the system, according to the maxim “garbage in, garbage out.” Power-line interference can be prevented or reduced by proper shielding and grounding, by appropriate skin preparation and electrode application. Muscle tremor can be reduced or removed by having the patient comfortable and relaxed, while respiratory baseline wander can be minimized by breath holding.

The front-end of an ECG processing system consists of analog amplifiers. Present-day technology even allows them to be incorporated in the electrodes and to transmit the signals by a local wireless system to the processing unit. The amplifiers must be of adequate bandwidth for a faithful rendering of the signals. For further technical details, the reader is referred to [Chap. 12](#).

A digital computer can handle data only in numerical form, and therefore, the original continuous (or analog) voltage variations of ECG signals need to be converted into a series of numbers, corresponding to the voltage levels of the leads at any moment of time. General principles concerning analog-to-digital (A-D) conversion of the ECG have been reviewed by Berson et al. [67, 68]. The time and amplitude resolution of the A-D conversion is dependent on the sampling rate, the word size of the converter and the dynamic range of the analog input.

Sampling rates for ECG data in various programs originally varied from 250 to 500 samples per second. The American Heart Association [69] and the CSE Working Party [34] have recommended for clinical application a high-frequency cutoff of the analog amplifiers of 150 Hz and a sampling rate of 500 Hz for the A-D conversion. In the pediatric ECG, the waves, especially the QRS, are of shorter duration at often elevated voltage which results in high rates of acceleration and deceleration of the signal with corresponding high frequency content. This requires an extension of the minimal high-frequency cutoff to 250 Hz [70].

The more bits per word in an A-D converter, the greater the possible resolution. In addition, the dynamic range of the amplifiers must be wide enough to accept the largest possible excursion of the signal amplitude. Modern electrocardiographs have 16 or 18 bit converters, with quantization levels of  $1.22\ \mu\text{V}$ – $4.88\ \mu\text{V}$  for the least significant bit.

Until the introduction of “stand-alone,” microprocessor-equipped systems for ECG analysis, ECG records needed to be transmitted to a central computing facility. This was possible by transferring magnetic tapes on which ECGs were recorded, or by sending the signals on-line over ordinary telephone lines. This involved frequency modulation and demodulation which noticeably contributed to recorder noise. In the present digital era, the total analysis of the ECG can be done on a stand-alone electrocardiograph. The central ECG management system is required for storage and retrieval, a necessary utility for serial analysis; as well as for providing a means of editing interpretations. Interchange with the central facility may occur through a local area network, possibly by wireless transmission, or the ECGs are conveyed on some digital storage medium.

In the acquisition device, all 12 leads are acquired simultaneously so that time coherence between the signals is preserved. In practice, eight independent leads are recorded (I, II, VI-V6) and the other four are reconstructed from leads I and II using the classical relations such as  $\text{lead III} = \text{II} - \text{I}$ . In some systems, additional leads may be entered simultaneously for the VCG or for other purposes. The signals are stored in memory and can be displayed for a visual quality check. The computer may interact with the operator and warn of excessive noise in a lead or indicate electrode reversal. Reversal between right and left arm is detected by most programs. Other forms of electrode interchange require more sophisticated approaches [31, 71]. After approval by the operator, the signals are processed.

While the electrodes may have been placed in the correct order, without interchange, they still may be ill-positioned, for example, one interspace too high or too low on the chest. These errors are almost refractory to detection and correction [72, 73].

Conventionally, 12-lead ECGs were presented on multichannel writers in four lead groups of 2.5 s, often with a 10.0 s rhythm strip, on one page. Sometimes 5.0 s was taken per lead group, requiring two pages, or 6-channel writers were used. With the entire ECG present in memory and the availability of a thermal writer or laser printer, a modern device will allow considerable flexibility of output format. The signals, in addition, are preprocessed by digital techniques in such a way that mains interference and baseline drift have been reduced to a minimum to produce a neat paper output.

## 37.7 Signal Preprocessing and Conditioning

---

ECG records may be disturbed by different types of artifacts as enumerated previously, namely, power-line interference, baseline wander, muscle noise, spikes, and amplitude saturation. The aim of the preprocessing stage is to detect and correct these artifacts as far as possible. In hopeless cases, rejection of a part or the whole of the recording may be inevitable. The problems of signal improvement have been a challenge to many capable technical minds and have resulted in an abundant literature on the subject. Some of the algorithms require that the locations of the QRS complexes are known, and thus are not properly part of the preprocessing stage. This will be mentioned when the case occurs. The evaluation of the performance of these algorithms applied to real ECGs is not straightforward since the undisturbed signals are unknown. This may in particular be an issue in treating baseline wander and muscle noise. A common approach to studying the problem is to add simulated noise to a clean, “noise free,” ECG signal. This approach can be carried one step further by simulating both noise and signal. As with all simulations, the validity of the evaluation results will depend on how well the simulated signals mimic those that occur in practice.

### 37.7.1 Power-Line Interference

---

Power-line interference is a common problem and is characterized by its periodicity of 50 or 60 Hz (higher harmonics may also be observed). Different digital filters have been proposed for the removal of power-line interference [74, 75]. They can be categorized in three types:

1. Notch filters, which attenuate frequencies in a narrow frequency band around the interference frequency [76, 77].
2. Global filters, which make a single estimate of the interfering noise over the total duration of the signal and then subtract this estimate from the signal. Cramer et al. [75] describe two such global approaches. One is based on a least-squares error fit of the interference. The other approach requires the sampling rate to be an integer multiple of the power-line frequency, say  $n$ , and calculates an average amplitude for each of the  $n$  phase points in one period of the interference. Both approaches only perform well if the line frequency is stable within 0.02 Hz of the nominal frequency [75], which in practice may often not be the case. Also, these methods, by definition, cannot adjust to amplitude changes of the interference. Levkov et al. [78] proposed estimating the interference from each isoelectric or slowly changing part of the ECG signal, which allows tracking of interference amplitude changes. To ensure that the sampling rate was an integer multiple of the power-line frequency, they used a hardware-synchronized A-D converter. More recently, a software solution to adjust for interference frequency variation was proposed, involving estimation of the interference period and resampling of the ECG signal [79]. An extensive review of the method is given by Levkov et al. [80].
3. Adaptive filters, which use an auxiliary reference signal containing the interference alone [74, 81–83]. This reference is adaptively filtered to match the interfering sinusoid as closely as possible, and is then subtracted from the primary signal. An interesting variant of the classical adaptive filter approach is the “incremental estimation” filter proposed by Mortara [84] and further investigated by others [74, 85–87]. The filter generates a prediction of the power-line interference  $v(n)$  contained in the signal  $x(n)$ , based on the noise estimate  $w(n)$  at the previous two samples:

