35 Preparation for Dialysis

Mark G. Parker[1] & Jonathan Himmelfarb[2]
[1]Maine Medical Center, Portland, ME, USA
[2]University of Washington, Seatle, WA, USA

Proper preparation of chronic kidney disease (CKD) patients for renal replacement therapy is a multidisciplinary process orchestrated by the nephrologist. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines state "preparation for kidney replacement therapy" as the principle clinical action of stage 4 (glomerular filtration rate, 15–29 mL/min/1.73 m^2) of CKD [1]. Current prevalence estimates suggest that this group comprises 400,000 individuals in the adult population in the USA [2]. Over 8 million people are thought to have stage III CKD or worse. Indeed, many nephrologists introduce discussions of replacement therapy preparation in the latter portions of stage III CKD in concert with ongoing care directed at ameliorating the metabolic derangements of declining renal function. Strategies for slowing renal disease progression and treating complications of CKD, such as hypervolemia, hyperkalemia, metabolic acidosis, renal osteodystrophy, hypertension, and anemia, are explored in detail in chapters 30 to 34. The subsequent discussion focuses on the approach to dialysis modality selection and preparation for specific modalities.

Timeliness of nephrology referral and outcomes

A significant body of literature has emerged over the past decade pertaining to the timing of referral of the CKD patient to a nephrologist and its impact on outcomes. The importance of timely referral may be related to intensified progression delay strategies and expert treatment of CKD complications but has been studied more specifically in relation to adequate preparation for renal replacement therapy.

The earliest study of the impact of timing of referral on outcome was performed on a small patient cohort over 20 years ago [3] in Oxford, England. Fifty-five patients who started maintenance dialysis in 1981 were divided into two groups: those meeting the nephrologist less than 1 month before initiation of renal replace-

ment therapy (late referral), and all others (early referral). All dialysis was initiated in acute hospital care. The primary outcome was severe complications protracting hospital stay. Sixteen of 23 patients (70%) in the late referral group fulfilled the outcome definition, as opposed to only 3 members (9%) of the early referral group.

Little was published on this topic again until a series of articles appeared beginning in the late 1990s. The majority of these studies followed patients prospectively from the time of entry into dialysis but relied on retrospective record review and patient recall to characterize the nature of each individual's pre-end-state renal disease (ESRD) care. The principle outcomes reported were mortality or, in the case of incident hemodialysis patients, type and timing of permanent vascular access use. A single-center study from the UK [4] of 198 patients reported shorter hospital stays upon initiation of dialysis (median hospital days, 9.7 vs. 25 for patients referred >3 months prior to the start of dialysis compared to those referred later) but did not demonstrate a survival benefit. This study may not have been adequately powered with regard to mortality. Cohorts studied from much larger databases have repeatedly demonstrated a survival disadvantage for late referral, however [5–8].

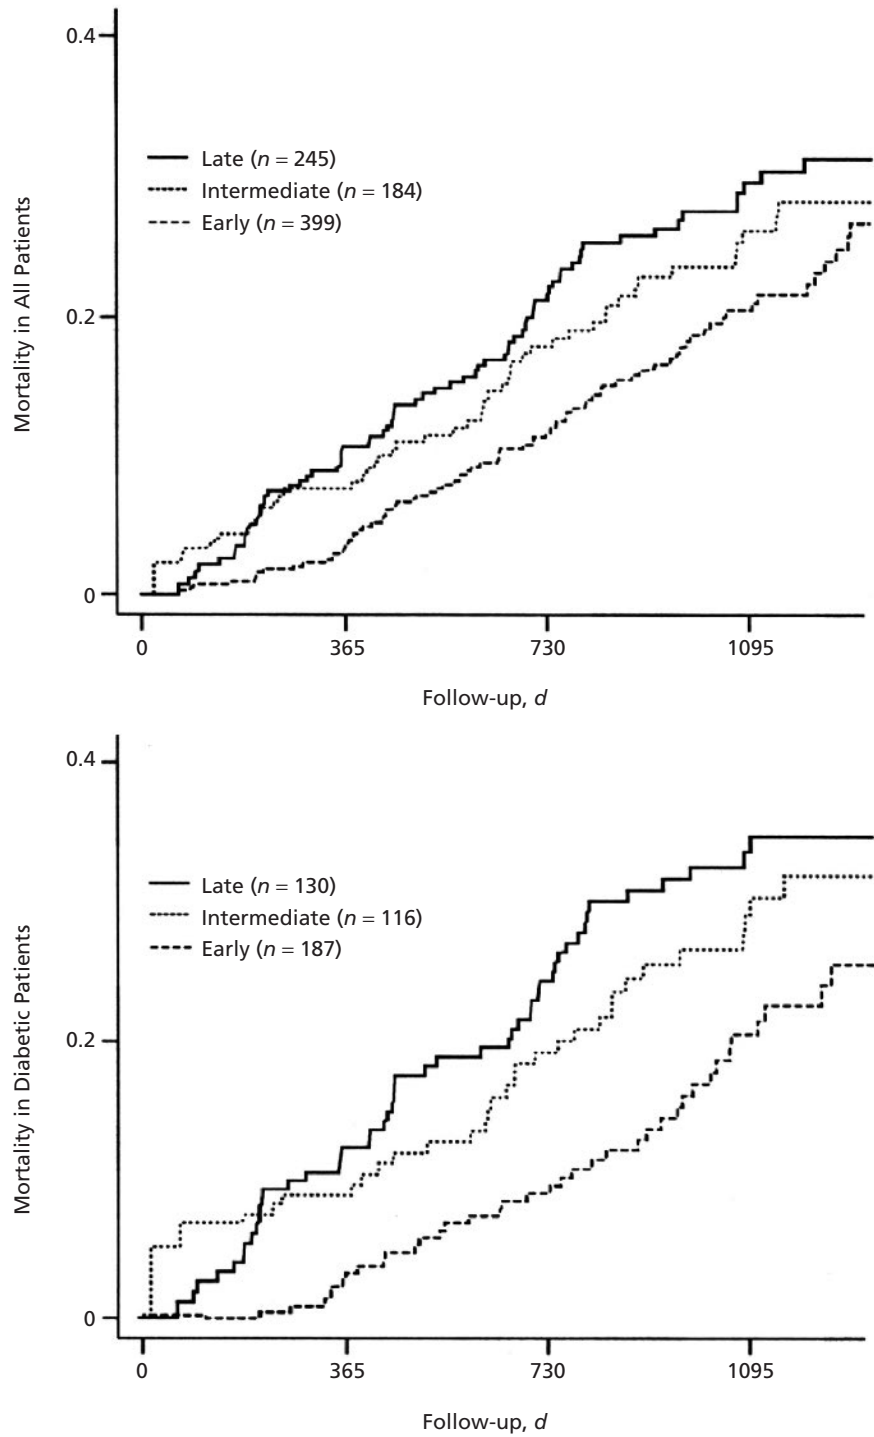
The Choices for Healthy Outcomes in Caring for End-Stage Renal Disease (CHOICE) investigators studied a cohort of over 800 patients at 81 centers from 1995 to 1998 [6], 25% initiating with peritoneal dialysis and 75% starting with hemodialysis. Patients were characterized by time of nephrology referral as >12 months (early), 4–12 months (intermediate), and <4 months (late). Thirty percent of patients were referred late. First-year mortality in the three groups was 4.3, 9.5, and 13.3%, and separation in mortality in the three groups persisted through 3 years of follow-up (Figure 35.1). A graded increase in hazard ratio persisted after adjustment for comorbidities and demographics. In this US study, late referral patients were more likely to be black, uninsured, and have a greater burden of comorbidity. A similar gradation of worsening mortality from early through intermediate to late referral was reported in EPIREL, a multicenter study in Lorraine, a metropolitan administrative region of France [5]. With early referral patients as the reference group, the odds ratio for death within 90 days


Figure 35.1 Cumulative mortality in patients undergoing early, intermediate, or late evaluation by a nephrologist. (Reprinted with permission from reference 6.)

of initiation of dialysis was 2.7 in the intermediate group and 4.9 in the late referral group. The EPIREL investigators also reported "emergency" first dialysis and temporary vascular access catheter use for first dialysis in over 80% of late referrals, compared with approximately 30% of the early referral patients. Stack [7] reported on the Dialysis Morbidity and Mortality Study (DMMS) Wave 2 patient cohort, demonstrating an adjusted relative risk of death for late referral (<4 months before dialysis initiation) versus early referral of 1.68 at 1 year into ESRD and 1.23 at 2 years. He also found that late referral patients were more likely to be black or Hispanic, less frequently had permanent vascular access, and had poorer metabolic and nutritional characteristics at entry into dialysis. The largest cohort study of this type utilized claims data from the Centers for Medicare & Medicaid Services (CMS) database and was a retrospective assessment of 109,321 Medicare-eligible patients (>66 years old) entering dialysis in the USA from 1995 to 1998 [8]. Pre-ESRD care was characterized by duration and frequency of nephrology contact. Of these patients, 50% had no nephrology specialist care prior to dialysis initiation and 37% had their first nephrology visit within 6 months prior to ESRD. Overall first-year mortality was 36%, and the adjusted hazards ratio was greatest, 1.51, for the group with no significant pre-ESRD nephrology contact.

Several investigators have focused on the timing and type of vascular access for hemodialysis as the principle outcome measure of referral timing studies. Clearly, catheter use is associated with increased morbidity and mortality [9,10]. Late referral patients are more likely to initiate dialysis with a vascular access catheter. The CHOICE investigators demonstrated this finding in the subgroup of their study patients who initiated hemodialysis therapy [11]. Only 10% of patients referred <1 month prior to ESRD initiated with an arteriovenous access, as opposed to 30% of patients referred between 1 and 12 months and 46% referred at >12 months. The median duration of catheter use was 202 days in the late referral group compared to 57 days for those requiring catheters in the earliest referral group. Early referral patients were far more likely to have an arteriovenous access in use within the first 6 months of dialysis than the latest referrals (82% vs. 56%). Similar findings were reported previously in a smaller cohort from the New England Medical Center [12]. These investigators also noted that patients from health maintenance organizations had a 4.5 times greater odds of being referred late compared to Medicare patients. This observation may have been unique to the regional practice patterns of the era (1992–1997), however.

A lingering uncertainty of the foregoing studies is the possibility that late referral is not an independent variable that influences outcome; rather, late referral is merely a surrogate for poor access to health care in general. Winkelmayer *et al.* [13] have attempted to address this through propensity analysis, a scoring system that attempts to discern the expected probability of receiving a treatment based on a patient's baseline characteristics. Studying a group of over 3000 New Jersey Medicare and Medicaid patients incident to dialysis from 1991 to 1996, these investigators concluded that

overall mortality was indeed markedly higher in the late referral group, but the effect appeared to be limited to the first 3 months after initiation of dialysis.

The economic implications of late referral were assessed by McLaughlin *et al.* using decision analytic modeling with a simulated cohort of 1000 typical incident dialysis patients [14]. Allowing fixed assumptions about rates of CKD progression, hospitalization, initiation of dialysis, modality switching, and death, the model predicted a 20.3% cost savings over a 5-year period for early referral compared to late referral.

Modality selection

Counseling CKD patients about renal replacement therapy options for ESRD is a distinct educational process. Patients in late stage 3 and stage 4 CKD should be instructed about a range of potential options, including home and in-center dialysis modalities, transplantation, and in appropriate cases, withholding of renal replacement therapy. It is particularly important to note that there is an allograft survival advantage when kidney transplantation is performed preemptively, that is, without previous initiation of dialysis [15]. Moreover, early consideration of transplantation is of prime importance for diabetic patients, who stand to gain a substantial survival benefit compared to long-term dialysis therapy [16,17]. Preparation for transplantation is addressed elsewhere in this textbook. Unless there is absolute certainty about a patient's prospect for preemptive live donor kidney transplantation, it is preferable to provide dialysis preparation in parallel with or as an alternative to transplantation evaluation.

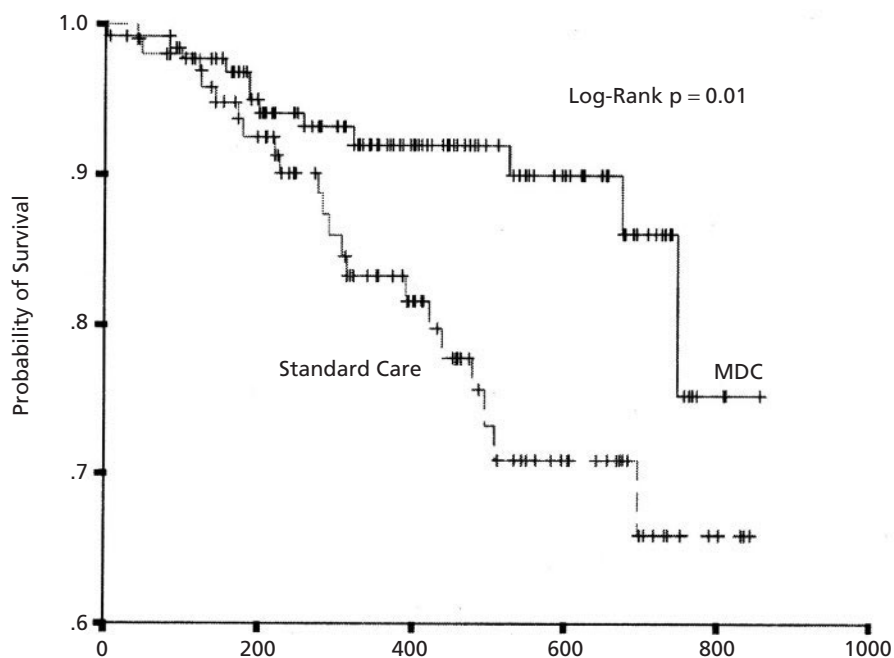
A small body of literature has evolved on the value of pre-ESRD patient education and subsequent outcomes. Some of this work has focused on specific predialysis interventional programs, while other studies have encompassed dialysis-specific education in a broader paradigm of CKD indoctrination. Two multicenter studies in Spain addressed the value of predialysis education. Gomez *et al.* [18] provided over 200 patients with a standard informational package that included a flip chart presentation, books, and video. Using pre- and postinformational questionnaires, these investigators demonstrated a substantial improvement in knowledge about treatment options. In particular, subjects gained knowledge about peritoneal dialysis, the modality least familiar to patients prior to the formal instruction program. Marron *et al.* [19] studied 621 patients from 24 centers for the effect of pre-ESRD care and patient education on the nature of dialysis initiation. They characterized initiation as either "planned" (outpatient start with the use of a permanent vascular or peritoneal access) or "unplanned" (defined as uremia requiring emergency dialysis). Although three-fourths of the patient population had received nephrology care for at least 3 months pre-ESRD, only half had received a specific educational program on dialysis modalities. Nonplanned starts occurred 49% of the time. Even patients with early nephrology referral had nonplanned entry into dialysis in 33% of cases, a somewhat startling


Figure 35.2 Kaplan-Meier survival curves for patients after starting chronic dialysis therapy: comparison of patients seen prior to dialysis initiation in the multidisiciplinary clinic versus standard nephrology care. (Reprinted with permission from reference 22.)

commentary on the fractured care that continues to exist in the nephrology community despite increased efforts to provide coordinated care. Among patients receiving dialysis-specific pre-ESRD education, however, a planned start happened in 73.4%. Dialysis-specific programs were also associated with a higher number of pre-ESRD visits and increased probability of choosing peritoneal dialysis as treatment modality: 31% versus 8% in the "uneducated" group.

Broader multidisciplinary educational and care team approaches, termed by some as "psychoeducational intervention" [20,21], for CKD and pre-ESRD care have been evaluated and the results have been published [20–23]. Most of these studies have originated in Canada. Such teams typically include a nephrologist, nurse educator, social worker, dietician, pharmacist, and peer support. The information that is provided is specific to ongoing CKD care and renal replacement therapy counseling when appropriate. Positive outcomes have generally been described with regard to biochemical indices, dialysis access preparation, and survival, although none of these studies was performed in a prospective, randomized, controlled fashion. A Canadian–Italian cooperative case–control study of this type, the Can-It Impact study [22], demonstrated a significant survival advantage (Figure 35.2) for incident dialysis patients who had received multidisciplinary clinic care as opposed to "standard" nephrology care.

Evidence indicates that it is prudent to educate patients and selected family or friends in a systematic manner using some combination of multidisciplinary renal team personnel. Potential dialysis patients need information not only about the mechanics of specific dialysis modalities but also the associated features of such therapy to help make informed choices. Factors such as modality-specific dietary restrictions, travel and time commitments for in-center therapy, nature of the home environment and self-care capability for home therapy, and adaptability of a modality to particular career or recreational life-styles all play a role in the choice of therapy. Furthermore, utilizing the expertise of the extended care team to assess the suitability of an individual patient for a specific modality may help guide the nephrologist in counseling the patient.

Patients often wish to know if a specific dialysis modality conveys a beneficial health outcome advantage. A number of observational studies, both small and large in scope, have attempted to answer this question and have been inconclusive. Several studies have suggested a slight survival advantage in the first 2 years after ESRD for patients on peritoneal dialysis compared to hemodialysis [24–26]. Speculation on the reason for this result has centered on the importance of preserved residual renal function for peritoneal dialysis patients early after ESRD onset. Other investigators demonstrated no difference in mortality between the two modalities [27–29] or a lack of early outcome difference (1–2 years) followed by a relative mortality risk in favor of hemodialysis [30,31]. Still other investigators have concluded that the results vary by analytical method [32] or by stratification of patients according to risk factors [33]. In the latter example, an analysis of 398,940 US Medicare incident dialysis patients from 1995 to 2000 suggested that mortality risk

favored peritoneal dialysis for nondiabetic patients in aggregate and young diabetic patients without significant comorbidity but favored hemodialysis in older diabetic patients. Outcomes were neutral among nondiabetic and diabetic patients with significant comorbidities, as well as the nondiabetic elderly.

Importance of comorbidities

The importance of comorbidity at entry into dialysis cannot be overlooked. In a Canadian multicenter observational study, Murphy *et al.* [34] concluded that apparent survival rates favoring peritoneal dialysis disappeared when adjusted for the overall lower comorbidity burden of the peritoneal dialysis cohort. Similarly, the CHOICE investigators concluded that the number and severity of comorbid conditions tended to be lower in patients choosing peritoneal dialysis in their cohort [35], again, possibly explaining mortality differences. One important comorbid condition, congestive heart failure, was specifically studied in a University of Texas analysis [36] of CMS patients entering dialysis from 1995 to 1997. The prevalence of this condition at dialysis initiation was 33%. Mortality outcome favored hemodialysis, with a relative risk of 1.3 for peritoneal dialysis patients.

Only one group of investigators [37] has attempted a randomized, controlled trial of the two dialysis modalities. Not surprisingly, the trial was stopped after only 38 patients were enrolled in 3 years due to a low participation rate of eligible subjects. A survival benefit at 5 years appeared to favor peritoneal dialysis patients, but the number of subjects was far too low to draw reliable conclusions. At present, it is reasonable to advise prospective dialysis candidates that there is not a preponderance of evidence favoring one modality over the other.

Home hemodialysis as a variation of hemodialysis delivery, particularly when provided nocturnally, has enjoyed a resurged interest in recent years in the nephrology community. Numerous reasons have been cited to consider this modality, including improved blood pressure and volume control [38,39], enhanced quality of life [40–42], cost-effective health care delivery [39,43], and possibly, a survival advantage [44–48]. The purported benefits have yet to be confirmed in a prospective, randomized comparison to in-center hemodialysis. Nonetheless, it is sensible to discuss home hemodialysis in pre-ESRD modality counseling. Most hemodialysis patients will start with in-center therapy prior to tackling the training period necessary for home therapy.

Certain comorbidities or patient characteristics may suggest a relative or absolute contraindication to a specific dialysis modality. These features are highlighted in Table 35.1. Patients should be counseled in this regard and guided towards more suitable therapy when such barriers are encountered. Patients should also understand that no care plan is completely inflexible, and modality switching can and should occur if an initial choice is deemed less than optimal by the patient and kidney care team. The initial choice of therapy, however, should be followed by a plan for vascular or peritoneal access preparation.

Table 35.1 Contraindications to specific dialysis modalities.

Hemodialysis
  Relative contraindications
  - Difficult vascular access
    – Severe peripheral arterial vascular disease
    – Central vein stenoses or occlusion
  - Desired home dialysis with lack of appropriate home environment or partner

Peritoneal dialysis
  Absolute contraindications
  - Extensive abdominal adhesions
  - Hydrothorax or diaphragmatic defects
  - Loss of peritoneal membrane function (ultrafiltration, solute clearance)

  Relative contraindications
  - Morbid obesity
  - Severe protein calorie malnutrition
  - Loss of residual renal function
  - Bowel disease
    – Ischemic
    – Chronic inflammatory
    – Diverticulosis or diverticulitis

Vascular access planning for hemodialysis

Evidence for primary arteriovenous fistula first

Vascular access remains the Achilles' heel of hemodialysis therapy. To be sure, the greatest source of complication or substandard treatment is suboptimal vascular access. The native arteriovenous fistula (AVF), either of the classic Brescia-Cimino variety [49] or of the upper arm, remains the best and most durable of the potential choices. Construction of a native fistula requires sufficient lead time for maturation. Furthermore, it has become clear that many native AVFs that fail to develop can be salvaged with aggressive monitoring and intervention [50,51]. Additional time may be needed for revision and satisfactory development. Consequently, although an excellent AVF may mature and be cannulated within 4–8 weeks of creation, the initial attempt at creation of the native AVF should occur at least 6 months before ESRD is anticipated. The maturing fistula should be examined 4–6 weeks after creation [52] and at CKD visit intervals thereafter. Evidence of insufficient development should prompt further evaluation and intervention [51].

Although there have been no specific studies dedicated to the adequacy of vein preservation for a native AVF, it has long been recommended that the nondominant arm should be avoided for needle puncture. Antecedent venous injury may impair the development or function of an AVF. Referral to an experienced surgeon is often accompanied by Doppler assessment of arm veins to select the most suitable site [53,54]. Historically, the initial choice of the AVF site has been the distal upper extremity,

thereby allowing preservation of proximal sites as needed for later vascular access attempts. Although sonographic study has improved the number of successful AVF creations in general, success rates remain suboptimal in women, diabetic patients, and the elderly. Miller *et al.* [55] have advocated consideration of upper arm sites as the first choice in these groups. Salvage procedures have been useful in these patients [50,51,56]. Konnor *et al.* [57] achieved superb results, even in high-risk groups, with a combination of careful preoperative examination, ultrasonographic study, use of a variety of AVF locations, and an experienced operator. Under these conditions, primary access survival ranged from 51 to 75% (depending upon gender and diabetes status) for 2 years, and assisted access survival was 75–96% for the same period.

The preference for the native AVF is supported by abundant outcome literature over the past decade. Mortality is clearly influenced by type of vascular access in large cohorts, including the CHOICE study [58], DMMS Wave I [9], and the ESRD Network 6 [10] analysis. In all such studies using AVF patients as the reference group, mortality risk increased in a graded fashion for prosthetic arteriovenous grafts (AVG) and cuffed, tunneled catheters. The increase in mortality is largely attributable to infection. High rates of bacteremia have been described with use of tunneled catheters in particular: 5.5 episodes/1000 catheter–days were reported by Saad [59]. In his study, over 50% of bacteremias were gram-positive cocci, 26.7% were gram-negative rods, and 20.9% were polymicrobial. Endocarditis occurred in 3.5% of patients. Oliver *et al.* [60] found a graded increase in the risk of sepsis from "early" AVF creation, >4 months prior to ESRD, compared to creation 1–4 months prior to ESRD and creation <1 month prior to or after ESRD. This association was presumably due to the need to use catheters as a bridge towards a functioning AVF.

In selected patients, native AVF creation is not feasible due to unsuitability of vessels. The second choice of vascular access is the prosthetic AVG with polytetrafluoroethylene or polyethaneurea. Although these access options do not achieve the long-term durability of the native AVF, primary patency rates are comparable [61–63]. Polytetrafluoroethylene AVG are not cannulated for at least 14 days to allow tissue ingrowth into the graft, but polyethaneurea AVG can be successfully cannulated sooner [64]. Prosthetic AVG typically require repeated intervention for thromboses and stenoses after 2–3 years in order to extend access longevity. Interestingly, although native AVF use has been highly prevalent outside the USA for many years, AVG use within the USA exceeded AVF use into the late 1990s [65–67]. These reports and others spurred the 2000 NKF K/DOQI targets to be at least 50% incident and 40% prevalent native AVF use for hemodialysis patients [68]. Progress towards these goals appeared to be improving in the DOPPS II study [69], with 31% prevalent AVF use, but was still not to target. More recent developments have included the CMS Fistula First initiative [70], which touted achievement of the prevalence target in August 2005 and has extended the goal to a 66% AVF prevalence by June 2009.

Use of tunneled cuffed cannulas

When dialysis need is imminent and vascular access has not otherwise been prepared, the intervention of choice is the placement of a cuffed, tunneled central venous access catheter for hemodialysis. The internal jugular vein, ipsilateral to the dominant arm, is the preferred site. A number of investigators have demonstrated an unacceptably high incidence of subclavian vein stenosis when this vein has been used for dialysis vascular access catheters [71–74]. The subclavian vein should be avoided. Femoral vein catheters are sometimes used when internal jugular sites are not accessible, but this is uncommon in the new ESRD patient. Catheters convey the advantage of immediate use and short-term durability but carry the previously described infection risks and potential for permanent vessel injury through the development of stenoses, thrombosis, or occlusion. Use of catheters remains high even among hemodialysis patients with existing AV fistulae or grafts. Danese *et al.* [75] recently reported a catheter insertion rate of 44/100 patient–years, representing 57% of all Medicare patients incident to hemodialysis from 1996 to 2001. Reasons for catheter use included insufficient AVF maturation or revision, thrombosis, or failure of the permanent AV access.

Late stage 3 and stage 4 CKD patients who are being prepared for hemodialysis therapy are best served by timely referral for a native AVF. It should be noted that inadequate development of the AVF in the pre-ESRD patient might prompt consideration of invasive vascular access imaging to identify potential avenues for salvage, such as angioplasty or venous collateral ligation or coiling. Until recently, the field was evolving to increased use of gadolinium as the contrast agent of choice due to the increased risk of acute kidney injury with iodinated contrast exposure in advanced CKD. However, in the USA, the Food and Drug Administration has recently issued an alert [76] advising caution in the use of gadolinium, at least for CKD stage 5. Concern was prompted by reports of nephrogenic systemic fibrosis and nephrogenic fibrosing dermopathy associated with the use of this agent in patients with very low glomerular filtration rates [77]. In stage 4 CKD patients, at least, a recent report suggested that judicious use (i.e. volumes of <10 mL) of a nonionic, low-osmolarity iodinated contrast agent for fistulography was associated with only a small incidence (4.6%) of contrast-induced nephropathy [78]. None required immediate dialysis.

Peritoneal access planning for peritoneal dialysis

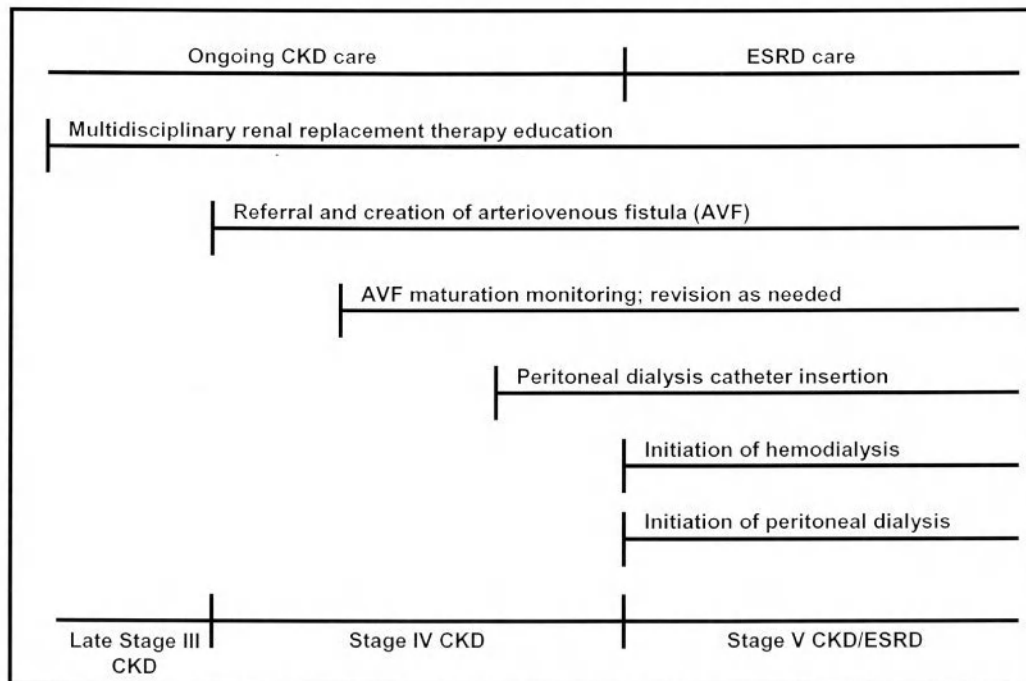
The timing of peritoneal catheter placement for peritoneal dialysis therapy typically occurs much closer to anticipated dialysis initiation, often at early stage 5 of CKD, than vascular access creation for hemodialysis therapy. There are no specific studies or trials published which have addressed the optimal timing of peritoneal catheter placement. Observational experience suggests that peritoneal catheters require at least 2 weeks for satisfactory healing


Figure 35.3 Timeline for preparation for dialysis.

and avoidance of peritoneal fluid leakage. They are occasionally used sooner in select circumstances. Nonetheless, referral for evaluation and placement of peritoneal catheters should be done in a fashion that avoids precipitous need to start dialysis and minimizes infection risks.

A variety of catheter types are potentially available, as reviewed elsewhere in this textbook. The most commonly used catheters are made of silicone rubber or polyurethane. A dual-cuffed silicone rubber catheter, the Tenckhoff catheter, is most frequently used. Double-cuffed catheters have been reported to have better longevity and reduced infection risks in several studies [79–82]. However, this was not corroborated in a prospective, randomized, controlled trial of single-cuff versus double-cuff Tenckhoff catheters [83]. Local practice expertise probably is the best benchmark of catheter choice and insertion technique.

Exit site infections and peritonitis have the greatest influence on catheter longevity, and therefore, impact longitudinal success of peritoneal dialysis in general. Successful measures to reduce the incidence of infection at the time of insertion and in the early postoperative period include perioperative antibiotic use [84–86] and immobilization of the external portion of the catheter in an undisturbed fashion (i.e. minimal dressing changes) during the first 1–2 weeks after surgery [87]. Moncrief *et al.* [88] introduced a technique for burying the exterior portion of the catheter subcutaneously for the first 3–5 weeks after surgery, followed by exteriorization. Peritonitis rates appeared to be reduced with this technique compared to historical controls [89]. A subsequent prospective, randomized study [90] of 60 incident peritoneal dialysis patients

did not confirm an advantage for this technique over traditional catheter placement, however. Neither exit site infection nor peritonitis rates differed during the first 24 months of dialysis.

Peritoneal dialysis training by appropriate dialysis personnel usually occurs commensurate with the need to initiate and maintain chronic dialysis therapy. In most circumstances, patients can be taught basic techniques for manual dialysate exchanges within a few days, and subsequent consideration of cycler therapy is tailored to individual situations as detailed in chapters 43–45.

Summary

Successful preparation of the CKD patient for dialysis requires early involvement of the nephrologist. A timeline for subsequent pre-ESRD interventions is summarized in Figure 35.3. Multidisciplinary assessment and education by the kidney care team allows psychological adjustment and an informed modality choice to be made by the patient with the enhanced potential for positive ESRD outcomes. Timely referral for vascular access preparation for potential hemodialysis patients is essential to increase the likelihood of successful creation and maturation of a native AVF. Vascular access catheters are to be avoided, if at all possible, due to a clear association with increased ESRD morbidity and mortality, although there continues to be a subset of patients who require this form of access due to a precipitous need for dialysis or inadequate arteriovenous access. Peritoneal access planning and intervention fall later in the CKD timeline, with greater proximity

to ESRD. However, this form of dialysis preparation is also dependent upon appropriate timing and technique considerations in order to maximize the potential for successful ESRD outcomes. Systematic renal replacement therapy planning has been convincingly demonstrated to influence ESRD morbidity and mortality and is the key to a successful transition from CKD to ESRD.

6 Chronic Kidney Disease Stage 5: Hemodialysis

36 When to Start Dialysis and Whether the First Treatment Should Be Extracorporeal Therapy or Peritoneal Dialysis

Raymond T. Krediet

Division of Nephrology, Department of Medicine, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands

When to start dialysis

Introduction

The issue of timing of initiation of dialysis was first raised by Bonomini *et al.* in the 1970s [1,2]. They reported the highest survival rate in hemodialysis (HD) patients with a residual creatinine clearance between 15 and 21 mL/min. However, criteria for the selection of patients based on residual renal function were not provided. The issue of an "earlier" start, which means with a higher glomerular filtration rate (GFR) than usual, reappeared again in the last decade when the process of developing guidelines for dialysis was started.

Early start or timely referral

A distinction should be made between the timing of referral to a nephrologist and the timing of the start of dialysis treatment. Failure to make this distinction has confused the discussion. It should be emphasized that all studies on late referral to a nephrologist are either retrospective, based on surveys, or prospective cohort studies. Nevertheless, the results are strikingly similar. Late referral for maintenance dialysis is associated with increased mortality [3–11] and decreased quality of life [12,13]. The excess mortality associated with late referral was independent of demographic characteristics, socio-economic status, and comorbidity. Moreover, late referral influenced the dialysis modality choice; patients who obtained predialysis care had a stronger preference for peritoneal dialysis (PD) than patients who did not (late referrals) [14]. In addition, patients who were referred late and started with PD were more likely to switch to HD during the first 6 months compared with patients who were referred in a more timely manner [15]. Despite all the evidence pointing to a beneficial effect of timely referral to a nephrologist, almost one-fourth of patients were referred less than 1 month before the start of dialysis in a survey of eight different European countries [16].

Guidelines and studies

The timing of initiation of dialysis has been the subject of many opinion-based guidelines in the last decade. The US National Kidney Foundation Dialysis Outcomes Quality Initiative (K/DOQI) Workgroup on Peritoneal Dialysis published an opinion-based guideline on the initiation of chronic dialysis treatment [17]. The work group advised that dialysis should be initiated when renal K_t/V_{urea} had fallen to 2.0/week. For a 70-kg man this equals a urea clearance of 8 mL/min, a GFR of 10 mL/min, and a creatinine clearance of 12 mL/min. A lower K_t/V_{urea} would only be acceptable when the normalized protein equivalent of nitrogen appearance, an index of protein intake in stable patients, was at least 0.8 g/kg of body weight/day and the patient was in a good nutritional state. These recommendations were retained in the update, published in 2001. The clinical practice guidelines of the Canadian Society of Nephrology for treatment of patients with chronic kidney disease, published in 1999, were not significantly different from the US guidelines but set the target for the start of dialysis at a GFR of 12 mL/min when symptoms were present, but with an absolute minimum GFR of 6 mL/min [18]. The European Best Practice Guidelines for peritoneal dialysis recommend consideration of initiation of dialysis when the GFR is below 15 mL/min in combination with evidence of poorly controlled conservative treatment. An absolute minimum value was set at 6 mL/min [19].

At the time these guidelines were published many patients typically started dialysis at much lower clearances. In one study from the UK the mean urea clearance was 3.9 mL/min [20]. A study from the USA reported that 63% of the patients had an estimated GFR between 5 and 10 mL/min/1.73 m^2, and 23% had an estimated value below 5 [21]. Although the above guidelines are not evidence based and are far from current practice, they have caused a trend towards earlier initiation of dialysis treatment [22,23].

Currently, no randomized controlled study on the initiation of dialysis is available. The cohort studies do not point to a real benefit for an early start [24,27–30]. The Netherlands Cooperative Study on the Adequacy of Dialysis (NECOSAD) is a multicenter prospective cohort study in which all new dialysis patients are

included and followed at 6-month intervals. GFR is measured as the mean of creatinine and urea clearance at the start of dialysis and thereafter. An analysis of 253 patients showed that 37% started dialysis treatment later than the K/DOQI recommendations (late starters) [24]. The others were defined as timely starters. The adjusted difference in estimated survival time after 3 years on dialysis treatment was small: a benefit of 2.5 months (95% confidence interval, 1.1–4.0) in favor of timely starters. However, this is likely to be explained by lead time bias. Lead time may have an effect on the observed lower mortality risk, and thus longer survival time, in patients classified as timely starters and may be simply a reflection of initiating dialysis at an earlier stage of disease. The lead time could not be measured in the NECOSAD analysis, but taking the normal decline of GFR into account [25,26], it could be estimated as a period of about 6 months. Consequently, the apparent gain in survival from a timely start was presumably due to lead time, instead of an actual improvement in the course of the disease. All patients, timely and late starters, showed a marked improvement in quality of life during the first 6 months after the start of dialysis treatment [27]. Patients who commenced dialysis in time had a significantly better quality of life at initiation of treatment than the late starters. However, these differences disappeared after 1 year on dialysis, and both groups reported a similar quality of life at that time.

A retrospective analysis of a small single-center cohort of new, mainly HD patients from Austria showed no difference in creatinine clearance at the start of dialysis between patients who survived less than 1 year compared with those who survived more than 1 year on dialysis [28]. An analysis of the electronic patient records at the Glasgow Royal Infirmary made it possible to identify patients with an estimated creatinine clearance (Cockcroft-Gault formula) of less than 20 mL/min and who could be followed before the initiation of dialysis and during dialysis with exclusion of late referrals [29]. The date from which a creatinine clearance of 20 mL/min was calculated was used to determine survival time. Patients were divided into an early or late start group by the median creatinine clearance, which was 8.3 mL/min. The authors found no benefit in patient survival from an earlier start of PD. Instead, patients who started dialysis with a lower creatinine clearance tended to survive longer. Although not investigated in this study, the effect may have been due to the well-known fact that dialysis is often started earlier in sicker patients and those with more comorbidity.

An analysis of the Dialysis Morbidity Study Wave II, which is part of the US Renal Data System (USRDS), demonstrated essentially the same finding [30]. Patients with a higher estimated GFR at the start of dialysis had a higher mortality than those with lower values, with a hazard ratio of 1.14 in multivariate analysis.

Conclusions on the start of dialysis

In the absence of randomized controlled studies, the bulk of evidence has shown that late referral to a nephrologist is associated with increased morbidity and mortality. No retrospective or prospective cohort study has shown a benefit of an early start of dialysis on mortality, whereas the effects on quality of life were only temporary. A randomized controlled trial is currently being performed in Australia and New Zealand (the IDEAL study), but given the present evidence, it is unlikely that the results will be different from the evidence that is currently available.

PD or HD as initial renal replacement therapy

Both PD and HD have positive and negative features. Consequently, these options have to be weighed in individual patients according to their needs, with the aim of providing a patient-tailored renal replacement therapy. The only randomized controlled trial comparing PD and HD as initial renal replacement therapy was underpowered but showed a survival advantage for PD in a cohort of 38 incident ESRD patients in the Netherlands, with unadjusted or age and comorbidity adjusted hazard ratios for death over 5 years for patients randomized to HD vs. PD of 3.8 (95% confidence interval [CI], 1.1–12.6) and 3.6 (95% CI, 0.8–15.4), respectively [31]. The primary outcome of this study, quality of life, showed a trend favoring HD in the first 2 years. Given the effort that was invested to obtain a sufficient number of patients, it is unlikely that more randomized controlled trials on this subject will be performed.

A number of retrospective or prospective studies, performed with cohorts or by using registries, have shown a number of advantages of PD that are especially marked in the first years of treatment. Besides patient survival, these include higher hemoglobin levels [32], better preservation of residual GFR [33–38], and better results after kidney transplantation with regard to delayed graft function [39–41]. Furthermore, when a patient has to be transferred to HD, vascular access surgery can be planned in a timely fashion.

Studies comparing patient survival according to dialysis modality have given divergent results, that is, no difference between HD and PD, better results for HD, or better results for PD. This may be due to differences in study design, study populations, sample size, data collection, and availability of relevant data [42]. Additionally, differences between countries that influence outcomes can be present that are not explained by the above, such as access to health care and the health care system. The CANUSA study showed that the relative risk of death for incident PD patients in the USA was 1.95 compared to those in Canada [43], showing that results of studies on comparisons of survival between PD and HD were different when performed in the USA or in Canada and western Europe.

A retrospective multicenter study performed in the USA with 939 incident patients was published in 1990 [44]. A nonsignificant tendency for better survival for PD patients was found. In contrast, an analysis of a large sample of incident patients from the USRDS found no difference in survival between HD and PD patients, except among diabetic patients, who had a higher relative risk of death when treated with PD [45]. A USRDS analysis of prevalent patients showed that patients treated with PD had a 19% higher adjusted mortality risk than those treated with HD [46], particularly in patients over 55 years, those with diabetes mellitus,

Table 36.1 Comparison of mortality between HD and PD patients: studies from North America.

and in women. However, another analysis of incident USRDS patients showed no differences between survival on PD and HD in various 2-year cohorts from 1982 up to 1993, with the exception of female diabetic patients, who did worse with PD [47]. Another study, however, performed in the same period in the USA reported better survival for PD patients [48].