$$v(n) = 2 \cos(2\pi f / f_s) w(n-1) - w(n-2),$$

with  $f$  the nominal frequency of the interference and  $f_s$  the sampling rate. If  $v(n)$  is a good prediction, then the difference  $x(n) - v(n)$  should be zero apart from a possible constant offset. Assuming a slowly changing signal, the difference  $x(n-1) - w(n-1)$  is taken as an estimate of this offset, and the error

$$e(n) = (x(n) - v(n)) - (x(n-1) - w(n-1))$$

indicates how well  $v(n)$  predicts the interference amplitude. A final estimate is then produced by incrementing or decrementing the value of  $v(n)$  with a fixed amount  $\delta$ , depending on the sign of  $e(n)$ :

$$w(n) = v(n) + \delta \text{sgn}(e(n)).$$

Finally, the output  $y(n)$  of the filter is

$$y(n) = x(n) - w(n).$$

The value of the increment  $\delta$  is chosen heuristically. A value which is too small may cause sluggish adaptation to the interference amplitude and poor tracking of its changes. A value which is too large, on the other hand, may cause the estimate  $w(n)$  to jitter around the power-line interference, introducing extra noise. Also, since the assumption of a slowly changing signal does not hold true for the QRS complex, large increments will result in ringing artifacts. An incremental value of 1.25  $\mu\text{V}$  was proposed by Mortara [84]. Using a few simplifying assumptions, Talmon [85] analyzed the relationship between the amplitude of the sinusoidal disturbance, the increment, and the bandwidth of the filter. Glover [88] showed that the filter reduces to a standard notch filter if the nonlinear sign function in the update equation is replaced by a linear increment function.

A number of different filters, representative of the above filter types, were compared by McManus et al. [74]. They applied the filters both to artificial test signals simulating various forms of interference (including second and third harmonics of the nominal frequency), and to a small subset of real ECGs from one of the CSE databases. Tested against a list of 14 desiderata for an ideal interference filter, no single filter consistently performed better than the others for all requirements. Remarkably, the incremental estimation filter and the global filter were the only ones that did not produce a ringing effect at the end of the QRS as is the usual accompaniment of large-amplitude QRS complexes when filtered, as illustrated by  Fig. 37.2. In another study [87], the incremental estimation filter was compared to a nonadaptive second order notch filter. The better transient behavior of the adaptive filter produced less distortion in the ST segment and removed the interference more effectively.

■ **Figure 37.2**

Effects of different interference removal filters on an ECG, which has no interference: (a) original ECG, and tenfold magnified differences between filter-input and output of two notch filter methods (b and c), three adaptive methods (d, e, and f; f is the incremental estimation filter), and a global method (g). Several filters can be seen to generate sizable differences during the QRS complex (From McManus et al. [74]. © Elsevier. Reproduced with permission).

### 37.7.2 Baseline Wander

Baseline wander is another annoyance. The source of low-frequency fluctuations of the baseline may be sought in changing electrode impedances, such as caused by respiratory movement. More abrupt changes may result from the patient being restless. The frequency content of baseline wander is typically less than 0.5 Hz. Baseline wander may severely disturb ECG beat morphology. A variety of techniques for estimating and removing baseline wander has, therefore, been developed.

In the 1975 recommendations of the American Heart Association (AHA) [89], for baseline wander removal a standard 0.05 Hz single pole high-pass filter was advised. While such a filter largely avoids the problem of phase nonlinearities, it does very little to suppress the baseline wander that can typically be observed in ECGs. In their 1990 recommendations, the AHA stipulated that a baseline removal filter should have a flat amplitude response within 0.5 dB from 1 to 30 Hz, with a  $-3$  dB cutoff frequency of less than 0.67 Hz, and should adhere to certain test criteria based on triangular and rectangular wave impulse responses [69, 90].

A general problem in the evaluation of baseline correction methods is the difficulty in discriminating between baseline wander and the genuine ECG [85, 91]. Most studies only provide a qualitative assessment, showing ECGs before and after application of a correction algorithm. In a few studies, artificially generated baseline wander is added to “clean” ECGs constructed by concatenating identical beats [92, 93]. Since baseline correction may introduce new distortions, several algorithms try to identify periods with minimal or no baseline wander and skip these periods in the filtering [85, 93, 94].

Two main remedial approaches have been followed:

#### 1. Interpolation.

Linear interpolation approximates the baseline by straight-line segments between isoelectric levels, usually estimated from the intervals preceding QRS onset [85, 94]. The estimated baseline is subsequently subtracted from the ECG signal. Boucheham et al. [95] proposed a piecewise linear correction based on “dominant” points as detected by a curve simplification algorithm [96]. An interesting feature of their algorithm is its capability to correct for sudden baseline shifts.

A more elaborate interpolation method estimates the baseline by a third-order polynomial, or cubic spline [97]. Each PR segment provides a “knot” through which the cubic spline must pass. Meyer [97] described an elegant and fast state-space approach for the computation of the cubic splines.

Talmon [85] compared the linear interpolation and cubic spline methods on a set of real ECGs, and concluded that both approaches performed similarly. Linear baseline correction, however, is to be favored because cubic spline correction is more difficult to apply in the presence of sudden baseline shifts.

Since all interpolation methods assume that reference points or knots can accurately be determined, they may break down if this assumption is not met, for example, in the case of a premature beat merging with the preceding T wave [98–100]. Performance may also degrade at lower heart rates as the knots become more separated.

## 2. High-pass filtering.

Infinite impulse response (IIR) filters are generally unacceptable due to their nonlinear phase response, which may induce distortions in particular in areas of the ECG where amplitudes change abruptly [90]. However, in off-line situations, or if some time delay between acquisition and processing of the signal is accepted, forward-backward or bidirectional filtering can be applied [100, 101], yielding overall linear-phase response [102]. Alternatively, De Pinto [103] proposed a linear-phase high-pass filter. He subtracted the output of a linear phase low-pass IIR filter from the original signal with a delay equal to the pass-band group delay of the low-pass filter. The filter was shown to adhere to the 1990 AHA recommendations.

Linear phase filtering is easily accomplished with finite impulse response (FIR) filters. However, these filters typically have very long impulse responses, resulting in many multiplications and long time delay [91, 104], which may be unacceptable for short-term resting ECG recordings. Van Alste et al. [104] proposed an FIR filter that combines removal of baseline wander with that of power line interference, and greatly saves on the number of computations. QRS complexes may heavily influence the baseline estimate. This may cause a shift of the assumed baseline with respect to the true one, resulting in measuring errors especially in diagnostically sensitive low-frequency segments such as the ST segment. Sörnmo et al. [92] described an approach in which the QRS complexes are removed prior to filtering the signal by one of a bank of linear low-pass filters with variable cut-off frequencies. The method was tested on ECGs with different types of simulated baseline wander and showed superior performance as compared to standard high-pass filtering or cubic spline interpolation (➤ Fig. 37.3), especially when the baseline wander contained frequencies  $>0.5$  Hz. It must be noted that the method requires that beat classification is performed prior to correction, to minimize the effects of ectopic beats.

A two-step method combining interpolation and filtering techniques was proposed by Shusterman [93]. First, the magnitude of baseline wander is determined and classified as small or large. If large baseline drift is present, the signals are filtered with a bidirectional high-pass filter with a cut-off that depends on the estimated frequency content of the baseline wander. In a second step, any residual, small baseline wander is removed by simple linear interpolation between PQ and TP segments.

A two-stage cascade filter was described by Jane et al. [105]. First, a high-pass notch filter is applied with a cut-off frequency at 0.3 Hz [83]. Any remaining baseline contamination at higher frequencies is then removed with an adaptive impulse correlated filter. The reference input consists of a sequence of unit impulses correlated with the QRS complexes. This filter was shown to be equivalent to an exponentially weighted average [106] and requires a QRS detector. It also removes other disturbances not correlated with the QRS complex, such as muscle noise or line interference. When tested on a few records of the MIT-BIH database [107], the filter was shown to perform better than cubic spline correction.

Park et al. [108] described a wavelet adaptive filter. The filter consists of two parts. A wavelet transform decomposes the ECG signal into seven frequency bands. The signal of the lowest frequency band (0–1.4 Hz) is then fed into an adaptive filter. The wavelet adaptive filter was compared with a “commercial standard filter” with a cutoff of 0.5 Hz and with a general adaptive filter. Using test data from the MIT-BIH and the European ST-T [109] databases, the wavelet filter was shown to perform better than the other two filters, especially with respect to distortion of the ST segment. When tested on a triangular wave, as recommended by the AHA, the wavelet filter showed negligible distortion of the ST segment, whereas the standard filter and the adaptive filter produced severe distortions.

Finally, nonlinear filtering methods for baseline correction have been proposed [110]. Sun et al. [111], building on earlier work of Chu and Delp [112], described an approach using morphological filtering, a technique widely used in the field of image processing [113]. Testing on simulated ECG signals, they compared their approach with the wavelet adaptive filter [108] and found morphological filtering to produce better results.

### 37.7.3 Muscle Noise

Muscle noise, another signal deformity, is caused by the electrical discharges of skeletal muscles. Common causes are patient restlessness, nervousness, cold shivers, and Parkinson tremor. Reduction of muscle noise is often effected by one of the other tasks in ECG signal processing as, for example, when the ECG signal is band-pass filtered for the purpose of QRS detection. Since most of the energy of the QRS complex is contained in the frequency band from 10 to 25 Hz, noise components outside the pass band can effectively be suppressed. For P-wave detection, even stronger noise reduction is possible because the frequency content of the P wave is lower. In these applications it is unnecessary to keep the original signal undistorted. For accurate amplitude and duration measurements, however, the requirement is to improve signal-to-noise ratio (SNR) without loss of signal information.

A common method to reduce muscle noise is coherent averaging. ECG complexes of one family are summed and the sum is divided by their number, giving an averaged ECG complex while uncorrelated noise averages out and disappears. Coherent averaging is one way of improving the SNR, as will be discussed later.

A number of other noise reduction techniques have been proposed. Adaptive filtering for muscle noise suppression was described by Thakor and Zhu [83]. To cancel the noise in a particular lead, they proposed employing, as a reference signal, another lead perpendicular to the first, in order to ensure that the noise in the two leads is uncorrelated.

Talmon et al. [114] describe an adaptive Gaussian filter, based on earlier work of Hodson [115]. The frequency characteristics of the filter are dependent on the estimated curvature of the signal to be filtered. A curvature estimate is obtained by fitting a polynomial function. The width of the filter is then adjusted according to the curvature, where low curvature (e.g., in the PR interval) implies a low-frequency cutoff, and a high curvature (e.g., in the QRS complex) a cutoff at higher

frequencies. A related approach is proposed by De Pinto [103], who describes a low-pass filter with time-varying bandwidth. The bandwidth is maximal during the QRS complex, and decreases in the interval between QRS complexes. The bandwidth is varied in increments by selecting one of six sets of coefficients, controlled by an estimate of the slope of the ECG signal.

Another approach, termed noise consistency filtering, was initially proposed by Mortara [30] and later investigated by Wei et al. [116]. This filter method requires the availability of multiple, simultaneously recorded leads, and exploits the redundancy in the ECG signals. Reconstruction coefficients are determined to synthesize each of the eight independent ECG leads from the remaining seven leads. The filter output is the original lead signal multiplied by a time-varying coherence measure with a value between 0 and 1, dependent on the correspondence between the predicted and the original signal. The lower the coherence, the stronger is the filtering, and vice versa. The filter was reported to reduce noise by a factor of 10, provided the noise in the leads is uncorrelated [30].

Wei et al. [116] proposed two modifications to the filter as it was described by Mortara. Firstly, to avoid problems with baseline wander, the signal is split into a low-frequency and a high-frequency part, and only the latter is filtered according to the source consistency method. Secondly, a modified coherence measure is used, to reduce unwanted filtering effects that were observed by the authors. The modified filter performance was verified on simulated and real ECG signals, and compared with the original source consistency filter and conventional low-pass filters. Results show more effective noise suppression and less distortion of the QRS complex with the modified filter.