A more recent analysis by Vonesh *et al.* in 398,940 incident dialysis patients (11.6% PD) identified three factors that influenced the relative risk of death in HD and PD patients: 1) the cause of end-stage renal failure (diabetic vs. nondiabetic patients), 2) age, and 3) the presence or absence of comorbidity at initiation of dialysis [49]. In these analyses HD was associated with an increased risk of death in nondiabetic and young diabetic patients, with no reported baseline comorbidity. When comorbidity was present, no difference in the relative risk of death was found between HD and PD. Their findings differ from the findings of Ganesh *et al.* and Stack *et al.*, who reported an association of increased mortality with PD in certain segments of this same US incident dialysis cohort based on somewhat different analytical methods [50,51,52]. Of potential clinical relevance, Stack *et al.* evaluated the impact of modality choice on survival in individuals with congestive heart failure and separately in patients with very high body mass indices. They reported a survival advantage with HD for patients with CHF and very large body habitus. Whether an age effect, as suggested by the analysis of Vonesh *et al.*, might have accounted for some

of the reported advantage of HD over PD in the latter analyses was not determined. A recently published multicenter prospective cohort study in the USA (CHOICE; 81 dialysis units, 1041 incident patients, 26% PD) reported no difference in adjusted mortality rates between PD and HD patients during the first year of treatment for their entire cohort of incident dialysis patients [53]. However, after the second year, the risk of death was significantly higher in PD patients. This study can be criticized because not all participating dialysis centers provided both dialysis modalities. Furthermore, the as-treated analyses were influenced by the lower technique survival of PD compared with HD.

Results of studies performed in Canada and western Europe are different from those in the USA. The first study comparing continuous ambulatory PD (CAPD) with HD in incident patients was performed in the UK. Using Kaplan-Meier analyses, the patient survival was not different after up to 3 years of follow-up [54]. A similar study from Spain also found no differences in mortality between CAPD and HD [55]. Also, a multicenter comparison between 480 PD and 373 HD patients in Italy showed similar 7-year survival rates for both dialysis modalities after adjustment for differences in case mix [56]. For patients older than 54 years, the risk of death was significantly higher in HD than in CAPD patients. An analysis of the Canadian Organ Replacement Register among 11,970 ESRD patients showed a relative risk of death of 0.73 in PD patients compared with HD. The difference was especially evident

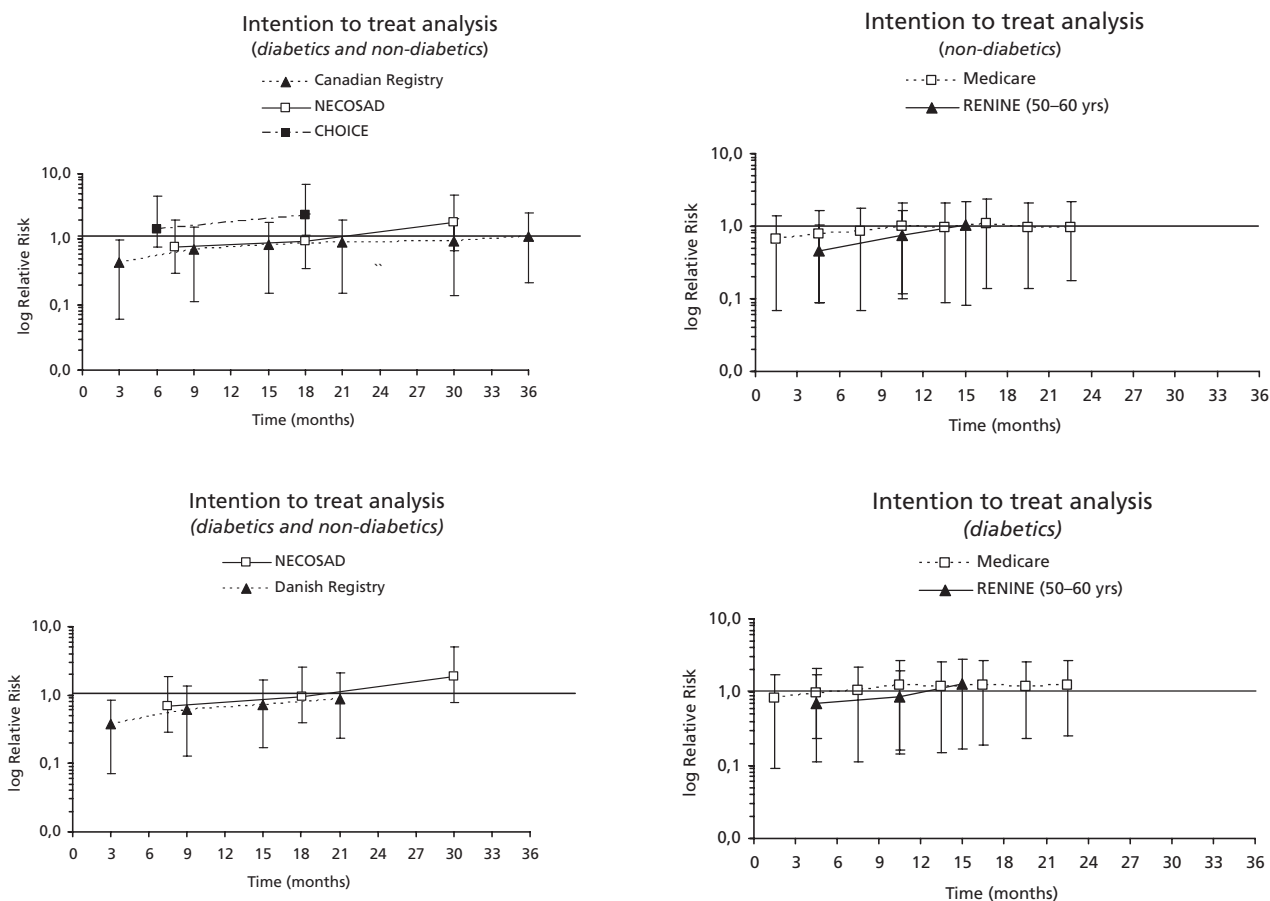

Figure 36.1 Effect of duration of dialysis on relative risk of death of incident PD patients compared with HD (relative risk for HD is 1), plotted on a logarithmic scale. The vertical lines depicts the 95% CI of the relative risk. Left panels show aggregated data for diabetic and nondiabetic patients from the Canadian registry [57], NECOSAD [62], CHOICE [53], and the Danish registry [64]. Right panels show separate analyses for diabetic and nondiabetic patients from the Medicare registry [48] and RENINE, the Dutch registry [65]. For the latter, only results for patients aged 50–60 years are included.

during the first 2 years on PD [57]. A prospective observational cohort study from Canada in 822 incident patients (34% PD), using a scoring system for comorbidity, reported no significant difference in adjusted mortality risks [58].

More recent studies reported either no differences in survival between PD and HD patients [59–62] or a reduced relative risk of death in PD compared to HD [63–65]. The results of the various studies are summarized in Tables 36.1 and 36.2. Large registry studies from Denmark [64] and the Netherlands [65] established better survival rates for incident PD patients in Europe, especially during the first years on treatment. The relative risks of death according to the duration of PD are given in Figure 36.1.

All the studies discussed above are either analyses from registry data or results obtained in prospective cohort studies. Differences in case mix or in determinants of the choice for either dialysis modality cannot be excluded with certainty. This would require a randomized controlled trial. Such a trial would be extremely difficult to perform due to difficulties in patient recruitment, as was the experience with the single randomized controlled trial performed to date [31]. In light of the difficulty in performing such a clinical trial, a targeted randomized controlled trial in patients with diabetes mellitus and/or CHF or a large body habitus might be informative. One small randomized controlled trial in a European population has been published [31]. Although underpowered because of the above reasons, patient survival, a secondary outcome of this study, was better in the PD group than in those randomized to HD after 2 years.

The current state of evidence, that is, the potential benefits of PD, as mentioned in the beginning of this section on PD versus HD as initial renal replacement therapy, combined with the better survival on PD during the first 2 years reported in some observational studies, provides support for the recommendation that PD be considered as initial renal replacement therapy in patients who agree to this and in whom no major contraindications are present, where the definition of the latter may change as new evidence emerges from ongoing analyses of registry data and other observational studies. As elaborated in section 8 of this textbook, to confer the greatest survival and quality of life benefit, a timely transfer to HD should be considered when patients develop severe problems on PD, such as recurrent peritonitis or ultrafiltration failure. This concept of integrative care was first developed by Van Biesen *et al.*, as they showed in a retrospective analysis of their center that patients who started PD and were subsequently transferred to HD had a better survival than those who were treated with HD for the total duration of follow-up [59]. Patients should be informed of the potential benefits of this integrated approach as part of their modality education in the predialysis period.

37 Modalities of Extracorporeal Therapy: Hemodialysis, Hemofiltration, and Hemodiafiltration

Kannaiyan S. Rabindranath[1] & Norman Muirhead[2]

[1]Renal Unit, Churchill Hospital, Oxford, UK
[2]Division of Nephrology, University of Western Ontario, London, Ontario, Canada

Introduction

The removal of fluids and solutes in humans with kidney failure by an extracorporeal dialysis circuit was first accomplished by George Haas in Germany in 1924. Initial attempts at chronic hemodialysis were unsuccessful, mainly owing to problems with the dialysis membranes and the lack of definitive and convenient arterio-venous access. Conventional chronic hemodialysis became possible with the development of the Scribner shunt and the Brescio-Cimino fistula in the 1960s. Dialysis technology has advanced considerably, and multiple different modalities of extracorporeal renal replacement therapy (RRT) are currently available, including hemodialysis (HD), hemofiltration (HF), hemodiafiltration (HDF), and acetate-free biofiltration (AFB). HD remains the most common form of RRT for end-stage renal disease (ESRD), although there is significant regional variation in practice. In Austria, Belgium, and Germany, 7, 14, and 12.4% of the chronic dialysis population is on HDF, respectively [1,2]. For HF, this proportion is 1.1% in Germany and 1% in Greece [1–3].

Principles of extracorporeal RRT modalities

Extracorporeal RRT involves withdrawing a patient's blood and passing it through a dialysis filter. Within this filter, fluids and solutes are removed from the blood compartment across a semipermeable membrane referred to in the literature as the dialysis membrane or sometimes simply as the membrane or dialyzer. In HD, HDF, and AFB there is passage of dialysis fluid (dialysate) through the dialysis filter on the opposite side of the membrane from the patient's blood in a direction counter to that of the blood flow, whereas HF does not involve the use of a dialysate. The movement of fluid and solutes across the dialysis membrane depends on their molecular weight, hydration radius, and charge, the osmotic gradient across the membrane, the electrochemical gradient across the membrane, the size of pores in the dialysis filter, and the charge on the dialysis membrane.

Fluid is removed principally by ultrafiltration, which is achieved by creating a difference in the transmembrane pressure such that the hydrostatic pressure is greater in the blood compartment than in the dialysate compartment. Solutes can be removed by diffusion or convection. In diffusion, solute removal is driven by the electrochemical transmembrane gradients. In convection, solute removal is by solvent drag, that is, when fluid is removed, solutes passively follow the fluid. The biophysical principles that underlie solute and fluid transfer across a membrane determine the unique properties of each of the modalities discussed in this chapter. A detailed description of the biophysical and mechanical principles of dialysis are beyond the scope of this chapter. Rather, this chapter will address the evidence of how each of these modalities might impact clinical outcomes and the clinical trials evidence that might inform the choice of which modality to select for each clinical indication.

The expected clinical outcomes with each RRT prescription are determined importantly by the biophysical properties of the dialyzer membrane materials. These help determine the water and solute flux characteristics and the biocompatibility of the dialyzer membrane. Dialyzer membranes are composed of two main categories of material, cellulose-based or synthetic. With substituted cellulose membranes, acetyl groups are substituted for hydroxyl groups. By varying the degree of substitution, cellulose acetate, cellulose diacetate, and cellulose triacetate membranes are manufactured. Cellulose-based membranes made by the cuprammonium process (Cuprophane) are hydrophilic and have high porosity but low permeability to solutes. Substituted cellulose membranes, however, are more hydrophobic and have greater solute permeability. Cellulose membranes are relatively inexpensive, are sometimes "recycled," and are therefore the most commonly used membranes worldwide. Synthetic dialysis membranes are composed of a variety of materials, including polyamide, polyacrylonitrile, polysulfone, and polymethylmethacrylate. These membranes are hydrophobic and have larger pore sizes and higher hydraulic permeabilities and solute clearances.

The two main characteristics of dialysis membranes that most affect patient outcomes are their biocompatibility and their flux characteristics. Membranes can be biocompatible or bioincompatible and have high-, mid-, or low-flux characteristics.

Biocompatibility refers to the ability of a material to contact human tissues and blood without inciting a clinically significant inflammatory response. Bioincompatible dialysis membranes typically elicit a brisk inflammatory response, whereas biocompatible membranes elicit little or no clinically apparent inflammatory response. Dialyzer membranes have been shown to cause a variety of inflammatory responses, including activation of the alternate complement pathway, production of chemokines and adhesion molecules, activation of platelets and leukocytes, and induction of a decreased responsiveness of neutrophils and monocytes [4–6]. Such inflammatory responses are thought to have important consequences for the patient, and several adverse patient outcomes have been attributed to them. These include hypoxemia, "dialyzer reactions" (flu-like symptoms, pruritus, nausea, vomiting, headache, and hypotension), and increased production of β_2-microglobulin and its consequent deposition in the tissues, eventually resulting in dialysis-related amyloid arthropathy, increased susceptibility to infection, and increased protein catabolism [7–11]. Given that inflammation is a well-known atherogenic factor, the use of bioincompatible membranes could contribute to the cardiovascular mortality and morbidity in the hemodialysis population. To date, this specific question has not been addressed by either a randomized controlled trial (RCT) or a well-designed observational study.

Flux (classified as high, mid, and low) refers to the permeability characteristics of the dialysis membranes. Hydraulic permeability is measured by the dialyzer ultrafiltration coefficient (kUF), which is defined as the volume of ultrafiltrate formed per hour per millimeter of Hg transmembrane pressure, as determined at a blood flow of 200 mL/min. Membranes with a kUF of >12 mL/h/mmHg or β_2-microglobulin clearance of >20 mL/min are classified as high flux, and those with a kUF of <12 mL/h/mmHg or β_2-microglobulin clearance of <10 mL/min are classified as low flux. These criteria are derived from the HEMO study [12] and the US Food and Drug Administration dialyzer flux criteria [13].

In general, unsubstituted cellulose membranes are bioincompatible and low flux, whereas substituted cellulose membranes are more biocompatible and typically allow for mid- or high-flux characteristics. Synthetic membranes are considered the most biocompatible and can be manufactured to have either low-, mid-, or high-flux characteristics.

The newer RRT modalities, HF, HDF, and AFB, involve convection as the predominant solute clearance modality. All such modalities require high-flux dialysis membranes. In HF, a hemofilter replaces the traditional dialysis filter and no dialysate is used. Fluid is continuously ultrafiltered in excess of the actual fluid removal targets. In a typical HF session, this may involve the generation and removal of 30–40 L of ultrafiltrate. This excess removed ultrafiltrate is replaced by infusion of a suitable replacement fluid either prior to the membrane filter (predilution) or after the fil-

Table 37.1 Current guidelines on membrane characteristics and RRT modality usage.

Guideline	Country	Year	Recommendation
Biocompatibility			
K/DOQI	USA	2006	Avoid use of unsubstituted cellulosic membranes in favor of synthetic dialysis membranes
Renal Association (UK)	UK	2007	Use modified/substituted cellulose and low-flux synthetic membranes over unsubstituted cellulose membranes
CARI	Australia	2005	No recommendation
European Best Practice Guidelines	Europe	2002	Biocompatible high-flux membranes should be preferred
Membrane flux			
K/DOQI	USA	2006	No recommendation
Renal Association (UK)	UK	2007	Use of high-flux dialysis membranes for patients likely to remain on HD for several years and prevalent patients who have been on dialysis for longer than 3.7 yrs
CARI	Australia	2005	No recommendation
European Best Practice Guidelines	Europe	2002	Use of biocompatible high-flux membranes
RRT modality			
K/DOQI	USA	2006	No recommendation
Renal Association (UK)	UK	2007	Use of HDF or high-flux dialysis in patients who are likely to be on dialysis for several years or in prevalent patients who have been on dialysis for greater than 3.7 yrs
CARI	Australia	2005	No recommendation
European Best Practice Guidelines	Europe	2002	No recommendation

ter (along with the venous return; postdilution). HF may be less effective than other methods in removing small solutes, such as urea [14]. HDF is a hybrid system that includes both convection and diffusion [15]. In HD and HDF, the dialysate is buffered either with acetate or bicarbonate buffers. Currently, bicarbonate is the preferred buffer for both HD and HDF, as acetate has been shown to depress myocardial contractility and may, therefore, cause intradialytic hemodynamic instability [16]. AFB, an HDF technique, was introduced in 1985 to avoid the use of acetate in the dialysate. In this technique a hypertonic sodium bicarbonate solution is infused postdilution to manage treatment-related acidosis [17].

Biocompatibility, dialysis membrane flux, and the dialysis technologies themselves have been considered to have major impacts on patient outcomes. Current clinical practice guidelines with respect to these dialysis technology-related factors (Table 37.1) and

the available evidence from systematic reviews and randomized controlled trials are reviewed below.

Review of current clinical practice guidelines

Biocompatibility

The Caring for Australians with Renal Impairment (CARI) guidelines [18] make no recommendations regarding dialysis membrane biocompatibility. The National Kidney Foundation's Kidney Diseases Outcomes Quality Initiative (K/DOQI) guidelines recommend avoiding the use of unsubstituted cellulose membranes in favor of synthetic dialysis membranes [19]. The Renal Association (UK) recommends the use of modified or substituted cellulose and low-flux synthetic membranes over unsubstituted cellulose membranes [20]. The European Best Practice Guidelines (EBPG) state that biocompatible high-flux dialyzers are preferred [21]. These differing recommendations result in considerable regional variations in dialyzer membrane utilization patterns.

Membrane flux

No recommendations on optimal membrane flux have been made by CARI or K/DOQI [18,19]. The Renal Association (UK) recommends the use of high-flux dialysis membranes for incident patients likely to remain on HD for several years and prevalent patients who have been on dialysis for longer than 3.7 years [20]. The EBPG state that biocompatible high-flux dialyzers are preferred [21].

RRT modality

CARI, EBPG, and K/DOQI do not recommend the use of any specific extracorporeal RRT modality [18,19,21]. The Renal Association (UK) recommends the use of high-flux HD or HDF in patients likely to remain on HD for several years and prevalent patients who have been on dialysis for longer than 3.7 years [20].

Availability of evidence

There have been a number nonrandomized studies, randomized studies, and systematic reviews reporting patient outcomes based on membrane composition and RRT modality. Apart from the systematic review comparing low- and high-flux dialysis membranes (published in abstract form), the other such reviews that are referred to below have been published in the Cochrane Library. Although these reviews have evaluated several outcomes, we have summarized the results only for the most important clinical outcomes for each of the comparisons mentioned above.

Evidence from nonrandomized studies

Epidemiological studies have generally reported favorable outcomes for biocompatible high-flux membranes compared with unsubstituted cellulose membranes. Woods and Nandakumar used historical controls and found that 463 patients treated with high-flux polysulfone membranes had a 30% improvement in 5-year survival rate (high-flux group, 90%, vs. low-flux group, 60%; $P = 0.029$) [22]. Another retrospective study comparing 107 patients on high-flux HD with 146 on low-flux HD found a significant reduction in relative risk for mortality for patients on high-flux HD (relative risk [RR], 0.24; 95% confidence interval [CI], 0.12–0.49) [23]. Hakim *et al.* in their analysis of 2410 patients from the US Renal Data System (USRDS) reported that the RR for mortality for patients dialyzed with more biocompatible modified cellulose or synthetic membranes was 20% lower than in patients treated using unsubstituted cellulose membranes. In a retrospective cohort study ($n = 12,791$) Port *et al.* [24] reported that those patients dialyzed with synthetic membranes had a significantly lower mortality than patients dialyzed with cellulose-based membranes (RR, 0.82; 95% CI, 0.72–0.93; $P = 0.002$) and that among the synthetic membranes, use of low-flux compared to high-flux membranes was associated with a significantly higher mortality risk (RR, 1.24; 95% CI, 1.02–1.52; $P = 0.04$) [25]. An analysis of 6440 patients in the Lombardy Registry in Italy between 1983 and 1995 found that patients on HF or HDF had a significantly lower risk for carpal tunnel syndrome surgery, a surrogate marker for dialysis-associated amyloidosis (RR, 0.58; 95% CI, 0.35–0.95; $P = 0.03$) compared with those on low-flux HD, but mortality rates were not different (RR, 0.90; 95% CI, 0.76–1.06; $P > 0.05$) [26]. In contrast, Koda *et al.* in a retrospective study of 248 patients reported that patients dialyzed with high-flux membranes had a significantly lower risk of carpal tunnel syndrome (RR, 0.50; 95% CI, 0.25–0.96; $P = 0.03$) as well as a lower mortality (RR, 0.61; 95% CI, 0.40–0.91; $P = 0.02$) [27]. Chanard [28] reported that patients on high-flux HD had less hypotension and other dialysis-related symptoms than those on HD with low-flux cellulose membranes. A study of 15 patients that used a crossover design (online predilution HF to high-flux HD to online predilution HF) reported that patients during the HF phases had significantly fewer intradialytic hypotension episodes per patient per month ($P < 0.04$), significantly fewer muscle cramp episodes, and less need for saline and plasma expanders [29] compared to HD.

Evidence from systematic reviews of RCTs

In the systematic reviews discussed below, comparative data on treatment effects of each extracorporeal RRT method are summarized either as RRs with 95% CIs for dichotomous outcomes or as weighted mean differences (WMD) with 95% CIs for continuous outcomes. These data inform the clinical questions regarding the impact of RRT modality, membrane biocompatibility differences,

and flux rates on clinical outcomes and will be described separately below.

Biocompatibility

There were 32 RCTs included in a systematic review comparing cellulose-based membranes (unsubstituted and substituted or modified cellulose) with synthetic membranes (Tables 37.2–37.3) [30]. This review allows one to compare the risks for each of the major side effects attributable to differences in bioincompatibility of each dialyzer membrane type, more specifically, to evaluate the risk for hypotension, dialysis-associated symptoms, infection, β_2-microglobulin accumulation, hypoalbuminemia, increased protein catabolic rate, and mortality.

Hypotension

In this review, eight studies [31–38] reported data on dialysis-associated symptomatic hypotension or hypotension requiring treatment, but only one study [32] reported data that were suitable for meta-analysis. This study of 328 patients assessed the occurrence of intradialytic symptoms over one dialysis session in which the patient and the medical staff were blinded to the type of dialysis membrane. This RCT did not reveal any difference between patient groups. Similarly, none of the other seven studies reported a decrease in incidence of dialysis-related hypotension with the more biocompatible membranes. In one study that reported the composite occurrence of hypotension requiring treatment, symptomatic hypotension, and asymptomatic hypotension [39], there

Table 37.3 Results of the meta-analysis of RCTs comparing cellulose-based and synthetic membranes.

Outcome analyzed	No. of studies	No. of patients	Results	
			RR (95% CI)	WMD (95% CI)

Total cholesterol (substituted cellulose vs. synthetic membranes)	1	39	–	0.60(−0.04 to 1.24)
Total cholesterol (unsubstituted cellulose vs. synthetic membranes)	1	28	–	−0.49(−1.07 to 0.09)
HDL cholesterol (substituted cellulose vs. synthetic membranes)	1	39	–	0.11 (−0.41 to 0.63)
HDL cholesterol (unsubstituted cellulose vs. synthetic membranes)	1	28	–	0.07 (−0.06 to 0.20)
Triglycerides (substituted cellulose vs. synthetic membranes)	1	39	–	−0.03(−0.43 to 0.37)
Triglycerides (substituted cellulose vs. synthetic membranes)	1	28		−0.06(−1.18 to −0.14)
Residual renal function at end of study period	1	30	–	1.10 (0.80 to 1.40)[b]
Average rate of loss of residual renal function	1	20	–	−0.13(−0.17 to −0.19)[b]

Abbreviation: HDL, high-density lipoprotein.

[a] Difference for this outcome significantly in favor of cellulose-based membranes ($P < 0.05$).

[b] Difference for this outcome significantly in favor of synthetic membranes ($P < 0.05$).

was no difference between those dialyzed with Cuprophane membranes and those dialyzed with either low- or high-flux polysulfone membranes. Similarly, another study reported intradialytic hypotension after 10% of treatments with cellulose compared to 11% with polysulfone membranes [40].

Dialysis-associated symptoms

Four trials [33,34,36,41] reported data on the occurrence of dialysis-associated symptoms, including headache, nausea and vomiting, and pruritus. All of these studies were of a crossover design. None reported significant differences between cellulose-based and synthetic membranes for dialysis-associated symptoms.

Infection

One study (15 patients) reported that 3 of 8 patients in the cellulose-based membrane group had infectious episodes compared with 0 of 7 patients in the synthetic membrane group [42]. Another study reported that 9 of 74 patients allotted to either polysulfone or cellulose triacetate membranes developed infections during a study period of 2 weeks [43], but it did not report to which treatment group the patients belonged or whether the between-group incidence of infection was significantly different.

β_2-Microglobulin

Seven trials measured predialysis β_2-microglobulin at the beginning and end of their studies [39,44–49]. The data from the four studies that could be combined by meta-analysis showed that the use of synthetic membranes was not associated with a significantly lower predialysis β_2-microglobulin level in comparison with cel-lulose membranes (WMD, −14.67, 95% CI, −33.10 to 4.05). There was evidence of significant heterogeneity between these four studies. Neither Hakim's nor Locatelli's team could demonstrate that β_2-microglobulin levels were lower with the use of a low-flux synthetic membrane compared with cellulose membranes [39,45]. However, in six of the seven studies the β_2-microglobulin values rose during the trials when cellulose membranes were used [44–49].

Serum albumin

Data from four trials [39,47,50,51] showed no difference in serum albumin levels between synthetic and cellulose membrane groups (WMD, 0.04; 95% CI −0.13 to 0.21). Parker showed a significantly higher mean serum albumin level in patients treated with synthetic membranes but only after 10 months of the study [51]; by study termination at 18 months there were no differences observed.

Protein catabolic rate

Three studies have reported data on protein catabolic rate as an outcome [39,47,52]. A meta-analysis that included two of these studies [39,47] showed no significant difference attributable to the membrane used (WMD, 0.10; 95% CI, −0.15 to 0.35). One study did not provide the means and standard deviations for the different membrane types but stated that no difference was found ($P = 0.94$) [52].

Mortality

None of the studies reported to date has been sufficiently powered to detect differences in mortality. Three studies that lasted more

than 1 year, however, did report mortality [39,40,51]. All compared unsubstituted cellulose versus synthetic membranes, and none of these reported a difference in overall or cardiovascular mortality (overall mortality RR, 1.18; 95% CI, 0.63–2.22).

Membrane flux

A total of 22 RCTs were identified for a systematic review that forms the basis of the discussion in this section, comparing high-flux with low-flux HD (unpublished data) (Tables 37.4 and 37.5). The patient characteristics and interventions in the included RCTs are summarized in Table 37.4, and the results of the meta-analysis are in Table 37.5. This review excluded RCTs comparing HD with HF, HDF, or AFB, as these have been the subject of a separate review. Of these 22 RCTs, only the HEMO study was designed to assess the effect of dialysis membrane flux on mortality (Figure 37.1). This study had a two-by-two factorial design, comparing high-flux versus low-flux dialysis membranes and also conventional dialysis dose (equilibrated Kt/V, −1.05; single-pool Kt/V, −1.25) versus high dialysis dose (equilibrated Kt/V, −1.45; single-pool Kt/V, −1.65).

Mortality

At the end of the trial period in the HEMO study, 429 of 921 patients in the high-flux-group and 442 of 925 patients in the low-flux group had died [12]. Although no significant difference in all-cause mortality between the patient groups was observed for the entire study period, use of high-flux dialysis membranes was found to reduce cardiovascular mortality and all-cause mortality significantly in patients who had been on dialysis for more than 3.7 years. In the systematic review (Table 37.4), the results from six trials that reported mortality data with a follow-up of 1 year or longer were analyzed. There was a trend toward a difference between high- and low-flux membrane groups even when the analysis was repeated, excluding the HEMO study (RR, 0.89; 95% CI, 0.71–1.13). A meta-analysis of two studies [12,53] showed no significant difference between patient groups for cardiovascular mortality (RR, 0.84; 95% CI, 0.69–1.02).

β_2-Microglobulin and dialysis amyloid-associated complications

High-flux HD has consistently been shown in randomized studies to achieve significantly lower predialysis β_2-microglobulin concentrations than low-flux dialysis (WMD, −13.50; 95% CI, −15.91 to −10.19). One randomized study of 20 patients followed for over 4 years showed that patients on high-flux dialysis had a significantly lower risk of developing dialysis-related arthropathy (0/10 in the high-flux group vs. 8/10 in the low-flux group; RR, 0.10; 95% CI, 0.00–0.90), but these results may reflect, in part,

Table 37.5 Results of meta-analysis of RCTs comparing high- and low-flux membranes.

[a] Difference for this outcome significantly in favor of high-flux membranes ($P < 0.05$).

the higher-than-expected rate of arthropathy in the conventional dialysis group [54].

Lipid profile

High-flux dialyzers have been reported to have favorable effects on lipid profiles. Meta-analysis of four RCTs showed that high-flux HD resulted in a significant lowering of triglyceride levels alone compared with low-flux HD (Table 37.5). The clinical importance of this observation is not known.

Quality of life

Data from the HEMO study [55] showed that quality of life as measured using three validated tools, the Index of Well-Being, the Kidney Diseases Quality of Life Long-Form Questionnaire, and the Short Form-36 Questionnaire, was not significantly different between patients on high-flux versus low-flux dialysis.

Extracorporeal RRT modalities

A Cochrane Systematic Review compared HD, HF, HDF, and AFB and identified 20 RCTs reporting clinically relevant outcomes [56] (Table 37.6). We have summarized below the results from this Cochrane Review for mortality, hypotension, β_2-microglobulin, dialysis-related amyloidosis, and quality of life. All results are shown in Table 37.7.

Figure 37.2 Effects of RRT modality on mortality (HDF vs. HD).

HF versus HD

Three RCTs compared HF with HD [57–59]. One study of 32 patients (24 HD vs. 8 HF) followed for 4 years reported no deaths [59]. Furthermore, there was no difference in the number of episodes of hypotension between patient groups in one crossover study of nine patients [58]. This study's duration, however, was only one dialysis session. In the study by Schiffl *et al.* HF was associated with significantly higher β_2-microglobulin levels in the ultrafiltrate compared with high-flux HD, and there was virtually no β_2-microglobulin detected in the dialysate of patients on low-flux HD when Cuprophane membranes were used [59]. The implications of these findings for clinically important outcomes, especially in light of current practices, are unknown.

HDF versus HD

Eight RCTs compared HDF with HD [39,60–66]. Mortality data were obtained from three studies [39,61,66]. A meta-analysis of these studies showed no difference between patient groups (RR, 1.68; 95% CI, 0.23–12.13) (Figure 37.2). The largest RCT [39] comparing HD with HDF had four treatment arms. Mortality was not different when any of the three HD arms was compared separately with HDF; a comparison of the three combined HD groups with the HDF group indicated a higher mortality with HDF (6/155 in the HD group vs. 7/50 in the HDF group; RR, 3.62; 95% CI, 1.27–10.26); this result should be interpreted with caution, as this study was not designed to assess mortality [39]. None of the studies assessed the incidence of symptomatic hypotension, but one study reported that the intradialytic blood pressure was significantly higher and the maximal drop in intradialytic blood pressure lower in patients on HDF [61]. Based on data from two studies, HDF was reported to be associated with significantly lower predialysis β_2-microglobulin values compared with low-flux but not with high-flux HD [39,66]. None of the studies reported data on the incidence of dialysis-related amyloid arthropathy. Two further studies [61,65] reported quality of life results. One study [65] used a validated tool, the Kidney Diseases Questionnaire, and the other used a nonvalidated tool, the Patient Well-Being Score [61].

Patients on HDF had significantly higher end-of-treatment Patient Well-Being scores, whereas no significant difference was found when quality of life was assessed with the Kidney Diseases Questionnaire, with the exception of the physical symptoms component of this tool, which showed that quality of life improved equally with either modality during the course of the study.

AFB versus HD

Six RCTs compared HD versus AFB [67–72]. Data from two studies of 12 months or greater in duration did not report any patient deaths in either RRT group [68,70]. One study of 20 patients found no significant difference in the number of hypotensive episodes in patients undergoing either of these RRT modalities [70]. The remaining studies had crossover designs and hence did not provide mortality data for analysis. None of the studies reported any data on β_2-microglobulin levels.

AFB versus HDF

Two RCTs assessed AFB versus HDF in a total of 24 patients [73,74]. Both were crossover trials and hence the data could only be summarized in a narrative fashion. There was no difference in the number of dialysis sessions for patients reported to have hypotension between patient groups (HDF, 10/72 sessions, vs. AFB, 9/72 sessions). Data on mortality could not be analyzed from these crossover studies. No data on β_2-microglobulin levels were reported.

HF versus HDF

A comparison of HF versus HDF was performed in one RCT [75]. Patients on HF experienced significantly fewer episodes of hypotension per patient per month (HF, 0.5 vs. HDF, 1.1; $P = 0.017$) if they were randomized to start on HDF and crossed over to HF. Predialysis β_2-microglobulin values were also not significantly different between patient groups. Long-term clinical outcomes, such as mortality and cardiovascular morbidity, could not be assessed in this crossover design trial.

Critique of the evidence and guidelines

There are considerable data from observational studies indicating that biocompatible high-flux HD and convective technologies, compared with HD with low-flux cellulose-based membranes, are associated with significant reductions in adverse outcomes, the most important of which are mortality, dialysis-associated amyloid complications, and dialysis-related side effects such as hypotension. The data from RCTs, however, are less compelling.

Of all the RCTS conducted in this area, only the HEMO study was designed with sufficient statistical power to evaluate differences in mortality outcomes for high- and low-flux and high- and low-efficiency dialysis prescriptions. This study did not show any statistically significant differences in mortality between groups. It has, however, been criticized for several reasons, including the use of prevalent rather than incident patients, exclusion of patients over 100 kg in weight, dialyzer reuse, and overrepresentation of women and blacks (both over 60% of the study population). There remains uncertainty, therefore, over the impact of membrane type and flux characteristics on outcomes in HD.

Although cellulose-based membranes elicit more of an inflammatory response than synthetic membranes and therefore could theoretically cause more dialysis-related side effects, none of the RCTs that have examined this question has shown a consistent difference in dialysis-related symptoms with the different membrane types. Thus, an increase in dialysis membrane-related inflammatory responses does not result in predictable adverse clinical symptoms in the short term, nor is it associated with long-term increases in mortality. Whether such inflammation is injurious in the long term remains unknown.

Convective technologies when compared to HD appear in observational studies to result in lower rates of dialysis-related hypotension. Importantly, however, this has not been demonstrated in any of the RCTs that have compared convective technologies to HD. One recent RCT, published after the Cochrane Review, showed that when HD is performed under optimal conditions the hemodynamic parameters and the incidence of hypotension are the same as in HDF [76]. A review of the effects of extracorporeal techniques on blood pressure-related outcomes reached the same conclusion [77]; the authors emphasized that future trials comparing HF and HDF with HD must ensure standardized treatment conditions so that comparisons of the outcomes of the various treatment modalities will be valid.

Even less information is available regarding the impact of membrane type on dialysis-associated amyloidosis. The few published studies were small and generally of too short a duration to draw firm conclusions regarding an outcome that is both uncommon (5–10% of patients at 5 years, 15–30% of patients at 10 years) [78,79] and develops slowly over a period too long for most clinical trials. Although further large observational studies may clarify some of these residual questions, the quality of such evidence is poorer than that which arises from RCTs and will undoubtedly leave uncertainty.

Although some clinical practice guidelines continue to prefer the use of biocompatible membranes, such recommendations are based mostly on opinion rather than RCT evidence. For high-flux membranes, the EBPG [21] recommend their use in all patients whereas the Renal Association (UK) recommends their use in incident patients likely to be on dialysis for several years or prevalent patients who have been on dialysis for more than 3.7 years [20]. The Renal Association (UK) guidelines suggest that HF or HDF may also be beneficial in patients likely to be on dialysis for several years or for long-term prevalent patients, because of improved middle-molecule clearance with these techniques [20]. However, RCTs have not shown HDF to be superior to HD, especially in comparison to high-flux HD. Although HDF may be better than HD in reducing predialysis β_2-microglobulin levels, it is not superior to high-flux HD in this regard. None of the RCTs has shown a significant reduction in dialysis-related hypotension or other symptoms with HDF versus HD.

Conclusions

Despite more than 40 years of experience with RRT, it is surprising and disappointing that the evidence base on which important clinical decisions hinge is not more solid. Several studies have important design flaws, are of insufficient statistical power, or have not addressed appropriate clinical end points. There is a clear need for additional clinical trials that lack these limitations to provide unambiguous guidance for decision making. Future studies must also address important clinical end points, such as mortality, morbidity, and quality of life, and should ideally include rigorous economic evaluations, given the expense of extracorporeal therapies.

At present there are a number of large studies under way that may help to address some of the current deficiencies. The Membranes Permeability Outcomes study is a multicenter study evaluating high- versus low-flux membranes in 600 incident patients (<2 months on RRT) [80]. The CONTRAST study will compare HDF versus low-flux HD in 800 patients and will include a detailed economic evaluation [81]. Another RCT will assess cardiovascular stability and blood pressure control in 246 patients assigned to either HDF or HF compared to low-flux HD [82]. It is hoped that the results of such studies will provide more solid evidence to inform best clinical practices.

38 Dialysis Delivery and Adequacy

Peter Kotanko,[1,2] Nathan W. Levin,[2] & Frank Gotch[2]

[1]Krankenhaus der Barmherzigen Brüder, Department of Internal Medicine, Graz, Austria
[2]Renal Research Institute, New York, USA

Introduction

It is generally accepted that the delivery of "adequate" or optimal dialysis is associated with improved survival, where adequacy is sometimes defined as that intensity of dialysis that results in the generally most favorable mortality and morbidity outcomes. Findings that have emerged from observational studies and epidemiologic comparisons between countries have suggested that some of the differences in mortality rates observed between countries may be attributable to country-specific differences in customary prescriptions for dialysis dose. These observations have led to a consensus opinion that is reflected in US, UK, European, Canadian, and Australian guidelines that dialysis dose be measured and an adequate dose of dialysis be targeted in all patients on chronic hemodialysis. Kinetic modeling has proven a powerful tool to define the parameters of adequate dialysis, to compare dialysis dosing from one study to the next, and to identify those aspects of the dialysis treatment and the clinical characteristics of the individual patient that might interfere with delivery of the targeted dialysis dose. In this chapter, we shall describe the biophysical basis for kinetic modeling of dialysis and its utility in describing the clinical biochemical impact of chronic dialysis for the individual patient. We shall evaluate observational and randomized clinical trials evidence with regard to competing measures of dialysis adequacy and the impact of observed strata of levels of achieved dialysis clearance on morbidity and mortality that have emerged from these trials.

Kinetic modeling

Kinetic modeling is a widely used analytic process for examining all aspects of the dialysis prescription and its delivery. It is a powerful technique because it describes a system from mass balance. It requires that all model parameters be rigorously defined,

since the validity of the model can be directly determined from the mass balance in the system. It provides a logical system for understanding the clinical problem of adequacy of dialysis. All the stages involved in its analysis must be highly disciplined, because a precise mathematical definition is required for each parameter. Unlike the approximations that are used commonly to evaluate dialysis dose, the relative effect of each parameter can be quantitatively assessed.

The major practical goal of modeling in dialysis is to be able to prescribe and deliver a predetermined dose that is reproducible primarily for urea but analogously for other solutes. The uremic syndrome is only partly responsive to current methods of dialysis therapy, and much morbidity continues to be present and to progress even in well-dialyzed patients. The high mortality rate characteristic among dialysis patients is strongly dependent on background cardiovascular disease and propensity for infection. In addition, since fluid removal is not part of the kinetic model prescription, ultrafiltration time may determine dialysis time in excess of the model. Because even a fully "adequate" dose of dialysis does not directly affect these comorbidities and clinical problems, the dose cannot be determined by clinical symptoms. The current dosing recommendations have evolved from being based largely on data from observational studies to a greater reliance on data from the limited number of randomized controlled trials that have examined this question rigorously. However, uncertainty still exists as to the dialysis dose needed for smaller individuals and for women. Dialysis is almost universally given three times per week. With increasing knowledge of daily short or nocturnal long dialysis, the current approach to dose may need to be changed as evidence emerges from new randomized controlled trials currently in progress.

Calculation of the dose of dialysis is also quite complicated both conceptually and with respect to practical details. While the adequacy of dialysis using urea kinetic modeling (UKM) has been initially defined by observational studies, more recently the evidence derived from randomized trials has provided information that has been formalized in practice guidelines to guide dialysis prescription.

Dialysis delivery

The concept of prescribing the dose of dialysis as Kt/V grew out of examination of the outcomes of the National Cooperative Dialysis Study (NCDS) in the USA [1,2]. The NCDS was designed to study two levels of predialysis blood urea nitrogen (BUN; 70 and 110 mg/dL) and was controlled by UKM. UKM is based on the law of conservation of mass and the concept of urea mass balance, which requires that the amount of urea removed during a dialysis session must equal the amount generated between sessions [3,4]. Removal of urea at any instant is determined by the product of dialyzer urea clearance and plasma urea concentration, whereas urea generation (Gu) is determined by the net rate of protein breakdown or protein catabolic rate (PCR), which in turn, in the absence of acute illness, is determined by the dietary protein intake. Urea generation is normally constant, but removal varies from zero between dialyses to very high rates at the beginning of each individual dialysis session, when the BUN is high, to very low rates at the end, when the BUN has fallen maximally. UKM is derived from mathematical modeling of urea removal and urea generation in dialysis therapy and is used to calculate Gu and to determine the volume of distribution of urea in the body (Vu) from the BUN profile and the dialyzer clearance, treatment time, and frequency of dialyses. In the NCDS, UKM was used to calculate Gu, that is, PCR and Vu, and from these values the magnitude of dialyzer clearance and treatment time required to achieve the targeted predialysis BUN levels in thrice-weekly therapy could be calculated. A further step is necessary to calculate the blood and dialysate flow rates required to achieve optimal dialyzer urea clearance. This is accomplished with use of the dialyzer overall permeability (Ko) and area (A) product or (KoA), which has a specific value for each dialyzer and depends on its membrane area and flow geometry [4,5]. From the KoA, the required blood and dialysate flows can be calculated to effect the desired clearance. These computations are readily available in PC kinetic modeling programs.