More elaborate filtering methods, involving the discrete cosine transform and singular-value decomposition, have been described by several investigators [117–119]. These approaches are computationally demanding and were mainly developed for the suppression of excessive muscle noise during exercise testing.

Finally, several studies used morphological filtering for muscle noise suppression [110–112]. Morphological filtering was also employed to detect muscle noise, without attempting to suppress it [120].

### 37.7.4 Spikes

Spikes are sudden pulses of short duration and high amplitude. They may be due to an interfering electrical source in the environment or to an implanted artificial pacemaker.

Accurate pacemaker spike detection has become increasingly important with the growing population of patients with implanted pacemakers. Because of the small spike width, in the order of 0.2–0.5 ms, many electrocardiographs use high-bandwidth front end amplifiers and analog circuitry to detect pacemaker spikes before A-D conversion. To reduce the number of false detections that this approach may induce, it has been combined with software algorithms that must confirm the presence of the spikes in the diagnostic bandwidth (0.05–150 Hz) signals. Alternatively, signals have been sampled at very high frequency, of the order of several kHz, and then software is used to detect the spikes.

Only a few algorithms have been described that attempt to detect spikes in diagnostic bandwidth signals. As these signals have been sampled at no more than 500 Hz; one may wonder how it is possible to detect pulses that have a duration well below the sampling interval. The reason is that the anti-aliasing low-pass filtering broadens the spikes. However, this filter also greatly reduces the amplitude of the spikes, which makes detection more difficult. The presence of narrow QRS complexes mimicking spikes, high-frequency noise and other artifacts further complicates the detection task.

The Louvain VCG analysis program [121] used a simple spike detector: if the spatial velocity exceeds a fixed threshold, a spike is assumed to be present [122]. In the AVA program [123] a number of tests based on slope differences between four consecutive points (8 ms) in a single lead were performed to detect spikes or discontinuities in the input signals [122]. No evaluation of these methods has been given.

Talmon [85] described a spike detector that operates in two stages. First, signals are filtered with a parabolic filter and the root-mean-square (RMS) of the residuals is computed. If the residual at a certain time instant exceeds three times the RMS value in that signal, a potential spike is assumed to be present. In a second stage, an additional number of criteria, structured in a decision tree, are tested to verify whether a spike has truly been detected. The algorithm was tested on an independent test set of 1,908 ECGs and VCGs, showing a sensitivity of 90.9% and a positive predictive value of 95.4%.

Helfenbein et al. [124] proposed another pacemaker spike detector. The algorithm detects a spike if a steep slope exceeding a threshold is followed by an opposite polarity slope within a short time window. The threshold is adaptive and computed as a function of the maximum slope in a window preceding the spike. When tested on a set of 1,108 adult ECGs

containing a variety of pacemaker types and modes, excellent performance (sensitivity 99.7%, positive predictive value 99.5%) was obtained. On another set of 1,382 non-paced pediatric ECGs, only four false-positive QRS complexes were reported.

### 37.7.5 Amplitude Saturation and Sudden Baseline Shifts

No substantial literature is available dealing with the detection of amplitude saturation and sudden baseline shifts. In descriptions of various ECG processing systems, a statement is made that these artifacts are searched for, but the algorithms are not described.

## 37.8 Detection of QRS Complexes

The detection of QRS complexes is probably the most extensively studied problem in ECG signal analysis [86, 125–131]. A host of different algorithms has been proposed, most of them originating from applications in the fields of coronary care monitoring and Holter recording. Consequently, many of these QRS-detection algorithms were designed to operate on a single lead. In computerized resting ECG and VCG interpretation, three simultaneously recorded leads were used from early times. Now, multiple simultaneously recorded leads have also become increasingly common in the non-resting ECG.

Basically, a QRS detector consists of two stages [132]: a preprocessing stage, in which the signal is filtered and signal features are determined, and an identification stage, in which a decision is made about the presence and location of a QRS complex. Algorithms are commonly distinguished with respect to their preprocessing stages.

An extensive survey of single-lead QRS-detection algorithms is given by Kohler et al. [130]. The most common approaches are based on high-pass and band-pass digital filters, but many other approaches have been proposed, based on wavelet transforms [133, 134], artificial neural networks [127, 135], and genetic algorithms [136]. Some algorithms [137, 138] employ techniques from syntactic pattern recognition, but it has been difficult to demonstrate the practical utility of this approach [139].

In the multiple-lead algorithms, the simultaneous leads are transformed to a detection function. The transformation brings out the QRS complexes amongst the other parts of the signal, in order to increase the QRS detection rate. One of the most commonly used transformations is the computation of the spatial velocity of the VCG or of a similar derived function for the 12-lead ECG. The spatial velocity (SV) is defined as:

$$SV(n) = \sqrt{\sum_{k=1}^3 (d_k(n))^2}$$

where  $d_k(n)$  denotes the first derivatives of the VCG leads X, Y, and Z. Various difference equations have been proposed to approximate the derivatives [130]:

$$\begin{aligned} d(n) &= x(n+1) - x(n-1); \\ d(n) &= 2x(n+2) - x(n+1) - x(n-1) - 2x(n-2); \\ d(n) &= x(n) - x(n-1). \end{aligned}$$

In the case of the 12-lead ECG, the VCG leads can be reconstructed from the ECG leads by linear transformation, or approximated by a quasi-orthogonal set of ECG leads [140]. Alternatively, a pseudo-SV has been computed by combining the derivatives of all ECG leads.

The detection signal is then gauged against a threshold to detect the occurrence of a QRS complex. The threshold may be fixed, but more commonly is adaptive, changing with varying signal characteristics [140–142]. Some algorithms also require that the detected QRS complexes fulfill certain amplitude constraints. Other algorithms compute a second derivative,

$$d^2(n) = x(n+2) - 2x(n) + x(n-2),$$

and use a combination of first and second derivatives as the detection function. Balda et al. [143] used the sum of the absolute first and second derivatives over three simultaneous leads. This detection function was called the “waveform boundary indicator” as it also provided an estimate of the onset and the end of QRS complexes. A single-lead implementation of the method was given by Ahlstrom and Tompkins [86].

Once a potential QRS complex is detected, most of the algorithms apply further heuristic criteria to exclude false-positive detections, for example, by requiring a minimum time lag between adjacent QRS locations [140]. Laguna et al. [144] apply a single-lead detection algorithm to each of a set of simultaneously recorded leads, and then enter into a decision process comparing the detection positions over all leads to decide which detections are true or not.

An inventory of different methods used in seven VCG and eight ECG programs can be found in the second progress report of the CSE project [122]. However, only few developers of these ECG computer programs have published detailed evaluation results of their detection algorithms. On a set of 2,889 QRS complexes from the CSE multilead library, Kors et al. [140] found no false positive or false negative detections at all. Contrasting with the parsimonious communications on multilead QRS-detection algorithms, performance results for single-lead algorithms have been reported in fair abundance (see [130] for an overview). Many of these algorithms were evaluated on (part of) the MIT-BIH arrhythmia database, and achieved excellent results (>99% sensitivity and positive predictive value) [130]. A comparative study on noise sensitivity of nine single-lead QRS-detection algorithms for five different types of noise also indicated very good detection performance of most algorithms for all but the highest levels of noise [126]. In general, considering that the multiple leads of the standard 12-lead ECG offer redundancy of information and that noise levels in the resting situation are typically less troublesome than under monitoring conditions, it may be concluded that near-perfect QRS detection in the resting ECG is feasible.

### 37.9 Detection of P Waves

Detection of the P waves remains one of the most difficult tasks in automated ECG analysis. Failure of P-wave detection will jeopardize the rhythm interpretation program. Problems may arise owing to low amplitude, variable morphology and diverse timing of P waves. A P wave superimposed on a T wave, and even more so, a P wave that coincides with a QRS complex, are difficult to distinguish in surface ECGs (► Fig. 37.4). Their probable location can only be extricated by considering the sequence of the preceding and following P waves and by recognizing small irregularities in the expected contour of QRS or T. This requires long and continuous recordings. Even then, problems remain in deciphering morphology and polarity. While P-wave detection on surface ECG leads may already pose problems to the eye of the cardiologist,

► Figure 37.4

ECG showing an AV dissociation, with one P wave superimposed on a T wave and another P wave merging into a QRS complex.

more problems await the computer programmer working in this field [145]. The human ability to recognize even low-voltage P waves hidden in other waves and amidst noise and artifacts is indeed still far superior to the performance of all presently available ECG wave-recognition programs.

Different approaches with respect to automatic detection of P waves have been described in the literature. Stallman and Pipberger [6] applied a threshold approach to the smoothed spatial velocity curve. McManus [146] has worked further on this method. Bonner and Schwetman [147] used a piecewise approximation of the ECG, followed by tests on level crossings and slope changes. A two-stage detection method was introduced by Hengeveld and Van Bommel [148], and later on refined by Talmon [85]. First, QRS-linked P waves are searched for, based on histograms of local signal extrema in the intervals preceding the QRS complexes. If they are not found, non-QRS-linked P waves are sought by cross-correlation of signal amplitudes with an empirical P-wave template. Schnyders and Jordan [149] applied an energy correlation technique on the 12-lead ECG with apparently good results. Martinez et al. [131] proposed a wavelet-based P-wave detector. Once the location of the QRS complex is found, local maxima in the wavelet transform of the higher scales (i.e., in the lower frequency bands) are sought in an RR-dependent search interval. If at least two local extrema exceed a certain threshold, a P wave is considered present. Gritzali et al. [150] used as a detection function the length transformation of a signal, which essentially is the length of the signal curve within a time window. The length transformation can be defined for more than one lead by adding the curve lengths of the individual leads. Simple thresholding of the transformation is used to detect the P waves, as well as their onsets and ends.

It can be very difficult to distinguish P waves from flutter waves. In the presence of 2:1 AV block it may be hard, even for a human observer, to choose between flutter and sinus tachycardia. In various programs, separate routines are applied to determine whether atrial flutter waves are present [37, 141]. Talmon et al. [151] described a method that detects the periodic components characteristic of flutter waves (► Fig. 37.5). After appropriate filtering and removal of the QRS complexes, the resulting signal is autocorrelated. Flutter waves are assumed to be present if the autocorrelation function has a sufficiently large local maximum at a lag between 150 and 300 ms (corresponding with flutter rates between 200 and 400/min) and a second local maximum at twice the lag of the first maximum. A sensitivity of 86% and a specificity of 99.9% were reported. Taha et al. [152] employed a QRST subtraction technique and spectral methods to distinguish between atrial flutter, atrial fibrillation, and other rhythms. They obtained a sensitivity for flutter of 80%, at a specificity of 98.7%. Giraldo et al. [153] tried to detect the boundaries of atrial flutter and fibrillation waves, and used the coefficient of variation of the wave amplitudes to distinguish between flutter and fibrillation. They tested their approach on 40 short signal segments with flutter or fibrillation from the MIT-BIH database, but did not include segments with other heart rhythms in their analysis. Christov et al. [142] propose an atrial flutter-fibrillation parameter that is the mean value of the filtered and rectified signal, after subtraction of QRS-T complexes. On a test set, they obtained 76% sensitivity for flutter and fibrillation combined, at 97.9% specificity.

The detection rate of P waves varies according to the different algorithms that are applied. McManus [146] reported failures from 0–3%. For the 250 ECGs in the multilead CSE library [61], Kors et al. [140] obtained a sensitivity of 98.1% and a positive predictive value of 99.9%. Oversensitive methods cause difficulties in cases with atrial fibrillation. In the AVA program [123], as well as in several other programs, a P-wave search is only performed in an interval between the end of the T wave and the onset of QRS. In addition, only one P wave can be detected per QRS complex, which practically excludes the diagnosis of AV block or AV dissociation with an atrial rate higher than the ventricular rate. Programs that do attempt to detect more than one P wave per cycle have not reported detailed results [37, 141, 154], but judging from the results of arrhythmia detection (see section on rhythm interpretation), the success rate of these algorithms must be rather unsatisfying. A confounding factor is that P waves may alter their appearance in one recording, suddenly, from one beat to the other, or gradually, and that precisely this behavior is an element in rhythm diagnosis. To our knowledge, no work has been done on P-wave typing, that is, the distinction between different P-wave morphologies in one and the same recording.