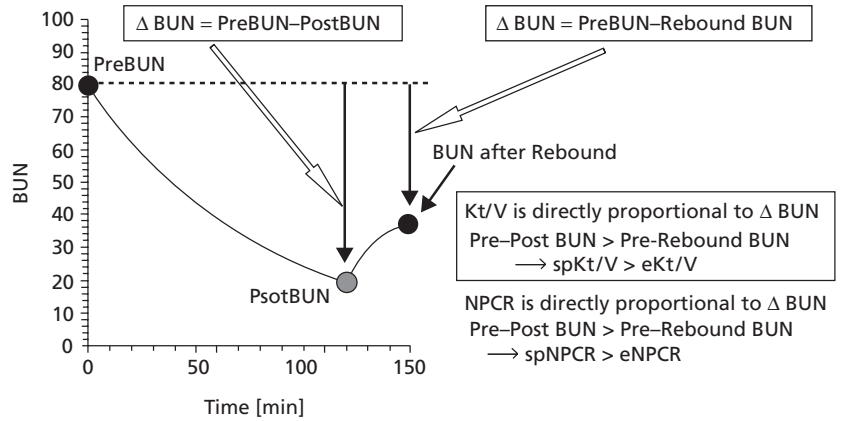
Poor clinical outcome (a global clinical composite outcome of *de novo* uremic symptoms, hospitalization, and death during follow-up) in the NCDS could not be predicted from the predialysis BUN alone as anticipated [1]. The NCDS recommended empirically a normalized PCR (nPCR) of 0.8 g/kg/day. When NPCR was ≥0.8 g/kg/day, the high BUN did predict poorer outcome, but when NPCR was <0.8 g/kg/day the global composite clinical outcome was poor irrespective of predialysis BUN. Kinetic analysis showed that outcome could be predicted in all groups when dose was expressed as the product of dialyzer urea clearance and treatment time divided by the urea distribution volume, or Kt/V. In patients with very low nPCR and Gu, very low levels of Kt/V were required to maintain the BUN at target, and these low levels of Kt/V correlated significantly with the global composite clinical outcome failure of the therapy. This relationship was consistent with the concept that urea per se is not the critical toxin, but that it could serve as a surrogate for all low-molecular-weight toxins when the therapy dose is expressed as Kt/V, a relationship which would apply to other low-molecular-weight toxins also. Consequently, UKM no longer aims to reach a specific urea concentration but provides a rational method for prescribing the dose of dialysis, defined as Kt/V, and to monitor dietary protein intake from a determination of Gu. Because all errors in delivery of the dose appear in the calculated value for Vu, when an aberrant Vu is calculated it can be concluded that the dose has not been delivered [3,4].

eKt/V and spKt/V

The calculated Kt/V is proportional to the decrease in BUN during a dialysis session. The single-pool Kt/V (spKt/V) is calculated from the predialysis BUN and the postdialysis BUN obtained 15 s after the end of dialysis. This delay is included to circumvent any access recirculation that might be present, which would lower the BUN and result in an erroneous increase in spKt/V [3,4].

Equally important is the concept of urea "rebound." At the end of the dialysis session the concentration of BUN is lower in the blood and extracellular fluid than in cells [3,4,6]. It requires 30–40 min of urea diffusion between the compartments until there is a uniform concentration (diffusion equilibrium). The difference between the two BUN levels is the rebound. Therefore, the spKt/V calculated using the end-dialysis BUN will be higher than an equilibrated Kt/V (eKt/V), which is calculated from the BUN after postdialysis equilibration. It is the eKt/V that more accurately reflects the effective dose of dialysis. If one accepts that Kt/V represents an accurate picture of dialysis dose with respect to urea and water removal, it should be apparent that one should wait until equilibration is completed to determine Kt/V so that the clinical values used to compute the Kt/V are accurate and errors in prescription are avoided.

The rebound phenomenon and effects on Kt/V and nPCR are illustrated in Figure 38.1. The BUN at the end of dialysis is used to calculate the equilibrated BUN value using validated equations in UKM programs, such as in the Fresenius Medical Care North America (FMCNA) system, rather than by keeping the patient for 30–60 min after termination of dialysis to take the final blood sample. The magnitude of rebound is determined almost entirely by the rate at which the dialysis dose is delivered. The rate of dialysis is defined by spKt/V divided by the treatment time (t), which equals K/V (K is the delivered clearance and V is the volume of distribution of urea equivalent to the total body water). The greater the K/V, the greater the rebound. Because most patients are treated at about the same blood flow (300–400 mL/min) and with the same dialyzer urea clearance (K), the smallest patients (with small V values) will tend to have the highest K/V ratios and the highest rebounds. For example, if a small patient is given the same dose of spKt/V over the same time as a larger patient, the rebound will be identical. That, however, happens infrequently in clinical therapy, and smaller patients are usually treated at higher rates and have more rebound.

Figure 38.1 The Kt/V and nPCR are both calculated from the magnitude of BUN decrease during dialysis. The apparent drop in BUN will always be larger before rebound occurs. Because spKt/V and spnPCR are calculated from predialysis BUN minus the postdialysis BUN, while eKt/V and e-nPCR are calculated from the predialysis BUN minus the rebound BUN, spKt/V and spNPCR will always be larger than eKt/V and eNPCR.


Dialysis dosing target

The spKt/V obtained from blood urea measurements immediately before and immediately after the completion of dialysis does not account for the change in urea from any rebound and therefore provides a value of dialysis clearance that overestimates the true dialysis urea clearance as determined by the eKt/V by a percentage that is influenced by the magnitude of the rebound. A comparison of the consequences of different dialysis prescriptions on achievement of the customary target measures of adequacy using either spKt/V or eKt/V illustrates some factors that could influence achievement of adequate dialysis and the potential consequences and limitations of protocols that use spKt/V as the measure of achieving true adequacy. The relationship between spKt/V and eKt/V is illustrated in Figure 38.2A, in which the ratios of eKt/V and spKt/V are each plotted as functions of treatment time, t. The Tattersall equation [6] was used to calculate eKt/V over a spKt/V range of 1.3–1.7 and independently of volume, dialyzer clearance, and Gu, with treatment times fixed at six levels ranging from 2.0 to 4.5 h. The lower limit of 1.3 is the lower limit recommended in the National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines, and it permits an appropriate dose of dialysis with a reserve in case of delivery problems. The upper limit of 1.7 was chosen because there is no evidence of a benefit with higher spKt/V. Over the ranges calculated, eKt/V is a highly linear function of spKt/V when time is held constant, so a family of six lines is seen (Figure 38.2A). The eKt/V dose target of 1.2 is depicted as a horizontal line on the *y* axis and the spKt/V dose target of 1.4 as a vertical line on the *x* axis. The regression lines for the different dialysis times are depicted as solid lines for all segments with eKt/V of ≥1.20 and dashed lines for all segments where eKt/V is <1.20. Note that the two adequacy targets agree only in the left lower portion of the plot, where eKt/V is <1.20 and spKt/V is <1.40. Here they define a domain of inadequacy common to both criteria. Some of the regression lines for spKt/V of >1.4 pass through the inadequate zone because of their high rebound with shorter dialysis times.

The required spKt/V to achieve an eKt/V of 1.20 is shown for each treatment time (Figure 38.2B) by a vertical arrow to the *x* axis at the point that each regression line reaches the minimum level for adequate dialysis, defined by eKt/V of 1.20. It can be seen that the spKt/V necessary to provide an adequate Kt/V can range from 1.32
Figure 38.2 (A) Two definitions of adequate dialysis: eKt/V of ≥1.20 and spKt/V of ≥1.40. Note that a substantial number of adequate doses by the criterion of a spKt/V of ≥1.40 are inadequate by the eKt/V ≥1.20 criterion. (B) When treatment time (t) varies in the patient population, there must be a family of spKt/V values ranging from 1.35 to 1.58 to ensure all doses are equivalent to an eKt/V of 1.20.

to 1.58 over a range of dialysis times to provide an eKt/V of 1.20. Therefore, an eKt/V can be associated with several spKt/V values, depending on the dialysis time. In contrast, a single target eKt/V of 1.20 permits determination of the optimal time and spKt/V for each patient in the population.

The nPCR is calculated from the amount of urea removed, which is considered equal to the Gu based on the PCR [4]. As noted above, the postdialysis BUN is artificially low, so if it is used for calculation of nPCR, the urea removal will be overestimated, because it is the difference between this BUN concentration and the predialysis BUN of the next treatment that is used. The nPCR will therefore behave like the Kt/Vs (as above).

Impact of residual renal urea clearance on eKt/V and estimated nPCR

Intermittent hemodialysis is very inefficient. With thrice-weekly hemodialysis of 3–4 h/HD session, urea is being cleared for only 5–7% of the total weekly time while urea and other solutes are generated continuously throughout the week. Consequently, high dialyzer urea clearances are used, which result in an exponential drop in BUN and very inefficient removal of urea and other solutes in the later part of dialysis. A low continuous clearance is far more efficient because the BUN does not fall to very low levels, which is the reason that a lower total clearance is required in continuous ambulatory peritoneal dialysis (CAPD) and potentially with prolonged daily hemodialysis prescriptions as yet to be determined [7]. A weekly Kt/V$_{CAPD}$ of 2.00 with CAPD is equivalent to an eKt/V of 1.2 with thrice-weekly hemodialysis. Recent clinical trials suggest that even this dose of CAPD might be higher than required for optimal outcomes. These data are reviewed in section 8 of this textbook. The standard Kt/V (stdKt/V) calculation [4,7] quantifies the effects of both intermittent and continuous dialysis, giving a dose that applies to all dialysis frequencies and intensities ranging from CAPD, short and long daily HD, to twice-weekly HD. However, in the specific case of thrice-weekly hemodialysis, the residual renal function can be directly expressed as a quantity of eKt/V (abbreviated as eKrt/V) in accordance with the equation eKrt/V = 4.5 × Kru/V (with V in liters and Kru in mL/min, the units of the coefficient 4.5 are liters per milliliter per min Kru per dialysis).

Assuming a V of 30 L, a Kru of 1 mL/min contributes an additional equivalent of 4.5 L of urea clearance per dialysis session, which translates into a gain of eKt/V of 0.15 (4.5/30). If a patient has a Kru of 3 mL/min, it will add 3 × 0.15, or 0.45 to the eKt/V provided by hemodialysis (abbreviated as eKdt/V), a highly significant addition. With this Kru being present, the total equilibrated dialysis dose (eKdrt/V) is simply the sum of eKdt/V and eKrt/V, so that a Kru of 3 mL/min raises an eKt/V of 1.2 to 1.65.

The impact of Kru on total eKdrt/V and estimated nPCR (e-nPCR) is illustrated in Figure 38.3A and B. In Figure 38.3A the Kdrt/V is plotted as a function of Kru for an average-size patient and four levels of eKdt/V (0.40, 0.60, 0.80, and 1.00; these are
Figure 38.3 (A) Solution for eKdrt/V as a function of Kru for average patient volume (V) of 30 L. As shown, in the average-sized patient, each milliliter of Kru increases eKdrt/V by about 0.15 units of eKt/V. (B) Solutions for "apparent" nPCR if residual Kru is not included in UKM. The presence of Kru lowers the predialysis BUN, which will result in spurious lowering of the nPCR calculated if Kru is not included in the modeling equations. The error introduced will be about −4% for each milliliter per minute of Kru in the average-sized patient.

the y axis values shown when Kru is 0). As discussed above, eKrt/V is additive to eKdt/V. The UKM program in the FMCNA system can calculate the Kdrt/V for thrice-weekly and also twice-weekly dialysis.

In Figure 38.3B the impact of Kru on nPCR is illustrated. Using the UKM, nPCR values of 0.8, 1.0, 1.2, and 1.4 are shown with Kru increasing from 0 to 8 mL/min. The "apparent" e-nPCR values that would be calculated if Kru were present but not measured and assumed to be zero are depicted. For example, if the nPCR were 1.0 and an unmeasured Kru of 3 mL/min were present, the apparent e-nPCR calculated would fall to 0.80 and would be interpreted as a marginal protein intake. Thus, residual renal function (when measured and applied) can have a marked impact on eKt/V and e-nPCR and will further exaggerate the differences between the single-pool and equilibrated measures.

Standard Kt/V

The calculation of standard Kt/V based on the relationship between urea generation and the mean predialysis BUN level makes
Figure 38.4 Results of solution of the stdKt/V model over wide ranges of eKt/V and weekly dialysis frequency (N). Note that by inspection stdKt/V can be seen to increase linearly as N increases and logarithmically with eKt/V. The doses of adequate continuous ambulatory peritoneal dialysis and thrice-weekly hemodialysis are the same with this model, the weekly stdKt/V of 2.

it possible to compare different doses at different treatment frequencies from one to seven times per week (Figure 38.4).

Use of approximation equations

A number of attempts have been made to greatly simplify urea kinetic calculations [6,8–14]. None of these approximations calculate the urea distribution volume, which is essential to assess therapy delivery and to quantify the dietary protein intake based on PCR. Also, it is not possible to prescribe a desired dose of dialysis (spKt/V) without calculation of V and without prescription calculation routines. The Daugirdas equation [9] is the only reliable equation to estimate spKt/V, but it will not detect errors in therapy delivery because the individual components defining a particular Kt/V (e.g. treatment time, blood flow, residual renal function, and V) are not computed by a kinetic model but lumped together instead, so that a prescription based on the individual components cannot be accurately determined. A volume change with formal UKM suggests that the prescription has not been delivered or that blood drawing errors have occurred.

The most rigorous equation to estimate eKt/V is the Smye equation [13], but this equation is very sensitive to small BUN errors. The most usefully rigorous equation is the Tatersall equation [6] to calculate eKt/V. The Depner-Daugirdas equation [10] provides a reasonable estimate of nPCR but cannot be used to estimate PCR and errors in delivery cannot be identified, for the same reasons as with the Daugirdas equation.

The urea reduction ratio (URR) [12] is widely used to judge adequacy of dialysis dose. It is a very crude estimate of dose but very inexpensive and easy to obtain and therefore widely used. It is probably reasonably suitable for analysis of populations on dialysis but is of limited usefulness for individual patients because a URR cannot be prescribed. The URR is quite sensitive to the magnitude of ultrafiltration, will not identify errors in delivery, and cannot be used to monitor the nutritional status of the patient.

The NCDS and HEMO studies

The utilization of UKM and the Kt/V methodology may have been in part responsible for decreasing hemodialysis times and concomitant increases in mortality observed in dialysis populations in the USA during the 1980s and 1990s. UKM became widely applied after the results of the NCDS were published [1,2]. The NCDS was a landmark study, as it was the first prospective randomized trial for dialysis. A total of 160 chronic dialysis patients undergoing thrice-weekly hemodialysis were observed over a minimum of 6 months and randomly allocated to four treatment arms. Dialysis doses were randomly distributed over a very wide range, with a spKt/V between 0.42 and 1.45. The primary end point in the NCDS was the probability of failure, which was a global clinical composite of *de novo* uremic symptoms, hospitalization, and death during follow-up. The NCDS found that a Kt/V urea above 0.9 with thrice-weekly treatment provided an adequate dialysis prescription in that the patient failure rate of 13% was substantially below that in patients with a lower Kt/V. Although the NCDS included no diabetic patients or those with other important comorbid conditions, a Kt/V of 1.0 was widely accepted after publication of the study results as representing adequate dialysis.

Subsequent observational data from Tassin, France (with an spKt/V of >1.6) [15] and Minnesota (spKt/V of >1.3) [16] reported improved survival with increased spKt/V, and this improvement in survival occurred despite a striking increase in comorbidity, which should have resulted in an overall decreased survival. Using the URR as a measure of dialysis adequacy, it was shown that survival was significantly reduced at URR below 60% [12]. Observational data also suggested that more intensive dialysis leads to improved survival. In one study, increasing the mean spKt/V from 0.82 (pre-1988) to 1.33 led to a reduction in the gross mortality rate from 22.8 to 9.1%/year [17]. It is important to note that an increased spKt/V was only one of multiple parameters that improved from the first period to the second period in these analyses. During this same period the magnitude of inflammatory response induced by dialysis presumably improved with the introduction of more biocompatible dialysis membranes, the observed nPCR increased and plasma albumin concentrations rose. Thus, enhanced nutrition and possibly fewer inflammatory problems might have contributed significantly to if not entirely to the observed improvement in survival. A national sample in the dialysis population in the USA suggested a 7% reduction in mortality for each 0.1 unit increase in spKt/V [18].

It is of note that some studies observed an increased relative risk (RR) of death among patients with high spKt/V values (>1.6) or URR between 75 and 79%, possibly reflecting a subset of the population with disease or malnutrition-imposed reduction in

body mass or reflecting errors in postdialysis blood collection leading to artificially low blood urea values [19]. These results were, however, corroborated by data showing that a spKt/V greater than 1.68 was associated with lower survival compared to a range of spKt/V values between 1.23 and 1.68 [20]. Therefore, based upon these observational studies, the optimal dose of hemodialysis remained undefined.

The Hemodialysis (HEMO) study, begun in 1995, aimed to clarify this issue [21]. It was a multicenter clinical trial of hemodialysis prescriptions for patients on thrice-weekly hemodialysis treatment. During the pilot phase of the HEMO study the proposed dose in the standard arm of the study was a spKt/V of 1.1–1.2. However, by the time the final protocol was written, the practice in the USA was to provide doses close to a spKt/V of 1.40, which precluded any investigation of the equivalent dose ranges used in the NCDS. Ultimately, participants (1037 men, 809 women) from over 65 US dialysis facilities were randomized in a two-by-two factorial design to dialysis prescriptions targeted to a standard dose (eKt/V of 1.05, which is equivalent to a URR of 65% or a spKt/V of 1.25) or a high dose (eKt/V of 1.45, which is equivalent to a URR of 75% or a spKt/V of 1.65) and to either low-flux membrane (mean β_2-microglobulin clearance of <10 mL/min) or high-flux membrane (mean β_2-microglobulin clearance of >20 mL/min and ultrafiltration coefficient of >14 mL/h/mmHg).

Despite important exclusion criteria, such as severe congestive heart failure and serum albumin of <2.6 g/dL at baseline, the HEMO study population was representative of the majority of chronic hemodialysis patients. The primary outcome was death from any cause, whereas the main secondary outcomes were the rate of hospitalization and the composite outcomes of first hospitalization for a cardiac problem or death from any cause, first hospitalization for an infectious cause or death, and first decline of greater than 15% of serum albumin from baseline value or death. Mean follow-up was 4.5 years.

The risk of death from any cause (the primary outcome) was the same in the high-dose and standard-dose groups (RR of 0.96 for high versus standard dose, 95% confidence interval [CI], 0.84–1.10). Similarly, there was no difference in all-cause mortality between the high-flux and the low-flux groups (RR, 0.92; 95% CI, 0.81–1.05). The risk of the main secondary outcomes was also the same for both dialysis doses. The prespecified subgroup (unadjusted) analysis revealed a possible interaction between survival and gender, that is, a benefit for women receiving a high dialysis dose (19% lower risk of death than for women in the standard dose group) and, conversely, an increased risk of death for men receiving high-dose dialysis that was 16% higher than that for men receiving standard-dose dialysis in the unadjusted analysis [22].

Post hoc analysis of the HEMO study [23] data showed that the high-flux intervention seemed to be associated with reduced risks of specific cardiac-related events, such as cardiac death (RR for the high-flux arm, 0.80; 95% CI, 0.60–0.99) and the composite of first cardiac hospitalization or cardiac death (RR, 0.87; 95%

CI, 0.76–1.00). Dialysis vintage may interact with the effects of high-flux dialysis on outcomes. In the subgroup that had been on dialysis for >3.7 years before study entry (median time of dialysis for the entire study population), randomization to high-flux dialysis was associated with lower risks of all-cause mortality (RR, 0.68; 95% CI, 0.53–0.86) and cardiac deaths (RR, 0.63; 95% CI, 0.43–0.92) during the time on the study. This apparent benefit seemed to be attenuated when the time before entry was included in the analysis of morbidity. For the subgroup of patients with <3.7 years of dialysis before the study, assignment to high-flux dialysis had no significant effect on any of the examined clinical outcomes.

Originally, the HEMO study was analyzed on an intention-to-treat basis. A subsequent as-treated analysis showed that each 0.10 reduction in achieved eKt/V below the group median was associated with a mortality risk increase of 58% in the standard-dose group and 37% in the high-dose group [24]. Patients in the highest quintile of the standard-dose group had better survival than those in the lowest quintile of the high-dose group. The discrepancies between the results of the intention-to-treat and the as-treated analyses could reflect extraneous factors that were associated with both increased mortality and lower achieved eKt/V, and they provide another concrete example of the problems inherent in relying principally on findings from observational studies, which tend to overestimate the benefits of any therapy, rather than on data from rigorous randomized controlled trials when informing clinical practice decisions. In the HEMO study, factors associated with lower achieved eKt/V were larger anthropometric volume, black race, and comorbidity at baseline, and follow-up factors included use of catheters and grafts (both versus fistula), hospitalization rate, and declining serum albumin levels. Additionally, data from the HEMO study also revealed a coefficient of variation within patients of ~0.1 spKt/V units. In order to provide 95% confidence that the dose will not decrease to less than 1.2 per dialysis for any individual dialysis session, the target dose has to be increased to a spKt/V of 1.4 per dialysis.

Dialysis adequacy: current recommendations

The optimal dose for adequacy of an individual hemodialysis treatment to produce the lowest rate of morbidity and mortality when hemodialysis is administered thrice weekly remains uncertain. The NCDS suggested that there was some minimum level of clearance below which patients would predictably do less well. This finding is relatively intuitive. The HEMO study suggests that this threshold might differ for patients with different baseline characteristics and comorbidities. On the basis of the totality of evidence, however limited the randomized controlled trial evidence might be, several national and international bodies have issued recommendations for hemodialysis adequacy, and these are listed in Table 38.1.

Table 38.1 Recommendations from various countries for adequate thrice-weekly hemodialysis.

Country or region (year recommendation issued)	Recommended minimum (target)[a] values		
	spKt/V	eKt/V	URR (%)
Canada (1999)	1.2		65
Australia (2005)	1.2 (1.4)		65 (70)
Europe (2002)	1.4	1.2	65
UK (2006)	1.3	1.2 (1.4)	65 (70)
USA (2006)	1.2 (1.4)		65 (70)

[a] The target value (shown in parentheses) to achieve the minimum dose with 95% confidence.

The Frequent Hemodialysis Network trial

Observational studies have suggested improvements with frequent hemodialysis, but its true efficacy and safety remain uncertain. The multicenter, randomized controlled Frequent Hemodialysis Network (FHN) trial aims to compare nocturnal home dialysis (six times per week; 125 patients) with conventional in-center dialysis (125 patients) and short daily in-center dialysis (six times per week; 125 patients) with conventional thrice-weekly hemodialysis (125 patients). The trial will be performed with high-flux dialyzers.

Patient enrollment commenced for the FHN trial in early 2006. Each patient was to be treated and followed for 12 months. Daily HD was to be delivered for 1.5–2.75 h, 6 days/week. The dialysis prescriptions target an eKt/V of 0.9 at each of the six weekly dialysis sessions. Patients assigned to the six-times-per-week nocturnal dialysis followed any dialysis prescription, provided their prescribed weekly stdKt/V was at least 4.0 and treatment time was at least 6.0 h, six times per week. In the conventional hemodialysis group, subjects remained on their usual dialysis prescriptions, subject to a minimum prescribed eKt/V of 1.1. The composite of mortality with the 12-month change in left ventricular mass index (by magnetic resonance imaging) and SF-36 RAND Physical Health Composite are specified as coprimary outcomes. Trial feasibility will be assessed during the first 12 months of enrollment (Vanguard phase). The FHN trials will help to elucidate whether more frequent hemodialysis might improve outcomes in chronic hemodialysis patients. The trial will have important implications for dialysis therapy in the next decades.

39 General Management of the Hemodialysis Patient

Robert Mactier[1] & David C. Wheeler[2]

[1]NHS Greater Glasgow & Clyde, Scotland, UK
[2]Royal Free and University College Medical School, London, UK

Introduction

In the past, the provision of hemodialysis has focused on achieving prespecified standards of small solute clearance (chapter 44), with little attention given to the more general clinical and laboratory indices of hemodialysis adequacy. A holistic, multidisciplinary approach to the optimal care of the hemodialysis patient should include maintenance of satisfactory nutritional status, correction of metabolic disturbances (including disordered lipid metabolism, predialysis hyperkalemia, and metabolic acidosis), and control of high blood pressure (while avoiding hypotension). These aspects of care should be addressed in addition to the management of anemia (chapter 31), renal bone disease (chapter 34), infection (chapter 40), and vascular access (chapter 42). Despite a paucity of robust clinical data, monitoring and management of the more general aspects of hemodialysis are considered an important component of good practice and have been addressed in clinical practice guidelines developed in Australasia [1], Canada [2], Europe [3–6], the UK [6,7], and the USA [8,9]. Where data from randomized controlled trials are lacking, these guidelines have defined ranges of relevant parameters associated with optimum outcomes reported in large observational studies [10], or when such data are lacking, have used biological plausibility expressed as expert opinion. Such indices typically relate to patients receiving thrice-weekly hemodialysis, although there is no intuitive reason to believe that they should not be applicable to those receiving alternative hemodialysis regimens or hemodiafiltration. This chapter sets out to summarize the available evidence relevant to these more general aspects of the management of the hemodialysis patient as it relates to chronic hemodialysis treatment.

Hyperkalemia

Hyperkalemia is a common indication for emergency hemodialysis and accounts for between 3 and 5% of deaths among dialysis patients [11]. Noncompliance with the dialysis prescription and diet are thought to be the most common contributory factors, although medications such as angiotensin converting enzyme inhibitors, angiotensin receptor blockers, nonsteroidal anti-inflammatory drugs, beta-blockers, and potassium supplements may be implicated. The general principles of the assessment and treatment of disorders of potassium metabolism (hypo- and hyperkalemia) are detailed in chapter 10.3 of this textbook. The specific problem of potassium as it relates to patients on hemodialysic is discussed below.

Treatment of hyperkalemia

Hemodialysis is the most appropriate emergency treatment for hyperkalemia in the dialysis patients. In the chronic dialysis patient with a working vascular access, hemodialysis can be initiated quickly. Serum potassium levels usually fall by 1 mmol/L during the first hour of treatment and by a further 1 mmol/L over the next 2 h [12]. The rate of potassium removal may be enhanced further by increasing the dialyzer blood flow rate or by either raising the bicarbonate or lowering the potassium concentration of the dialysate [13]. An urgent electrocardiogram is of proven value in guiding management of non-hemodialysis-dependent patients with a serum potassium above 6 mmol/L [14] and can be used to dictate which patients should receive additional emergent interventions, such as the administration of intravenous calcium chloride. The results of a Cochrane meta-analysis of controlled trials of nondialytic emergency interventions for hyperkalemia, which was not limited to dialysis patients, can be extrapolated in the absence of better evidence cautiously to the dialysis patient with hyperkalemia. The authors of the Cochrane review concluded that intravenous glucose with insulin and nebulized or inhaled salbutamol were effective in reducing serum potassium levels, but studies were limited by the absence of data on cardiac

arrhythmias and mortality rates [13]. The evidence for efficacy of intravenous bicarbonate and potassium exchange resins in dialysis patients is equivocal, and neither can be recommended as sole therapy in severely hyperkalemic hemodialysis patients [13], especially in light of the effectiveness of hemodialysis in reducing total body potassium burden.

Hypokalemia occurring towards the end or immediately after hemodialysis is common, may increase the risk of cardiac arrhythmias, and can be corrected by increasing the dialysate potassium concentration [15,16]. Table 39.1 shows recommendations for predialysis blood potassium concentrations taken from the available English language clinical practice guidelines.

Metabolic acidosis

Metabolic acidosis is usually detected in dialysis patients by measurement of serum bicarbonate concentrations, although assessment of severity may require analysis of arterial blood pH and gases. In stable hemodialysis patients, the main contributory factors for metabolic acidosis appear to be inadequate dialysis delivery, excessive intake of animal proteins, and high interdialysis weight gain [17,18]. In sick patients, increased protein catabolism, increased lactate production (induced by hypotension or hypoxia), and bicarbonate losses (associated with comorbid illness) may exacerbate the problem [17]. Adverse consequences of a metabolic acidosis include an increase in protein catabolism, there being a well-established association between metabolic acidosis and markers of poor nutritional status [18]. Other adverse associations include a negative inotropic effect, loss of bone mineral, insulin resistance, growth retardation in children, reduced thyroxine levels, altered triglyceride metabolism, hyperkalemia, low serum leptin levels, and enhanced accumulation of β_2-microglobulin [18].

In a large cohort study, predialysis venous blood bicarbonate values between 17.5 and 20 mmol/L were associated with the lowest risk of death among 13,535 hemodialysis patients, whereas the relative risk was increased threefold if the predialysis venous bicarbonate was less than 15 mmol/L [9]. Among more than 7000 unselected hemodialysis patients in the Dialysis Outcomes and Practice Patterns study, the corrected midweek blood bicarbonate concentration averaged 21.9 mmol/L and correlated inversely with the normalized protein catabolic rate (nPCR) and serum albumin [19]. In this observational study, moderate predialysis midweek acidosis was associated with a better nutritional status (nPCR, albumin, PO_4) and a lower risk of death and hospitalization compared to patients with severe acidosis (serum bicarbonate levels of less than 16 mmol/L) or a sodium bicarbonate 24 mmol/L greater than [19].

Correction of metabolic acidosis

Several small crossover studies have suggested short-term benefits associated with correcting predialysis acidosis from below 19 mmol/L to above 24 mmol/L, either by increasing the dialysate bicarbonate concentration [20–23] or by the addition of oral bicarbonate supplements [24]. Correction of acidosis reduced whole body protein degradation [20], increased the sensitivity of the parathyroid glands to serum calcium [21,22], improved nutritional status (assessed by measurement of triceps skin fold thickness) [23], and increased serum albumin after 3 months without changes in body weight, Kt/V, or nPCR [24]. However, other studies have shown no increase in serum albumin after correction of acidosis [25]. Furthermore, these studies have not demonstrated any direct impact on mortality or significant morbidities in the long term.

Complete correction of predialysis metabolic acidosis in hemodialysis patients could theoretically contribute to an increased risk of postdialysis metabolic alkalosis with hypoventilation, phosphate transfer into cells, and a higher risk of soft tissue and vascular calcification. Furthermore, the prerequisite sodium load associated with the additional oral or dialysate bicarbonate

Table 39.1 Guidelines for predialysis serum potassium and bicarbonate concentrations in hemodialysis patients.

Clinical practice guideline [reference]	Date of update	Recommendation for predialysis serum potassium concentration	Recommendation for predialysis serum bicarbonate concentration[a]
Caring for Australasians with Renal Impairment [1]	2005	Reduce dietary potassium if >5.5mmol/L	Increase to 23–24 mmol/L
Canadian Society of Nephrology [2]		No recommendation	No recommendation
European Best Practice Guidelines [5]	2007	Reduce dietary potassium if >6 mmol/L	Midweek predialysis target, 20–22 mmol/L
UK Renal Association [7]	2007	3.5–6.5 mmol/L	Target range, 20–26 mmol/L
NKF K/DOQI [8]	2003	No recommendation	Aim for >22mmol/L

[a] Predialysis serum bicarbonate concentration should be measured in a fully filled sample bottle with minimum delay after venipuncture without using a tourniquet.

requirement may contribute to fluid retention and hypertension. In one recent randomized crossover study, the use of standardized bicarbonate bath concentration (32 mmol/L) resulted in more frequent hypotensive episodes despite the greater potential sodium load when compared in the same patients to the use of a low bicarbonate bath concentration (26 mmol/L) [26]. A summary of the recommended targets for predialysis blood bicarbonate levels in hemodialysis patients taken from clinical practice guidelines is shown in Table 39.1 and indicates that a mild degree of predialysis acidosis is generally accepted to minimize the risk of adverse events based on this limited trials evidence.

Hypertension

Although hypertension has been established as an important risk factor for the development of cardiovascular disease in the general population, whether such an association exists in hemodialysis patients, what the actual clinical impact of hypertension treatment is in this population, and what the optimal target for achieved blood pressure should be are all less clear for patients on hemodialysis [27]. A recent systematic review of the available literature showed an association between predialysis hypertension and total mortality in incident cohorts of hemodialysis patients and between better control of predialysis blood pressure and higher patient survival rates [28]. In an observational study of 16,059 incident hemodialysis patients in the USA, baseline systolic blood pressure above or equal to 150 mmHg was associated with a higher risk of death in patients who had survived for at least 3 years, whereas baseline systolic blood pressure below 120 mmHg was associated with a higher risk of death during the first 2 years of dialysis [29]. Systolic blood pressure records obtained outside the dialysis unit were stronger predictors of left ventricular hypertrophy than blood pressure measurements taken while patients were attending for dialysis [30].

Control of blood pressure
Given the association of the highest blood pressure levels with poorer outcomes, the above observations led to the conclusion that control of hypertension is beneficial in the hemodialysis population and more recently to the conclusion that excessive control might be harmful. However, evidence-based target ranges and the optimum timing and method of measurement of blood pressure in hemodialysis patients have not been rigorously defined. Nevertheless, in view of the high cardiovascular morbidity and mortality, clinical practice guidelines recommend tight blood pressure control. For example, the authors of the US Kidney Disease Outcomes Quality Initiative (K/DOQI) extrapolated treatment recommendations from blood pressure control in the general population and advocated a target predialysis blood pressure below 140/90 mmHg and postdialysis blood pressure below 130/80 mmHg [31].

Control of hypertension is facilitated by maintaining a patient at their "dry" body weight, and this is more likely to be achieved with longer-duration or more frequent hemodialysis treatments [31].

Very low mortality rates were observed in a cohort of patients treated with long-duration thrice-weekly hemodialysis, among whom survival was independently associated with improved blood pressure control [32]. Furthermore, lower cardiovascular mortality was related to better long-term optimization of dry body weight [32]. Conversely high-efficiency, short-duration, thrice-weekly hemodialysis has been associated with poor blood pressure control [33]. Retrospective data from a large Japanese cohort showed that patient survival improved with increments in dialysis duration up to 5.5 h beyond baseline after adjusting for dialysis dose [34]. Despite a lack of strong supporting evidence, some clinical practice guidelines recommend that dietary sodium intake not exceed 100 mmol/day in order to facilitate control of hypertension while reducing thirst and minimizing interdialytic weight gains [6,31].

Dialysis-related hypotension

Hypotension is the most frequent complication of hemodialysis and can shorten treatment times, thus reducing the delivered dialysis dose [35]. Dialysis-related hypotension is an independent predictor of poor patient survival [36]. Patients experiencing frequent episodes are at higher risk of death [37], probably because low blood pressure during dialysis can be a marker of severe cardiac disease [38]. The frequency of dialysis-related hypotension is, therefore, an important indicator of the quality of dialysis.

Preventing dialysis-related hypotension
Adjustment of the rate of fluid removal, dialysate sodium concentration, and dialysate temperature (or combinations thereof) minimize the likelihood of hypotension during dialysis [39–42]. Dialysate sodium modelling, or "ramping," can reduce intradialysis cramps and hypotension but may increase thirst, weight gain, and hypertension between dialysis sessions [43]. A recent randomized trial of intradialytic blood volume monitoring demonstrated no difference in weight, blood pressure, or frequency of dialysis-related complications, although hospitalization and mortality rates were higher than in a control group assigned to conventional monitoring [44]. This result was unexpected and might be explained by the unusually low hospitalization and mortality rates in the control group compared with local prevalent hemodialysis patient population. A recent systematic review of 22 studies concluded that a reduction in dialysate temperature is effective in decreasing the incidence of intradialytic hypotension without affecting dialysis adequacy [45].

Nutrition

Malnutrition may develop in hemodialysis patients despite the delivery of an adequate dialysis dose and protein intake [46] and is prevalent in up to 72% of adult hemodialysis patients [47,48]. Nutritional status may start to decline before a patient reaches

end-stage kidney disease and should influence the clinician's decision to initiate renal replacement therapy [49]. Chronic inflammation and cardiovascular disease are commonly associated, leading to the concept of the malnutrition–inflammation–atherosclerosis syndrome [50]. It is generally considered that malnutrition and a decline in nutritional status over time are associated with adverse outcomes in hemodialysis patients [51,52], although this has not been confirmed by all studies [53]. Such discrepancies may result from the use of different nutritional markers and reflect a general lack of agreement as to how best to assess nutritional status in hemodialysis populations.

Assessment of nutritional status

Clinical practice guidelines developed in Australasia [1] Canada [2], Europe [5], the UK [6,7], and USA [8,54] make specific recommendations with respect to the assessment of nutritional status in hemodialysis patients (Table 39.2). Although these guidelines differ in terms of which nutritional indices they endorse, they all agree that no single measure alone can be used to assess

nutritional status and that a combination of the measures outlined below should be used. Canadian, UK, and US guidelines clearly state criteria for the diagnosis of malnutrition based on these measurements.

Subjective global assessment

The use of subjective global assessment (SGA) is recommended by all five guidelines and comprises an evaluation of gastrointestinal symptoms (appetite, anorexia, nausea, vomiting, diarrhea), a recording of weight change over time, an estimation of functional impairment, and a subjective visual quantification of subcutaneous tissue and muscle mass [55]. SGA has the advantages of being readily available, cheap, and easy to perform [56]. However, it has not been adequately validated as a measure of malnutrition. While this tool may distinguish those with severe malnutrition from those who are adequately nourished [57], and predicts poor outcomes for those identified by this measure as most severely malnourished [56]. When it does not reliably assess protein malnutrition in dialysis patients compared with more complex methods [57].

Table 39.2 Recommended tools for nutritional assessment and criteria for malnutrition based on current guidelines in hemodialysis patients.

Guideline [reference]	Date updated	Recommended tools for assessment of malnutrition	Criteria for malnutrition
Caring for Australasians with Renal Impairment [1]	2005	Measure of nutritional intake (dietary evaluation, PCR) Long-term measures of nutritional adequacy (total body nitrogen, DEXA, BIA) nPNA, Albumin Urea and creatinine Edema-free body weight SGA	No criteria stated
Canadian Society of Nephrology [2]	1999	Serum albumin nPNA Dietary energy intake SGA Edema-free lean body mass	Albumin <30 g/L Lean body mass <70% (men) or <60% (women)
European Best Practice Guidelines [5]	2006	Dietary assessment, BMI, SGA, anthropometry, nPNA, albumin, prealbumin, cholesterol, technical investigations	No criteria stated
UK Renal Association [7]	2002	SGA Height and weight (BMI) Serum albumin	Unintentional fall in edema-free weight (>10% in last 6 mos). Unintentional fall in BMI, or BMI <18.5 kg/m^2 SGA score less than 5 (on 7-point scale)
K/DOQI [54]	2003	Predialysis serum albumin Percentage of usual body weight Percentage of standard body weight, SGA Dietary interviews and diaries nPNA	Albumin >4 g/dL Prealbumin <30 mg/dL Predialysis creatinine <10 mg/dL

Abbreviations: BMI, body mass index; PCR, protein catabolic rate; DEXA, dual-energy X-ray absorptiometry; nPNA, normalized protein nitrogen appearance; SGA, subjective global assessment.

Markers of visceral protein stores

Like SGA, all five guidelines recommend the use of measurements that reflect visceral protein stores, for example, serum albumin. However, a low serum albumin is strongly correlated with inflammation and is influenced by other factors, such as hydration status [58]. Other readily measurable blood markers of nutritional status include creatinine and thyroid binding protein (prealbumin or more correctly transthyretin). Plasma creatinine concentrations reflect muscle mass, somatic stores, dietary protein intake, residual kidney function, and dialysis dose, but may nonetheless be of value as a marker of nutritional status [59]. Blood transthyretin levels change rapidly when hepatic protein production is impaired and provide useful prognostic information independent of albumin levels in hemodialysis patients [60].

Dietary protein intake

In addition to SGA and markers of visceral protein stores, a measure of dietary protein intake is recommended in the Australasian [1], Canadian [2], European [5], and US [54] guidelines. This generally involves the patient keeping a diary or recalling their recent food intake. A simpler method is to evaluate protein nitrogen appearance (PNA), which is mathematically identical to protein catabolic rate (PCR) and roughly equivalent to protein intake [61]. Under steady-state conditions, nitrogen intake roughly equals total nitrogen loss (total nitrogen appearance) [62]. Thus, PNA can be calculated from total nitrogen appearance (the sum of dialysis, urine, and fecal nitrogen losses) and should be normalized (nPNA) to fat-free, edema-free standardized body weight. Because of the difficulty in measuring nitrogen in stool, equations have been derived to estimate PNA from nitrogen in serum, urine, and dialysate, although these are more accurate in peritoneal dialysis patients, in whom dialysate urea concentrations can be measured directly rather than estimated [54].

Assessment of changes in lean body mass

Another approach is to monitor lean body mass over time. This is best done in practice by using anthropometrics, multifrequency bioimpedance assay (BIA), and dual-energy X-ray absorptiometry (DEXA). BIA parameters indicative of poor nutritional status predicts mortality in dialysis patients [63], and although sequential DEXA measurements are reproducible [64], they have not been validated as outcomes measures. Hand grip strength can also be used as a readily measurable marker of muscle mass and predicts clinical events in men but not women receiving hemodialysis [56].

Management of malnutrition

Regardless of the cause, ongoing provision of an adequate nutritional intake is generally recommended for the prevention and treatment of malnutrition in adults receiving hemodialysis. Although intensive nutritional support undoubtedly improves markers of poor nutritional status, there is currently insufficient evidence to suggest that either the administration of oral supplements [65] or intradialytic parenteral nutrition [66] improves clinical outcomes among such individuals. This should be kept in mind when evaluating the various randomized controlled trials that have used nutritional markers, such as albumin, as a surrogate for clinical benefit [67–75]. These studies, which have examined the value of various dietary interventions and intradialytic parenteral nutrition, are summarized in Table 39.3.

Despite the lack of evidence of benefit, proactive management of malnourished hemodialysis patients is generally recommended [1,2,6–8,54]. The general principles are to ensure that the patient is receiving an adequate dialysis dose and that reversible factors such as inflammation are corrected [76]. In a stepwise approach to nutritional support, attempts should be made initially to increase intake of ordinary foods with the addition of oral supplements as necessary [77]. However, when these strategies fail and assuming that the gastrointestinal tract is functional, enteral feeding should be considered [78], either by nasogastric tube or percutaneous endoscopic gastrostomy. Patients in whom oral nutrition is not feasible or poorly tolerated should be considered for either intradialytic parenteral nutrition or total parenteral nutrition [79]. The benefits of these more aggressive interventions on mortality and morbidity outcomes in either moderately or severely malnourished hemodialysis patients have not been determined in randomized controlled clinical trials.

Dyslipidemia

Pattern and prevalence of dyslipidemia

Hemodialysis patients exhibit a dyslipidemia characterized by elevated plasma triglyceride levels, reflecting the accumulation of chylomicrons [80] and non-high-density triglyceride-rich lipoprotein particles [81]. This results from both an increase in the rate of synthesis and decreased clearance [82]. High-density lipoprotein (HDL) levels are generally reduced, and the distribution of HDL subfractions is abnormal. Whereas low-density lipoprotein (LDL) levels are usually normal, LDL particles tend to be small and of increased density [83], which are characteristics associated with enhanced atherogenicity [84] in the general population.

Clinical practice guidelines developed in Europe [4], the UK [6,7], and USA [85] recommend desirable limits for plasma lipid concentrations in hemodialysis patients (Table 39.4), based largely on ranges felt to be optimal in the general population. For example, the US K/DOQI guidelines use threshold values for LDL, HDL, and triglycerides recommended by the US National Cholesterol Education Program Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults. Using these criteria, only 20.2% of 1047 hemodialysis patients in the Dialysis Morbidity and Mortality Study had normal plasma lipid values, and 61.1% qualified for treatment [85]. The above pattern of dyslipidemia is seen across a wide spectrum of chronic kidney disease and the evidence supporting specific steps in management of these dyslipidemias is reviewed in detail in chapter 32. This chapter will focus on these issues as they relate to hemodialysis patients.

Table 39.3 Published randomized trials assessing the impact of nutritional interventions in hemodialysis patients.

Study author [reference]	Population	Intervention	Outcome marker	Follow-up	Outcome
Cano [67]	26 malnourished HD patients	Peridialytic parenteral nutrition 3× weekly vs. no treatment	Albumin, prealbumin transferrin, body weight, arm circumference	3 mos	Intervention associated with improved serum albumin, prealbumin, body weight, and arm circumference
Cockram [68]	79 normally nourished HD patients	Standard formula vs. two disease-specific supplements (as sole source of nutrition)	Gastrointestinal symptoms, urea kinetics, nPCR	2 wks	No differences in GI symptoms; compared to standard formula; lower phosphorus on disease-specific products
Hiroshige [69]	28 malnourished elderly HD patients	Oral branched-chain amino acids (12 g/day) vs. placebo (crossover)	Serum albumin, anthropometric indices	6 mos	Supplementation increased albumin and improved anthropometric parameters
Kloppenburg [70]	50 HD patients	High-protein diet (and increased dialysis dose)	Protein intake (total nitrogen appearance), food diaries, serum albumin, lean body mass	10 wks	Protein intake increased on high-protein diet but no change in albumin or lean body mass
Kuhlmann [71]	18 malnourished HD patients	Group A: 45 kcal/kg/day with 1.5 g protein/kg/day; Group B: 35 kcal/kg/day with 1.2g protein/kg/day; Group C: usual diet supplemented with 10% protein intake	Serum albumin, prealbumin, dietary intake, and body weight	3 mos	Serum albumin increased in group A only; weight change correlated with mean dietary protein intake
Leon [72]	83 HD patients	Dietician-directed interventions vs. usual care	Change in albumin	6 mos	Dietetic intervention improved albumin levels
Sharma [73]	40 nondiabetic HD patients with BMI <20, albumin <4 g/dL	Disease-specific or standard enteral nutritional supplements vs. usual care	BMI, albumin, functional status	1 mo	Increase in BMI, serum albumin, and functional status among patients receiving supplements
Tietze [74]	19 HD patients	Fish protein vs. placebo (crossover)	Serum proteins, anthropometrics	6 mos	Body weight and arm muscle circumference but not albumin or other anthropometric markers improved during active treatment
Toigo [75]	21 HD patients	Essential amino acids vs. standard amino acid supplement (control)	Biochemisty, anthropometrics, PCR	6 mos	PCR increased more and albumin decreased in those receiving standard amino acids compared to essential amino acids group

Abbreviations: HD, hemodialysis; nPCR, normalized protein catabolic rate; PCR, protein catabolic rate.

Dyslipidemia and cardiovascular disease

Because dialysis patients are at high risk of vascular events, dyslipidemia represents a potentially attractive target for therapeutic intervention. However, although in the general population high blood LDL and low HDL concentrations are associated with increased cardiovascular risk [86], epidemiological studies have failed to demonstrate these relationships in hemodialysis populations [87]. This may be due to the confounding effects of malnutrition and inflammation, because the expected relationships are partly restored when these factors are taken into account [88]. Whether other markers (which might more clearly define the extent of disturbed lipoprotein metabolism) perform better than cholesterol in predicting cardiovascular outcomes in hemodialysis patients remains to be established.

Management of dyslipidemia

Recommendations relating to the management of dyslipidemia usually start with therapeutic life-style changes. Low-fat, low-cholesterol diets [89] and exercise programs [90] favorably modify blood LDL and HDL concentrations in the general population, and at least one small randomized controlled trial has suggested that exercise lowers triglyceride levels in dialysis patients [91]. Fibrates are generally recommended for lowering blood triglyceride concentrations and raising HDL, although use of these agents in hemodialysis patients may be associated with an increased risk of myositis and rhabdomyolysis [85], and benefits have not been properly assessed in outcomes studies.

Statins reduce adverse vascular events in a wide range of populations, particularly in patients with (or those at high risk of

Table 39.4 Current guidelines on targets for lipid reduction in hemodialysis patients.

Guideline	Date updated	Recommendation	Notes
Caring for Australasians with Renal Impairment [1]		No recommendation	
Canadian Society of Nephrology [2]		No recommendation	
European Best Practice Guidelines [4]	2002	LDL cholesterol <100 mg/dL, triglycerides <180 mg/dL, non-HDL cholesterol <130 mg/dL	Blood collected in fasting state
UK Renal Association [7]	2002	Primary prevention: Total cholesterol <195 mg/dL or 30% reduction from baseline	
K/DOQI [85]	2003	LDL cholesterol <100 mg/dL; triglycerides <200 mg/dL; non-HDL cholesterol <130 mg/dL	Bloods collected in fasting state if feasible

developing) cardiovascular disease there is no threshold below which a lower LDL level is not associated with clinical benefit [92]. Whether such benefits apply to hemodialysis patients is less clear. A recent Cochrane review [93] identified six randomized controlled trials that assessed the efficacy of statins in lowering blood lipid levels in hemodialysis populations [94–96] or in populations that included hemodialysis patients [97–99]. These trials are listed in Table 39.5. The authors of the review concluded that when patients were treated for 12 weeks, statins decreased blood cholesterol as effectively as in the general population, although based on these short-term studies they were unable to comment on safety and outcome benefits [93]. A large retrospective study including 3716 incident dialysis patients showed a 36% reduction in cardiovascular events in patients prescribed statins at baseline [100], suggesting that such patients may gain benefit from these agents. However, the

only published prospective randomized controlled trial examining the impact of statin therapy on outcomes among hemodialysis patients has not supported these observational data. In Die Deutsche Diabetes Dialyse (4D) study, 1255 patients with type 2 diabetes receiving hemodialysis were randomized to receive atrovastatin at 20 mg/day or placebo [101]. Active therapy was associated with a 42% reduction in LDL cholesterol levels but made no difference to the primary composite end point of fatal cardiovascular events, nonfatal myocardial infarction, and nonfatal stroke.

Two ongoing studies, the Study of Heart and Renal Protection (SHARP, with simvastatin at 20 mg and ezetimibe at 10 mg versus placebo) [102] and AURORA (A study to evaluate the Use of Rosuvastatin in subjects On Regular hemodialysis: an Assessment) of survival and cardiovascular events; using rosuvastatin at 10 mg versus placebo [103] will provide additional outcome data in

Table 39.5 Randomized trials evaluating the impact of statins on blood lipid levels in hemodialysis patients.

Study author [reference]	Patients	Treatment	% Change compared to baseline or placebo[a]			
			Cholesterol	LDL	HDL	TG
Fiorini [94]	12 HD	Atorvastatin, 10 mg titrating to 40 mg, vs. placebo	−26*	−36*		
Lins [95]	42 HD	Atrovastatin, 10–40 mg	−33*	−43*		
Diepeveen [96]	23 HD, 25 PD	2×2 factorial, Atrovastatin, 40 mg, and alpha-tocopherol 800 IU daily	−34 +1.9	−43 +4.4	−1.9 +4.8	−34 −4.2
PERFECT [97]	107 on HD or PD	2×2 factorial, simvastatin, 10 mg, and enalapril	−13*	−17*		−12*
Saltissi [98]	34 HD, 23 CAPD	Simvastatin, 5–20 mg, vs. placebo, both with dietary intervention	−21 −12	−25 −14	−6 −3	−18 −14
Chang [99]	62 HD	Simvastatin vs. placebo	−16 +2	−41 +3	+3 −3	−17 +2

Abbreviations: HD, hemodialysis; PD, peritoneal dialysis.
[a]*, treatment group significantly different from placebo or control.

hemodialysis populations consisting of predominantly nondiabetic patients. In the interim, the benefits of lipid-lowering therapy in such patients remains uncertain.

Conclusion

Optimal management of the hemodialysis patient should include attention to the more general aspects of care outlined in this chapter and requires a multidisciplinary approach. Failure to address specific aspects such as predialysis hyperkalemia can result rapidly in adverse events, whereas correction of complications such as hypertension and dyslipidemia may have long-term clinical outcome benefits. Despite a lack of robust clinical data, management of these general aspects of care of the hemodialysis patient is considered to be sufficiently important to justify inclusion of target ranges in most clinical practice guidelines. These targets are likely to need revision in the future as the results of outcomes trials become available.

40 Infections in Hemodialysis

Behdad Afzali & David J. A. Goldsmith

Department of Nephrology and Transplantation, Guy's Hospital, London, UK

Introduction

The number of patients referred for consideration of management of end-stage renal disease (ESRD) with renal replacement therapy (RRT) has continued to grow inexorably over the last 3 decades. This has arisen because of a large, mostly unreferred population who meet the criteria for chronic kidney disease (CKD) [1–4], together with increasing societal longevity, prosperity, and willingness to offer expensive medical therapies such as RRT [5,6].

Survival on RRT is markedly compromised by a combination of factors that include cardiovascular disease, malignancy, and infectious diseases. Infection is the second most common cause of death in this cohort and a very frequent cause of patient morbidity [7,8]. It thus constitutes a significant economic outlay [9]. In comparison to the general population, patients on hemodialysis (HD) are much more likely to die of infectious diseases [10], which is the result not only of a higher frequency of infections but also of greater severity of infections in these subjects [10].

Although this phenomenon can be partly explained by negative selection, that is, that healthier HD patients are selected for transplantation, there is nevertheless a very real susceptibility to infection in patients on HD, the etiology of which is multifactorial and includes a state of acquired immunodeficiency, immunocompromise, and increased risk of exposure to pathogenic microorganisms.

It is our intention in this chapter to describe the reasons for the increased risk for blood-borne bacterial infections in HD patients and to explore the evidence for prophylaxis, intervention, and treatment in this complex clinical situation as it relates specifically to infections of the dialysis access catheters. The epidemiology and etiology of non-access-related nosocomial infections that are nevertheless related to the dialysis procedure and the current guidelines for their prevention and management will be discussed in the next chapter.

Susceptibility to infection in patients receiving HD: immunodeficiency

Immunodeficiency can be acquired as part of the process of uremia and is demonstrated by the observation that responses to vaccinations in patients with CKD are poorer than in the general population [11–13] and become less pronounced as CKD progresses [14]. Defects in most components of the immune system have been described and include failure of T-cell costimulation [15,16], altered cytokine production [17], immune deviation toward Th1 responses [18,19], with consequent defective B-cell activity, dysregulation in innate immune mechanisms, defective phagocytosis [20], oxidative stress [21], and inhibition of cellular responses with iron therapy or iron overload [22–25]. In addition, immunodeficiency can arise as a direct result of the underlying cause of the renal failure (e.g. leukopenia in association with multiple myeloma [26] or HIV [27]) or as part of its treatment (e.g. immunosuppression for vasculitis [28]). These many predispositions are further exacerbated by contributory factors such as the marked trends in RRT populations towards increasing age and an increasing proportion of RRT patients whose ESRD has arisen secondary to diabetes mellitus [29]. Malnutrition is common in RRT populations [30] and is yet another factor strongly correlated with increased risk of infections.

Patients on HD are thus immunocompromised in many significant and complementary ways. In addition, there is another highly significant risk factor for infection in HD patients, the presence of plastic lines (dialysis catheters and pacemaker wires) and dialysis needles which circumvent immunological barriers (the skin) and provide ready access for microorganisms to reach the bloodstream. Not surprisingly, the presence of artificial vascular access for HD is the leading risk factor for the development of bacteremia in chronic HD patients [31]. Indwelling plastic materials and wires (as well as polytetrafluoroethylene used in arteriovenous grafts)

also act as niduses of microbiological colonization and subsequent infection, including endovascular infections such as endocarditis, inhibiting normal eradication of microorganisms by immune cells and antibiotics [32].

In-hospital HD exposes patients to hospital-acquired microorganisms, which are generally more fastidious and resistant to antibiotics than their community-acquired counterparts (although this pattern is slowly changing, with the emergence of more resistant organisms in the community [33,34]). Replacement of the endogenous flora with those from the hospital environment is therefore likely and is driven by repeated hospitalization and by the common use of broad-spectrum antibiotics. Many of the above factors also explain the increased incidence of *Clostridium difficile* in CKD and RRT populations. Not surprisingly, the repeated use of broad-spectrum antibiotics in this cohort of individuals has led to a selection in favor of the growth of resistant species, such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococcus, and others [35,36]. Nasal carriage of *S. aureus* is not only a prevalent finding in patients on HD (and in HD unit caregivers) but also a strong risk factor for bacteremic episodes [37–39]. A formal measure of prevalence of MRSA carriage in patients on HD in any specific country has not been published, but estimates in patients on peritoneal dialysis stipulate a carriage rate of around 16% [40]. Carriage rates are potentially higher among in-center HD patients, for whom the opportunity for colonization may be higher due to thrice-weekly close proximity to other recently hospitalized patients. Current recommendations in the USA do not require isolation of MRSA patients in free-standing dialysis units beyond universal precautions.

Additionally, HD patients can acquire infectious agents from a number of other sources, including exposure to intravenous substances (such as blood-borne viruses or translocation of skin organisms into the bloodstream during transfusions), dialysis water that may contain killed bacteria or bacterial products, such as endotoxin (fortunately, the occurrence of this in practice is very rare [41] and is reviewed in the next chapter). There are some risks associated with newer trends in HD practice, including bicarbonate-containing dialysate fluid, high-flux dialyzers, and dialyzer reuse, each of which may increase the threat of endotoxin transfer [42,43]. These risks are reviewed in the next chapter. Finally, "holiday dialysis" places the patient in contact with hospital organisms of the receiving institution (risking transport of potentially resistant bacteria between units [44]) and exposure to environmental pathogens, such as malaria-causing *Plasmodium* spp. and hepatitis A virus in certain parts of the world.

Infectious diseases in HD recipients can be divided into those that are related to vascular access and those that are not related to vascular access. Patients with non-vascular access-related infections are usually treated like patients without end-stage kidney failure, although the morbidity and mortality in HD patients presenting with septicemia or bacteremia are generally significantly higher, as these patients present by definition with at least one or-

gan failure (ESRD) and typically multiorgan failure, e.g. cardiac failure or cardiovascular disease.

The remainder of this chapter is focused on septic diseases related to vascular access in HD patients.

Infections related to vascular access

Dialysis-related infections (those that result from vascular access for HD) account for the significant majority of all infections in HD patients and can take a number of forms that will reflect the type of dialysis access *in situ*. Infection can be local or systemic, simple or complicated.

Local infections, as the name implies, are localized to catheter exit site and/or tunnel and may present as purulent drainage from the exit site or as cellulitis of the skin overlying a surgical access site (arteriovenous fistula [AVF] or graft [AVG]) or tunneled dialysis line. Systemic infections arise from infected dialysis lines or surgical access and show features of systemic sepsis, sepsis syndrome, or septic shock. Complicated infections are those in which the access infection results in the following: 1) loss of access because of access thrombosis or surgical excision necessitated for treatment of sepsis [45,46]; 2) metastatic infection from the infected access to distant sites resulting in infective endocarditis [49,50], osteomyelitis or septic arthritis [51], septic pulmonary emboli [52], intervertebral discitis [53,54], and spinal epidural abscess [55] (Table 40.1); and 3) sepsis syndrome and/or death. Infection arising within a thrombosis of a graft [47,48] is also considered a complicated infection.

The overall incidence of access-related infections reported by most studies is on the order of 5 episodes/1000 catheter days [56,57], but it varies according to access type (Table 40.2). As illustrated in Table 40.2, the lowest risk for infection is observed in patients with primary AVF. The risk with AVF is lower roughly by a factor of 4 compared to the risk with AVG, and the risk with AVG is an order of magnitude lower than the risk with tunneled catheters. The data in Table 40.2 have remained consistent in comparisons from country to country and over time. Tunneled cuffed dialysis catheters have a lower risk of infection than their "untunneled" counterparts [58–60].

Table 40.1 Incidence of complications of HD catheter-associated bacteremic episodes.

Complication	Incidence (%)
Sepsis syndrome	6.9–12
Endocarditis	5.8–9.8
Osteomyelitis	2.3
Septic arthritis	2.3
Septic pulmonary emboli	Not known
Spinal epidural abscesses	1.2
Death	12–25.9

Table 40.2 Incidence of bacteremic episodes according to form of dialysis access.

Vascular access type	Infection rate (no. of episodes/ 1000 catheter days)
Untunneled central venous catheters	5.0 (range, 3.8–6.5)
Femoral	7.6 (>10% after 1 wk)
Internal jugular	5.6 (>10% after 2–3 wks)
Subclavian	2.7 (>10% after 4 wks)
Tunneled cuffed central venous catheters	3.5 (range, 1.6–5.5)
Polytetrafluoroethylene arteriovenous graft	0.2 episodes/patient-year
Primary arteriovenous fistula	0.05 episodes/patient-year

Source: Reproduced from Saxena and Panhotra 2005 [156] with permission.

Table 40.3 Bacteria associated with HD catheter-related infections.

Organism	% of isolates[a]
Gram-positive cocci	52–70
Staphylococcus aureus	21.9–60
Staphylococcus epidermidis	8.8–12.6
MRSA	6.0–8.0
Enterococcus faecalis	2.4–8.0
Gram-negative bacilli	24–26.7
Pseudomonas aeruginosa	2.3–15.2
Escherichia coli	10.4
Acinetobacter species	12.8
Serratia marcescens	1.2–2.3
Klebsiella pneumoniae	6.4
Enterobacter cloacae	8.8
Polymicrobial	16.2–20

Source: Reproduced from Saxena and Panhotra 2005 [156] with permission.
[a] Figures are composites from a number of studies and therefore do not add up to 100%.

The higher risk associated with central venous catheters (CVCs), tunneled or not, may be mostly attributable to the formation of a highly organized bacterial biofilm, that is, a hydrated polymeric matrix containing bacteria in which individual bacteria live in specific "microniches" [61] on plastic surfaces [62], which excludes penetration by antibiotics [63], especially glycopeptides [64], and antibodies and which frustrates phagocytosis [32]. Episodic release of planktonic bacteria from the biofilm, which may be a programmed event [61], appears to precede bacteremia and septic symptoms [65]. Indeed, the majority of patients developing metastatic complications of dialysis-related infections are dialyzed via CVCs [66]. In the case of right-sided endocarditis, this may be, at least in part, due to the proximity of internal jugular CVCs to cardiac valves. This propensity for infection might account for the recently reported observations from epidemiological studies that consistently show higher mortality rates among patients dialyzing via a CVC or AVG compared with an AVF [67]. In one recent study, the adjusted relative hazard ratios for death were 1.5 and 1.2 for CVC and AVG, respectively, compared to AVF [67]. This may not be entirely attributable to increased infection rates, as there are likely to be several potential confounding factors; for example, patients referred late to dialysis services who have a higher mortality rate than early referrals [68–70] are more likely to commence dialysis via a CVC than are planned RRT starters. Additionally, patients with diffuse vascular disease ("vasculopaths"), who are generally older, more frail, and possess a greater background cardiovascular morbidity, are more likely to be dialyzed using CVCs. Furthermore, patients dialyzed via fistulae obtain higher blood flow rates on dialysis and obtain a greater effective dialysis dose per session. Vasculopaths, with probable concomitant coronary vessel disease, are more likely to be dialyzed via CVCs than are more fit subjects, who are often younger and in whom an AVF is more likely to mature and be employed successfully.

There are two distinct but overlapping time points for vascular access-related infections: primary infection, occurring at the time of access insertion, or secondary infection, which occurs later and is temporally related to use. In the case of CVCs, microbial infection can occur through the extraluminal or intraluminal routes, referring, respectively, to migration of bacteria from a contaminated catheter exit site down the catheter to the bloodstream or by translocation of bacteria from catheter hubs contaminated during manipulation [71–73]. The former occurs early (typically within less than 10 days [74]), whereas the latter occurs late (generally after 10 days [75]) after catheter insertion and is associated with the extent of and care in handling of the catheter.

The most frequent bacterial microorganisms associated with CVC-related infections are similar to the bacteria associated with infections of AVGs and AVFs (Table 40.3). Although these relative frequencies will differ from center to center, it is nevertheless the case that approximately two-thirds of all infections are caused by gram-positive organisms, whereas the remaining third are accounted for by gram-negative bacteria. Anaerobic, mycobacterial, and fungal infections are rare. The pathological determinants of infection relating to a CVC include the interaction between the material of which the catheter is constructed (some catheters, such as polyurethane, Teflon, and silicone elastomer, are more resistant to infection than polyethylene or polyvinyl chloride [76,77]), its thrombogenicity [78,79], and the virulence factors of local microorganisms. Not surprisingly, organisms with a predilection for skin colonization and biofilm formation are the most frequent causes of catheter-associated infection, and *S. aureus* (methicillin sensitive or resistant) heads the list [80]. Specific pathogenic mechanisms, such as adherence to host adhesion molecules on endothelial cells [81], extracellular matrix [82], platelets [83], and red blood cells [84], confer additional advantages to *S. aureus* in causing invasive and metastatic infections in this setting.

Management of access-related infections in HD

Management of access-related infections can be divided into measures aimed at prevention and those pertaining to treatment once infection has occurred. It is important to stress that although there have been a number of publications looking at the epidemiology of access-related infections and their associated mortality and morbidity, there have been no large-scale controlled trials of interventions aimed at prevention or treatment. Therefore, most guidelines and recommendations are not based on level A evidence.

Prevention of access-related infection
Insertion
Needless to say, primary catheter and surgical access infections can be significantly reduced by good aseptic barrier technique during insertion [85] and use of antiseptic solutions. There have been some suggestions from observational studies that chlorhexidine-based solutions (e.g. 2% in 70% isopropyl alcohol) may be superior to povidone–iodine [86,87]. With whatever cleansing solution is chosen, care is needed to ensure that the substance of the vascular catheter is not adversely affected (e.g. handling that leads to line splitting or disintegration). Polyethylene-based or polyvinyl chloride-based catheters should be avoided in favor of catheters based on polyurethane, Teflon, or silicone elastomer, as the former may be more prone to infection [76,77]. The site of catheter insertion may or may not alter the risk of infection. The evidence comparing the subclavian, jugular, and femoral sites is conflicting but suggests septic episodes are reduced if the subclavian route is selected [88–90]; nevertheless, most tunneled catheters for dialysis are inserted into an internal jugular vein, as the risk of subsequent venous stenosis is significantly higher when a catheters is placed in the subclavian location compared to the internal jugular vein.

Exit site cleansing and skin care
Application of dry gauze rather than transparent film dressings probably has little advantage in prevention of exit site colonization [91,92]. There may be a benefit in treatment of catheter exit sites with mupirocin ointment [93], although there also is a potential risk of damage to polyurethane- or silicone-based catheters from mupirocin [94–96] as well as a potential for development of mupirocin resistance [97]. There is likely, also, to be benefit from topical antiseptic agents, such as chlorhexidine and povidone–iodine [98,99] or other agents such as antibiotic and iodophor ointments [100,101], at the risk of favoring colonization of fungal species [100,101]. There is also evidence from a randomized controlled trial that topical application of honey to exit sites may be effective in reducing catheter-associated infections in hemodialysis patients, although this study was limited by a small number of subjects studied [102]. The maintenance of nursing staff experienced in the care of intravascular catheters [103,104] at adequate levels [105] is paramount. It follows from the evidence that ma-nipulation of HD catheters and changes of HD catheter dressings should only be performed by trained dialysis staff.

Dialysis cannula characteristics
Given that colonization and subsequent infection are the result of interactions between the catheter material and virulence factors of local microorganisms, a number of catheters are now available which are impregnated with antiseptic or antimicrobial agents. Although there is some evidence demonstrating effectiveness in reducing line-associated infections, one must acknowledge the caveat that the trials have almost exclusively involved the use of triple-lumen uncuffed lines *in situ* for short periods of time (typically less than 30 days). How these results extrapolate to dialysis lines maintained for much more prolonged periods is unknown. Broadly speaking, available impregnated lines include those manufactured with a covering of chlorhexidine and silver sulfadiazine either on the external surface [74,106] or on both the internal and external luminal surfaces [107]. Minocycline and rifampin [108,109], in addition to platinum silver [110], have also been tried, as has silver on the cuff alone [111]. The first two may offer short-term antimicrobial protection, directed mainly against *Staphylococcus epidermidis*, although the evidence is conflicting [74,106,108,109,112,113]. There are concerns about the possibility of selection in favor of resistant organisms [74], and there is an additional risk of anaphylaxis with catheters coated with chlorhexidine and silver sulfadiazine [114] with little evidence in favor of these agents [110,111,115,116]. There are some reports regarding the use of silver-impregnated lines in HD of humans and animals, but the studies have, in general, been small and largely inconclusive due to low event rates (reviewed in reference 117). The antibacterial properties of covalently linked heparin [118] and electrically charged catheters [119] require additional study, and the use of these strategies cannot be supported with the current evidence.

Antibacterial lumen locks
In recent years, some interest has focused on the utility of antimicrobial locks in vascular catheters. Three studies in neutropenic cancer patients compared the use of heparin versus heparin plus vancomycin [120,121] or heparin versus heparin plus vancomycin and ciprofloxacin [122], with encouraging results. In each case, the rate of bacteremia (with vancomycin-sensitive organisms) was lower with the antibiotic-containing locks than with heparin alone, and the time to develop bacteremia was longer. Nevertheless, these were small studies in cohorts that differed significantly from patients on HD, such that the findings may not easily translate to the HD setting. Small-scale randomized controlled studies in patients on HD evaluating gentamicin locks (with citrate or heparin as the anticoagulant) in comparison to heparin alone have shown a reduced incidence of bacteremia and longer catheter survival in the antibiotic treatment arm [123,124]. However, the number of patients recruited was and the duration of these trials was short; therefore, the long-term effects of this approach, namely, long-term efficacy, gentamicin ototoxicity [125,126], and emergence of antibiotic resistance, cannot be properly gauged. Similarly, a

citrate–taurolidine–containing lock solution has been reported to confer an advantage over heparin locking alone in the prevention of dialysis catheter-related sepsis, although this study barely reached statistical significance and the event rate over 90 days of follow-up (four infections vs. none) was small [127]. Given the uncertainties noted above regarding an optimal locking solution, whatever locking solution chosen, vascular access-related infection should be the subject of regular and continuing audit loops to ensure that any changes in clinical practice confer the expected benefits in morbidity reduction.

Because most studies have consistently shown *S. aureus* to be a major pathogen in dialysis-related infections and to be associated frequently with complicated sepsis, the development of vaccines against *S. aureus* has been an important goal in the prevention of dialysis-related infections. The first efficacy trial of a vaccine against *S. aureus* (against serotypes 5 and 8, which account for 85% of all clinical isolates [128]) at a high dose in patients on HD demonstrated an approximately 80% response rate by 2 weeks (i.e. in 80% of subjects an antibody response of at least 80 μg/mL, the minimum protective level, was elicited), which then fell to 26% by the end of the study period (54 weeks). Nevertheless, 11 of 892 versus 26 of 906 subjects developed *S. aureus* bacteremia in the vaccine and control arms, respectively [129]. Unfortunately, the promise of this intervention has not yet been fulfilled. The possibility of developing a "working" staphylococcal vaccine for the dialysis population should not be discounted at this time. However, consideration should be given to inoculating patients at a time before they reach ESRD in order to maximize the immune response to the vaccine, in much the same way as is currently recommended with the hepatitis B and pneumococcal vaccines. Attempts at eliminating nasal carriage of *S. aureus* by topical application of mupirocin ointment [130,131] or oral rifampin [132] are fraught with the potential for the emergence of resistance [131,133] and recolonization after discontinuation of the antibiotics [132] and are, therefore, not likely to be viable long-term solutions.

Despite the measures described above to reduce the incidence of dialysis access-related infections and the potential for future prophylactic regimens, it is clear that the most important method of minimizing infections from dialysis is to reduce the number of patients dialyzed via CVCs in favor of surgically fashioned access, preferably AVFs. Nevertheless, the worldwide trend accompanying the growth of the ESRD population has been an increase in the number of patients dialyzed via tunneled cuffed CVCs and AVGs in preference to AVFs [134]. With the "Fistula First" campaign in North America and many other regional and national initiatives has come the good news that AVF rates are now climbing again: in the UK (based on data from the UK Renal Registry 2005 Report [see chapter 6]), less than 70% of established HD patients were being dialyzed using definitive vascular access and less than 50% of patients known to renal care units started HD with definitive access. Staphylococcal blood infection rates averaged 13/year/100 patients, with 4 cases/year/100 patients being MRSA. It was estimated that about 8–10% of the national UK MRSA burden came from renal dialysis patients. This scandalous state of affairs has prompted much effort at vascular access service process redesign and numerous initiatives to reduce infections. This is not merely a reflection of limitations imposed by surgical theater time and surgical availability but a very real indication of increasing numbers of patients referred late to renal services who commence dialysis as hospital inpatients via plastic lines [68–70,135] and of patients who have already exhausted all other options for dialysis access.

Treatment of access-related infections

Correct treatment of access-related infection in patients on HD relies critically on early diagnosis and the clinical acumen and experience of the relevant clinicians. Excessive tardiness in removal of infected lines risks complications that include increased mortality and prolonged hospitalization, while overzealous line removal exposes the patient to unnecessary procedures which themselves carry an associated mortality and morbidity. In addition, many patients dialyzed through long-term tunneled lines have already exhausted other forms of access, thereby making line removal precarious. It is certainly in some cases a complex and difficult decision, and there have been no randomized controlled clinical trials or high-quality observational studies to help inform this decision.

The diagnostic criteria for HD catheter-related infections, as defined by the US Centers for Disease Control and Prevention [136,137], are summarized in Table 40.4, although there is some disagreement in the literature [138–140]. Unfortunately, while the diagnostic criteria are formulaic, in practice positive cultures are not always obtained, and when they are interpretation is problematic, as the positive predictive values of catheter and peripheral blood cultures are only 63% and 73%, respectively [141]. Clinical findings are not always reliable; fever, for example, has poor specificity, while encrustment or inflammation of an exit site has poor sensitivity. Furthermore, judgment plays an important role in the diagnosis and management of line-associated infections. Nevertheless, patients on HD who have a fever should have at least two sets of blood cultures sent to the laboratory before commencement of empirical antibiotic treatment.

In general, broad-spectrum antibiotics for common organisms are administered in the hope of eradicating the infection and decolonizing the line. Vancomycin and gentamicin offer coverage against most gram-positive organisms, including the increasingly prevalent MRSA and gram-negative organisms, and are the first-line choice for empirical treatment in many hemodialysis units (Renal Association Clinical Practice Guidelines 2007; http://www.renal.org/guidelines/module3b.html). However, these recommendations are tempered by concerns that overzealous use of vancomycin contributes potentially to the emergence of vancomycin-resistant bacterial species and that the use of gentamicin might contribute to a more rapid decline in residual renal function where preservation of the latter is associated in observational studies with some improvement in long-term outcomes and survival. Thus, whenever possible the antibiotic choice should be modified by initial response to empiric therapy and culture

Table 40.4 Diagnostic criteria for CDC definitions of HD catheter-related infections.

Infection type and criteria[a]
Catheter exit site infection
Erythema, tenderness, induration, or purulence within 2 cm of the skin at exit site of catheter
Positive culture of drainage material (if present)*
Catheter tunnel infection
Erythema, tenderness, induration, or purulence >2 cm of the skin at exit site of catheter
Positive culture of the drainage material (if present)*
Catheter colonization
No clinical symptoms or signs of infection
Positive culture from proximal or distal catheter segment
>1000 CFU on quantitative culture
≥ 15 CFU on semiquantitative culture (e.g. roll-plate method)
Catheter-related bloodstream infection
Clinical symptoms and signs of sepsis
Isolation of same organism from quantitative or semiquantitative culture of distal segment of catheter and from blood[†]
No other source of infection

Source: Summarized from references 136 and 137.
Abbreviations: CDC, Centers for Disease Control and Prevention; CFU, colony-forming units.
Note: Quantitative and semi-quantitative catheter culture methods are preferable over qualitative methods in which a single contaminating microbe can lead to false positive results (71;157).
[a] Symbols: *, laboratory confirmation is not a necessary requirement; [†], in the absence of laboratory confirmation, resolution of fever after removal of a vascular catheter suspected of infection can be considered indirect evidence of catheter-related bloodstream infection.

Table 40.5 NKF K/DOQI suggested indications for removal of infected HD catheters.

Type of infection and indication(s) for HD catheter removal
Catheter exit site infections[a]
Failure of infection to respond to antibiotic therapy
Catheter-related bacteremia[a]
Persistence of symptoms despite more than 36 h of appropriate antibiotic treatment
Any clinically unstable patient

Source: National Kidney Foundation 2000 [142].
[a] New permanent access should not be inserted until blood cultures, performed after cessation of antibiotic treatment, have been negative for at least 48 h.

results when these become available. The length of antibiotic treatment reasonably depends on severity of sepsis, presence or absence of complications (osteomyelitis, for instance, frequently requires long-term antibiotic treatment), and the microorganism and its sensitivity.

Although patients with mild line-associated infections do not usually require line removal, more severe infections usually necessitate prompt removal of the septic focus; in most cases this is the dialysis catheter. Similarly, single positive blood cultures in an otherwise-well patient usually require repetition rather than hasty administration of antibiotics or line removal. The National Kidney Foundation Dialysis Outcomes Quality Initiative's (K/DOQI) guidelines suggested indications for removal of infected HD lines [142] are summarized in Table 40.5. These guidelines are based principally on expert opinion and some observational data. To these, one should perhaps add that unless there are good reasons not to, lines should be removed where there is severe catheter tun-

nel infection unresponsive to antibiotics or in the presence of septic complications, especially endocarditis and septic embolization.

Although many of these end points seem indisputable, there are suggestions, from small studies, that some lines may be salvaged by antibiotic administration alone. The study of Marr *et al.*, for example, showed a 32% salvage rate of infected catheters through antibiotic treatment in a cohort of 38 bacteremic patients [51]. This approach is not entirely risk-free, and the potential for serious complications is appreciable [55]. Similarly, the K/DOQI guidelines advocate that at least 3 weeks of antibiotic treatment are required to eradicate catheter-associated bacteremia (although there is little compelling evidence for this value) and that blood cultures should be negative for at least 48 h before a new tunneled access is inserted [143]. An alternative approach is to replace the existing, infected catheter by exchange over a guidewire while covering the procedure with appropriate antibiotics, the theory being that exchange removes the biofilm as well as the catheter. This approach has met with some success in the small number of small-scale studies in the published literature. Some of these studies reported an almost 90% treatment success rate [144,145]; however, a high incidence of septic complications has also been demonstrated [146], calling into question the safety and utility of this approach.

Exclusion of antibiotics from bacteria growing in biofilms is a common cause of antibiotic failure in line-associated infections. Indeed, antibiotic concentrations must be several orders of magnitude higher (up to 1000 times) in order to kill bacteria in biofilms [147,148]. A number of investigators have, therefore, studied the efficacy of antibiotic locks for the eradication of colonization from infected lines. These have included vancomycin, gentamicin, amikacin, and ciprofloxacin. In general, the reports have been quite encouraging, with several authors demonstrating an almost negligible incidence of bacteremic episodes with this approach [149–151]. Nevertheless, this approach is far from commonplace at present, rarely works for fungal organisms [152], and would be inappropriate for the management of extraluminal infections.

It is important when considering the management of access-related infections in dialysis patients to actively look for the presence of complications, particularly when high-risk organisms are

encountered. *S. aureus* and *Candida* species, when presenting as causative organisms of line-related infections, are more likely than other organisms to be associated with complications [153]. *Candida albicans*, in particular, carries a risk of endophthalmitis [154], so attention to visual acuity and ophthalmoscopy should be mandatory in such cases. Persistent positive cultures for any organism (particularly after line removal) should prompt a search for new niduses of infection other than the line, in particular, cardiac valve vegetations and bone involvement [155].

Conclusions

The current risk of infection for HD patients remains unacceptably high. This clinical problem has largely remained unchanged over the situation seen when HD first emerged as a chronic therapy for ESRD and, as such, this is gravely disappointing. There are many competing and interacting reasons for the marked increase in infection in HD patients. These include the compromised immune systems of these patients consequent upon chronic uremia and dialysis-specific risks. The excessive use of CVCs is one of the most important potentially remediable infection risks in HD populations. Thus, no effort must go unspared in the timely formation of definitive vascular access (AVF). Recognition of the very strong patient benefits that result when HD is performed via an AVF has resulted in the "Fistula First" program as a priority for the US Centers for Medicare & Medicaid Services and US ESRD programs. Meticulous care to avoid microbiological contamination (whether using a CVC, graft, or AVF) in HD units is also of the greatest importance. Even with these precautions, the use of prophylactic procedures, such as exit site antimicrobial treatments, attempts to decolonize patients colonized with methicillin-sensitive or -resistant *S. aureus*, and CVC line locks should be seriously considered. Unfortunately, and disappointingly, there is very little high-quality evidence evaluating the effectiveness of any of these interventions in HD populations. This is a truly shocking state of affairs in the fourth successive decade of RRT, which has involved more than 2,000,000 subjects to date. Above all, detection and prevention of infection in this vulnerable patient group must be accorded the very highest priority by all responsible dialysis practitioners.

41 Non-Access-Related Nosocomial Infections in Hemodialysis

Brett W. Stephens & Donald A. Molony

Division of Renal Diseases & Hypertension, University of Texas Medical School, Houston, USA

Introduction

Infection is the second most common cause of death among dialysis patients, trailing only cardiovascular disease [1]. Although a significant focus has been placed on access- and catheter-related infections in hemodialysis patients, nosocomial outbreaks and the consequent potential transmission of infection to those on dialysis remains a significant issue. Patients on dialysis are at an increased risk of blood-borne viruses and bacterial infection from contamination [2]. The goal of this chapter is to review nosocomial, non-catheter-related infections that occur on dialysis as well as current guidelines on their prevention, with emphasis on dialysis quality control. Catheter-related infections will be covered in chapter 40.

Background

Several factors account for the pathogenesis of nosocomial infections in dialysis patients, including impaired host immunity, bacterial virulence factors, and exposure created by the dialysis procedure itself (Figure 41.1).

Neutrophils and cell-mediated immunity are both affected by uremia. Impaired chemotaxis, phagocytic activity, and apoptosis are all demonstrated by neutrophils, and decreased lymphocyte proliferation and immunoglobulin levels have been observed. Factors thought to contribute to these findings include malnutrition, iron deficiency or overload, hyperparathyroidism, element deficiencies, and uremia itself.

Increased virulence of bacteria is enhanced by protease, superoxide dismutase, catalase, polysaccharide biofilms, and adherence factors [3]. These patterns of resistance are amplified in nosocomial settings, where resistance is common.

The patient's skin, the water system, dialysate, dialyzer, medication vials, prior patients, and staff are all potential sources of contamination [3,4]. Strategies for prevention and management of these nosocomial infections are based on an understanding of their dialysis center-specific epidemiology.

Epidemiology

Several prior observational studies have shown sepsis rates to be around 11% among end-stage renal disease (ESRD) patients within the first several years of dialysis initiation [5]. A study of 393,451 dialysis patients from 1991 to 1999 showed hospitalization rates for sepsis within the first year of hemodialysis to range from 11 to 17% [5]. Septicemia accounts for more than 75% of infectious deaths, with annual death rates from pneumonia and septicemia significantly higher in dialysis patients than in the general population, from 10- to 100-fold higher in the 65- to 75-year-old age group [3]. The risk factors for increased incidence of infection and mortality among ESRD patients are summarized in Table 41.1 [1,3]. Hospitalization for septicemia in ESRD patients is associated with an increased risk of stroke, congestive heart failure, myocardial infarction, and peripheral vascular disease, both in the short term and up to 5 years after the event [3,6].