### 37.10 QRS Typing

QRS typing is essentially a clustering task followed by a classification task, as the case requires. The clustering attempts to distinguish between different types, or families, of QRS complexes (if more than one). Within one family the complexes are similar in QRS morphology. If more than one type has been detected, the classification task is to determine which one

■ Figure 37.5

Example of the processing steps in a flutter wave detection algorithm (From Talmon et al. [151]). From top to bottom: original signal; signal after sampling rate reduction; signal after bandpass filtering; bandpass filtered signal after removal of QRS complexes; ternary signal; autocorrelation function.

is the dominant type. The term “dominant” is not synonymous with “most numerous.” It may well be that in a recording the “dominant” sinus complexes are outnumbered by ectopics, for example. We define the term dominant as the indication for the family of complexes to be used for the morphological (or contour) diagnosis. The nondominant complexes may be further divided into several types, such as premature ventricular or supraventricular complexes (possibly from different foci) and escape beats. This makes it clear that correct QRS typing is indispensable for a reliable rhythm interpretation. Typing, however, is a less straightforward endeavor than one would wish. Commonly, the dominant complexes are sinus

beats, but they might also be of atrial or nodal, or even ventricular origin. What if the pacemaker site changes during the recording? And, quite annoyingly, complexes from the same origin may show sudden variation in QRS morphology, for example, in intermittent right bundle branch block. Which one will be labeled as the dominant morphology? Differentiating aberrantly conducted complexes from ectopic complexes is the next problem. Also, similar QRS complexes are not always followed by similar ST-T segments, a complication that inspired only a few investigators to take a closer look at ST-T typing [85, 155].

A variety of clustering methods and features for QRS typing has been proposed. All methods compute a similarity measure between a newly presenting complex and one or more of the complexes in each of the already existing clusters. The new complex is then assigned to the group with the complexes that are most similar to it, unless the similarity is below a certain threshold, in which case a new group is formed. Different similarity measures have been proposed, such as the area between the normalized spatial velocity curves of the two complexes [156], the difference in so-called arc lengths of the complexes [94], or the Mahalanobis distance using four morphological QRS features [157]. To determine whether two complexes were of similar type, Talmon [85] used a decision tree that involved two similarity measures, reflecting similarity in shape and in power. Lagerholm et al. [158] decomposed the QRS complexes into five orthogonal Hermite functions and used the resulting coefficients, together with RR-interval parameters, as features to cluster the complexes into 25 groups by means of a self-organizing map.

When more than one type of QRS complex has been found, it must be decided which is the dominant type. As mentioned above, this may not be so self-evident since the most frequent type is not necessarily the dominant one. More elaborate decision logic has been developed [85, 141], involving QRS duration, RR interval length preceding the complex, and the number of beats of each type.

Few quantitative results on QRS typing in the resting ECG have been published. Using the ECGs from the CSE multilead library, Kors et al. [140] found an error rate of 0.3% for their multilead ECG program in classifying four types of complexes. Lagerholm et al. [158], using the MIT-BIH database with 16 different beat types, report a chance of 1.5% that a beat ends up in the wrong cluster.

Several investigators have approached QRS typing primarily as a beat classification task [127, 159–162], rather than as a clustering task, possibly followed by a classification stage. They trained one or more classifiers based on a labeled set of beats of different morphology. For example, Hu et al. [127] applied artificial neural networks to distinguish between normal and abnormal beats (involving 12 different beat morphologies), using raw QRS samples from the MIT-BIH arrhythmia database as the input. They obtained a total accuracy of 90.6%, which compared favorably with the 73.0% accuracy of a simple nearest neighbor classifier, but this level of accuracy would not seem high enough for clinical application. This may not come as a surprise considering the large interindividual variability of QRS morphology. Only when the classifier was trained on patient-specific ECG data, were more acceptable results obtained [159]. Christov et al. [162] applied a nearest neighbor rule to 26 parameters derived from two ECG leads. Again, when tested on the MIT-BIH arrhythmia database, a general classifier performed poorly, but patient-specific classifiers showed good performance. However, the patient-specific approach to QRS typing requires initial human labeling of beats and, therefore, is of little value for computer programs that should analyze the short-duration resting ECG fully automatically.

### 37.11 Forming a Representative Complex

---

Most diagnostic ECG computer programs operate on a single “representative” P-QRS-T complex from the “dominant” family [37, 121, 122, 141, 163, 164]. From this representative complex, the measurements needed for the diagnostic interpretation stage are derived. Mostly, the representative complex (sometimes called a “template” complex) is obtained by the computation of an averaged beat or a median beat from as many complexes in the record as may qualify for the purpose. Such a procedure presupposes complexes of similar morphology, and thus requires that QRS typing has been performed. The following techniques are in use:

1. Coherent or ensemble averaging is a simple technique in which the average of the time-aligned complexes is calculated at each sample point. The technique has been shown to be equivalent to low-pass comb filtering and to yield optimal noise reduction for Gaussian distributed noise [165, 166]. Under this condition, the SNR improvement is equal to the

- square root of the number of complexes being averaged. Since the average is vulnerable for outliers, it is imperative that complexes affected by sudden baseline shifts or other major disturbances are excluded from averaging.
2. Another approach is finding the median value for each sample point of the time-aligned complexes. The median beat is less sensitive to baseline shifts, but low-frequency baseline wander may introduce discontinuities in the median beat and result in reduced noise suppression [85, 167].
  3. To reduce the effect of averaging widely differing amplitudes, Macfarlane et al. [94] compute a so-called modal beat. They assign weights to each sample of each QRS complex, with similar amplitudes across complexes having a high weight, the others having lower weights. The approach performed well [85], but was computationally expensive. In later versions of the Glasgow program, the technique was, therefore, abandoned in favor of simple averaging or, if any individual beat significantly deviated from the average, computation of a median cycle [141].
  4. A hybrid approach, trying to combine the advantages of the averaging and median techniques, was proposed by Mertens and Mortara [167]. They first split the QRS complexes in three equally-sized groups and determine the averaged complex for each group. These three averaged complexes are then partitioned in their low- and high-frequency components with a simple moving average filter, and for both signals the median complex is determined. Finally, the two median complexes are added to form the representative complex.

For all these methods precise beat alignment is essential. In several programs [122, 163, 164], synchronization is performed by a cross-correlation method. In the MEANS program [37, 85], alignment is based on a reference point within the QRS complex, the position of an extremum in the band-pass filtered signal, whereas the Louvain program [121] uses the onset of individual QRS complexes. If complexes are not accurately aligned, beat-to-beat variations in the timing between peaks in the complexes may reduce the peak amplitudes [85]. To avoid this problem, some programs select only one “typical” complex for further analysis [168]. While this approach obviously does not need beat alignment, it does not help to improve the SNR.