The recent HEMO trial by Allon and colleagues found an infectious etiology in 23.1% of all deaths, with an annual infection-related death rate of 3.8%. The annual rate of infection-related hospitalizations was 35%, with 77% of the cases being non-access-related [1]. In one study of 433 dialysis patients followed over a 9-year period, the infection rate was found to be 5.7 episodes/1000 days of dialysis, with 18% of the infections being nosocomial [7]. These were not, however, divided into catheter-related versus non-catheter-related infections in this specific study. No study to date has demonstrated the true incidence of nosocomial infections related to the dialysis procedure itself, but this likely remains an important potential source for infections.
Figure 41.1 Pathogenesis of nosocomial infections [3].

Dialysis-related infections

Bacterial infections

Outbreaks of bloodstream infections in dialysis centers are usually related to contamination of the water treatment and distribution systems, reprocessed dialyzers, or improper setup procedures. Most of our insights into these infections have come from epidemiologic investigations into nosocomial infection outbreaks. One report in Canada showed nine patients in whom *Enterobacter* bacteremia was diagnosed, which was traced to infected, incompetent one-way waste-handling valves. When the dialysis machine was primed, the arterial line was attached to the waste-handling option drain port to discard the saline. After priming, the line was detached from the port and attached to the patient's access. Disinfectants were run through the drain port per the protocol, but the

valves were not checked for competency, possibly allowing backflow of fluid. Cultured bacteria from the case patients and from valves showed identical genomic patterns, which were different from the sink cultures outside the room [8]. Three other similar outbreaks were reported in the USA, UK, and Israel in 1997 due to improperly functioning drain valves [9,10].

Another outbreak also reported during this time in Chicago included 29 episodes of bloodstream infections, with 21 hospitalizations for an average stay of 7 days. Again, the etiology was traced to improper handling of connections and faulty valves [4]. In 1996 the Centers for Disease Control and Prevention (CDC) and Gambro Healthcare surveyed 595 dialysis centers to characterize methods used to disinfect the machines and methods established for quality control. Responses showed that 62% were not disinfecting the sampling ports as often as recommended and only 14% performed the recommended daily quality control of the drain valves [9]. These findings underscore the importance of proper training and quality control measures.

In 1999, an outbreak of *Serratia* bloodstream infections and pyrogenic reactions was traced to contaminated single-use erythropoietin vials that had undergone repeated puncture [2]. Several case reports have also shown infection outbreaks attributed to improper sterilization of reusable dialysis filters [11].

Viral infections

Of particular concern for chronic dialysis patients is the transmission of viral hepatitis B and C, as well as HIV. In England in the late 1960s, there were 12 reported outbreaks of hepatitis B virus (HBV)

in dialysis centers that affected more than 300 patients and staff, with a reported mortality rate of 5% [12]. In the USA in 1974, the incidence of HBV was 6.2% for all dialysis patients. This number decreased to 0.06% in 1999 as a result of infection control, vaccination, screening of blood products, and identification and isolation of hepatitis B-positive patients on dialysis [2]. In other parts of the world, such as Africa and the Asia-Pacific region, the prevalence is reported to be as high as 20% [12]. HBV is transmitted by percutaneous or permucosal exposure to contaminated blood. It is a relatively stable virus that can remain viable at room temperature on environmental surfaces for up to 7 days. It may be present on equipment without any evidence of visible blood. Thus, outbreaks still occur when contaminated surfaces are touched by health care workers and spread to others. Other reports have shown transmission from infection control lapses, such as contamination of multidose medication vials [2,13].

Hepatitis C virus (HCV) has been reported to have an incidence of 0.73–3% per patient–year in hemodialysis patients in the USA, with prevalence rates varying from 8% to 59% worldwide [2,12]. Risk factors associated with HCV infection include a history of blood transfusions, the volume of blood transfused, and the number of years on dialysis [2]. In 2001 in France, an outbreak of 22 HCV infections in a single dialysis unit over a 9-month period was reported. No common risk factor or exposure could be found among the patients [14]. Nosocomial HCV transmission has been demonstrated in other dialysis centers, but the exact modes of transmission remain unclear. Studies have demonstrated that patient-to-patient transmission occurs via equipment, devices, multidose vials, and between patients on the same shift who do not share equipment [15]. Reuse of dialyzers has been implicated, and recent studies suggest that patients sharing machines may be at increased risk [2,12,13,15], although the CDC currently does not recommend isolation of HCV-positive patients [16]. Other viral hepatotropic viruses, such as hepatitis GB virus C, hepatitis G virus, and TT virus, have unknown clinical significance in hemodialysis patients [12].

HIV is transmitted by blood and bodily fluids that contain blood. No patient-to-patient transmissions have been reported in dialysis centers in the USA, but there have been case reports of needle stick transmission from patients to staff [2].

Other viral transmissions have been reported, including one case report of possible transmission of West Nile virus. In October 2003, the Georgia Division of Public Health was notified of two patients diagnosed with West Nile virus, both having been dialyzed on the same dialysis machine. They were the only two reported cases of West Nile virus in that Georgia county in 2003 [17], but other modes of transmission not related to dialysis could not be entirely excluded.

Water quality

Every week, dialysis patients are exposed to approximately 400 L of water used in the production of dialysis fluids. This water must meet certain quality standards, which are often stricter than municipal water standards. Municipal drinking water must satisfy standards of turbidity and contamination, all based on the assumption of limited intake of approximately 2 L/day/person. In addition, drinking water has the benefit of being filtered by the gastrointestinal mucosa, unlike dialysate. Thus, tap water must be thoroughly processed before dialysis. Water in the dialysis unit is not only used for dialysate production, but also it may be used for dialyzer rinsing and reuse [18].

Municipal water can contain a variety of chemical and microbiological contaminants. Mineral salts, agricultural products (fertilizers, nitrates, and pesticides) and discarded medications contaminating reservoirs and groundwater sources, heavy metals from pipes, and added agents from a processing plant (iron, aluminum, chlorine, fluoride) may all be present in low levels in drinking water. These amounts become significant when presented in large volumes of dialysate over time, and they have been found to cause acute and chronic poisoning syndromes (Table 41.2) [18]. Specific symptoms include nausea and vomiting, muscular asthenia, acidosis, hypotension or hypertension, hemolysis, anemia, encephalopathy, neurologic problems, fever, and bone alterations [19]. Microbiological contaminants include bacteria, endotoxins, and peptidoglycans, and rarely fungi, viruses, and protozoa. Most of the problems encountered with microbiologic contamination

Table 41.2 Maximum allowable contaminant levels in water.

Contaminant	EPA maximum contaminant level for drinking water (mg/L)	AAMI maximum contaminant level for dialysis (mg/L)	Lowest concentration associated with dialysis toxicity (mg/L)

in dialysate are related to the characteristics and maintenance of water treatment and distribution systems within the dialysis unit [18].

Many dialysis centers use an initial pretreatment of tap water with filters of different porosities to remove suspended particles. These filters also decrease the hardness of the water through sodium exchange cationic resins. Activated carbon filters then remove chlorine and other organic products. These filters, however, can serve as a medium for bacterial growth. Water is then processed by reverse osmosis, a process that involves bulk transport of water under pressure through a semipermeable membrane. This removes 95–98% of dissolved salts, bacteria, endotoxins, and substances with molecular masses of >200 Da [18]. Some centers use two reverse osmosis systems in series, and many combine another purification technique of deionization using ion exchange resins. Water is then distributed under hydraulic pressure to the machines. Reserve tanks are avoided, with the goal of continuous circulation and lack of stagnant zones. Sterilization of the entire system must be conducted at regular intervals [18]. The Association for the Advancement of Medical Instrumentation (AAMI) [20] and the European Pharmacopea [21] have established guidelines for the purity of water (discussed below).

Several studies over the last decade showed that 7.4–35% of all dialysis centers tested did not comply with the AAMI standards, and only 28% performed monthly disinfection procedures [18].

Many *in vitro* and clinical studies have evaluated differences in standard and sterile (ultrapure) dialysate. *In vitro* studies show that transfer of bacterial and endotoxin fragments across dialysis membranes is dependent on both the concentration of endotoxin and the type of membrane used [22]. Cuprophan membranes have the highest permeability to endotoxin [22]. Notably, only high concentrations of endotoxin typically transverse polysulfone or polyamide membranes [22]. Clinical studies have shown that patients dialyzed with ultrapure dialysate, compared to those dialyzed with standard dialysate, have slightly lower levels of C-reactive protein (in both groups, however, the C-reactive protein levels were within the normal reference range), β2-microglobulin levels, and incidence of carpal tunnel syndrome. These studies, however, have not demonstrated significant differences in such hard outcomes as mortality or cardiovascular events [23]. Studies have also shown some decrease in pyrogenic reactions with high-flux membranes when ultrapure dialysate is used [24]. Again, these differences were small and no convincing data have been reported to date that ultrapure dialysate reduces the generation of proinflammatory cytokines in patients [22]. Thus, there is currently no good clinical trials evidence that shows that ultrapure dialysate improves morbidity and mortality outcomes.

Dialyzer reuse

Since the early experimental years of dialysis, dialyzers have been reused and processed by various methods. Approximately 63% of centers in the USA reuse dialyzers for some of their patients. Japan

currently prohibits reprocessing of dialyzers, and reuse practices vary widely from country to country in Europe [11]. Cleaning and sterilizing methods have changed over the last century. The most common cleaning agents have been hypochlorite and hydrogen peroxide, and the most common sterilizing agents have been formaldehyde and peracetic acid. Heat sterilization has recently come into favor in combination with the above agents. Currently, a majority of centers in the USA use peracetic acid instead of formaldehyde, owing to the lower toxicity, easy removal from stored dialyzers, and decreased environmental problems. Its disadvantages include degradation by heavy metals and organic material at high temperature. Glutaraldehyde is also occasionally used as a sterilizing agent [11].

In 2002, the US Food and Drug Administration approved a new personal hemodialysis machine for home usage (Personal Hemodialysis System, PHD, Aksys, Ltd., Lincolnshire, IL). The machine reuses the dialyzer and lines so that they do not need to be changed more often than once monthly. The machine checks dialyzer performance and prepares ultrapure, infusion-quality dialysis solution. Prior to each dialysis, the entire system is filled with reverse osmosis water, heated to 85°C, and circulated for 1 h, sterilizing the entire system [11].

The advantages of reuse include potential cost savings and a potential for reduced frequency of first-use dialyzer reactions. The first use of dialyzers has rarely been associated with symptoms of respiratory distress, malaise, back pain, chills, or fever. This constellation of symptoms, termed the "new dialyzer syndrome," is thought to be due to traces of substances that remain from the membrane production processes [23], including possibly ethylene oxide, glycerol, alcohols, copper, cyanates, and polyurethane. Reprocessing of these filters causes leaching of these substances [11]. A study by Flemming *et al.* showed that the mean number of symptoms per patient was significantly higher with new dialyzers than with reprocessed ones [23]. New production and sterilization methods and changes in preuse dialyzer preparation within the dialysis unit have almost eliminated this new dialyzer syndrome.

Disadvantages of dialyzer reuse include allergic reactions to disinfecting solutions, residual chemical infusion, pyrogen reaction, inadequate concentration of disinfectant allowing for bacterial contamination, and changes in membrane integrity [23]. Allergic reactions have been seen with formaldehyde and glutaraldehyde exposure, and some association has been found between adverse reactions, angiotensin converting enzyme inhibitors, and reprocessed dialyzers [23]. Several infection outbreaks have been reported following insufficient concentration of sterilizing solutions [11,23,25]. Although some studies have reported an increased incidence of pyrogenic reactions with reuse, other studies have demonstrated the pyrogenic reactions are more strongly associated with dialysate contamination than with dialyzer reuse [23].

Other concerns with reuse include changes in membrane integrity and clearance. Studies in the 1980s showed that a 20% reduction in fiber bundle volume decreased clearance by only 4–11% [23]. Subsequent studies have shown that clearance of both

Study	No. of patients	Study design	Follow-up (years)	Outcome on mortality
Collins *et al.* 1998 [35]	34,348	Retrospective	2–3	No difference
Port *et al.* 2001 [26]	12,791	Retrospective	1–2	No difference
Collins *et al.* 2004 [27]	49,273	Retrospective	1–2	No difference
Lowrie *et al.* 2004 [25]	71,122	Retrospective	1	Mortality lower in those switched from reused to single-use dialyzer
Fan *et al.* 2005 [28]	75,831	Retrospective	1–2	No difference

Table 41.3 Studies on the association between mortality and reused versus single-use dialyzers.

Source: The studies reported in references 23–31 were reviewed.

large and small substances were maintained for up to 30 uses. Even high-flux dialyzers with blood flows of 400 mL/min and 80% fiber bundle volume maintain measured Kt/V values. These optimistic results are not uniformly observed. Thus, studies have shown conflicting results between various lots of the same dialyzers [23]. Additionally, studies have shown decreased Kt/V values with formaldehyde usage, with lower blood flows that result from fiber bundle volume loss and with increased numbers of reprocessing [23]. Thus, the National Kidney Foundation Task Force on Reuse of Dialyzers recommends at least monthly Kt/V or urea reduction ratio determinations to assess dialyzer performance [23].

Dialyzer reuse and mortality have also been examined in several large retrospective studies over the last decade (Table 41.3) [25–31]. Studies prior to this time were conflicting and were confounded by differing practice patterns, reuse procedures, dialyzer membranes, and patient characteristics. A large study of over 12,000 patients in the mid-1990s showed no discernible difference in mortality between single use and reuse and even demonstrated decreased mortality in reuse of high-flux membranes reprocessed with bleach [26]. A subsequent study in the late 1990s of over 49,000 patients confirmed no difference in mortality or first hospitalization between the single-use and reuse groups [27]. Medicare data in 2001 also showed no advantage to single-use dialyzers [28], but a recent study did show a survival advantage in patients who were switched from reuse to single use dialyzers [25]. There have been no high-quality prospective, randomized controlled studies to date to address this issue.

Current National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines recommend that dialysis centers reusing dialyzers do so in accordance with AAMI standards while monitoring for delivered dialysis dose [29].

Guidelines and recommendations

Immunizations

Immunization of health care workers with the hepatitis B vaccines has been shown to reduce HBV events, and it should be routinely implemented for all health care and dialysis staff. A 2005 Cochrane systematic review of 21 trials showed that plasma-derived and recombinant vaccines are equally effective in eliciting antibody levels, with the deltoid intramuscular site preferred. The standard vaccination schedule (0, 1, and 6 months) elicited a better antibody response than the rapid vaccination schedule (0, 1, and 2 months), but it is unclear if booster vaccinations to nonresponders enhance seroconversion [32].

Given the occasional outbreaks of hepatitis in dialysis centers, hepatitis B vaccination should be considered for all ESRD patients. A 2004 Cochrane systematic review of chronic kidney failure patients and hemodialysis patients receiving hepatitis B vaccine did not, however, demonstrate any difference between immunized patients and the placebo group in HBV infection rates [33]. The studies did not show any adverse events secondary to vaccination, however, and so additional randomized trials need to be conducted to provide more sound clinical guidance on this question. The Advisory Committee on Immunization Practices currently recommends that adult dialysis patients receive the hepatitis B vaccine series, pneumococcal vaccine, yearly influenza vaccinations, tetanus-diphtheria toxoids, and varicella vaccine, if susceptible. Antibody levels for HBV should be checked annually and boosters considered if levels are below protective levels [34].

Isolation

Isolation practices for HBV were first implemented in 1977 after factors for transmission were identified. The US CDC recommends routine serologic surveillance of patients and staff, separate isolation rooms for HBV-positive patients, assignment of designated staff and equipment to HBV-positive patients and not to susceptible patients during the same shift, routine cleaning and disinfection of nondisposable items and surfaces, and glove changes between each patient (Table 41.4). With the implementation of these recommendations, a 70–80% reduction in transmission of HBV in hemodialysis facilities has been seen, with occasional outbreaks occurring when there has been a breakdown in one of the above guidelines [6,16].

HCV transmission has been attributed in various studies to contaminated hands of staff members, shared multidose vials of parenteral medications, and inadequate sterilization of dialyzers and machines. No conclusive evidence has shown that HCV is transmitted through sharing of the same machine when proper infection control measures are used, but no studies have proven the contrary [13–15,35]. Recent studies, however, have found

Table 41.4 CDC infection control guidelines for dialysis centers.

Topic	Recommendation(s)
Infection control precautions	Use gloves when touching patient equipment
	Wash/cleanse hands between patients
	Use dedicated supplies at each station
	Prepare all medication in a separate clean area
	Deliver medication individually without common medication carts
Disinfection	Clean environmental surfaces (chair, countertops, external control panel of dialysis machine) after each patient treatment
Cleaning of areas	Designate separate clean areas for storage and preparation of medications; keep contaminated products out of the clean area
Routine serologic screening	Determine HBV surface antigen (HBsAg) level on admission and monthly in HBV-susceptible patients
	Determine anti-HBs antibody titer yearly in those with established protection to evaluate need for booster
	Determine anti-HCV antibody titer semiannually in HCV-susceptible patients
Vaccinations	Vaccinate all susceptible hemodialysis patients and staff
Isolation	HBV-positive patients should be in a separate room.
	HBV-immune patients can be a buffer between the isolation room and HBV-susceptible patients
	Staff should not be assigned to both HBV-positive patients and susceptible patients during the same shift
	HCV-positive patients require no special isolation

Source: Alter *et al.* [16].

associations with transmission and machine usage, and trials of isolation of HCV-positive patients have reported decreased transmission rates [15,36]. The CDC does not, however, recommend isolation of HCV patients. They have concluded that evidence of sufficient strength does not exist to justify these measures [16] beyond universal infection control procedures.

Universal infection control procedures recommended by the CDC include using gloves when touching equipment, washing hands between patients, dedication of supplies to each dialysis station or disinfection before returning to a common area, preparing medications in a separate clean area, keeping contaminated products out of the clean area, and avoiding common medication carts (Table 41.4) [6].

No special isolation precautions have been recommended to date for HIV-infected dialysis patients [16].

Water control

AAMI guidelines [20] state that water used in dialysate production should contain a total microbial count of less than 200 colony-forming units (CFU)/mL and an endotoxin concentration of less than 2 endotoxin units (EU)/mL. At levels of 50 CFU/mL and 1 EU/mL, respectively, AAMI standards require that actions be taken, such as disinfection of the components of the water purification and processing system and dialysate preparation and storage reservoirs where indicated by the culture results. After disinfection of the system, retesting is required by AAMI standards to confirm

improvement in levels and to prevent levels from reaching unacceptable ranges. Microbiologic monitoring should be performed at least monthly, and chemical contaminant monitoring should be done yearly if reverse osmosis and deionization are used. Guidelines for levels of residual sterilization chemicals (Table 41.5) and recommended features of purification systems have also been established. The AAMI has also set guidelines for maximum allowable levels of contaminants. The European Pharmacopoeia has set slightly stricter standards for microbiologic content, with a microbial count of less than 100 CFU/mL and endotoxin concentration of less than 0.25 EU/mL [20].

Dialyzer reuse

AAMI guidelines state that dialyzers used on HBV-positive patients should not be reprocessed. Otherwise, the decision to reprocess dialyzers is left to the physician, and informed consent must be

Table 41.5 Limits on disinfectant residues.

Disinfectant	AAMI recommended limit (mg/L)
Formaldehyde	<5

[a]Limit based on dialyzer manufacturer's suggestion.

obtained from the patients. The AAMI guidelines allow for a 10% variance of urea clearance after processing but recommend that the dialysis prescription account for these changes. Fiber bundle volume should be at least 80% of the original volume. Various recommended concentrations and contact times for the sterilizing agents used in cleaning and storage of reprocessed dialyzers have been established and depend on the properties of the sterilizing agents used [20].

Summary

Nosocomial infections related to the dialysis process, although uncommon, continue to occur. An understanding of their etiology and strategies for their prevention have emerged largely from observational studies and evaluations of nosocomial infection outbreaks. These observations have led to the current guidelines that govern the technical aspects of handling of water purification, production and delivery of dialysate, cleansing of equipment, handling of medications, and infection precautions as they relate to patients and staff. Reprocessing of dialyzers introduces additional opportunities for transmission of infection. The benefits and risks of dialyzer reprocessing and optimal therapeutic strategies to minimize risk have not been rigorously investigated with randomized controlled clinical trials. Rigorously conducted clinical trials are needed to address unambiguously the contributions of reuse, if any, to the transmission of bacterial, viral, and fungal infections, to the incitement of an inflammatory cascade that could result in a further deterioration in the immunocompentency of ESRD patients, to the induction of pyrogenic reactions from allergic or chemical exposures or endotoxins, and to overall morbidity and mortality.

42   Vascular Access for Hemodialysis

Kevan R. Polkinghorne

Department of Nephrology, Monash Medical Centre, Melbourne, Victoria, Australia

Introduction

Hemodialysis is the dominant form of therapy for patients with end-stage renal disease and requires repetitive, complication-free access to the peripheral blood circulation. Hence, the establishment and maintenance of vascular access is pivotal and has long been labeled the "Achilles' heel" of hemodialysis due to its vital role in the delivery of dialysis [1].

Vascular access for hemodialysis can be achieved in three ways: the native arteriovenous fistula (AVF), the arteriovenous graft (AVG; usually polytetrafluoroethylene), or the cuffed (or uncuffed) central venous catheter (CVC). The main role of the cuffed CVC is as a bridge until either an AVF or an AVG can be constructed or as permanent access in the patient who has exhausted all other vascular access possibilities.

It is well-established that the vascular access of first choice is the AVF [2–4]. This stems from both superior patency rates [2,3], lower infection risk [5], lower costs [6,7], and a lower mortality risk compared with either AVG or CVC [8,9]. Clinical practice guidelines for the USA [3], Canada 4], and Australasia [2] all indicate that AVF is the vascular access of first choice for hemodialysis patients.

Recent randomized controlled trials (RCTs) have focused on the maintenance of vascular access and can be divided into three broad areas: first, the use of vascular access surveillance in prolonging vascular access survival; second, pharmacological approaches to preventing AVF and AVG failure; finally, therapies for preventing cuffed CVC-related bacteremia (CRB). In this review I will summarize the results of RCTs in these three broad areas.

Screening and vascular access survival

Once vascular access has been established, the major clinical goal is to prevent complications, principally, vascular stenosis resulting in failure (thrombosis) of the AVF or AVG. Screening tests must be efficient at detecting the presence of an underlying significant stenosis, and any correction of a stenosis thus detected should result in a reduction in access thrombosis rates and prolonged access survival. The ability to prevent AVF and AVG failure is an important clinical goal, as early elective repair can avoid interruption to dialysis. Several methods have been advocated as screening for access stenosis, including dynamic venous pressure (DVP) and static venous pressure (SVP), Doppler ultrasound (DU) screening, and the measurement of vascular access blood flow (Qa) 3,4].

Blood flow screening: RCTs

Vascular access blood flow can be measured by indicator dilution techniques or by estimating Qa using either DU or magnetic resonance angiography [3]. Prospective studies including one RCT [10] have sought an association between Qa and the risk of thrombosis and/or the presence of stenosis [10–15]. AVGs are at risk of thrombosis at higher flows (cutoffs of 500–750 mL/min) [12,13] and AVFs are at risk with lower flows (300–500 mL/min), which makes comparisons difficult [15]. All RCTs reporting the effect of Qa surveillance on vascular access survival or thrombosis rates have used ultrasound dilution to measure Qa, and the principles of this method have been well-described [16,17] and reviewed [18–21].

Five RCTs have examined the effect of Qa surveillance and preemptive repair (angioplasty in the majority of studies) on vascular access thrombosis rates and long-term access patency [22–26] (Table 42.1). All studies were small, of variable quality, and used different monitoring frequencies and flow thresholds for the triggering of investigation.

The three studies on AVGs failed to demonstrate a benefit of Qa surveillance despite significantly higher intervention rates in the surveillance groups [23–25]. In one study the Qa group had a significantly higher thrombosis rate than the control group, this being driven largely by multiple thromboses in three AVGs [24]. The positive result in the smallest study was largely driven by an abnormally high thrombosis rate in the control group [22]. Finally, in the study by Smits *et al.* [23], 21 of the 42 thrombotic episodes

Table 42.1 RCTs assessing effects of access blood flow surveillance on access thrombosis rate.

[c] DU was performed every 6 months in all patients.

[d] Further surgical intervention required in 10%.

[e] Results here for the Qa arm versus control.

[f] Overall failure including thrombosis and abandonment HR for control versus treatment (95% CI, 1.42–10.93).

occurred after a positive screening test but before intervention and were excluded from the analysis, reducing the power of the study. Despite this, no difference was seen in thrombosis rates in the Qa surveillance group compared with the control DVP groups.

In the above three negative studies, there were more interventions performed in the Qa surveillance groups, suggesting that more stenoses had been detected, particularly in the two more recent studies [24,25]. Furthermore, in these two studies preemptive angioplasty was performed in all patients, and in the study by Smits *et al.* over 90% of the interventions included angioplasty [23]. The efficacy of the angioplasty procedure in the Qa group is thus in doubt. An increase in Qa immediately postangioplasty, and not necessarily with radiological success (reduction in the stenosis diameter), has been shown to predict outcome postangioplasty [27,28]. However, Qa was not measured immediately postangioplasty in these studies, although Moist *et al.* reported no difference in the postangioplasty Qa rise between the two groups, suggesting that the angioplasty procedures in both groups were equivalent. Whether elective surgical revision of the AVG stenosis would have resulted in an improved outcome has not been studied in any RCT. However, there is evidence that surgical revision may be superior to angioplasty in the treatment of AVG thrombosis [29].

Both studies of AVF demonstrated a significant reduction in thrombosis rate with Qa surveillance. One [22], while positive, had a unusually high background thrombosis rate in the control arm (27.1% in 6 months). There were some methodological flaws in the Tessitore group's study of stenotic AVF [26]. Randomization was by coin toss, and there was no blinding of surveillance allocation. Patency of the AVF in the Qa group lasted significantly longer

than the control group; the specific thrombosis rates in each group, however, were not reported. In addition, a third study that randomized functioning stenotic AVF to angioplasty or no treatment demonstrated a significantly improved AVF survival with angioplasty [30]. These three small studies thus suggest possible benefits of Qa surveillance on AVF survival. However, before definitive recommendations can be made, a larger multicenter study is required. Assuming an annual AVF thrombosis and revision rate of 12–15%/year [31], at least 300 subjects would be needed in each arm to detect a reduction of 30% (relative risk [RR], 0.70; 90% power) in AVF thrombosis and revision rates as a result of Qa screening [10]. Such an RCT is also required to determine whether AVF screening is cost-effective [32].

DU stenosis screening: RCTs

DU screening is a noninvasive procedure that in addition to the measurement of Qa can provide anatomic information on the vascular access. As such, it has been advocated as a screening technique to identify access that is at risk of thrombosis by identifying the anatomic presence of a significant stenosis. It requires, however, specialized equipment and skill and is expensive. A discussion of the technical aspects of DU is beyond the scope of this review, but these issues have been recently summarized by Lockhart and Robbin [33].

Six RCTs [24,34–38] assessing the effect of DU screening for stenosis of AVGs combined with either angioplasty or surgical repair on access thrombosis and survival have been performed (Table 42.2). One study was published in abstract form only [36]. All trials excluded AVF. Two [36,37] of the six studies demonstrated a

Table 42.2 RCTs assessing effects of ultrasound stenosis screening on AVG patency or thrombosis.

Study [reference]	No. of patients	Control	Surveillance	Blinding	ITT	Intervention	Patency[a]	Follow-up
Mayer 1993 [34]	70	Clinical	3 monthly USS	No	Yes	Surgery	80% vs. 62%	2 yrs
Lumsden 1997 [35]	64	No intervention	3 monthly USS	No	Yes	PCTA	51% vs. 47%	2 yrs

[d] Patency defined as thrombosis or need for preemptive PCTA.

[e] Patency data were not presented in the study report; unadjusted relative risk of access failure in control was 3.75 (95% CI, 1.7–8.1).

[f] Cumulative survival.

significant increase in patency rates with DU screening and preemptive angioplasty, whereas another study [34] demonstrated a significant reduction at 6 but not at 12 months follow-up. In addition a subanalysis of the study by Lumdsen *et al.* assessing only new AVGs ($n = 21$) [39] demonstrated a significant prolongation of AVG patency ($P = 0.035$) and a reduction in thrombosis rate in the treatment group (0.10 vs. 0.44 thrombosis/patient–dialysis year). The DU arm in another study [24] had the highest preemptive angioplasty rate and a longer thrombosis-free survival, although this outcome did not reach statistical significance ($P = 0.10$). However, neither event-free survival nor 2-year AVG survival (62 vs. 64%) was significantly better in the ultrasound group. The authors have subsequently argued that DU screening, whereas not prolonging AVG survival, reduces morbidity and costs through the reduction in thromboses and less interruption to the hemodialysis treatment [40]. In the most recent study [38], while the frequency of preemptive graft angioplasty was 64% higher in the ultrasound group (1.05 vs. 0.64 events/patient–year; $P < 0.001$) due to an increase in the detection of AVG stenosis, the cumulative graft survival was similar (median survival, 38 vs. 37 months for the DU and control groups, respectively; $P = 0.93$). The thrombosis rates also did not differ (0.67 vs. 0.78/patient–year in DU and control groups, respectively; $P = 0.37$). As with the surveillance studies (Table 42.1), the largely negative results of these trials raise questions on the efficacy of angioplasty to correct the underlying stenosis. However the only study to use surgery also failed to demonstrate any conclusive benefit [34] from DU-based surveillance.

Other screening techniques: RCTs

Numerous other techniques have been advocated, including physical examination and the measurement of access recirculation (AR), dynamic, and/or static venous pressures. Physical examination of the access plays an important role, and some have suggested that this element has been largely ignored [41,42]. Physical findings suggesting a significant venous stenosis include edema of the access extremity, prolonged bleeding postvenipuncture, and changes in the physical characteristics of the pulse or thrill.

AR resulting in reduced dialysis efficiency occurs when the dialyzed blood, returning via the venous needle of the extracorporeal circuit, is taken up again through the arterial needle, bypassing the systemic circulation. It occurs, within the AVG or AVF, when Qa is less than the dialyzer blood flow (Qb) [43]. Thus, the presence of AR signifies a reduced Qa resulting from the presence of a hemodynamically significant stenosis. The clinical usefulness of AR measurements in AVG surveillance is limited because the risk of thrombosis in AVG is high once Qa is reduced to 500–800 mL/min, a range of blood flow which is too high to cause AR [3]. Unlike AVG, AVF blood flow can be decreased to below prescribed dialyzer blood flow and still maintain patency. Thus, the measurement of AR can be a useful tool to detect AVF stenosis, although there have been no RCTs performed to date to evaluate this approach. The measurement of AR using saline dilution failed to detect a significant number of patients with documented low AVF blood flow and thus does not indicate any extra benefit to Qa monitoring [14,44,45].

Pressure within AVGs and AVFs can be considered as a surrogate of blood flow, but the relationship between pressure and flow differs between them (reviewed in reference 46). Pressure is measured either at the venous drip chamber during dialysis (DVP) or with the blood pump stopped (SVP). The standardized methods for measuring both DVP and SVP are outlined in the latest National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines [3]. Schwab *et al.* [47] first described an association between raised DVP and the presence of AVG stenosis at the venous anastomosis and subsequently developed a screening and monitoring protocol [48]. Serial measurements should be performed with the trend being more important than single values, remembering that any lesions within the body of an AVG will not be detected if proximal to the venous needle [45]. Given the problems associated with measuring venous drip chamber pressure;

Besarab *et al.* suggested the measurement of intra-access pressure [45,49]. While they demonstrated a reduction in the thrombosis rate using historical controls [49], at present no RCT of either dynamic or intra-access pressure measurements in AVG or AVF has been performed. An RCT of SVP monitoring versus clinical evidence of access dysfunction in AVG [50] showed screening using SVP with angioplasty did not prolong AVG survival, with a trend to a poorer outcome in the SVP group (hazard ratio [HR], 1.75, 95% confidence interval [CI], 0.80–3.83; $P = 0.16$). After adjustment for gender, diabetes, PVD, and access location, the SVP group had a significantly greater risk of access abandonment (HR, 2.91; 95% CI, 1.17–7.20; $P = 0.02$) despite a significantly higher intervention rate. While venous pressure monitoring is widely practiced, the evidence that the detection and treatment of a significant stenosis in AVG prolongs graft survival is of poor quality and requires further study. Since the presence of collaterals prevents the rise in venous pressure consequent to a reduction in Qa due to a stenosis, K/DOQI has not recommended DVP to detect significant stenoses in AVF [3]. Furthermore, normalized venous segment pressures do not correlate with the presence of significant AVF stenosis [45].

Pharmacological approaches to preventing AVF and AVG failure: RCTs

The use of antiplatelet or anticoagulant agents or other drugs to prevent AVF and AVG failure was first discussed in 1967 [51], with a number of studies performed from the mid-1970s using antiplatelet agents [52–55]. Subsequently, with the increased morbidity associated with AVG thrombosis, a number of larger RCTs have recently been performed [56–58]. In addition there are at least two large multicenter studies under way, one with clopidogrel in AVF [59] and one using dipyridamole plus aspirin in AVG [60].

Nine RCTs have been performed, with the majority of the studies using antiplatelet agents [52–56,61] (Table 42.3). One study assessed low-dose warfarin [57] and one evaluated fish oil [58]. In addition, a Cochrane systematic review was published in 2003 [62] that included studies published up to October 2002.

All four RCTs for AVF have assessed the effect of aspirin or ticlopidine on early AVF failure (at 1 month) [52,54,55,61]. One of the study end points was AVF patency rather than its successful use for dialysis. Two of the three smaller studies demonstrated a significant reduction in thrombosis rates in the treatment group [52,55]. However, a subsequent larger study, underpowered due to slow recruitment and a lower-than-expected event rate, failed to confirm this [61].

Four studies assessed thrombosis in AVG at different follow-up times [56–58,63]. Sreedhara *et al.* [63] compared aspirin alone, dipyridamole alone, and dipyridamole plus aspirin with placebo in AVG. Thrombosis rates in the dipyridamole group were significantly lower compared with placebo, while aspirin was associated with a nonsignificant increased thrombosis rate. The combination of aspirin and dipyridamole gave a nonsignificant reduction compared with placebo. The study comparing the combination of

[b] New AVG only.

[c] Cumulative thrombosis rates at 18 months.

[d] RR, 0.35 (CI, 0.15–0.80).

[e] RR, 1.99 (CI, 0.88–4.48).

[f] RR for this comparison was not given in the paper.

[g] This study was stopped early during recruitment due to adverse effects (see text).

aspirin and clopidogrel with placebo was stopped early due to a twofold increase in the incidence of bleeding events in the treatment group [56]. Overall there was no difference between the two groups in terms of thrombosis rates (HR, 0.81; 95% CI, 0.47–1.40; $P = 0.41$). Thus, at present the evidence that antiplatelet agents prevent thrombosis in AVG is weak, and the combination of agents may cause harm with increased bleeding risks.

The use of low-dose warfarin (international normalized ratio [INR], 1.4–1.9) compared with placebo was addressed in a well-designed study with blinding of both patients and physicians by using central warfarin monitoring and sham INR values [57]. Treatment with warfarin did not reduce the thrombosis rate; rather, there was a nonsignificant increase in thrombosis rate (HR, 1.76; 95% CI, 0.72–4.34; $P = 0.21$). In addition six major bleeding events occurred in the warfarin group compared with none in the placebo group ($P = 0.03$). Finally, Schmitz *et al.* [58] performed a small RCT assessing fish oil (80% ω-3 fatty acid ethyl esters) versus a control oil (corn oil). Fish oil produced a significant reduction in the thrombosis rate, 24.4 versus 85.1% in the control group at 1 year ($P < 0.05$). Given the small sample size, a confirmatory trial

with a larger sample size is needed to confirm not just the efficacy but also the safety of this treatment before fish oil treatment can be recommended.

Preventing cuffed CRB: RCTs

With the increasing use of cuffed CVC, the prevention of complications related to their use has become a major focus [64]. Commencement of dialysis with a CVC is associated with a higher risk of infectious and all-cause mortality [9], and different strategies to prevent CRB have been the subject of a number of RCTs in the last 5 years. Here I will focus solely on RCTs primarily assessing interventions aimed at reducing cuffed (tunneled) CRB, given that they are the predominant CVC used in chronic hemodialysis patients.

Such trials can be divided into two broad groups; those where the intervention is administered at the exit site to reduce skin bacteria and subsequent catheter colonization, and those where antibiotic catheter lock solutions are instilled to limit the formation

Table 42.4 RCTs of prophylaxis of cuffed (tunneled) CRB in hemodialysis patients.

of a biofilm, which can act as a nidus for CRB. In addition, one study compared silver-coated CVC to standard CVC and did not demonstrate any benefit [65].

All eight studies of catheter lock solutions [66–73] demonstrated a reduction in CRB; although the reduction was not statistically significant in two studies [67,72]. Two other studies demonstrated a significantly lower CRB-related mortality in the antibiotic lock group [69,70]. There are, however, concerns regarding gentamicin-induced ototoxicity [71], the use of high-dose citrate potentially causing fatal arrhythmias [74], and the emergence of antibiotic resistance [75]. Therefore, the optimal antibiotic lock solution has yet to be determined [75].

Three studies have investigated the use of exit site ointment on CRB; two compared an antibiotic ointment to placebo or no ointment [76,77], and a third compared mupirocin with honey [78] (Table 42.4). Both mupirocin [77] and polysorin ointment [76] significantly reduced the incidence of CRB compared with placebo or no treatment although in the mupirocin study the CRB rate in the control group was unusually high. Johnson *et al.* then compared honey with mupirocin [78], given the concerns regarding the emergence of mupirocin resistance [79]. This novel study did not demonstrate any difference in CRB rates between the two interventions, but the study was small. The use of honey would avoid the emergence of antibiotic resistance and is worth further investigation. Whether antibiotic lock solutions are more effective than exit site ointment is currently unknown; the rates of CRB seem similar across the studies, but no RCT has compared them directly.

Conclusions

The establishment and maintenance of vascular access for hemodialysis are major components in the treatment of end-stage renal disease patients. An AVF is the first-choice vascular access for hemodialysis, and attempts to increase the prevalence of AVF have been a major focus of care [2–4]. In addition a large number of recent RCTs have assessing different strategies aimed at maintaining vascular access survival. Further large trials are needed to assess possible cost and benefits of access surveillance and pharmacological interventions to prevent access thrombosis, especially in patients with AVF. Catheters will continue to have a role, and further studies are needed to determine the most effective and safe methods of preventing CRB.

7 Chronic Kidney Disease Stage 5: Peritoneal Dialysis

43 Selection of Peritoneal Dialysis as Renal Replacement Therapy

Norbert Lameire, Raymond Vanholder, & Wim Van Biesen

Renal Division, Department of Internal Medicine, University Hospital Ghent, Ghent, Belgium.

Introduction

Patients with end-stage renal dysfunction (chronic kidney disease [CKD] stage 5) will need replacement of their failed kidney function to maintain homeostasis and remain alive.

This renal replacement therapy (RRT) has to comply with some basic objectives: 1) prolong the survival of the patient as much as possible; 2) improve the quality of life (QoL) of the patient as much as possible; 3) be affordable for all patients and societies. There are three major RRT modalities that can be offered to the patient with CKD stage 5: peritoneal dialysis (PD), hemodialysis (HD), and transplantation. Maximal conservative treatment should also be considered, especially in the elderly or in severely disabled patients.

A recent Cochrane review [1] demonstrated the lack of strong evidence to support preferences of one dialysis modality (PD vs. HD) over the other. This review suggested that a randomized controlled trial (RCT) should be performed on this topic. Until now, only one RCT to compare outcomes between HD and PD patients has been conducted [2], but it was terminated prematurely because of problems with patient recruitment, showing that such a randomized trial is not feasible in clinical practice. In addition, there is evidence indicating that a succession of modalities in a flow chart model rather than a "conflictive" (one vs. the other) model should be the preferred methodology to describe and analyze RRT modalities and their outcomes [3]. Indeed, instead of considering HD and PD as competitive methods, it makes more sense to consider them as synergetic methods, in view of the probabilities of technique failure of both modalities [4]. This view holds true for transplantation also, as a transplant kidney will not be immediately available for everybody, thereby necessitating a period on either PD or HD. Technique failure is also a common outcome of transplantation, resulting in patients having to switch back to PD or HD. This model of integrated care (Figure 43.1), in which pa-

tients are offered the three different modalities in a predefined way, according to the needs of the moment, is therefore suggested as the optimal model to maximize survival of patients with end-stage renal disease (ESRD) [5].

Factors driving modality selection

It is clear that modality selection is driven by both medical and nonmedical factors.

Nonmedical factors

Nonmedical factors are far more important in the decision making process for RRT modality selection than previously thought [6–8]. Some important nonmedical factors are the referral pattern of the patient [9,10], the patient education process [11,12], the reimbursement of the different modalities [13,14], and experience of the treating team with PD [8,15].

All epidemiological studies have unequivocally demonstrated that patients who have been referred to a nephrology center less than 3 months before start of RRT are unlikely to start with PD [9]. Some studies indicate that merely "early" referral is not enough to increase the likelihood of patients starting on PD but that a structured education program about the different RRT modalities is necessary [16–20]. This type of pre-ESRD education has a beneficial impact on the overall outcome for the patient, both for life expectancy and QoL. PD patients are more likely to be transplanted in the first year of RRT, which is probably also related to their better preparation [20,21].

There is evidence that it is less costly to treat a patient on PD, compared with HD, even when transfers from PD to HD have been included [22]. HD has a greater labor and "hardware" cost, compared to PD, whereas the biggest costs for PD are the disposable materials [14]. PD also has some hidden economical advantages: no need for patient transport, reduced erythropoetin requirement [23], and fewer investigations, especially for biochemistry and radiology. Given these data, as expected, PD is used more frequently than HD in otherwise-comparable situations and countries with a

471
Figure 43.1 Schematic representation of the integrated care concept. Patients with a GFR below a certain threshold should be timely informed about the different treatment options for renal replacement therapy (PD, HD, and TX), taking into account eventual medical contraindications. As a patient's residual renal function declines, renal replacement therapy is started at a level where there is beginning to be uremic damage (e.g. decline of nutritional parameters, incipient fluid overload, etc). Eventual transfers between modalities are planned in function of development of eventual side effects of these modalities.

public-based versus a private-based organization of ESRD health care [24].