The single complex approach is being taken a step further when wave recognition and measurements are done on each individual complex followed by computing an average or median of the measurements across the complexes [123, 143, 154, 169, 170].

There has been some discussion on the merits of signal averaging versus measurement averaging. Talmon [85] was not able to show any significant difference in QRS duration if wave recognition were performed on single complexes or on an averaged complex, after proper beat alignment [85]. The averaging method, however, offers the advantage of increasing the SNR. Based on results of extensive noise tests performed in the CSE project, a measurement strategy that uses selective averaging has been recommended for diagnostic ECG computer programs [171, 172].

## 37.12 Waveform Recognition

The goal of waveform or boundary recognition is to determine the inflectional points P onset, P end, QRS onset, QRS end, and T end, as much as possible in conformity with their visually determined counterparts (► Fig. 37.6). No attempt is made in any ECG computer program to determine the end of the U wave, the orphan wave of electrocardiology. The CSE Working Party [34] stated that the inclusion or exclusion of isoelectric segments in the initial or terminal parts of a wave may lead to differences in wave duration of more than 10 ms between leads, and, therefore, urges that “the true onsets and offsets of P and QRS as well as the end of T should be determined using at least three simultaneously recorded leads.” (cf. ► Fig. 37.1) The end of T deserves special attention in this respect. In 1990, Campbell and his group introduced the concept of QT dispersion (QTd) [173], defined as the difference between the longest and the shortest QT in any of the 12 surface ECG leads. QTd was supposed to reflect the dispersion of repolarization within the myocardium. The idea caused a tidal wave of papers but in due course became severely criticized [174–177]. Differences in QT duration will arise from differences in the projection of the spatial T vector onto the different leads, which in some leads may result in terminal isoelectric segments of various lengths and hence in shortened QT [174]. Also in QTd measurements, the U wave was regarded as a nuisance, obscuring the end of T. If it were too prominent, the lead was simply excluded from QTd determination. The U wave, however, might deserve more attention than this. Viewed in simultaneous leads, it may be seen in some as a separate wave, detached from the T; in other leads it may encroach on the T wave, and in still other leads it may blend in with the T wave. In fact, searching for the common end of the T wave is not pertinent if T and

■ Figure 37.6

In the waveform recognition, onset and offset of P, QRS, and T are determined, as indicated by the *vertical bars*. QRS offset and J are identical points. A true 0-level cannot be identified: the onset of QRS is superimposed on the atrial repolarization wave (Ta), at the J point ventricular repolarization is already underway, and the end of T coalesces with the U wave, the end of which is hidden in the next P. As the operational 0-level for QRS and T the *horizontal line* through QRS onset is recommended, likewise for the P the horizontal through P onset. Amplitudes are measured with respect to these 0-levels.

U form a continuum as has been proposed [178], in the same way as it is impossible to ask for the common end of a Q wave in the QRS. Whatever the ultimate truth, it seems best for the time being and for practical purposes, for example, for QT duration measurement in drug safety testing, to let the computer determine T offset over multiple simultaneous leads.

As pointed out above, single lead, “one-dimensional” measurements systematically produce shorter measurements of wave duration than when, “multidimensionally,” the first onset and latest offset in any lead are taken. Most ECG computer programs, therefore, use the spatial velocity or a similar multidimensional function as the detection function for waveform recognition (see ▶ Sect. 37.8). For single-lead recordings, other detection functions, such as the envelope of the ECG signal [179] or wavelet transforms [131, 133], have been applied. Basically, three different approaches of boundary recognition can be distinguished [180]. Each has to be trained and tested by human observers.

### 1. Thresholding

The most straightforward method is to apply a simple threshold to the detection function. For the onset, usually the maximum of the detection function is localized from where it is traced backward until where it first becomes smaller than an absolute or relative threshold. This point is considered to be the wave onset. The end of a wave is determined similarly.

According to an inventory of waveform-recognition methods used in various ECG computer programs in the CSE project [122], most programs applied threshold detectors. A number of different thresholding algorithms to detect the end of the T wave in single leads were described and compared by McLaughlin et al. [181, 182]. Using a threshold detector, Vila et al. [183] attempted to determine not only the end of the T but also the end of the U wave. They mathematically modeled the TU complex and used the modeled signal for detection. Laguna et al. [144] applied a single-lead threshold detector to each of the leads of multilead ECGs and then combined the wave boundaries in the individual leads to find overall onsets and offsets of P, QRS, and T.

### 2. Signal matching

A second approach is to search for the point where the weighted least-square difference between a reference waveform and the detection function is minimal [184]. The reference waveform is obtained from a learning set of detection functions with known wave boundaries, as indicated by one or more human observers. Rubel and Ayad [184] compared the

performance of a signal matching algorithm for different detection functions using the CSE database. They obtained the best results for QRS onset and offset detection with an unfiltered spatial area detection function.

### 3. Template matching

The template method takes into account information on the time-amplitude distribution of the detection function in a window around the inflectional point [185]. A template is constructed from a series of detection functions in which the wave boundaries have visually been assessed by a human observer. The boundary point in a new ECG is then located at that point where the cross-correlation between the template and the new detection function is maximal. Details of this approach and an efficient way of implementation have been described by Talmon [85].

A somewhat different approach, obviating the need for thresholding or matching, was proposed by Zhang et al. [186]. As a detection function, they took the output of a signal integrator in a window sliding over the T wave. With recourse to some simple assumptions, the maximum of the detection function was shown to coincide with the end of the T wave. A model-based approach to delineate single-lead QRS onset and offset was described by Sörnmo [187]. He statistically modeled the low-frequency segments (containing P and T waves) and high-frequency segments (QRS complex), and applied a maximum-likelihood procedure to estimate the points where a change occurred between low- and high-frequency segments.