Medical factors
Patient survival
Modality choice should be based on relative survival. As transplantation is not an option for many patients, most studies have tried to compare HD and PD as opposite modalities (Table 43.1). There are major differences in statistical and epidemiological approaches in these studies, resulting in apparently conflicting results [25,26]. Some studies evaluated "modality survival," the survival on one single modality with patients being censored at their transfer to another modality. Other studies have used an intention-to-treat principle, where patients were assigned to the modality they started

Table 43.1 Overview of studies comparing outcomes on PD and HD since 1995.

RRT on, even if they transferred to another modality. Large differences in outcome and interpretation might also arise with the choice to select prevalent (patients already on RRT) or incident (only patients starting newly on RRT) patients, or a mixture [27]. All these studies are confounded by differences in patient mix, differences in experience with one of the two modalities, and differences in technique survival of the two modalities. The difference in technique survival is especially important, as most patients on PD will be transferred to HD during the course of their treatment, or they will be transplanted. Therefore, the question should not be which single RRT modality should be used but which flow chart or succession of RRT modalities will result in the most optimal patient survival: the integrated care approach [5].

There are several theoretical arguments why PD should be a good modality to start RRT: preservation of residual renal function [28,29], avoidance of blood-borne infections [30], better outcome after transplantation [31–35], lower cost [22], and better QoL [2,36,37]. However, with time there might be deterioration of the peritoneal membrane [38] and of residual renal function [39], making adequate PD more difficult and leading to technique failure. In the landmark paper on integrated care, it had already been reported that patients who were maintained on PD too long had a worse survival than those transferred in a timely manner onto HD. Other studies have found an increased mortality in the year after transfer from PD to HD [40,41], a sign that these patients have probably been maintained too long on PD. A timely transfer should be encouraged in such circumstances. In contrast, other patients can be maintained on PD for years, without any change in peritoneal membrane function [42,43]. Differences in genetic makeup [44] and comorbidities probably play an important role in the rate of decline of the peritoneal membrane.

There is also compelling clinical and epidemiological evidence that PD has advantages as the first RRT modality [45–47]. The single randomized trial of PD and HD suggested that PD may have improved survival compared with HD [2]. Evidence coming from large registries and other observational studies also supports the idea that survival is optimized by starting patients on PD and transferring them to HD (Table 43.1).

Quality of life and socio-economical considerations
QoL is an important, but sometimes neglected, issue in RRT. Depression, detected by a simple question on the mood of the patient, was the single best predictor of outcome on RRT [48]. Comparison of QoL with different treatments is difficult, especially in a heterogeneous population like the ESRD population, where different comorbid conditions might have a larger impact on the QoL than the RRT modality per se. Generally, most studies show that QoL is better in PD than in HD patients, certainly in the first year of treatment [49]. Some authors found no difference in QoL between the modalities after 1 year, but that may have occurred if lower QoL domains were falsely attributed to comorbid conditions such as anemia when they should have been more properly considered an effect of the modality itself [50]. Several studies have pointed to a higher employment rate in PD patients [51,52], but this might be attributable to the differences in case mix. There appears to be a beneficial effect of patient education programs [49] on QoL and patient satisfaction, and some advocate that the higher QoL and satisfaction in PD patients is attributable to this better education rather than the modality. It is conceivable, but data are lacking, that the sense of self-determinism felt by PD patients and having their treatment under their control invokes positive feelings early, but that the constant strain that this responsibility brings, and the increasing complexity of the exchange schedule with declining residual renal function, ultimately leads to burnout.

PD in special patient groups

Diabetics
The outcome for diabetic patients with ESRD is severely compromised by the presence of multiple comorbidities leading to increased cardiovascular risk. Diabetic ESRD patients have mortality rates twice that of nondiabetic patients. Comparisons of outcomes of diabetic patients on HD versus PD are conflicting. In the USA, the PD/HD death rate varies with age and gender [53]. For male patients, there is no difference in outcome between PD and HD. For patients younger than 50 years, there is a definite survival advantage with PD. For female patients older than 50 years, there is an increased mortality risk on PD. In Europe and Canada, in contrast, outcomes of PD and HD patients with diabetes appear to be comparable [47,54]. There is thus no clear reason to withhold PD from diabetic patients, with the exception of older, female diabetic patients.

Anuric patients
Because of the importance of residual renal function (RRF) on survival of PD patients, the use of PD in anuric patients has been discouraged [55]. However, RRF is also an important predictor of outcome in HD patients. Due to the intermittent character of HD treatment, the absence of RRF might be even more dangerous if dietary restrictions are discarded, as suggested by higher mortality in HD patients after a weekend [56,57]. Meanwhile, several large studies have demonstrated that PD in anuric patients is feasible [58,59] and leads to acceptable outcomes. However, to our knowledge, no comparative trials of PD versus HD for anuric patients are available.

It is uncertain whether adequacy standards are achievable in anuric patients, especially those with a higher body mass [58]. Ademex and EAPOS confirm that small-solute clearance is not an important predictor of outcome [58,60]. In EAPOS, ultrafiltration of more than 750 mL/day and nutritional status were related to survival [58]. Therefore, if patients do well clinically on PD and maintain a good nutritional and volume status, there should be no reason to transfer them to HD if they become anuric. Vigilance for overhydration, uremic symptoms, and deterioration of nutritional status should be high in these patients. Because of the importance of maintaining volume status and minimizing glucose load, icodextrin should be used in anuric patients [61,62].

Cardiac patients

Given that uremia is a risk factor for cardiovascular disease [63], there is no evidence that PD provokes more *de novo* heart disease than HD [54]. The emergence of hypertension and left ventricular hypertrophy in PD patients is related to their capacity to maintain an optimal fluid status, i.e. to their residual renal function [64] and their ultrafiltration capacity, although some recent studies have found that the prevalence of left ventricular hypertrophy in ESRD might be overestimated [65]. The use of icodextrin is a useful tool to help maintain adequate ultrafiltration, especially in patients with a more permeable membrane (fast transporters) [61,62], but dietary sodium restriction should also be emphasized, in view of its substantial impact on outcome [66,67].

In patients with preexisting coronary heart disease, it has been suggested that there is a higher mortality on PD than HD [68]. In patients with preexisting congestive heart failure, a poorer outcome was reported for PD than HD patients in one study [69], although another study on the same study population found a higher incidence of *de novo* heart failure in HD patients [70]. Both these studies were large but were retrospective and nonrandomized. As recently reviewed, these studies have some particular sources of bias which mean that the results cannot be generalized [71]. In short, there was a large difference in experience with HD and PD, with about 90% of patients being treated by HD. In addition, the exclusion of patients who died in the first 3 months of treatment biased in favor of HD. Also, both studies only evaluated US Renal Data System (USRDS) PD patients, who had no opportunity to be treated with icodextrin, which could have had an impact on mortality, especially in the patients with congestive heart failure.

In some single-center nonrandomized studies in patients with congestive heart failure, PD has been shown to have a beneficial effect on hospitalization, functional status, and QoL compared to medical treatment alone [72–76]. There is not a higher incidence of stroke between HD and PD patients when there is adjustment for cardiovascular risk factors and blood pressure control [77].

Elderly

Globally, the ESRD population is growing exponentially, and a majority of this increase is among elderly patients. PD has some advantages in these frail patients, such as the continuous, more stable nature of the treatment, in contrast with the fluctuating effects of HD, and home-based care. In addition, the metabolism and muscle mass of older patients is generally low, so that lower fill volumes and/or reduced numbers of exchanges are often sufficient to obtain efficient clearance. Outcome studies of PD in the elderly report acceptable results, comparable with those obtained with HD [17,78], although in the USA a higher mortality has been reported on PD [79].

Some elderly patients are not capable of self-treatment, and so PD may require intensive home-based nursing [80]. Others may prefer the social contact of the dialysis unit and its nursing staff and fellow patients and so opt for HD.

Large or heavy patients

Because of the caloric load inherent in glucose-based PD solutions and the difficulty of achieving standard adequacy measures of small-solute clearance in large or heavy patients, PD has been discouraged in overweight and obese patients. A large observational study [81] found that overweight patients were less likely to start on PD, but if they did, their survival was superior to their smaller counterparts. Abbott *et al.* [82] could not confirm a survival advantage for heavier patients in their analysis, although there probably was some overlap in the populations between the two studies. A large Australian observational study [83] found an increased mortality risk in overweight patients. All these studies are hampered by the lack of a reliable definition of "overweight," as body mass index (BMI) does not discriminate between fat and muscle mass, which have opposite effects on outcomes [84]. This is suggested because of the observation that BMI is positively related to outcome in African Americans (who had a higher muscle mass as the cause of their higher body mass) and negatively related to outcome in females (in whom body mass was mostly increased because of an increase in body fat content). As a general rule, in large, muscular patients where the BMI is mainly fat-free body mass, there is no contraindication for PD. In patients with a high BMI and a high fat mass, data are conflicting. In patients with a large abdominal girth, the abdominal fat mass precludes the use of large intraperitoneal volumes and the choice of PD should probably be discouraged [84].

PD before transplantation and in failed transplant patients

Failed kidney transplantation is one of the increasingly common reasons to start RRT. Assuming the integrated care concept, the impact of the pretransplant RRT modality on the longevity of transplant and patient survival should be considered, as well as whether PD is a suitable modality after transplantation. Here again, available data are from registries and single-center case series, as no RCTs are available.

It was previously thought that PD might have some detrimental impact on transplant survival, but it is now clear that transplant and patient survival after renal transplantation are at least equal to [85,86] or even better [31,32,34] in patients transferring from PD compared with HD. There is no reason why PD should not be started in patients on the waiting list for kidney transplantation.

For the question of whether PD is a suitable therapy after failed transplant, the evidence is even more scarce. From the Australian–New Zealand Registry [87], it is apparent that the survival in new patients starting on PD is comparable to those who start PD after a failed transplant. Some single-center studies [88,89] have shown that survival of patients with failed kidney transplant might be comparable on HD and PD. For the important question of whether it is better to maintain immunosuppression, to preserve RRF as long as possible, or to withdraw it, to avoid infections and other complications, there is no evidence and a randomized trial is warranted.

In conclusion, there is no evidence that PD cannot be advocated in specific patient groups, such as diabetic patients, anuric patients, cardiovascularly compromised patients, patients with failed transplants, or large patients. The evidence seems to indicate that the quality of care and the experience of the center are more important in the determination of outcome than the modality choice by itself.

44 Small Solute Clearance in Peritoneal Dialysis

Sharon J. Nessim & Joanne M. Bargman

Department of Medicine, Division of Nephrology, University of Toronto, Toronto, Canada

Introduction

The ideal method for assessing the adequacy of peritoneal dialysis (PD) has yet to be determined. Early studies attempting to quantify dialysis dose in hemodialysis patients used urea as a putative low-molecular-weight uremic toxin, eventually leading to the establishment of Kt/V_{urea} as a useful proxy for small solute clearance [1,2]. This term, Kt/V_{urea}, factored in several important parameters, including clearance of urea (K), time on dialysis (t), and the urea distribution volume, or total body water (V). At approximately the same time as the studies on Kt/V_{urea} were emerging in the hemodialysis literature, there was a relative paucity of data on quantification of dose of PD, with only one group addressing kinetic modeling of peritoneal transport [3,4]. The data on Kt/V_{urea} in hemodialysis were therefore extrapolated to PD, with the addition of creatinine clearance (CrCl) as an additional proxy. While the current approach to PD adequacy hinges on these measures of small solute clearance, little attention has been paid to clearance of higher-molecular-weight uremic toxins, the so-called middle molecules.

Investigations of the impact of PD dose have largely focused on patient survival, but they have also looked at several other outcomes, including technique survival, hospitalization, nutritional status, and quality of life. In this chapter, we will focus on the existing evidence with respect to the impact of peritoneal solute clearance and residual renal function (RRF) on patient survival, as well as evidence for the targets that are currently in use. We will also discuss strategies to optimize peritoneal solute clearance and preserve RRF, providing evidence when available.

Assessment of small solute clearance

Our understanding of the impact of small solute clearance on patient survival in PD has evolved over time. Early studies suggested

a beneficial effect of small solute clearance as assessed by Kt/V_{urea} and CrCl on survival. The largest of these early studies was the CANUSA study, which evaluated the association between adequacy of PD and patient survival among 680 incident continuous ambulatory peritoneal dialysis (CAPD) patients over 2 years [5]. In this study, total (renal and peritoneal) small solute clearance was found to be an independent predictor of patient survival. Based on a fitted model, there was a 5% decrement in expected patient survival for every 0.1 decrease in total weekly Kt/V_{urea} for values between 1.5 and 2.3 and a 7% decrement in expected survival for every 5 L/week/1.73 m^2 decrease in CrCl. The assumption was that peritoneal and renal contributions to small solute clearance were equal and therefore additive. Improved patient survival with higher clearance was also noted in a 3-year prospective study of 68 CAPD patients reported by Maiorca *et al.* [6]. In that study, a weekly total Kt/V_{urea} of >1.96 was an independent predictor of better patient survival. In a retrospective study by Genestier *et al.*, 201 incident CAPD patients were divided into three groups according to achieved Kt/V_{urea}, either <1.7, 1.7–2.2, or >2.2 [7]. After a mean of 2 years, a Kt/V_{urea} of <1.7 was independently predictive of a higher mortality, with a relative risk (RR) of 1.69. Four additional studies, using univariate models, reported improved survival with weekly Kt/V_{urea} values of at least 1.5, 1.89, 2.0, and 2.0 [8–11].

Based on these data, in 1997 the Kidney Disease Outcomes Quality Initiative (K/DOQI) of the National Kidney Foundation in the USA published guidelines for clearance targets [12]. The guidelines suggested that for CAPD patients, the delivered PD dose should be a total Kt/V_{urea} of at least 2.0 per week and a total CrCl of at least 60 L/week/1.73 m^2. Recognizing that this CrCl target was difficult to achieve in patients with slow peritoneal transport status in the absence of RRF, in 1999 the Canadian Society of Nephrology suggested that two CrCl targets be provided, depending on the patient's peritoneal membrane characteristics [13]. Specifically, the CrCl target remained 60 L/week/1.73 m^2 in high and high-average transporters but was lowered to 50 L/wk/1.73 m^2 in low and low-average transporters. This recommendation was later adopted in the 2000 iteration of the K/DOQI guidelines [14]. In patients on

automated PD (APD), although no data were available relating delivered dose of dialysis to patient outcomes, the guidelines recommended slightly higher targets based on the more intermittent nature of APD. For continuous cycling peritoneal dialysis (CCPD), the predominant form of APD, the suggested delivered dose was a total Kt/V_{urea} of at least 2.1 and a total CrCl of at least 63 L/week/1.73 m^2. For nocturnal intermittent peritoneal dialysis (NIPD), the suggested delivered PD dose was a total Kt/V_{urea} of at least 2.2 and a total CrCl of at least 66 L/week/1.73 m^2.

Since the initial studies on which the 1997 and 2000 K/DOQI guidelines were based, several new and important studies have led to the reevaluation of the impact of small solute clearance on outcomes. In 2002, the ADEMEX trial was published [15], representing the largest randomized controlled study published in the PD literature. Its purpose was to assess the effect of small solute clearance on survival. In this study, 965 incident and prevalent PD patients were randomized to a standard CAPD regimen of 2-L exchanges four times daily or a modified dialysis prescription to achieve a peritoneal CrCl of >60 L/week/1.73 m^2. In order to achieve this, individual dwell volumes were increased, followed by the addition of a fifth dwell if the target was not reached by 2 months. Patients were followed for a minimum of 2 years, with a primary end point of death. The mean age of patients enrolled was approximately 47 years, with an incidence of preexisting ischemic heart disease that was low in both groups (<5%) and not different between the two. Whereas the intervention group had significantly higher peritoneal Kt/V_{urea} (2.13 vs. 1.62) and peritoneal CrCl (57 vs. 46 L/week/1.73 m^2) than the control group, there was no difference in patient survival (69.3% vs. 68.3% at 2 years). The major cause of death in both groups was ischemic heart disease. In the control group, a higher death rate due to congestive heart failure and a combination of uremia, hyperkalemia, and acidosis was reported. It should be noted that hyperkalemia and acidosis are complications that rarely occur in PD patients, and it is especially rare to be severe enough to cause death. Because a composite end point of death due to uremia/hyperkalemia/acidosis was used, it is possible that uremia accounted for the majority of the difference between the groups. It is also reported that more patients in the control group withdrew from the study because of uremia. Unfortunately, uremia was not specifically defined, and because the study was not blinded, this may have introduced a significant bias. Knowing which patients were receiving a lower dialysis dose may have led physicians to attribute nonspecific symptoms or death in the control group to uremia. With regard to the higher mortality related to congestive heart failure in the control group, this is not necessarily attributable to underdialysis. Rather, it can be explained by a difference in ultrafiltration attributable to the use of an additional exchange in 22% of patients in the intervention group. In fact, the intervention group had approximately 100 mL/day more ultrafiltration on average than the control group. In contrast to peritoneal clearance in this study, renal Kt/V_{urea} and renal CrCl did emerge as predictors of improved outcome, with an RR of 0.89 per 10-L/week/1.73 m^2 increase in CrCl and 0.94 per 0.1 increase in Kt/V_{urea}.

A second randomized, controlled trial by Lo *et al.* confirmed the lack of survival benefit with increased peritoneal clearance [16]. In this study, 320 incident CAPD patients were randomly assigned to one of three groups: Kt/V_{urea} of 1.5–1.7, 1.7–2.0, or >2.0, and followed over 2 years. Patients with an initial renal Kt/V_{urea} of >1.0 were excluded. Renal Kt/V_{urea} in the study patients was not significantly different between the groups, so that the difference in Kt/V_{urea} was accounted for by differences in peritoneal clearance. Overall 2-year patient survival was 84.9%. After adjustment for age and diabetes, total Kt/V_{urea} did not affect survival in patients with Kt/V_{urea} of >2.0 versus 1.7–2.0, although there was a trend toward better survival in patients with Kt/V_{urea} of 1.7–2.0 versus 1.5–1.7 ($P = 0.054$).

Several observational studies have supported the findings from these randomized trials. The largest study was by Diaz-Buxo *et al.*, who retrospectively analyzed a cohort of 1603 prevalent PD patients for factors associated with a higher mortality over 1 year [17]. Although RRF was strongly correlated with patient survival, peritoneal clearance was not. Rocco *et al.* performed a prospective study in which a cohort of 873 prevalent PD patients followed for 7 months [18]. Again, while the peritoneal clearance achieved was not predictive of outcome, residual renal CrCl and renal Kt/V_{urea} were associated with improved patient survival. A subsequent reanalysis of the CANUSA data, focusing on the relative contributions of renal and peritoneal clearances, provided further supportive data for the impact of RRF on survival [19]. For each 5-L/week/1.73 m^2 increase in renal CrCl there was a 12% decrease in the RR of death. Furthermore, each 250-mL increment in urine volume was associated with a 36% decrease in the RR of death. Neither peritoneal CrCl nor peritoneal ultrafiltration was associated with patient survival. Several other prospective [20–22] and retrospective [23–25] studies have demonstrated a survival benefit with increased renal clearance, with two exceptions [26,27].

Other studies have also demonstrated a lack of survival benefit of increased peritoneal small solute clearance [26,28]. In a study by Jager *et al.*, peritoneal clearance was found to be an independent predictor of outcome, but this was only significant when solute removal was assessed by dialysate urea and creatinine appearance and not when measured by Kt/V_{urea} or CrCl [29]. Unfortunately, interpretation of dialysate urea and creatinine appearance can be problematic, because they are proportional to protein intake and muscle mass, respectively, and well-nourished patients would be expected to have a more favorable outcome. Only three prospective studies using Kt/V_{urea} and/or CrCl have shown a statistically significant beneficial effect of peritoneal clearance on survival, and these have all been in patients with little or no RRF [20,30,31]. The first study to show a positive effect of peritoneal clearance was reported by Szeto *et al.* and involved 140 anuric CAPD patients followed for 22 months [30]. In this group, there was a 6% decrease in the RR of death with an increase in Kt/V_{urea} of 0.1 U/week and a 12% decrease in the RR of death for each 5-L/week/1.73 m^2 increase in peritoneal CrCl. The same investigators subsequently evaluated 5-year follow-up of 270 incident and prevalent CAPD patients with a median residual glomerular filtration rate of

0.82 mL/min [20]. Whereas higher peritoneal Kt/V_{urea} was associated with improved survival generally, this was only the case for prevalent CAPD patients, a group with minimal RRF. A more recent study by Jansen *et al.* followed a cohort of 130 anuric CAPD patients over 2 years [31]. In these patients, peritoneal Kt/V_{urea} and CrCl were not associated with survival when analyzed as continuous variables, but when the results were analyzed dichotomously, a weekly Kt/V_{urea} of <1.5 and a weekly CrCl <40 L/1.73 m^2 were associated with an increased RR for death. Another study to address the issue of solute clearance and survival in anuric patients was published by Bhaskaran *et al.* [32]. In this retrospective cohort study of 122 CAPD and APD patients, after a median of 19.5 months of follow-up, there was a trend towards decreased mortality in those with a peritoneal Kt/V_{urea} of ≥ 1.85, although the results did not reach statistical significance (RR of death, 0.54; $P = 0.10$). Patients in these studies were mostly or entirely dependent on peritoneal clearance, suggesting that the beneficial effect of higher peritoneal clearance might be more apparent in those lacking RRF. Although the latter four studies suggest a possible benefit of greater peritoneal small solute clearance in anuric patients, there are some data to suggest that this may not be the case. In a prospective study involving a cohort of 177 anuric APD patients followed over 2 years, CrCl was not found to be a predictor of patient survival [33]. Furthermore, in a subgroup analysis of the ADEMEX trial, there was no difference in mortality when patients were stratified for anuria [15]. The studies assessing the effect of small solute clearance on patient survival are summarized in Table 44.1, while those studies specifically addressing clearance in anuric patients are summarized in Table 44.2.

Overall, there is now evidence from two randomized trials and several supporting observational studies that although total clearance is important, improved patient survival is related to renal clearance and not to peritoneal clearance. The basis for the survival advantage associated with RRF is unclear, with several possible contributors. First, the presence of residual urine output facilitates volume management, which may have a favorable effect on blood pressure control and subsequent left ventricular remodeling. Both hypertension and left ventricular hypertrophy are associated with loss of RRF [34,35] and are known to be independent predictors of mortality in PD patients [36]. Secondly, RRF allows for clearance not only of small solutes but also middle molecules [37–39]. The latter are not as easily removed across the peritoneal membrane due to the time dependence of their diffusion and the limited permeability of the peritoneal membrane. Finally, patients with preserved RRF may represent a population who are intrinsically healthier, and thus more likely to survive.

Recommended targets and monitoring of PD adequacy

Although increasing peritoneal clearance does not appear to provide benefit within the dose ranges studied, it is likely that there is a minimum total clearance below which outcomes are affected

[7,8,16,31]. We therefore recommend a *minimum* total Kt/V_{urea} of at least 1.7 per week in all PD patients. The most recent K/DOQI guidelines and International Society of Peritoneal Dialysis guidelines have not included a peritoneal CrCl target [40,41], but the European guidelines consider CrCl to provide added predictive value and continue to recommend a CrCl target of at least 50 L/week/1.73m^2[42]. It is important to point out that although these minimum targets do not differentiate between renal and peritoneal contributions, it is clear that renal and peritoneal clearance are not simply additive, in that any small solute clearance provided by residual renal function is accompanied by improved clearance of middle molecules and better salt and water control.

Because of the limitations of our current techniques to assess clearance, a patient's clinical status must always be taken into account when trying to determine the adequacy of dialysis. The outcome of interest in the studies discussed has principally been survival. There are no rigorous studies prospectively examining dose of PD and health outcomes other than death. Therefore, the guidelines all suggest that the dose be increased as a trial in the patient not doing well for reasons not explained by comorbidity, regardless of their current prescription.

In order to ensure a minimum total delivered Kt/V_{urea} of at least 1.7, solute clearances can be followed with the use of 24-h collections of dialysate and urine. While data on frequency of measurements are sparse, we would recommend the following schedule. The first measurement of peritoneal and renal Kt/V_{urea} should be performed approximately 1 month after initiation of PD. Subsequent monitoring of peritoneal clearance is somewhat controversial. Although the K/DOQI guidelines recommend checking peritoneal clearance at least once every 4 months, the peritoneal Kt/V_{urea} is unlikely to change in patients with a stable PD prescription. Therefore, an alternative approach would be to remeasure peritoneal clearance only if changes are made to the PD prescription or if there is deterioration in the patient's clinical status. In the event of an episode of peritonitis, peritoneal clearance measurements should not be made until at least 1 month after resolution of the peritonitis. If a patient has >100 mL/day of residual urine output and achieving a total weekly Kt/V_{urea} of at least 1.7 is dependent on the renal contribution, a 24-h urine collection to assess renal Kt/V_{urea} and urine volume should be performed at least every 2 months in order to avoid missing a decline in RRF.

Strategies for optimizing peritoneal solute clearance

The routine measurement of small solute clearance serves to screen patients for evidence of underdialysis. If a patient is not meeting the minimum recommended PD dose, the reason for this should be determined. Before assuming that a given PD prescription is inadequate, patient-related causes of failure, such as noncompliance, lack of understanding, or sampling and collection errors, should be sought. If none of these potential causes is found, several

strategies can be employed to optimize a patient's PD prescription in order to improve peritoneal solute clearance. Common interventions include increasing the individual dwell volumes, increasing the frequency of daily exchanges, or increasing peritoneal ultrafiltration [43,44]. Whereas the focus of these interventions is often to increase peritoneal small solute clearance, the importance of middle molecule clearance must also be considered, especially in patients with little or no RRF.

Table 44.2 Summary of studies assessing effects of small solute clearance on survival in anuric PD patients.

Study	Study design	No. of patients	F/U (mos)	Predictor	Outcome
Paniagua 2002	RCT (subgroup analysis)	527	22	Kt/V ↑ 0.1 U/wk	$P = $ NS

Increasing dwell volumes is an effective means by which peritoneal small solute clearance can be increased in both CAPD and APD patients [45]. The increase in Kt/V$_{urea}$ and CrCl is due to both an increased plasma-to-dialysate concentration gradient [46] and an increased effective peritoneal surface area [47]. Whereas increasing dwell volumes is often effective, this strategy leads to increased intra-abdominal pressure, which may lead to back pain and a higher risk of abdominal wall leaks and hernias [48], although this has not been borne out in some studies [49,50]. The lower intra-abdominal pressure in the supine position [51] may make increasing dwell volumes easier during the overnight exchange in CAPD patients or during the night exchanges in APD patients. An additional concern is that increasing exchange volumes may limit peritoneal ultrafiltration by increasing intra-abdominal pressure [52], but the greater persistence of the osmotic gradient is likely to offset this.

Another commonly used strategy is to increase the frequency of exchanges. In patients on CAPD, this may require increasing from three to four or from four to five exchanges daily. Potential disadvantages include the burden an additional manual exchange places on the patient and a decrease in middle molecule clearance due to a greater proportion of time spent draining and filling with less time for dialysate to dwell in the peritoneal cavity. In patients on cycler-based therapy, we advise against the use of NIPD unless a large amount of RRF remains or other special mitigating circumstances exist. An excellent method of increasing clearance in patients on NIPD is to add a day dwell. Maximizing the time spent with dialysate in the peritoneal cavity, especially with the use of a long dwell, is an important strategy because this leads to improvement in clearance of both small and larger solutes. Although increasing the frequency of night-time cycles can also augment peritoneal small solute clearance by maximizing the concentration gradient between blood and dialysate [53], there are some concerns with this strategy. First, if the cycles become too short, especially with larger dwell volumes, solute clearance will diminish owing to the "lost time" during draining and filling [54]. In addition, rapid cycling can lead to reduced net sodium removal due to sodium sieving [55]. For these reasons, we do not recommend routinely increasing frequency of cycles on APD to optimize peritoneal clearance.

Increasing peritoneal ultrafiltration is another method of increasing peritoneal clearance. Raising the gradient for diffusion with the use of hypertonic glucose or icodextrin is the primary means by which ultrafiltration can be increased [56,57], with the additional fluid removal leading to increased clearance via convective transport. However, use of long-term hypertonic glucose as a method to optimize peritoneal clearance is not generally recommended given the potential deleterious effects on the peritoneal membrane [58]. Icodextrin is a viable option for the long dwell in patients in whom poor ultrafiltration is an issue [59], but it is not generally recommended for the sole purpose of increasing clearance.

Ultimately, the decision about which strategy should be used to optimize peritoneal solute clearance will depend on the individual patient. Factors to consider include peritoneal membrane characteristics, the potential impact of increasing intra-abdominal pressure, and the patient's abilities and preferences. In general, attention should be focused on maximizing the time with dialysate in the peritoneal cavity.

Strategies for preserving RRF

Because of the impact of RRF on the outcome of patients on PD, its preservation is of utmost importance. Strategies to preserve RRF include use of medications that might slow the decline in RRF and avoidance of agents known to have deleterious effects. Because of the paucity of data, many of our current practices are extrapolated from patients with chronic kidney disease.

The only renal protective strategy for which there is evidence in PD patients involves use of agents that block the renin–angiotensin system (Table 44.3). Although this strategy is known to be effective in both hypertensive and normotensive patients with many forms of chronic kidney disease, the data for patients on dialysis are not as robust. Two randomized controlled studies have assessed the effect of renin–angiotensin system blockade on RRF, one using an angiotensin converting enzyme inhibitor (ACEi) and the other using an angiotensin receptor blocker (ARB). Li *et al.* randomly assigned 60 hypertensive PD patients to receive either ramipril at

Table 44.3 Summary of studies assessing effects of ACEi and ARBs on RRF in PD patients.

Study	Study design	No. of patients	F/U (mos)	Intervention	Outcome	Results
Li 2003	RCT	60	12	Ramipril vs. other antihypertensive	GFR change (mL/min)	−2.07 vs. −3.00 ($P = 0.03$)

5 mg daily or no treatment [60]. Over the 12 months of the study, the mean RRF decline was approximately 1 mL/min less in the patients treated with ramipril despite similar blood pressure control in both groups. Furthermore, at 12 months, fewer patients in the ramipril group were anuric. A smaller study by Suzuki *et al.* randomized 34 hypertensive CAPD patients to receive either valsartan or placebo and assessed the effect on RRF [61]. Similar to the Li study, use of valsartan was associated with a slower decline in RRF despite similar blood pressure control in the groups. A large retrospective analysis of 1032 PD patients also demonstrated favorable results, with use of an ACEi being associated with an adjusted odds ratio of RRF decline of 0.70 [62]. These results are in contrast to findings reported for two prospective cohort studies that assessed risk factors for decline in RRF [63,64]. Both studies found that the use of an ACEi was not an independent predictor of the rate of decline in RRF. Based on the above data, we would recommend the use of ACEis or ARBs in hypertensive patients and consider their use even in normotensive patients to preserve RRF.

Aminoglycosides are frequently used to treat peritonitis in PD patients because of their effectiveness as bactericidal agents and the ease of intraperitoneal administration. They are, however, also nephrotoxic. Several prospective cohort studies and one random-ized controlled trial have assessed the effect of aminoglycosides on RRF (Table 44.4). Shemin *et al.* assessed the rate of decline in RRF in 72 PD patients followed for 4 years [65]. Patients who had peritonitis episodes treated with intraperitoneal or intravenous aminoglycosides had more rapid decline in renal creatinine clearance and residual urine volume than either those who had never had a peritonitis episode or those who had peritonitis treated with other nonnephrotoxic antibiotics. In another study analyzing the risk factors associated with a faster rate of decline, use of aminoglycosides was found to be an independent predictor of a more rapid loss of RRF [64]. In contrast to the findings in the above studies, Baker *et al.*, using a prospective cohort design with a historical control, did not find an accelerated decline in RRF with the use of aminoglycosides to treat peritonitis [66]. Most recently, a prospective, randomized, controlled trial compared the use of cefazolin and ceftazidime with cefazolin and netilmicin for the empiric treatment of peritonitis in 50 PD patients with RRF [67]. In both groups there was a significant decline in RRF at 2 weeks that returned to near baseline by 6 weeks, but there was no significant difference in RRF between the groups. Although this represents the only randomized study of aminoglycosides and RRF, the follow-up period was short and some of the patients in the aminoglycoside

Table 44.4 Summary of studies assessing effects of aminoglycosides on RRF in PD patients.

Table 44.5 Overall evidence ratings and recommendations for small solute clearance target and renoprotective strategies.

Intervention	Overall evidence rating			Comment	Recommendation[a]			Comment
	High	Moderate	Low		I	II	III	
Minimum total Kt/V >1.7		X		2 RCTs and several corroborating prospective studies	X			Recommend minimum Kt/V > 1.7
RAS blockade to preserve RRF								Recommend ACEi or ARB in hypertensive patients, consider use in normotensive patients
Hypertensive patients		X		2 RCTs, but small number of patients	X			
Normotensive patients		X		No RCTs, extrapolated from CKD literature		X		
Avoidance of aminoglycosides to preserve RRF			X	Conflicting data		X		Suggest avoidance based on other effective alternatives

Abbreviations: RAS, renin–angiotensin system; RCT, randomized controlled trial.
[a] Recommendations based on quality of evidence. I, recommend; II, suggest; III, no recommendation possible.

group were exposed to only a few days of netilmicin. In summary, although the data are conflicting, we would suggest avoidance of aminoglycosides when possible in patients with RRF, given the availability of equally efficacious alternatives in the treatment of most cases of PD peritonitis.

Until recently, there were no data on the effect of radiocontrast media on RRF in dialysis patients. Within the past year, two small, prospective studies have addressed this issue [68,69]. Although one of the studies demonstrated a temporary decline in RRF 6 days after radiocontrast administration [68], neither study showed a lasting decline in renal clearance. Nevertheless, given the small numbers of patients in these dialysis studies and the clear data in patients with chronic kidney disease, it would be prudent to avoid using radiocontrast media if other acceptable alternatives exist. If use of radiocontrast dye is required, volume contraction should be avoided, and the smallest volume of the least toxic dye should be used. Where there are conflicting data on the use of *N*-acetylcysteine in chronic kidney disease [70] and there are no data for dialysis patients, its use could be considered based on the fact that it is relative safe and inexpensive. Despite the lack of evidence in dialysis patients, we would also recommend avoidance of nonsteroidal anti-inflammatory drugs or any other known nephrotoxins in patients with RRF.

If there is a significant decline in RRF that cannot be explained, consideration should always be given to the possibilities of volume depletion or obstruction, as these are easily correctable causes of loss of RRF.

Conclusions

Our understanding of the effect of PD adequacy on outcomes is subject to the limitations of the existing literature. In the absence of a gold standard for assessing adequacy, all studies to date have focused on small solute clearance. This has led to a relative neglect of the impact of middle molecule clearance on outcome. The data presented in this chapter highlight the relative contributions of renal and peritoneal clearance to PD adequacy, demonstrating that maintenance of residual renal clearance is critically important to patient survival. It is not yet clear if RRF is causally related to the survival advantage as a result of improved volume management and middle molecule clearance, or if it is merely an association, with RRF serving a marker of a healthier population.

While the existing data suggest that peritoneal clearance does not significantly impact patient survival, we cannot exclude the possibility that the dose ranges used in the studies assessing the effect of peritoneal clearance are too narrow to detect a difference. Further exploration of this possibility depends on the development of techniques that would allow achievement of much higher peritoneal solute clearance. Furthermore, it is possible that patient selection has had an impact on the results of some of the major studies discussed above. It is well-known that dialysis patients with several comorbidities tend to do poorly, so that increasing peritoneal clearance in these patients may not impact favorably on outcome. In contrast, the healthiest dialysis patients with few or no comorbidities are likely to do well over the relatively short duration of follow-up included in most studies, regardless of changes in peritoneal clearance. Thus, inclusion of these two extremes of patient groups could potentially dilute the impact of increasing clearance in a population at moderate risk. Studies particularly targeting this moderate risk population would therefore be informative.

Based on the available evidence, our recommendations (summarized in Table 44.5) include the following. In the absence of a better clearance marker, we recommend a minimum total Kt/V$_{urea}$ target of 1.7. Peritoneal and renal clearances should be followed serially to ensure that this target is met, with equal attention paid to the patient's clinical status for signs and symptoms of underdialysis. Efforts to improve peritoneal clearance must shift from a focus

on small solute clearance to one that includes middle molecule clearance. Furthermore, the true adequacy of PD as a form of renal replacement therapy depends not only on successful clearance of uremic toxins, but also on adequate volume management through a combination of peritoneal ultrafiltration and residual urine volume. Finally, given the survival advantage that is associated with renal clearance, every effort should be made to preserve RRF with the avoidance of potential nephrotoxins, the use of agents with potentially protective effects, and a search for reversible etiologies when a decline in RRF is noted.

45 Salt and Water Balance in Peritoneal Dialysis

Cheuk-Chun Szeto & Philip Kam-Tao Li

Department of Medicine & Therapeutics, Prince of Wales Hospital, The Chinese University of Hong Kong, Shatin, Hong Kong, China

Influence of salt and water removal

It is now recognized that cardiovascular disease is the most significant comorbidity among peritoneal dialysis (PD) patients [1], and there is increasing evidence that suboptimal fluid management is associated with cardiovascular risk and overall mortality [2].

PD patients are generally volume expanded when compared with hemodialysis (HD) patients [3]. Recently, Konings *et al.* [4] showed that extracellular fluid (ECF) volume significantly correlated with diastolic blood pressure and left ventricular end diastolic diameter in PD patients. In addition, continuous ambulatory PD (CAPD) patients with suboptimal blood pressure control have more expanded ECF volumes and a higher prevalence of left ventricular hypertrophy compared with those with well-controlled blood pressure [5]. Several studies in the 1990s showed that a higher peritoneal solute transport was associated with improved technique and patient survival [6–9]. In addition, observational studies showed that a higher peritoneal salt and water removal was associated with better patient survival [10,11]. For example, in the European APD Outcome Study (EAPOS), anuric patients on automated PD (APD) had worse survival if their baseline daily ultrafiltration (UF) was below 750 mL [11,12]. More recently, Chung *et al.* [13] showed that low total fluid removal on PD is associated with higher serum C-reactive protein levels, indicating systemic inflammation, as well as markers of poor nutrition. It is, however, possible that sodium and fluid removal in this study were simply a marker for a healthier, better-nourished patient who eats and drinks more [14].

Assessment and monitoring of salt and water balance

Monitoring of weight, course of residual renal function, and achieved UF with current dialysis prescription should be done

in all PD patients [15]. This approach will allow for early detection of and correction of problems. The volume status of patients on PD should be used as a core indicator of dialysis adequacy [15]. Constant reevaluation, by physicians and nurses, of the patient's target weight in the light of blood pressure and other indicators of fluid overload is required. Blood pressure should be normalized by fluid removal alone, without antihypertensive drugs, until it is proven that this strategy is not adequate. Routine performance of peritoneal function tests, described in the next section, should also be done, to identify patients with problems of peritoneal transport in whom monitoring of fluid status is particularly critical [15].

Tests of peritoneal transport

A patient's peritoneal membrane transport status should be evaluated in order to find an appropriate PD modality and prescription. Because both elimination of uremic toxins and UF account for adequacy, a test method should reliably evaluate both small solute and water permeability.

Peritoneal equilibration test

Numerous techniques for measuring peritoneal transport are available, of which the most widely used is the peritoneal equilibration test (PET) [16]. The PET was the first method to quantify individual peritoneal membrane characteristics, and it is highly reproducible. The procedure is summarized in Table 45.1. Based on population studies, patients are categorized as low, low-average, high-average, or high transporters. A problem with conventional PET is that it primarily measures small solute clearance and does not directly evaluate causes of UF problems (see below). The procedural steps in the PET may actually overestimate peritoneal membrane transport and underestimate the variation in peritoneal transport that may occur under actual clinical conditions [17]. PET alone does not give an assessment of dialysis adequacy.

Table 45.1 PET procedure[a].

1)	After an overnight exchange of an 8- to12-h dwell, 2 L of a 2.5% glucose concentration solution is instilled and allowed to dwell for 4 h.
2)	Several times during the dwell, the patient is requested to roll from side to side.
3)	Dialysate urea, glucose, sodium, and creatinine are measured at 0, 2, and 4 h.
4)	A blood sample is taken after 2 h.
5)	The drain bag is measured to assess both drain and net UF volume.
6)	Dialysate-to-plasma ratios (D/P) are calculated for creatinine, urea, and sodium at 0, 2, and 4 h.
7)	The ratio of glucose at drain time to the dialysate glucose concentration at time zero (Dt/D0) is measured.

[a] Adapted from Twardowski *et al.* 1987 [15].

Other tests of peritoneal function

Fast PET

Because the PET is labor-intensive, the fast PET [18] provides a simpler alternative by requiring only one dialysate sample. After draining the overnight dwell, the patient starts an exchange at home and arrives at the center in time for drainage of this 4-h dwell. A blood sample is taken at the end of the exchange. The analysis of the fast PET is identical to that for the standard PET, but only two reliable measures of peritoneal membrane permeability are determined, the dialysate-to-plasma ratio (D/P) for creatinine and dialysate glucose, after 4 h. If these two measures give contradictory results, it may be difficult to accurately interpret the test.

Short PET

The original PET was standardized for a long overnight exchange, but recent data have shown that this is unnecessary. For clinical purposes, the short PET [19] was introduced, accepting any dwell time between 3 and 12 h for the prior exchange.

Peritoneal function test

The peritoneal function test (PFT) has been extensively used and validated [20,21]. It measures the peritoneal mass transfer area coefficient during routine exchanges instead of under the highly controlled conditions required for the PET. This test also allows the clinician to assess total delivered dose of dialysis as well as protein and calorie nutrition. The PFT requires 24-h dialysate and urinary collection, and a specific computerized kinetic modeling program is used for calculations.

PD capacity program

The PD capacity (PDC) program is based on the three-pore model [22,23] and describes the peritoneal membrane characteristics using three parameters:

1) The area parameter, which determines the diffusion of small solutes

2) The final reabsorption rate of fluid when the glucose gradient has dissipated

3) The large-pore fluid flux, which determines the loss of protein.

Patients are asked to perform five exchanges. Data are combined with a computerized mathematical approach employing the three-pore model to estimate the parameters of membrane function.

Dialysis adequacy and transport test

The dailysis adequacy and transport test (DATT) was introduced by Rocco *et al.* [24,25]. For this test, the patients are asked to perform their exchanges as usual. Only a serum sample and a 10-mL aliquot from a pooled, well-mixed 24-h dialysate are required, and the 24-h D/P is calculated. DATT has only been validated for patients on a fixed CAPD schedule of three or four 2-L exchanges [26,27].

Accelerated peritoneal examination

The accelerated peritoneal examination (APEX) test has the same regimen as the PET, but it summarizes, in a single number, the peritoneal permeability for both glucose and urea [28] and represents the time at which glucose and urea equilibration curves cross. Generally, the APEX may be shorter than a PET, because most patients exhibit a crossing of the curves before 2 h. The shorter the APEX time, the higher the peritoneal permeability; the longer the time, the lower the peritoneal permeability. The APEX time may identify the optimum contact time between the functional peritoneal membrane surface area and the dialysate for the individual patient. If UF is the major goal, short dwell times should be used. If solute clearance is the major goal, longer dwell times should be used.

Standard peritoneal permeability analysis

The standard peritoneal permeability analysis (SPA) uses intraperitoneally administered dextran 70 to study fluid kinetics during a 4-h dwell [29]. The test was originally developed using the lowest glucose concentration. In the SPA, the mass transfer area coefficient (MTAC) of small solutes, the proportion of glucose absorbed, and the peritoneal clearances of serum protein are calculated. The PET parameters can be calculated from the SPA parameters. Conversely, the D/P creatinine and the Dt/D0 glucose values can be used with the drained volume to calculate the MTAC of creatinine and the proportion of glucose absorbed. Using SPA, with the highest glucose concentration, provides more valid data on UF, because the larger drained volume reduces measurement error and the sodium sieving phenomenon associated with a hypertonic glucose solution provides an assessment of aquaporin-mediated water transport. The magnitude of the dip in D/P sodium is a rough estimate of the water channel function.

Timing and frequency of the test

Peritoneal transport characteristics change significantly within the first month of PD, and so the results of the tests described above need to be considered in the context of how long an individual patient has been on PD. Peritoneal function tests performed during the first month of PD should be interpreted as preliminary and confirmed by an additional test 4 weeks later [30]. Like all tests, peritoneal membrane function tests, both in terms of solute clearance or UF, are subject to measurement error. Several exchanges within 24 h can be used to reduce this error, as with the PFT or PDC, as well as repeated testing over time. Because most creatinine assays based on the Jaffé method are also sensitive to glucose, dialysate creatinine concentrations are falsely high and need to be corrected for high dialysate glucose concentrations.

It is unclear how often peritoneal function should be assessed. The National Kidney Foundation Dialysis Outcomes Quality Initiatives guidelines recommend a measurement every 4 months [31]. The recommendation, however, may not be practical, because the tests are time-consuming for both patients and nurses.

Pediatric patients

A full discussion on peritoneal function tests in pediatric patients is beyond the scope of this chapter. Differences in peritoneal transport between children and adults have been postulated, but a recent study from Bouts *et al.* [32] did not confirm this theory. In general, all the tests described here are also applicable in children but, for most pediatric nephrologists, the standard PET is probably the test most commonly used.

Classification, diagnosis, and management of UF failure

The International Society for Peritoneal Dialysis Ad Hoc Committee on Ultrafiltration Management in Peritoneal Dialysis has published a comprehensive guideline in this area [15]. Patients presenting with the clinical syndrome of inability to maintain target weight and an edema-free state need to be carefully evaluated before being labeled "ultrafiltration failure" [15]. The clinical approach to PD patients with fluid overload and possible UF failure is outlined in Figure 45.1.

In general, reversible causes, such as dietary noncompliance, problems in the PD prescription, and mechanical problems, should be considered and may account for a large proportion of cases of fluid overload. Two groups of PD-related mechanical complications warrant more detailed discussion:

Dialysate leaks

Dialysate leaks from the abdominal cavity decrease drain volumes and net fluid removal. Net fluid removal from leaks into the abdominal wall or pleural space is decreased because of reabsorption

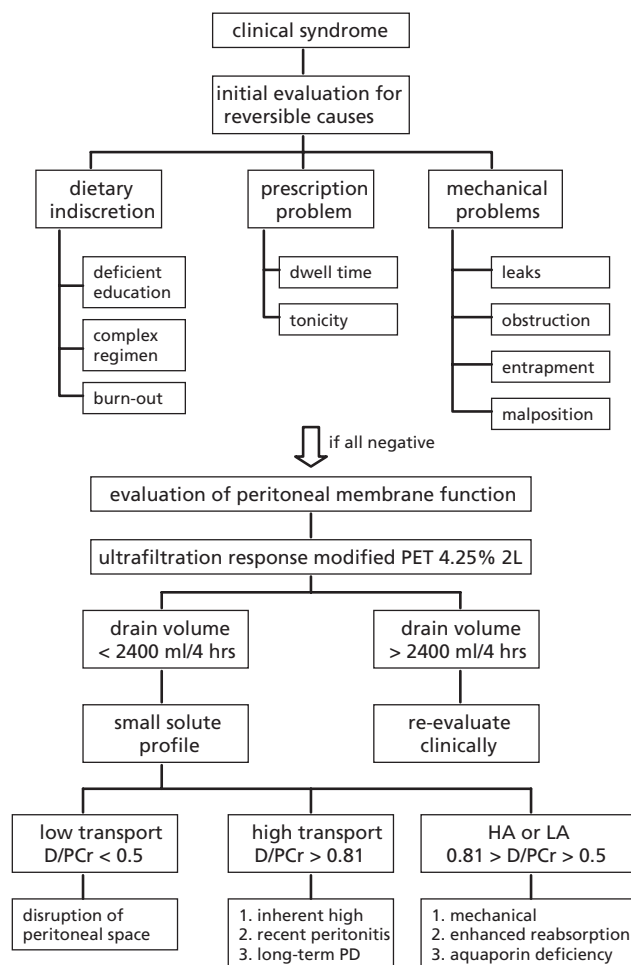
from the interstitial spaces or sequestration in the pleural space. Leaks into the interstitial space are commonly accompanied by abdominal wall edema with or without genital edema. Leaks can occur at any time but are often seen after being on PD for several months. They usually occur at the catheter insertion site but can occur at an abdominal wall hernia site or after abdominal surgery [33–35]. Diagnosis is confirmed by using radiographic techniques that include intraperitoneal infusion of a dialysis solution to which contrast has been added, followed by computed tomography (the so-called "CT peritoneogram"), or by the intraperitoneal infusion of radioisotope with peritoneal scintigraphy [33,34,36–42]. Leaks associated with hernias usually require surgical repair and a temporary transfer to HD. Leaks occurring in the absence of a hernia usually represent a tear in the parietal peritoneum. Small leaks may respond to peritoneal rest with HD support or the use of intermittent PD without the need for surgical repair. Recurrence may require surgical repair [35].


Figure 45.1 The clinical approach to PD patients with fluid overload and possible UF failure. HA, high-average transporter; LA, low-average transporter; D/PCr, dialysate-to-plasma creatinine ratio at 4 h. (Adapted from Mujais *et al.*, *Perit Dial Int* 2000 [15].)

Catheter problems

Catheter-related problems contributing to poor drain volumes include obstruction, entrapment, or malposition. Constipation is a also a common and readily reversible cause. Catheter obstruction, either partial or complete, often results from fibrin plugs within the catheter lumen but can be due to omentum obstructing the catheter ports or to a kinked catheter. The diagnosis is usually by exclusion, because radiographic evaluation is generally not helpful except in identifying kinked catheters. Treatment consists of aggressive flushing of the catheter with a dialysate-filled syringe or the use of fibrinolytic agents when fibrin-related occlusion is suspected. If the intra-abdominal portion of the catheter is entrapped in a compartment formed by adhesions, surgical lysis of the adhesions can be considered if the adhesions are not too extensive. If the adhesions are extensive, conversion to long-term HD is necessary.

Further evaluation of peritoneal function

If the initial workup does not identify a reversible cause, evaluation of the peritoneal membrane function is needed (Figure 45.1). Traditionally, peritoneal membrane function has been assessed by the PET, but this test has been standardized to classify membrane function [16] primarily in terms of small solute clearance and not for problems with UF. A modification of the standard PET introduced by Krediet *et al.* [43] offers a convenient alternative. The procedure of the modified PET is summarized in Table 45.2. Briefly, it consists of replacing the 2.5% dextrose solution of the standard PET with a 4.25% dextrose solution, thereby satisfying the criterion of maximal osmotic drive required for proper evaluation of UF capacity. A value of less than 400 mL net UF in a 4-h dwell correlates well with clinical behavior and avoids false-positive results [15]. The peritoneal conditions that would result in a drain volume of less than 2400 mL in 4 h can be separated by examination of the small solute characteristics (i.e. D/P creatinine ratio at 4 h).

Low drain volume and high transport

Patients with a low drain volume and D/P creatinine greater than 0.81 represent the largest group of patients with inadequate filtration due to peritoneal membrane problem. These patients fall into three groups:

1) Patients with an inherent high small solute transport profile at initiation of dialysis

2) Patients with current or recent peritonitis

3) Patients who develop a high transport profile in the course of long-term PD.

These patients tend to have adequate low-molecular-weight solute transport but have poor UF due to rapid absorption of glucose and dissipation of the osmotic gradient.

Inherent high transport

Around 10% of patients starting PD display an inherent high transport profile. Patients in this group have very efficient membranes for small solute clearance but difficulty in UF, particularly in long dwell cycles. These patients are at risk of high protein losses in the peritoneum. High levels of technique failure and mortality have been reported in this group [7,44,45]. These patients typically do well on CAPD until residual renal volume decreases, at which time it may become difficult to maintain euvolemia and blood pressure control on standard CAPD. APD and icodextrin for the long dwell are recommended therapeutic approaches.

Recent peritonitis

Fluid retention is common during episodes of peritonitis [46–48]. During peritonitis, there is an increase in the D/P ratio for creatinine, an increase in protein losses, and a decrease in net

---

Table 45.2 Modified PET procedure (4.25% dextrose)[a].

1) On the evening prior to the test, the patient should perform a standard CAPD 8- to 12-h overnight dwell.

2) With the patient upright, drain the overnight dwell over 20 min and note the volume drained. Save the sample for creatinine and glucose measurements to allow for determination of residual volume.

3) With the patient supine, infuse 2.0 L of 4.25% dialysis solution over 10 min. The patient should roll from side to side after each 400 mL of solution is infused.

4) Note the time the infusion is complete: this is the "zero hour'' dwell time.

5) At 0-h, 1-h, and 2-h dwell times:
   - Drain 200 mL of effluent into bag
   - Mix bag by inverting 2–3 times
   - Using aseptic technique, draw a 10-mL sample from medication port
   - Reinfuse the 190 mL of effluent into the patient
   - Transfer the 10-mL sample to red-top tube and label appropriately

6) At 2-h dwell time, draw blood sample for creatinine, sodium, and glucose measurements

7) At 4-h dwell time:
   - With patient upright, drain exchange over 20 min
   - Mix bag by inverting 2–3 times
   - Using aseptic technique, draw a 10-mL sample from medication port
   - Measure and record volume drained
   - Transfer 10-mL sample to red-top tube and label appropriately

8) Send all effluent samples and one blood sample to laboratory for creatinine, sodium, and glucose measurements

[a] Adapted from Mujais *et al.* 2000 [14].

UF—changes that are usually reversible. We have shown previously that the change of D/P, followed up for over 2 years, had no significant correlation with the total number of peritonitis episodes, but after severe peritonitis, patients had a greater change of D/P than patients who experienced no severe infection [49]. Previous studies suggested that reduced UF during peritonitis can be satisfactorily managed with the use of icodextrin [50].

High transport during long-term PD

The natural history of peritoneal membrane transport has been debated [51–57]. The emerging picture is that some increase in D/P creatinine does occur due to an increase in peritoneal membrane functional surface area [52,59–62]. A history of recurrent peritonitis and extensive use of hypertonic exchanges has been observed in some, but not all, studies. In contrast to the situation seen with peritonitis, the changes of solute transport in this group tend to be permanent, but it is often easy to maintain total solute clearance despite a tendency toward clinical volume overload.

In general, for patients with UF failure and a high transport profile of small solute clearance, APD and icodextrin for the long dwell are the recommended therapeutic approaches. Icodextrin solutions have been shown to be superior to glucose-based solutions in achieving net UF during long dwells in most patients, particularly in high transporters [63–69]. Icodextrin has also been shown to be effective during peritonitis [50]. In areas of the world where icodextrin dialysis solutions are not available, shortening dwell time is the preferred approach. In CAPD patients, this can be achieved with the use of an automated nighttime exchange device, which will shorten dwell time and has the additional benefit of improving small solute clearance with little impact on patient lifestyle. In patients on APD, omitting the daytime exchange and optimizing the nighttime regimen may be sufficient. If small solute clearance is inadequate, a short daytime exchange with midday drainage will improve solute clearance without compromising UF. In a few patients, adjunctive, temporary, or permanent HD may be required.

Low drain volume and low transport

The combination of low drain volume and low small solute transport is rare and reflects a major disruption of the peritoneal membrane or intraperitoneal fluid distribution [70]. It is usually due to adhesions, and the functional consequences may be related to fluid trapping in small spaces. Peritoneography may be helpful in making the diagnosis by identifying sequestered spaces. Poor UF in association with low transport is reported to occur in advanced stages of sclerosing peritonitis [70,71], but a high transport rate has also been described in the same setting [70–72]. Because this condition results in both inadequate volume and solute removal, transfer to HD is generally required unless patients have some degree of residual renal function [73]. Patients with a low transport rate, leaks, mechanical problems, or high lymphatic reabsorption also present with low drain volume and low small solute transport. These conditions need exclusion before low transport should be determined to be the reason for UF failure.

Low drain volume and high-average or low-average transport

In general, a low drain volume coupled with high-average or low-average transport can result from four possible etiologies [15]:
1) Mechanical problems
2) Lymphatic reabsorption
3) Tissue reabsorption
4) Aquaporin deficiency.

Mechanical problems

The possibility of mechanical problems needs to be reconsidered, particularly if the initial evaluation has not been thorough.

Lymphatic reabsorption and/or tissue reabsorption

These two conditions often coexist. Definitive proof of the condition requires identification of high macromolecule clearance from the peritoneal cavity [74,75]. Measurement of lymphatic flow is uncommon in clinical practice due to the complexity of the procedure. In the absence of such a test, the diagnosis is made by exclusion of mechanical catheter problems, aquaporin deficiency, and increased hydraulic conductance. Management encompasses all interventions that maximize UF, such as short dwell time and high-tonicity dialysate [76]. Use of pharmacological reduction of lymphatic absorption [77], intraperitoneal administration of phosphatidylcholine [78–80], and bethanechol chloride (a parasympatho-mimetic drug) [81] have been reported in small studies.

Aquaporin deficiency

Aquaporin deficiency is a rare condition, and only a small number of definite cases have been reported [82]. Various indirect methods can be applied in clinical practice to estimate the magnitude of aquaporin-mediated water transport. The so-called sieving of Na^+ is the simplest one [82–86]. Another simple way to assess aquaporin-mediated transport is to calculate the difference in net UF obtained after a 4-h dwell with 1.5% glucose and with 4.25% glucose dialysate [15]. Patients with aquaporin deficiency continue to have significant UF via nonaquaporin pathways, which can be enhanced by the use of icodextrin in long dwells, allowing for sustained fluid removal [66,69,87,88]. For glucose-based exchanges, short dwells are also preferable as in patients with a high transport profile.

Measures augmenting salt and water removal in PD patients

Dietary intake

It is generally accepted that dietary restrictions are more liberal in PD patients because of the continuous nature of the dialysis modality and the better preservation of residual diuresis. Tzamaloukas *et al.* [89], however, found that lack of dietary sodium restriction was a major independent risk factor for symptomatic fluid retention. Education on salt restriction resulted in weight reduction, blood pressure reduction, and decreased cardiothoracic index

(an indirect measure of left ventricular overload) [90]. Dietary counseling to reduce salt and water intake is therefore important [15] to maintain desired weight and reduce cardiovascular risk.

Hyperglycemia control

In diabetic patients, hyperglycemia can adversely affect the maintenance of an osmotic gradient across the peritoneal membrane [15]. Control of hyperglycemia may increase UF without the need to use hypertonic glucose solutions. Because glucose control is mostly self-monitored and managed, patients should be educated about the importance of glucose control for PD adequacy.

Increase urinary excretion

In patients with residual renal function, salt excretion can be increased by diuretics, particularly loop diuretics. Van Olden *et al.* [91] demonstrated that the effect varies with dose and degree of residual renal function. A single dose of 2 g of frusemide resulted in a median increase in urine volume of 400 mL and a mean extra sodium removal of 54 mmol/L [91]. In this short-term study, diuretics did not affect the residual creatinine clearance, and there were no alterations in peritoneal transport of solutes or water. The long-term effect over 1 year of frusemide in PD was evaluated by Medcalf *et al.* [92] using a dose of 250 mg/day versus placebo. In the group receiving frusemide, diuresis and sodium excretion were more preserved, but the rate of deterioration of residual renal function was no different between the groups. Maintenance of residual renal function is important in PD patients, as there is a clear relation with survival. Nephrotoxic drugs and contrast media should be avoided as much as possible. We have previously demonstrated the use of ramipril can slow the decline in residual renal function [93], and this was later supported by a study using an angiotensin receptor blocker [94]. The administration of biocompatible PD solution with low glucose degradation product also showed a beneficial effect on residual renal function [95].

Salt removal by PD

Considering UF to be equivalent to sodium removal is a dangerous paradigm [96]. During the initial period of a PD dwell, there is a considerable sodium sieving, resulting in almost pure water removal, without sodium. Short, hypertonic dwells, such as those applied during APD, result in a removal of hypotonic water, leaving the patient's plasma hypertonic, and thirst results.

Data from an uncontrolled study suggested that sodium removal during APD was lower than during CAPD [97]. However, two open-label randomized controlled trials did not show a significant difference in UF between APD and CAPD (Table 45.3) [98,99].

When used as the osmotic agent, the glucose polymer icodextrin facilitates the convective transport of sodium across the peritoneal membrane. A number of studies have demonstrated better UF and improvement in fluid status after the introduction of icodextrin for the long dwell for both APD and CAPD (Table 45.4) [100–108].

It has been suggested that sodium removal could be improved by enhancing the sodium gradient between plasma and dialysate with a low sodium dialysate. Such a low sodium solution has, however, a lower total osmolarity, necessitating a higher glucose concentration to achieve enough osmotic capacity. The results of two short-term studies were inconsistent (Table 45.5), probably due to the difference in actual sodium concentration of the solutions tested [109,110].

A number of intraperitoneal agents have also been tested (Table 45.6) [111–116]. Although many of these agents appeared to improve peritoneal clearance of small solute or water, all published trials were short term and small. The long-term efficacy and safety of these agents remain to be proved.

Preservation of peritoneal membrane function

The acute (and possibly chronic) impact of peritonitis on membrane function was discussed in the previous section. Minimization of damage to the peritoneal membrane by implementation of strategies to decrease the peritonitis rate should be universally applied, including the use of improved connectology systems [117].

The use of more biocompatible solutions may also influence membrane preservation. A retrospective observational study that compared incident PD patients treated with conventional PD solution to those treated with the new pH neutral lactate buffer solution, found a significant survival advantage with the new solution [118]. Available controlled studies show that the effect of biocompatible solution depends on the actual composition of the product (Table 45.7) [119–124]. In general, amino acid-based PD solution does not affect UF or sodium removal [119–121]. The

Table 45.3 Randomized controlled trials on the effects of automated PD versus CAPD.

Study [reference]	No. of subjects	Design	Treatment group	Duration (mos)	Effects
Bro *et al.* [98]	34	Open label	APD	6	Peritoneal transport and UF not described
Rodriguez *et al.* [99]	45	Open label	TPD, CCPD	2	Better peritoneal clearance of urea and creatinine; UF not described

Abbreviations: TPD, tidal peritoneal dialysis; CCPD, continuous cyclic peritoneal dialysis.

Table 45.4 Published trials on the effects of icodextrin PD solution on UF.

Study [reference]	No. of subjects	Dialysis type	Design[a]	Treatment group	Control group	Duration	Effects
Konings et al. [100]	40	CAPD	Open label	7.5% icodextrin	Standard glucose	4 mos	Better UF, 1670 ± 1038 vs. 744 ± 767 mL
Posthuma et al. [101]	38	APD	Open label	7.5% icodextrin	Standard glucose	2 yrs	Increasec UF by at least 261 mL
Davies et al. [102]	50	CAPD	Multicenter double blind	7.5% icodextrin	2.27% glucose	6 mos	Improved UF by 258.6 mL (control group: worse UF by −141.8 mL); also improved sodium removal
Wolfson et al. [103]	175	CAPD	Double blind	7.5% icodextrin	2.5% dextrose	52 wks	Better UF, 587.2 vs. 346.2 mL
Plum et al. [104]	39	APD	Multicenter double blind	7.5% icodextrin	2.27% glucose	16 wks	Better UF, 278 ± 43 vs. -138 ± 81 mL
Mistry et al. [105]	209	CAPD	Open label	7.5% icodextrin	1.36% and 3.86% glucose	6 mos	Better UF than 1.36% glucose at 8 h (527 ± 44 vs. 101 ± 48 mL); no difference from 3.86% glucose
Finkelstein et al. [106]	92	APD	Multicenter double blind	7.5% icodextrin	4.25% dextrose	2 wks	Improved UF 141.6 ± 75.4 to 540.2 ± 46.8 ml; no change in UF in control group
Posthuman et al. [107]	23	APD	Open label	7.5% icodextrin	4.25% dextrose	12 mos	Better UF, 218 ± 57 vs. 36 ± 115 mL; result was insignificant at 12 mos
Dallas et al. [108]	8	Both CAPD and APD	Randomized	7.5% icodextrin, 1.36% glucose	7.5% icodextrin	4 wks	Improved UF, 750 (650–828) to 1000 (889–1100) mL

[a] All studies were parallel, randomized controlled trials, except the one by Dallas et al. [108], which was a crossover study.

Table 45.5 Published studies on the effects of low-sodium PD solution[a].

Study [reference]	No. of subjects	Treatment group	Control group	Effect
Leypoldt et al. [109]	10	Na 105 mmol/L	Na 132 mmol/L	Low-sodium solution had better sodium and water removal
Amici et al. [110]	10	Na 126 mmol/L	Na 132 mmol/L	No difference in sodium or water removal

[a] Both studies focused on acute effects and used a crossover design.

Table 45.6 Published trials on effects of intraperitoneal agents on peritoneal transport.

Study [reference]	No. of subjects	Design[a]	Agents	Duration	Effect
Sjoland et al. [111]	21	Double blind	Tinzaparin	3 mos each	Reduced D/P creatinine, increased UF volume
Moberly et al. [112]	13	Open label	Hyaluronan	Single exchange	Marginal increase in UF volume, no change in creatinine clearance
el-Sherif et al. [113]	21	Open label	Minoxidil	Single exchange	Increase in UF volume
Hasbargen et al. [114]	7	Open label	Neostigmine	Single exchange	No effect
Kalra et al. [115]	25	Double blind	Sodium nitroprusside, chlorpromazine	Single exchange	Increased urea and creatinine clearance
Favazza et al. [116]	9	Open label	Clonidine, enalapril, nifedipine	2 weeks each	Increased creatinine and β2-microglobulin clearance by enalapril and nifedipine

[a] All studies entailed a crossover design.

Table 45.7 Published trials on the use of biocompatible PD solutions.

Study [reference]	No. of subjects	Design[a]	Treatment group	Duration	Effect(s)
van Biesen *et al.* [119]	10	Multicenter RCT	0.6% amino acid, 1.4% glycerol	3 mos	Improved PDE CA125 level; no difference in UF or nutritional parameters
Li *et al.* [120]	60	RCT	1.1% amino acid	3 yrs	Better NPNA, no difference in UF
Plum *et al.* [121]	10	Crossover	1% amino acid Bicarbonate buffered	1 day	No difference in UF
Schmitt *et al.* [122]	25[#]	Crossover	pH neutral, bicarbonate buffered	1 day	No change in peritoneal surface area
Williams *et al.* [123]	86	Multicenter crossover	pH neutral, lactate buffered, low GDP	12 wks each	Improved PDE markers of peritoneal membrane integrity and reduced circulating AGE, possibly better residual renal function
Tranaeus [124]	106	RCT	25 mmol/L bicarbonate + 15 mmol/L lactate	12 mos	Better UF of about 150 mL/day

Abbreviations: RCT, randomized controlled trila; GDP, glucose degradation product; PDE, PD effluent; AGE, advanced glucation end product; NPNA, normalized protein nitrogen appearance.

[a] All trials entailed an open-label design.

[b] Paediatric cases.

effects of neutral pH and/or bicarbonate-buffered solution have been inconsistent [122–124].

Temporary cessation of PD (the so-called peritoneal rest) has been used in a few patients with high small solute transport characteristics with some success and may be a reasonable option to consider if other approaches are unsuccessful [125–127]. Alternatively, reduction in exposure of the peritoneal membrane to glucose may lead to some improvement in transport parameters [128].

46 Impact of Peritoneal Dialysis Solutions on Outcomes

David W. Johnson[1] & John D. Williams[2]

[1]Department of Renal Medicine, University of Queensland at Princess Alexandra Hospital, Brisbane, Australia
[2]Department of Nephrology, Cardiff University, Heath Park, Cardiff, United Kingdom

Introduction

Over the past 25 years, peritoneal dialysis (PD) has become an established and successful form of renal replacement therapy for patients with stage 5 (end-stage) chronic kidney disease. Most published cohort studies suggest that the medium-term survival (up to 3–4 years) of patients treated with PD is at least comparable [1,2], and possibly superior [3,4], to that of patients receiving hemodialysis (HD). PD also potentially offers a number of other important clinical advantages over HD, including better preservation of residual renal function, reduced erythropoietic stimulatory agent and blood transfusion requirements, decreased risk of blood-borne infections (such as hepatitis B and C), improved quality of life, enhanced treatment satisfaction, preservation of vascular access sites, and improved subsequent renal allograft function [5,6].

However, the major drawback of PD is its limited technique survival. According to the Australian and New Zealand Dialysis and Transplant (ANZDATA) Registry, the crude technique failure rate for PD is 21.7/100 patient-years and only 4% of patients experience at least 5 years of continuous PD [7]. Even after censoring for kidney transplantation, the median technique survival on peritoneal dialysis is 2.5 years. Approximately half of all technique failure episodes are due to either peritonitis (27%) or peritoneal membrane failure culminating in inadequate small solute clearance and/or impaired ultrafiltration (23%) [7]. A large body of basic research in animal models and peritoneal cell culture systems has suggested that a major contributor to the high technique failure rate is the bioincompatible nature of conventional PD fluid. Such fluids may have a negative impact on host defense as well as having a profibrotic effect on the peritoneal membrane [8–10]. Conventional PD fluids are considered "unphysiological," based on their acidic pH (5.0–5.8), high lactate concentrations (30–40 mmol/L), high osmolality (320–520 mOsm/kg), high glucose

concentrations (31–236 mmol/L), and contamination by glucose degradation products (GDP) generated during the heat sterilization process [11]. Such solutions reduce the viability and growth of peritoneal mesothelial cells and fibroblasts in vitro, alter the turnover of structural collagen, and modify the homeostatic balance of cytokines and growth factors [10,12,13]. The viability and function of peritoneal phagocytic cells, such as macrophages, are also impaired by standard peritoneal fluids [11,12]. Moreover, experimental and clinical exposure of the peritoneal membrane to conventional PD solutions causes significant histopathological changes over time, including loss of the surface mesothelial cell layer, thickening of the submesothelial compact zone, and the development of a progressive vasculopathy [14,15]. Most of these adverse effects of dialysate on the peritoneal membrane appear to be accounted for by acidic pH and high concentrations of GDPs, because they were largely avoided in *in vivo* studies by the use of neutral-buffered, low-GDP fluids [10,11,16,17]. In addition to their direct cytotoxicity and stimulation of inflammatory cytokine production, GDPs promote the formation and deposition of advanced glycation end products (AGEs) in the peritoneal membrane, which in turn correlates with peritoneal membrane fibrosis and histopathology [18,19].

Recently, manufacturers of PD fluids have developed more biocompatible solutions, consisting of neutral pH, low-GDP, bicarbonate- or lactate-buffered solutions, in order to reduce membrane damage associated with PD. These fluids have consistently been shown in both *in vitro* and *in vivo* animal studies to better preserve peritoneal membrane structure and function compared with the less expensive, traditional fluids [10–12,20]. These fluids may also offer additional systemic benefits by reducing inflammation, lowering circulating AGE, and preserving residual renal function. However, whether these experimental benefits translate into improved outcomes for patients on PD needs to be demonstrated to justify the additional costs of the newer solutions. In addition to these biocompatible solutions, manufacturers have also developed "glucose alternative" solutions to improve PD as a therapy. So far, the available evidence indicates that fluid status, body composition, and diabetic control can be manipulated.

Additional peritoneal membrane benefits may be realized as a result of avoidance of glucose and AGEs.

The aim of this chapter is to review the impact of the newer PD solutions on clinical outcomes, based on the currently available randomized controlled trials.

Neutral pH, lactate-buffered, low-GDP fluids

The development of multicompartment bag systems, in which alkaline and acidic fluid compartments are kept separate, has permitted the sterilization of glucose at very low pH with greatly reduced GDP formation but the formation of neutral or near-neutral pH final dialysis solutions following mixing of the compartments prior to instilling into the peritoneal cavity. A summary of the randomized controlled clinical trials involving neutral pH, lactate-buffered, low-GDP, multichambered PD fluids is provided in Table 46.1.

Williams *et al.* [21] conducted a multicenter, open-label, randomized crossover study of conventional, acidic, lactate-buffered fluid (Stay-safe; Fresenius Medical Care, Bad Homburg, Germany) with neutral pH, lactate-buffered, low-GDP fluid (Balance; Fresenius Medical Care, Bad Homburg, Germany) in 86 prevalent continuous ambulatory PD (CAPD) patients from 22 centers in 11 European countries. The participants underwent a 4-week run-in phase on conventional fluid after which they were randomized in a

Table 46.1 Characteristics of the populations and interventions in the randomized trials of biocompatible solutions in PD.

Study ID [reference]	Interventions	No. of patients	Follow-up
Neutral pH, lactate-buffered, low-GDP vs. acidic pH, lactate-buffered, high-GDP fluids			
Williams [21]	Balance vs. Stay-safe	86 CAPD	24 wks
Rippe [22]	Gambrosol-Trio vs. Gamrosol	80 CAPD	2 yrs
Zeier [23]	Gambrosol-Trio vs. Gamrosol	21 CAPD	16 wks
Neutral pH, bicarbonate (± lactate)-buffered, low-GDP vs. acidic pH, lactate-buffered, high-GDP fluids			
Cooker [29]	Physioneal (25 mmol/L bicarbonate/15 mmol/L lactate) vs. Dianeal	92 CAPD	6 mos
Jones [30]	Physioneal (25 mmol/L bicarbonate/15 mmol/L lactate) vs. Dianeal	106 CAPD	6 mos
Fuesshoeller [31]	Physioneal (25 mmol/L bicarbonate/15 mmol/L lactate) vs. Dianeal	14 APD	12 mos
Mactier [33]	Bicarbonate/lactate (25/15 mmol/L) vs. bicarbonate (38 mmol/L) vs. Dianeal	18 CAPD	3 days
Tranaeus [35]	Physioneal (25 mmol/L bicarbonate/15 mmol/L lactate) vs. Dianeal	106 CAPD	12 mos
Carrasco [36]	Bicarbonate/lactate (25/15 mmol/L) vs. lactate (35 mmol/L)	31 CAPD	3 mos
Coles [39]	Bicarbonate/lactate (25/15 mmol/L) vs. bicarbonate (38 mmol/L) vs. lactate (40 mmol/L)	59 CAPD	2 mos
Feriani [38]	Bicavera (bicarbonate 34 mmol/L) vs. lactate (35 mmol/L)	123 CAPD	6 mos
Haas [32]	Bicavera (bicarbonate 34 mmol/L) vs. lactate (35 mmol/L)	28 APD	24 wks
Icodextrin vs. glucose exchanges			
Mistry [47]	7.5% Icodextrin vs. 1.36% or 3.86% glucose	209 CAPD	6 mos
Posthuma [48]	7.5% Icodextrin vs. variable glucose strengths	23 APD	6 mos
Plum [49]	7.5% Icodextrin vs. 2.27% glucose	39 APD	12 wks
Wolfson [50]	7.5% Icodextrin vs. 2.5% glucose	175 CAPD/APD	1 yr
Gokal [55]	7.5% Icodextrin vs. 1.36% or 3.86% glucose	23 CAPD	6 mos
Konings [58]	7.5% Icodextrin vs. 1.36% glucose	40 CAPD/APD	4 mos
Davies [59]	7.5% Icodextrin vs. 2.27% glucose	50 CAPD/APD	6 mos
Finkelstein [54]	7.5% Icodextrin vs. 4.25% dextrose	92	2 weeks
Selby [81]	7.5% Icodextrin vs. 1.36% glucose	8	2 days
Guo [62]	7.5% Icodextrin vs. 2.5% glucose	93	13 weeks
Posthuma [73]	7.5% Icodextrin vs. 2.5% glucose	38 CCPD	2 years
Ota [56]	7.5% Icodextrin vs. 1.36% glucose	18 CAPD	6 weeks
Amino acid dialysates versus glucose exchanges			
Qamar [79]	1.1% amino acids vs. 1.36% glucose (1 exchange daily)	7 CAPD	3 months
Misra [76]	1.1% amino acids vs. 1.36% glucose (1 exchange daily)	18 CAPD	6 months
Jones .(77)	1.1% amino acids vs. glucose (1 exchange daily)	134 CAPD	3 months
Qamar [80]	1.1% amino acids vs. glucose (1 exchange daily)	7 CCPD	3 months
Li [75]	1.1% amino acids vs. glucose (1 exchange daily)	60 CAPD	3 years
Tjiong [78]	1.1% amino acids vs. variable (1.36–3.86%) glucose	8 APD	7 days
Van Biesen [82]	0.6% amino acids/1.4% glycerol vs. variable glucose (1 exchange daily)	10 CAPD	3 months
Glucose-sparing regimens			
Le Poole [37]	1 x Nutrineal, 1 x Extraneal, 2 x Physioneal (NEPP) vs 4 x Dianeal	63 CAPD	30 weeks

1:1 ratio to the control versus intervention groups. After 12 weeks of monitoring in this first treatment phase, the groups switched therapies and were observed for a further 12 weeks. The method of allocation concealment was not explicitly stated. A total of 71 patients with complete measurements were included in the per protocol analysis (18% dropout rate). The primary outcome measure was the concentration of CA125, a possible marker of mesothelial cell mass and/or viability, in the dialysate effluent at 12 weeks and was significantly higher in the low-GDP fluid group. This was accompanied by higher effluent levels of procollagen peptide, lower levels of hyaluronan, and unchanged levels of vascular endothelial growth factor and tumor necrosis factor-α. Patients exposed to low-GDP fluids were also observed to have falls in circulating GDP (carboxymethyl-lysine and imidazoline) levels. Clinical measurements demonstrated increases in renal urea and creatinine clearances, increases in Kt/V, increases in urine volumes, and decreases in peritoneal ultrafiltration volumes (associated with an increased dialysate/plasma creatinine ratio). Peritonitis incidence was comparable in both groups, although the study was inadequately powered to detect a difference in this or other clinical end points. The study was significantly limited by its short duration, small sample size, use of surrogate markers, the possibility of co-intervention bias in view of the open-label nature of the study, and the potential for informative censoring as a result of the 18% dropout rate over 24 weeks.

Similar findings were reported in an open-label, parallel design, randomized controlled trial of conventional, acidic, lactate-buffered fluid (Gambrosol; Gambro, Lund, Sweden) with pH 6.5, lactate-buffered, low-GDP fluid (Gambrosol-Trio; Gambro, Lund, Sweden) in 80 CAPD patients followed for 2 years [22]. Although only 13 patients completed the 2-year study (84% dropout), the principal findings were that patients receiving low-GDP fluid treatment exhibited significantly higher dialysate CA 125, procollagen-1-C-terminal peptide, and procollagen-3-N-terminal peptide and significantly lower concentrations of hyaluronon in the overnight effluent. The new fluid did not significantly influence either the frequency of peritonitis or peritoneal transport characteristics compared with conventional fluid, but the study was not adequately powered for these end points, and baseline data were limited. Zeier *et al.* [23] also conducted a randomized crossover trial of Gambrosol versus Gambrosol-Trio over two consecutive observation periods of 8 weeks each in 21 stable, prevalent CAPD patients. They reported a significant 3.5-fold increase in dialysate effluent CA125 concentrations within 4 weeks of Gambrosol-Trio exposure.

To date, there have been no randomized controlled trials of neutral pH, lactate-buffered, low-GDP fluids versus conventional fluids that have been adequately powered to assess "hard" or patient-level clinical end points. A recent, large, retrospective, observational cohort study in Korea described superior survival in 611 patients treated with Balance compared with 551 patients using standard Stay-safe solution (74% vs. 62% at 28 months; $P = 0.032$) [24]. The hazard ratio for mortality was 0.75 (95% confidence interval, 0.56–0.99) in the Balance group, after adjust-

ment for age, gender, and diabetes mellitus in a multivariate Cox proportional hazards model analysis. A follow-up report of 1909 incident PD patients, in which prescription of low-GDP solutions reached between 70 and 80% by the year 2003, also demonstrated superior patient survival in patients treated with low-GDP fluids [25]. The major limitations of this study were the lack of stratification or statistical adjustment for cardiovascular disease, hypertension, and socio-economic status and potential selection bias with residual confounding. This is probable given that patients treated with low-GDP solutions were significantly more likely to be younger and treated at large PD centers than those patients who received standard PD solutions. There may also have been a center effect bias, given that 25 centers exclusively contributed Balance patients, 25 exclusively contributed conventional fluid patients, and the remaining 33 contributed a mixture of Balance and Staysafe patients. An open-label, multicenter, phase IV, randomized controlled trial of Gambrosol Trio ($n = 43$) versus Gambrosol ($n = 26$) was recently presented (Diurest study) [26]. Although not yet published, the investigators reported a significantly slower rate of residual renal function decline in those treated with Gambrosol Trio. However, this study was potentially confounded by a substantially higher glucose usage, higher initial weight loss, and appreciable initial blood pressure drop in the control group, raising the possibility that factors other than the type of fluid used (e.g. volume depletion) may have accounted for the differential decline in renal function between the two study groups. In contrast, Fan *et al.* [27] recently presented an abstract reporting results of a controlled trial of 120 incident PD patients randomized to receive Balance or conventional fluid (Stay-safe) for a mean follow-up period of 11.3 months. No differences were observed between the two groups in residual renal function, peritonitis, peritoneal transport characteristics, or the primary composite end point of time to death or transfer to HD. A large, multicenter, prospective, randomized controlled trial of Balance versus Staysafe in 420 incident PD patients followed for 2 years is currently underway in Australia, New Zealand, and Singapore (balANZ trial) [28]. The primary outcome measure will be rate of decline of residual renal function (analysis of covariance), with secondary analysis of time to anuria, patient survival, technique survival, peritoneal transport characteristics, measures of dialysis adequacy, and ultrafiltration. In the meantime, there is insufficient clinical evidence to draw conclusions about the relative efficacy and safety of neutral pH, lactate-buffered, low-GDP fluids compared with conventional PD fluids.

Neutral pH, bicarbonate ($\pm$ lactate)-buffered, low-GDP fluids

As with the lactate-buffered, low-GDP solutions, many clinical trials involving bicarbonate-buffered, reduced-GDP fluids have been small, short term, and primarily focused on unvalidated surrogate end points of dialysate effluent markers. Cooker *et al.* [29] demonstrated significant reductions in dialysate effluent

concentrations of interleukin-6 and vascular endothelial growth factor within 3 months in 61 patients randomly allocated to neutral pH, bicarbonate/lactate-buffered, reduced-GDP fluid (Physioneal; Baxter Healthcare) compared with 31 patients receiving conventional PD fluid (Dianeal; Baxter Healthcare). Similar results have also been described from other studies [30–32].

The most consistent clinical benefit demonstrated for bicarbonate-buffered fluids is a reduction of inflow pain [31,33–35]. Mactier *et al.* [33] conducted a double-blind, randomized, crossover trial to determine the effects of bicarbonate (38 mM)-containing and bicarbonate (25 mM)-lactate (15 mM)-containing PD solutions on infusion pain in patients who experienced inflow pain with conventional lactate (40 mM) solution. For all pain variables assessed, the bicarbonate-lactate solution was more effective than the bicarbonate solution in alleviating pain. Similar findings have been reported in open-label studies [31,34,35].