Using the multilead CSE database, Willems et al. [61] evaluated the measurement performance of 11 ECG and 6 VCG computer programs (Fig. 37.7), incorporating a variety of wave boundary detection algorithms [122]. Onset of QRS showed overall the smallest deviations from the reference, with the narrowest confidence intervals. End of T showed the largest scatter. The median of the waveform recognition results of all programs coincided best with the median results of referee cardiologists, corroborating findings of the former 3-lead CSE study [60]. However, individual program results

Figure 37.7

Comparison of individual program results (numbered 2–16) and median referee results (RF MED) with the median of all programs in the CSE multilead library. Mean differences and 99% confidence intervals are indicated by *small vertical lines* and *horizontal bars*, respectively (From Willems et al. [61]. © American College of Cardiology. Reproduced with permission).

were widely divergent. As a consequence, P, PR, QRS, and QT interval measurements also varied widely among the various programs.

Willems et al. [171] assessed the influence of noise on wave boundary recognition of eight ECG and six VCG programs. Seven different types of high- and low-frequency noise were added to each of ten recordings. Mains interference and baseline wander had no significant effect on boundary detection for the majority of programs, but increasing levels of high-frequency noise shifted the onsets and offsets of most programs outward. Programs which apply beat averaging techniques had more stable results than programs analyzing single beats, but it was noted that these results mainly occurred at high noise levels that reflect poor operational conditions and can be avoided by proper quality control [171]. In a second related study [172], the effect of noise on amplitude measurements was examined. Programs that showed the least variability in waveform onsets and offsets also exhibited the highest stability in waveform detection and amplitude measurements.

Laguna et al. [144] compared the waveform boundary results and interval measurements obtained by their own algorithm with the median program estimates and median referee estimates of the multilead CSE database. The standard deviations of the differences were shown to be within acceptable tolerance limits [34] for most of the measurements. Martinez et al. [131] used the same data set to evaluate their wavelet transform-based approach, but they obtained less favorable results for QRS end and T end.

An interesting method to assess and compare the results of various waveform recognition algorithms was proposed by Morlet et al. [188]. They use scatter graphs that picture the standard deviation of the differences between program results and reference when the largest differences are progressively removed. This information allows us to distinguish between the reliability of an algorithm, that is, its capacity to provide wave boundary estimates without flagrant errors, and its precision, that is, the standard deviation of the differences between its estimates and the references.

### 37.13 Parameter Computation

---

Once the onsets and offsets of the various ECG waveforms have been identified, parameter or feature extraction is the next step. Time intervals and wave durations follow directly from the established time points. The ambiguities around the QT interval have been pointed out in the previous section. For the amplitudes of the various deflections, a 0-line, or baseline, must be defined. It should be understood that there is no true 0-level anywhere in the ECG (Fig. 37.6). The T-P interval which has been recommended as such contains the U wave. The CSE Working Party defined baseline as “a horizontal reference line computed from a single base level” [34] and declared itself against the use of non-horizontal lines. For QRS and T combined, it recommended strongly the uniform use of a baseline through the onset of QRS in combination with a limited number of preceding sample points. For the P wave, the base level may be chosen at the onset of P. Voltage amplitudes are then simply determined with respect to the chosen baselines. A wave is defined as a discernible deviation from the baseline where at least two opposite slopes can be identified and where discernible means that both the amplitude and the duration of the deviation exceed certain minimum values [34]. Various amplitude ratios, such as Q/R and R/S, and also integrals and angles can be derived from these measurements. When simultaneously recorded orthogonal leads are available or are reconstructed from the 12-lead ECG [20, 189], spatial or planar vector magnitudes and directions, gradients and polar vectors can be obtained. The relative areas of the spatial QRS loop in each octant of the three-dimensional space are also measured in some systems [168].

Pipberger et al. [7, 8] applied the technique of time normalization of the QRS complex and the ST-T segment. Each was divided into eight equal time segments, regardless of their duration. In this way, measurements from QRS complexes with different durations can be compared one with another.

Advanced mathematical techniques, like Fourier analysis, polynomial fitting, or Karhunen–Loeve expansion, have been applied by some early investigators [190, 191]. It has been pointed out by Van Bommel [180] that parameters derived from these techniques may allow an accurate reconstruction of the overall shape of the ECG, but are not necessarily the best discriminating features in ECG classification.

Computer processing systems frequently make 250–300 measurements per ECG. Ultimately, only a limited subset is used in the diagnostic classification stage and a still smaller number is printed out in the final computer report, which is submitted to the requesting physician. Most ECG processing systems will optionally display the averaged or median

beat, if desired with markings for wave onsets and offsets as determined by the program. The ECG reader, therewith, has a check on the correctness of the measurements underlying the computer diagnosis.

## 37.14 Diagnostic ECG Interpretation

---

### 37.14.1 Strategies for Diagnostic Classification

---

After the initial waveform-detection, pattern-recognition, and measurement algorithms have been applied, the diagnostic stage is entered in which the ECG is classified into one or more of the various possible diagnostic categories. Two basically different approaches to diagnostic classification have been developed since the early days of computer assisted electrocardiography [192]. In the first, the deterministic or heuristic approach, the cardiologist's method of interpreting ECGs is simulated. The majority of existing ECG computer programs follows this approach. In the second, a statistical or probabilistic approach is adopted whereby an attempt is made by mathematical means to establish the probability that a given ECG belongs to a particular diagnostic category.

More recently, other approaches to diagnostic ECG classification have been tried. Some investigators have applied fuzzy set theory [170, 193, 194], others the "expert system" approach [195, 196] and, finally, neural-network techniques have been used [197–201]. However, clinical application of the latter techniques on a larger scale is lacking.

### 37.14.2 Deterministic ECG Computer Programs

---

The analysis follows a logical path of questions regarding the presence or absence of certain predetermined criteria for every diagnostic category, to be answered with yes or no. The questions and answers can be arranged in a decision table or in a decision tree resulting in diagnostic statements [85]. Such decision schemes, often quite elaborate, are implemented in all programs using the deterministic approach. The likelihood of the resulting diagnostic statements may be indicated by modifiers like "definite," "probable," and "possible."

Deterministic programs have the advantage that the diagnostic criteria used are familiar to the cardiologist, and that the logic is easy to follow and comprehend [192]. Much experience with conventional ECG interpretation present in the brain of the developer or published in the literature can, theoretically at least, be incorporated in these programs. Decision-tree programs are organic and flexible in structure and remain open for modification. With advancing insight and experience diagnostic pathways can be improved. Criteria selection can be guided by deductive reasoning based on knowledge of electrophysiological processes, a design that is inherently excluded in the statistical diagnostic approach. Also, new diagnostic categories can be added quite easily without the need for recruiting new statistical data.