In some studies, bicarbonate/lactate-buffered solutions have also been found to be associated with better control of metabolic acidosis compared with lactate-buffered solutions [36,37]. Carrasco *et al.* [36] reported a significant increase in venous plasma bicarbonate concentration by 3.1 mmol/L (95% confidence interval, 1.6–4.8) from a baseline level of 23.0 mmol/L during treatment with the bicarbonate-lactate solution. The number of acidotic patients (venous plasma bicarbonate of <24 mmol/L) was statistically significantly reduced at every treatment period visit in the bicarbonate-lactate group ($P < 0.05$). Similarly, a prospective crossover study of 74 patients allocated to four daily exchanges of standard PD solution (Dianeal) versus a glucose-sparing regimen (two exchanges Physioneal, one exchange Extraneal, and one exchange Nutrineal) observed that the latter regimen was associated with significantly higher plasma bicarbonate levels [37]. In contrast, three other randomized controlled trials did not find any significant differences in acid–base status between patients treated with bicarbonate-lactate solutions versus conventional fluids [35,38,39].

Conflicting results have also been reported for peritoneal ultrafiltration, with two studies (different fluids) observing increased drainage volumes with bicarbonate-lactate solutions [35,40] while other investigations found no alteration in ultrafiltration [32,36–39].

None of the trials to date have had sufficient samples sizes or follow-up times to evaluate the impact of bicarbonate/lactate-buffered, low-GDP solutions on peritonitis rates, residual renal function decline, technique survival, or patient survival. A prospective registry analysis of PD patients treated with alternative PD solutions in 12 countries observed that bicarbonate/lactate solutions were associated with decreased peritonitis duration and rate compared with standard PD fluids [9]. However, these results were likely to have been significantly influenced by selection bias.

The relative importance of the buffer (lactate versus bicarbonate) to peritoneal membrane biocompatibility has not yet been addressed by randomized controlled trials. A prospective, nonrandomized trial of 34 mmol/L bicarbonate-buffered versus 35 mmol/L lactate-buffered PD fluid in 36 patients over 12 months showed comparable peritoneal clearances and correction of metabolic acidosis between the two groups but better preservation of residual renal function in the patients receiving bicarbonate-buffered fluid [41]. However, this trial may have been confounded by selection bias since patients nonrandomly allocated to the bicarbonate group were significantly more likely to be female and have lower peritoneal ultrafiltration values at baseline. There is currently a randomized controlled study under way in which 60 pediatric PD patients will be randomly assigned to receive either lactate-containing Balance solution or the bicarbonate-buffered Bicavera solution for a period of 10 months to determine whether these fluids evoke any differences in preservation of peritoneal transport characteristics [13].

Icodextrin

Icodextrin is a starch-derived, high-molecular-weight glucose polymer that was first used as an osmotic alternative to glucose for PD in the 1980s [42]. Since that time, there has been increasing interest in the use of icodextrin-containing PD solutions because of their demonstrated ability to induce sustained peritoneal ultrafiltration. Fluid removal is achieved by colloidal, rather than crystalline, osmotic pressure and is most pronounced over prolonged (12–16 h) dwells [43]. There is also emerging evidence that this iso-osmotic solution may be less damaging to the peritoneal membrane than glucose-based dialysates (reviewed in references 44 to 46).

To date, there have been a number of open-label, randomized controlled trials of the glucose polymer, which have demonstrated that icodextrin is comparable to hypertonic (3.86%) glucose for net peritoneal ultrafiltration and small solute clearance during long (8–16 h) dwells (Table 46.1). The first of these investigations was the Multicentre Investigation of Icodextrin in Ambulatory Peritoneal Dialysis Study (MIDAS) [47]. In this multicenter trial, 209 stable patients from 11 centers (representing approximately 5% of the UK CAPD population) were randomly allocated to receive an overnight exchange with either 7.5% icodextrin ($n = 106$) or conventional (1.36 or 3.86%) glucose solutions. A total of 138 patients completed the 6-month study (67 icodextrin, 71 control). An intention-to-treat analysis demonstrated that the mean overnight peritoneal ultrafiltration achieved with icodextrin was equivalent to that of 3.86% glucose at 8 h (510 ± 48 vs. 448 ± 60 mL; $P = 0.44$). Following a 12-h dwell, icodextrin tended to promote a greater degree of fluid removal (552 ± 44 vs. 414 ± 78 mL), but the difference just failed to achieve statistical significance ($P = 0.06$). There were no reported adverse clinical effects over the period of the study. A second, smaller, single-center, randomized controlled trial in continuous cycling PD (CCPD) patients compared the ultrafiltration potential of icodextrin ($n = 23$) with that of variable glucose strengths ($n = 19$) during the daytime dwell (14–15 h) [48]. Daytime ultrafiltration volumes were significantly higher in icodextrin-treated than glucose-treated patients at 3 months (168 ± 57 vs. 42 ± 139 mL, respectively; $P < 0.05$), 6

months (218 ± 57 vs. 36 ± 115 mL; $P < 0.05$), and 9 months (224 ± 71 vs. −30 ± 87 mL; $P < 0.05$). Two other randomized controlled trials demonstrated that icodextrin promoted significantly higher ultrafiltration volumes than 2.5% glucose [49,50]. A subsequent, short-duration, randomized, sequential study of 2.27% glucose, 3.86% glucose, and 7.5% icodextrin during the long daytime dwell (13.8–15.5 h) in 17 CCPD patients confirmed that median ultrafiltration volumes were comparable between icodextrin and 3.86% glucose (260 vs. 100 mL; P not significant) but were significantly greater than 2.27% glucose (−190 mL; $P < 0.005$) [51]. Importantly, the difference in daytime ultrafiltration between icodextrin and 3.86% glucose was positively correlated with the dialysate/plasma creatinine ratio, suggesting that icodextrin may achieve superior fluid removal compared with glucose-based dialysates in subjects with higher peritoneal membrane transport characteristics. This finding was supported by several other transport studies [52,53]. A recent randomized controlled trial demonstrated that icodextrin was superior to 4.25% glucose for long dwell fluid removal in high and high-average transporters [54].

Several randomized controlled trials have also demonstrated that icodextrin offers an ultrafiltration advantage compared with glucose-based dialysates in patients with enhanced membrane permeability due to acute peritonitis. In the MIDAS study [55], 23 patients in the glucose group and 22 patients in the icodextrin group experienced CAPD-associated peritonitis. During these infective episodes, mean overnight ultrafiltration volumes decreased slightly from 218 ± 354 mL to 185 ± 218 mL in the glucose group (P not significant) but significantly increased in the icodextrin group, from 570 ± 146 mL to 723 ± 218 mL ($P < 0.01$). Similar findings have been reported by Ota *et al.* [56]. A randomized study in CCPD patients [57] found that mean daytime and total 24-h ultrafiltration fell significantly during peritonitis episodes by approximately 600 mL but were well-maintained in icodextrin-treated patients. The mean differences in daytime and 24-h fluid removal between the two groups exceeded 1000 mL.

Although augmented peritoneal fluid removal by icodextrin should intuitively help to correct fluid overload in PD patients, this outcome has been poorly studied. Konings *et al.* [58] randomly allocated 40 PD patients to icodextrin or 1.36% glucose during the long dwell. The use of icodextrin was associated with a significant reduction in extracellular water and left ventricular mass. Davies *et al.* [59] also reported significant improvements in fluid status in high transporters treated with icodextrin compared with 2.27% glucose. These findings, together with those of Finkelstein *et al.* [54], support the recommendations of the ISPD Ad Hoc Committee on Ultrafiltration Management in Peritoneal Dialysis that icodextrin be used for the long dwell in high transporter patients with a net peritoneal ultrafiltration of less than 400 mL/4 h [60].

Clinical experience with icodextrin in children is extremely limited. The best available study is a sequential trial by de Boer and colleagues [61] in which 11 children underwent peritoneal dwells with 1.36% glucose, 7.5% icodextrin, or 3.86% glucose for 12 h. The ultrafiltration achieved with icodextrin was comparable with that of 3.86% glucose but significantly greater than with 1.36%

glucose. No significant adverse effects were observed over a subsequent 6-week period of polyglucose administration.

Apart from the well-documented effects of icodextrin on peritoneal ultrafiltration, polyglucose solution has also been shown in one randomized controlled trial to promote clinically important improvements in quality of life scores within 13 weeks of treatment commencement compared with glucose solutions [62]. Although there are nonrandomized studies suggesting that polyglucose may additionally prolong PD technique survival [63–65], there is no high-level clinical evidence to support this.

Several *in vitro* and *ex vivo* studies have suggested that icodextrin may offer improved peritoneal membrane biocompatibility compared with conventional glucose-based dialysates by virtue of decreased glucose exposure, iso-osmolarity, and reduced carbonyl stress [66,67]. Short-term clinical studies involving generally small numbers of patients have demonstrated that dialytic small solute clearances and peritoneal transport characteristics remain well-preserved on icodextrin therapy for up to 24 months of follow-up [47,48,68–72]. Moreover, a prospective, open-label, randomized controlled trial of 38 CCPD patients in two centers showed that dialysate effluent concentrations of a variety of peritoneal membrane markers (CA125, interleukin-8, carboxy-terminal propeptide of type I procollagen, and amino-terminal propeptide of type III procollagen) did not differ between glucose- and icodextrin-treated patients over a 2-year period [73]. However, there have been no longer-term clinical studies comparing the relative effects of icodextrin and glucose on peritoneal membrane structure or function. Icodextrin use is associated with an increased incidence of rash, mild hyponatremia, mild elevations of plasma alkaline phosphatase levels, and elevation of plasma oligosaccharide concentrations, leading to overestimation of blood sugar measurements based on the glucose deshydrogenase pyrroloquinolenequinone method [50,74].

Amino acid dialysates

Dialysates using amino acids as an alternative osmotic agent to glucose may be more biocompatible by virtue of their more physiological pH (6.7), relatively low osmolality (365 mOsm/kg), and avoidance of glucose and GDPs. However, most available studies have not been of sufficient size or duration to demonstrate any clinically important effects on peritonitis rates, peritoneal transport characteristics, technique survival, or patient survival (Table 46.1). The largest trial to date involved 60 malnourished CAPD patients randomly allocated to replace one exchange daily with amino acid dialysate (Nutrineal; Baxter Healthcare) or to continue with dextrose dialysate (Dianeal; Baxter Healthcare) over a 3-year follow-up period [75]. The composite nutritional indices, daily ultrafiltration volumes, small solute clearances, and survival rates did not differ significantly between the two groups.

Some studies have suggested that malnourished PD patients may derive modest nutritional benefit from such solutions [76–78]. However, other randomized controlled trials have failed to

Table 46.2 Evidence ratings and recommendations for dialysate solutions in PD.

Intervention	Existing systematic reviews[a]	Overall evidence rating[b]			Very low	Comment	Recommendation[c]			Comment
		High	Moderate	Low			I	II	III	
Neutral pH, lactate-buffered, low-GDP vs. acidic pH, lactate-buffered, high-GDP fluids	None			?		Few RCTs, small sample size, short duration, suboptimal methodological quality, surrogate outcomes of questionable clinical relevance			?	Further trials with patient-level outcomes required
Neutral pH, bicarbonate (±lactate)-buffered, low-GDP vs. acidic pH, lactate-buffered, high-GDP fluids	None			?		Few RCTs, small sample size, short duration, suboptimal methodological quality, mostly surrogate outcomes of questionable clinical relevance		?		Neutral pH, bicarbonate (±lactate)-buffered, low-GDP fluids appear useful for ameliorating infusion pain; further trials required to examine impact on other patient-level outcomes (peritonitis, peritoneal transport characteristics, technique survival, patient survival)
Icodextrin vs. glucose exchanges	None		?			Moderate number of RCTs, small to moderate sample sizes, suboptimal methodological quality, consistent findings	?			Icodextrin promotes superior fluid removal compared with glucose exchanges, especially in high and high-average transporters; further trials required to examine impact on other patient-level outcomes (peritonitis, peritoneal transport characteristics, technique survival, patient survival)
Amino acid dialysates vs. glucose exchanges	None			?		Few RCTs, small sample size, short duration, suboptimal methodological quality, surrogate outcomes of questionable clinical relevance, inconsistent findings			?	Further trials with patient-level outcomes required
Glucose-sparing regimens vs, glucose exchanges	None				?	1 RCT, suboptimal methodological quality, surrogate outcomes			?	Further trials with patient-level outcomes required

[a] If no existing systematic review, overall evidence rating will start at moderate.

[b] Domains that are considered include study design, study quality, and consistency and directness of findings.

[c] Domains that are considered include trade-offs between benefits and harms, translation into clinical practice, uncertainty about baseline risk of population of interest, and quality of evidence. I, recommend; II, suggest; III, no recommendation possible.

demonstrate any significant nutritional benefit of amino acid dialysates [75,79,80]. The ultrafiltration effect is comparable to that achieved with 1.5% glucose.

Conclusions

The published studies of newer, "biocompatible" fluids have to date been limited by small sample sizes, relatively short durations, suboptimal methodologic quality, and a predominant focus on surrogate markers of questionable clinical importance (such as dialysate effluent concentrations of CA125) (Table 46.2). In spite of these limitations, there is reasonable evidence to recommend the use of neutral pH, bicarbonate-buffered or lactate-buffered, low-GDP fluids in patients with clinically significant infusion pain, and the use of icodextrin in the long dwell to enhance fluid removal in PD patients, particularly in high and high-average transporters. There is scant, conflicting evidence that amino acid dialysates may confer modest benefits to surrogate nutritional markers in malnourished PD patients. However, there is insufficient evidence to date to permit conclusions to be drawn about the impact of any of these biocompatible solutions relative to cheaper, conventional PD fluids based on "hard," clinical end points, such as peritoneal transport characteristics, peritonitis rates, residual renal function preservation, technique survival, or patient survival. Large, well-designed, adequately powered, randomized controlled trials are eagerly awaited.

Introduction

Peritoneal dialysis (PD) is an effective and widely used form of renal replacement therapy and accounts for 15–50% of renal replacement therapy for patients with end-stage renal disease (ESRD). The longevity of PD and its broader uptake are reduced by the risk of PD-related infections [1]. The overall incidence of peritonitis is about one episode for every 19 patient months on PD [2], although this figure ranges from 1 in every 9.1 to 1 in every 27.9 patient– months [3–5]. Peritonitis tends to be recurrent, with a very high rate of relapse (approximately 0.5 episodes/patient/year) [6]. Risk factors for developing peritonitis include advancing age [7,8], some ethnic groups [9,10], comorbidities such as diabetes and obesity [11], tropical climates [12,13], depression [14], nasal carriage of *Staphylococcus aureus* [15,16], and presence of exit site infections. Catheter design, implantation technique, and connection methodology also modulate the risk of peritonitis. It is unclear whether PD modality (continuous ambulatory PD [CAPD] or automated PD [APD]) affects peritonitis rates [17,18].

PD-related infections may also require hospitalization [19] and result in adverse effects from the required antibiotic treatment. Peritonitis, particularly due to *S. aureus*, is a major cause of catheter removal and subsequent technique failure in patients receiving PD [20]. Peritonitis is also associated with an increased mortality risk in some patient groups [21]. Longer-term consequences of peritonitis include the development of ultrafiltration failure [22] and an increased likelihood of developing encapsulating sclerosing peritonitis [23,24].

The ultimate goal for PD-related infections is prevention. To date, this has primarily focused on antimicrobial prophylaxis and modifications of the PD catheter and connection system. Antimicrobial interventions include oral and topical antibiotics [25], topical disinfectants, and prophylactic treatment of *S. aureus* nasal carriage [26]. All of these strategies, particularly cleansing and disinfection of the exit site, are widely accepted, but practice patterns are variable and trials results are conflicting [27–30]. Catheter-related intervention strategies that have been studied include modifications of catheter design, implantation technique, connection methodology, and PD modality [15,16].

When infection does occur, early and effective management is important to reduce complications such as progression from exit site infection to peritonitis and relapse of peritonitis. The mainstay of management of peritonitis is antimicrobial therapy, although adjunctive treatments such as fibrinolytic agents [31,32], peritoneal lavage [33], and intraperitoneal immunoglobulin administration [34] have been used. Peritonitis antibiotic regimens vary in the class of antimicrobial agent(s) used, route of administration, dosing frequency, and total duration of therapy. Center-specific factors such as patterns of antimicrobial resistance and regional isolation also play a role in making treatment decisions [35].

In this chapter we review current evidence about the prevention and treatment of PD-related infections.

Definitions

Definitions of exit site infections, tunnel infections, and peritonitis have varied in clinical trials, particularly regarding the time frame in which a second episode defines relapsed peritonitis rather than a new episode. Definitions have become more uniform in recent studies. Current guidelines on prevention and treatment of

peritonitis [3,36] are based on similar definitions, which are summarized below.

Exit site and tunnel infections

An exit site infection is present when there is purulent drainage from the exit site. This may be accompanied by pericatheter swelling, erythema, and tenderness. Erythema or serous discharge alone may or may not represent infection. A positive culture from a swab in the absence of clinical signs may represent bacterial colonization but not infection. Tunnel infections in the absence of concomitant exit site infection are rare. There may be signs of inflammation (erythema, edema, and or tenderness) over the subcutaneous tunnel, but some tunnel infections may be clinically occult and require sonographic studies for detection.

Peritonitis

Peritonitis may be directly related to the PD procedure (PD-associated peritonitis) or my be independent of the PD catheter and related to intra-abdominal events, such as perforated viscera. General criteria for diagnosis are discussed more extensively in the chapter, but definitions of different types of peritonitis are listed here:

- *Refractory peritonitis:* persistence of clinical symptoms and signs beyond day 4 or 5 of therapy
- *Relapsing peritonitis:* an episode that occurs within 4 weeks of completion of therapy of a prior episode with the same organism or one sterile episode
- *Repeat peritonitis:* an episode that occurs more than 4 weeks after completion of therapy of a prior episode with the same organism
- *Recurrent peritonitis:* an episode that occurs within 4 weeks of completion of therapy for a prior episode but with a different organism.

Diagnosis of peritonitis

Appearance of cloudy effluent suggests a diagnosis of peritonitis, but confirmation is required and is defined by the presence of two of three of the following findings:

1) Cloudy effluent fluid with leukocyte count over $100/mm^3$, with more than 50% neutrophils
2) Abdominal pain
3) Positive culture or Gram stain of peritoneal effluent.

The patient suffering from peritonitis often satisfies all these criteria. However, not all centers can perform a Gram stain, and culture becomes positive many hours and sometimes days after admission. Decision on treatment is therefore often based on the two first criteria. Clinical history, occurrence of fever, increased peripheral blood leukocyte count, and other typical symptoms of infection may be suggestive of the diagnosis.

Cloudy effluent

The sign of cloudy effluent requires confirmation by a differential cell count from the peritoneal effluent; a finding of >50%

neutrophils is equally important as the total white blood cell count of 100 cells/μl. Because an increase in white blood cell count can be delayed in some cases, a cell count lower than $100/\mu$l does not rule out the diagnosis of peritonitis. A repeat count on the effluent following an exchange often shows a cell count increase. Leukocyte esterase reagent strips are used in many centers to enable the patient to check the effluent at home, thereby reducing the time to diagnosis and confirming an increased white blood cell count as the cause of nonclear effluent. Sensitivity and specificity of the leukocyte esterase test are comparable to those with visual assessment and light microscopy.

A cloudy peritoneal effluent can also appear in conditions other than infectious peritonitis. A mild hemoperitoneum, due to capillary rupture, ovulation, or retrograde menstruation is not infrequent; the effluent has a characteristic red discoloration and only a few white blood cells are seen on microscopy. Cloudy effluent with an increased number of eosinophils can simulate infectious peritonitis. Peritoneal eosinophilia is arbitrarily defined as an absolute eosinophil count of $>100/\mu$l, or eosinophils $>10\%$ of total effluent leukocytes if the eosinophil count is $>40/\mu$l. It is considered to be due to an allergic reaction occurring after catheter implantation or from dialysate additives, air introduced into the peritoneal cavity, the PD catheter, plasticizers from the dialysis bag or tubing, or even mechanical trauma from a fill volume that is too large. Increased eosinophil counts have been reported with one brand of vancomycin and with fungal and parasitic infections.

Chylous effluent, due to a breach of lymphatic vessels, has an opaline appearance. This often increases after a meal and has a higher number of lymphocytes and measurable amounts of triglycerides. A cloudy effluent with an increased white blood cell count, mimicking infectious peritonitis, can also occur during chemical peritonitis due to accidental introduction of disinfectants into the peritoneal cavity; the differential diagnosis is based on clinical history, negative culture, and rapid spontaneous improvement. Peritoneal diffusion of malignancy can also cause cloudy effluent, but this is a rare event. Finally, a cloudy fluid often appears in the first bag exchange after a period of empty abdomen ("dry abdomen") and is due to the accumulation of cells in the peritoneal cavity. Clear effluent is typically observed when dialysis fluid is constantly present and regularly exchanged in the peritoneal cavity. Inappropriate suspicion of peritonitis in patients undergoing intermittent PD or APD may occur, as the first exchange is often cloudy in these patients. To obviate the risk, one should infuse 1 L of peritoneal dialysis fluid and permit it to dwell for a minimum of 1–2 h before draining and examining for turbidity and for cell count; alternatively, a rapid flushing of the peritoneal cavity with 1–2 L of dialysis fluid can precede that maneuver.

Abdominal pain

The symptom of abdominal pain is not unique to infectious peritonitis. In peritonitis, abdominal pain is typically generalized and is often associated with rebound tenderness. The first site of pain in PD-related infectious peritonitis is often the epigastric region, which then spreads to the whole abdomen. The intensity of pain is

very variable and may not correlate with the degree of cloudy effluent; some patients have a frank cloudy effluent with little pain, and others complain of severe pain but have relatively clear effluent. Different causative microorganisms cause different pain severities; streptococcal peritonitis, for example, is generally associated with severe pain. Peritonitis occurring in PD patients may also be secondary to primary disease in abdominal organs, and other abdominal conditions may mimic the pain of peritonitis. This differentiation is critical for therapy. Diverticulitis should be suspected when pain is localized to the left iliac fossa. Appendicitis should be ruled out when the first localized pain is in the right iliac fossa, and pain in the right hypochondrium necessitates consideration of cholecystitis.

Gram stain and culture

Gram stain is positive in up to 40% cases and is concordant with culture results. Despite the substantial false-negative rate, because it has a high specificity, when positive the Gram stain may provide early identification of the likely causative organism and so can guide empiric therapy. A positive culture confirms the clinical diagnosis of infectious peritonitis, often within 24–48 h after empiric therapy has commenced. Causative microorganisms include gram-negative and gram-positive bacteria, fungi, yeasts, and typical and atypical mycobacteria. The possibility of a viral peritonitis cannot be excluded, but literature on this topic is only anecdotal. Culture is negative in 10–20% of cases of clinically diagnosed infectious peritonitis. The low concentration of microorganisms in the effluent accounts for negative culture results, but other causes have been reported, including insufficient volume of the effluent sample, concurrent use of antibiotics, inadequate culture technique, and failure to concentrate by centrifugation. Other causes are endotoxins or contaminants of either the dialysis fluid or medications introduced in the peritoneal cavity.

Other signs and symptoms may also be present in peritonitis, including:

1) Pneumoperitoneum: appearance of a small amount of air in the peritoneal cavity is easily diagnosed by chest X-ray, and very small amounts can be detected by computed tomography. Pneumoperitoneum suggests bowel perforation but can also be due to accidental introduction of air during an exchange.

2) Amylase concentration in peritoneal fluid amylase is less than 100 U/L in PD patients with primary infectious peritonitis and higher during either pancreatitis or infections of other abdominal organs.

3) When peritonitis is suspected, the physical examination should include a careful inspection of the exit site and tunnel of the catheter, because peritonitis could be secondary to the peritoneal spread of bacteria from this site. Any drainage from the exit site should be cultured, along with the effluent. If the exit site is culture positive for the same organism as the peritoneal effluent, then it is very likely that the origin of peritonitis is the catheter.

4) Peripheral cell counts including a differential count. Infectious peritonitis is generally associated with an increase in the white blood cell count.

5) Fever and loss of appetite are also frequent. Chills, vomiting, lack of bowel sounds, tachycardia, and hypotension occur in the most severe cases. In some patients (e.g. the elderly or those on immunosuppressive therapy), these signs may be less severe.

Available guidelines for prevention and treatment of exit site and tunnel infection and peritonitis

Prevention of exit site and tunnel infections and peritonitis

The International Society for Peritoneal Dialysis (ISPD) [36], Australian and New Zealand Society of Nephrology (Caring for Australians with Renal Impairment [CARI]) [3], and the British Renal Association (BRA) have issued guidelines regarding use of antimicrobial agents for peritonitis prevention. All three recommend use of topical antibiotic agents to reduce the risk of *S. aureus* exit site and tunnel infections. The BRA guidelines recommend mupirocin applied to exit sites, whereas CARI and ISPD suggest both intranasal and exit site mupirocin administration. The ISPD also lists exit site gentamicin as a potential prophylactic agent. Further strategies recommended by both CARI and ISPD are prophylactic use of nystatin during antibiotic therapy to reduce the incidence of fungal peritonitis and prophylactic antibiotic administration at the time of catheter placement. CARI recommends use of a first-generation cephalosporin for this purpose.

With regard to catheter-related interventions, there is consensus among all three guidelines that no single type of catheter is superior in reducing infection rates. ISPD guidelines state that a downward-placed catheter may reduce infection rates. No other recommendations regarding catheter placement have been issued.

Treatment of exit site and tunnel infections

ISPD guidelines recommend prompt and aggressive treatment of exit site infections, particularly those due to *S. aureus* and *Pseudomonas aeruginosa*, as these organisms frequently lead to peritonitis. The guidelines state that treatment with oral antibiotics is as effective as intraperitoneal therapy, with the exception of infections due to multidrug-resistant *S. aureus*. CARI suggestions for clinical care indicate that antibiotic therapy should match the likely local pathogens but that no antibiotic regimen has proven to be superior.

Treatment of peritonitis

ISPD and CARI guidelines both state that empirical therapy with antibiotics that will cover both gram-negative and gram-positive organisms should be initiated at the time a diagnosis of peritonitis is suspected. Specific antibiotic agents are not recommended, but the ISPD guidelines suggest that local patterns of causative organisms and bacterial resistance should be taken into consideration by each center. Following identification of a specific organism targeted therapy should commence. The suggested duration

of therapy in the ISPD guidelines is 2 weeks in most cases but 3 weeks for severe infections, such as infection due to *Staphylococcus* or *Pseudomonas* species.

In addition to antimicrobial agents, ISPD recommends catheter removal for refractory and relapsing peritonitis and fungal peritonitis. CARI makes no recommendation about timing of catheter removal, due to lack of evidence, but does state that catheter removal is superior to urokinase.

Available evidence for prevention and treatment of exit site and tunnel infections and peritonitis

Systematic reviews of randomized trials of interventions to prevent and treat PD-related infections have been carried out. Specifically, there is one Cochrane Review covering the area of antimicrobial agents [37] and two covering catheter-related interventions to prevent PD-related infection [38,39]; there is also a published protocol of treatment for PD peritonitis [40], and preliminary results have been presented in abstract form [41]. Since completion of these reviews, one additional randomized controlled trial (RCT) has been published [42]. The characteristics of populations and interventions in the trials included in these Cochrane reviews (Tables 47.1 to 47.3) and their major findings (Tables 47.4 to 47.6) are provided at the end of the chapter.

Antimicrobial agents for prevention of PD-associated infections

Oral antibiotic prophylaxis has not been shown to prevent PD-related infections (Figure 47.1). The two interventions that have been shown to be effective in preventing PD-related infections are administration of intranasal mupirocin to PD patients colonized with *S. aureus* and preoperative intravenous antibiotic prophylaxis. In one trial, nasal mupirocin compared with placebo significantly reduced the exit site and tunnel infection rate and *S. aureus* nasal carriage, but no significant effect of mupirocin on peritonitis rates was observed [37] (Figure 47.2). These findings support the ISPD and CARI recommendations indicating that topical nasal therapy should be used. The benefit of mupirocin was only observed for the outcome measure of rates of exit site and tunnel infections, and not for the proportion of patients with these infections. This means that mupirocin may only reduce the risk of exit site and tunnel infections in patients who are frequent relapsers, or it is possible that these results simply demonstrate the trials are more likely to find an effect when event rates occur more commonly (episodes of infection rather than number of patients with exit site and tunnel infections). The greatest concern regarding routine use of topical mupirocin is the risk of emergence of mupirocin-resistant bacteria, although this remains a theoretical risk to date. The trial of nasal mupirocin, which has the longest follow-up duration available to date, had a follow-up period of only 18 months and was inadequate to assess the development of resistance [43].

The recommendation by CARI and BRA to apply mupirocin to the exit site is not supported by current evidence. There have been no reported RCTs which have assessed the effectiveness of application of mupirocin to the catheter exit site or to PD patients other than those with nasal colonization by *S. aureus*. However, this intervention is widely used and unlikely to cause harm.

Two other topical antimicrobial therapies are available in addition to mupirocin. Bernardini *et al.* prospectively compared topical application of mupirocin and gentamicin to the exit site in a randomized, controlled, blinded trial [42]. They found that topical gentamicin was associated with a reduction in the rate of catheter infections, time to first catheter infection, and catheter infections due to *Pseudomonas aeruginosa*. All-cause and gram-negative peritonitis rates were reduced in the gentamicin group when the results were analyzed according to treatment received, but there were no differences on intention to treat analysis (0.56/year with mupirocin vs. 0.30/year for gentamicin; $P = 0.08$). There were no reports of gentamicin ototoxicity. Although the results of this study appear favorable, the median follow-up in this study was 8 months, and long-term data on the development of gentamicin-resistant microorganisms will be important.

Medihoney has antimicrobial properties and may be associated with a lower risk of facilitating the development of multidrug-resistant microorganisms than antibiotics. Noninferiority of Medihoney with topical mupirocin has been demonstrated in the prevention of hemodialysis catheter-associated sepsis [44], but there are no published trials of Medihoney use in PD.

The use of perioperative intravenous antibiotic prophylaxis compared with no treatment has been shown to reduce the risk of early (<1 month postinsertion) peritonitis considerably but not the risk of exit site and tunnel infection [37] (Figure 47.3). There was no significant difference in the risk of peritonitis more than 1 month after catheter insertion. Postoperative infection rates in the control arms of each of the evaluated trials were high, ranging from 12–46%, and the applicability of these data to PD units with lower infection rates following PD catheter insertion is unclear. Current CARI guidelines suggest use of first-generation cephalosporins in this setting, based on extrapolations from the results of preoperative antibiotic trials in patients without ESRD [3], but the evidence supporting the use of first-generation cephalosporins in PD patients undergoing Tenckhoff catheter insertion is sparse. Four RCTs of different preoperative antibiotic prophylaxis regimens were identified in a systematic review [45–48]. These included parenteral gentamicin, vancomycin, cephazolin, and cefuroxime, with only two evaluating a first-generation cephalosporin. One small trial involving 27 PD patients found that cephazolin and gentamicin were ineffective compared with no treatment [45], and the largest of the meta-analyses (221 patients) observed that cephazolin was inferior to vancomycin with respect to preventing postoperative catheter-associated infections (7% vs. 1%; $P < 0.05$) [46]. The recommendation of a first-generation cephalosporin in preference to vancomycin may be a reasonable compromise because of the risk of vancomycin-resistant *Enterococcus* spp. and *S. aureus*. The ISPD guidelines address this issue by recommending

Table 47.1 Characteristics of populations and interventions in randomized trials of antimicrobial agents for prevention of peritonitis in PD.[a]

Study ID	% of patients that were diabetic	Interventions	No. of patients	Follow-up (mos)
Oral antibiotics vs. placebo/no treatment				
Blowey 1994[b]	NA	Rifampin (20 mg/kg/day) in 2 doses for 5 days + bacitracin (nasal) 2 times/day × 7 days	15	1

Poole-Warren 1991	17	Staphypan Berna	124	12
Perioperative intravenous prophylaxis vs. placebo/no treatment				
Bennett-Jones 1988	0	Gentamicin (i.v.) 1.5 mg/kg at time of catheter placement	27	1
Gadallah 2000[c, f]	23	Vancomycin (i.v.) 1000 mg 12 h before catheter placement	221	0.5
Lye 1992	40	Cefazolin (i.v.) 500 mg or gentamicin (i.v.) 80 mg 1 h before catheter placement	50	3
Wikdahl 1997	34	Cefuroxime (i.v.) 1.5 g at time of catheter placement + 250 mg i.p. in first dialysis bag	38	0.3
Nasal antibiotics vs. oral or nasal antibiotic				
Bernardini 1996	34	Mupirocin (2%) nasal ointment, daily applications vs. rifampin (oral) 300 mg × 2/day × 5 days, every 3 mos	82	25
Perez-Fontan 1992	16	Mupirocin (2%) nasal ointment t.i.d. × 7 days vs. neomycin sulfate (0.1%) nasal ointment t.i.d. × 7 days	32	3
Perioperative intravenous prophylaxis				
Lye 1992	60	Cefazolin (i.v.) 500 mg before catheter placement vs. gentamicin (i.v.) 80 mg <60 min before catheter placement	50	2

Abbreviations: NA, not applicable or not available; b.i.d., twice a day; t.i.d., three times a day; i.v., intravenous; i.p., intraperitoneal.

[a] Results of either placebo or no-treatment controlled trials or head-to-head trials of different antimicrobial regimens. Trials are grouped in alphabetical order and by type of intervention. Mean age ranged from 40–60 years for all trials with the exception of one pediatric trial.

[b] Pediatric trial.

[c] Trial with three arms.

[d] This trial focused on prophylaxis of *Candida* peritonitis in patients receiving treatment for bacterial peritonitis.

[e] The control group for this trial was soap and water.

[f] The control group for this trial was either no treatment or cefazolin (i.v.), 1000 mg, 3 h before catheter placement, or no treatment.

Table 47.2 Characteristics of populations and interventions in RCTs of catheter-related interventions for prevention of peritonitis in PD.[a]

Study ID [rerference]	% of patients that were diabetic	Interventions	No. of patients	Follow-up (mos)
Surgical catheter insertion technique				
Gadallah 1999[17]	36	Laparoscopy vs. standard laparotomy	148	36
Tsimoyiannis 2000 [18]	NA	Laparoscopy vs. standard laparotomy	50	21
Wright 1999 [19]	NA	Laparoscopy vs. standard laparotomy	50	24

Moncrief-Popovich 1998 [21]	NA	Subcutaneous buried vs. standard insertion	113	NA
Park 1998 [22]	43	Subcutaneous buried vs. standard insertion	60	24
Ejlersen 1990 [23]	NA	Midline vs. lateral	37	3
Rubin 1990[b] [24]	24	Midline vs. lateral	83	NA
Straight vs. *coiled catheter*				
Akyol 1990 [25]	12	Tenckhoff (straight) vs. Tenckhoff (curled) catheter	40	13
Dasgupta 2000 [26]	NA	Tenckhoff (straight) vs. Moncrief-Popovich (curled) catheter	41	NA
Eklund 1994 [27]	13	Single-cuff straight Tenckhoff vs. one bubble slanted flange single-cuff Swan Neck (coiled) catheter	40	NA
Eklund 1995 [28]	16	Two-cuff straight Tenckhoff catheter vs. two-cuff Swan neck (coiled) catheter	40	NA
Lye 1996 [29]	35	Double cuffed Swan-neck (coiled) vs. double-cuffed Tenckhoff (straight) catheter	40	12
Nielsen 1995 [30]	18	Tenckhoff (straight) vs. permanently bent Swan neck (curled) catheter	72	6
Rubin 1990[b] [24]	24	Straight vs. coiled catheter	83	NA
Scott 1994[c] [31]	NA	Double cuffed Tenckhoff (straight) vs. Toronto Western (curled) vs. standard coiled Oreopoulos	89	12
Y-set vs. *conventional spike catheter or modified Y-set*				
Cheng 1994 [32]	15	O-set versus conventional spike vs. UVXD[d]	100	>12
Churchill 1989 [33]	NA	Y-set plus sodium hypochlorite vs. standard system	124	12
Dryden 1992 [34]	15	Y-set (Freeline solo) vs. standard system	80	3–36
Li 1996 [35]	20	Y-set (Ultraset) vs. conventional spike	40	12
Lindholm 1988 [36]	28	5F take-off system vs. conventional	58	9
Maiorca 1983 [37]	NA	Y-set plus sodium hypochlorite vs. standard system	62	18–24
Owen 1992 [38]	NA	O-set vs. standard	60	>12
Rottembourg 1987 [39]	22	Y-set (Y-set or O-set or 5F safe-lock) vs. conventional	55	33
Viglino 1989 [40]	1	Y-set vs. Travenol Advanced Bystem	60	13
Viglino 1993 [41]	20	Y-set vs. T-set	122	15
Y-set vs. *double bag*				
Harris 1996 [42]	15	Y-set (standard) vs. double bag (Freeline solo)	66	18
Kiernan 1995 [43]	25	Ultra Y-set vs. Ultra Twin Bag	83	4.5
Li 1999 [44]	24	Y-set (Ultraset) vs. double bag (Ultrabag) system	120	16
Monteon 1998[c] [45]	50	Y-set vs. double bag vs. straight spike	147	12
Miscellaneous				
De Fijter 1991 [46]	NA	Y-set CAPD vs. CCPD	56	18
Bro 1999 [47]	4	Y-set CAPD vs. APD (NIPD or CCPD)	34	6
Eklund 1997 [48]	26	Single cuff vs. double cuff Tenckhoff catheter	60	20
Li 2002 [49]	38	Ultrabag vs. Stay-safe	102	>12
Pommer 1998 [50]	20	Silver ring vs. none	195	4.5
Trooskin 1990 [51]	NA	Antibiotic treated catheter vs. none	86	NA
Turner 1992[c] [52]	20	Immobilizer device vs. tape vs. no immobilization	66	0.25–15

Abbreviations: NA, not available; CCPD, continuous cycling PD; NIPD, nocturnal intermittent PD.

[a] Trials were all in adult populations. Trials are grouped in alphabetical order and by type of intervention.

[b] Trial with four arms.

[c] Trial with three arms.

[d] Ultraviolet irradiation connection box machine.

Table 47.3 Characteristics of populations and interventions in RCTs of interventions for treatment of peritonitis in PD.[a]

Study ID	% of patients that were diabetic	Interventions	No. of patients	Follow-up (days)
Same antibiotic IV vs. IP				
Bailie 1987	NA	Vancomycin 1g IP LD then 25 mg/L IP qid vs. vancomycin 1 g IV LD then 25 mg/L IP qid; 14-day course	20	NA
Bennet-Jones 1990	NA	Vancomycin 20 mg/L IP qid + tobramycin 4 mg/L IP qid vs. vancomyin 0.5–1 g IV days 1 & 6 + tobramycin 1 mg/kg IV LD then 20–60 mg IV according to levels; PO antibiotics at day 4; 10-day course	75	14
Same antibiotic oral vs. IP				
Boeschoten 1985	NA	Cephradine 500 mg IP LD then 250 mg IP qid vs. cephradine 500 mg PO LD then 250 mg PO qid; treatment until 1 week after dialysate cleared	39	14
Cheng 1993	NA	Ciprofloxacin 200 mg IP LD then 25 mg/L IP qid vs. ciprofloxacin 750 mg PO bd; 10-day course	48	28
Cheng 1997	NA	Ofloxacin 100 mg/L IP LD then 25 mg/L IP qid vs. ofloxacin 400 mg PO LD then 300 mg PO od; 10-day course	35	28
Different antibiotic oral vs. IP				
Bennet-Jones 1987	NA	Vancomycin 25 mg/L qid IP + gentamicin 8 mg/L qid IP 48 h then 4 mg/L qid vs. ciprofloxacin 750 mg PO td for 24 h then 750 mg PO bd; 10-day course	48	28
Chan 1990	NA	Cephalothin 250 mg/L IP qid + tobramycin 8 mg/L qid vs. ofloxacin 400 mg PO LD then 300 mg PO od ± rifampin 300 mg PO od; 10-day course	106	28
Cheng 1991	NA	Vancomycin 500 mg IP LD then 30 mg/L IP qid + aztreonam 500 mg/L IP LD then 250 mg/L IP qid vs. ofloxacin 400 mg PO LD then 300 mg PO od; 10-day course	45	28
Cheng 1998	NA	Vancomycin 1–2 g IP days 1 & 7 + netromycin 20 mg/L IP od vs. vancomycin 1–2 g IP days 1 & 7 + levofloxacin 300 mg PO od; 10-day course	100	28[b]
Gucek 1994	NA	Cephazolin 100 mg IP LD then 250 mg IP qid + netilmycin 80–120 mg LD then 40 mg IP daily vs. ofloxacin 300 mg PO LD then 200 mg PO od + netilmycin 80–120 mg LD then 40 mg IP daily; 10-day course	38	NA
Lye 1993	NA	Gentamicin 80 mg IP LD then 15 mg/2 L IP qid + vancomycin 1 g IP day 1 vs. pefloxacin 400 mg PO bd + vancomycin 1 g IP day 1; 14-day course	60	14
Tapson 1990	NA	Vancomycin 30 mg IP qid + netilmycin 30 mg IP to alternate exchanges vs. ciprofloxcain 500 mg PO qid; 10-day course	50	28
Continuous vs. intermittent IP antibiotics				
Boyce 1988	NA	Vancomycin 1 g IP LD then 30 mg/L qid vs. vancomycin 30 mg/kg days 1 and 8, treatment until 5 days after dialysate cleared	51	28
Lye 1995	NA	Gentamicin 10mg/ L IP qid + vancomycin 1g IP day 1 vs gentamicin 40 mg IP od + vancomycin 1 g IP day 1; 14-day course	100	28
Schaeffer 1999	NA	Vancomycin 15 mg/kg body wt LD then 30 mg/L qid + ceftazidime 250 mg/L LD then 125 mg/L qid vs. vancomycin 30 mg/kg IP days 1& 7 + ceftazidime 500 mg/L IP LD then 250 mg/L IP od ; OR Teicolpanin 7.5 mg/kg body wt LD then 20 mg/L qid + ceftazidime 250 mg/L LD then 125 mg/L qid vs. teicoplanin 15 mg/kg IP days 1 & 7 + ceftazidime 500 mg/L IP LD then 250 mg/L IP od; 10-day course (all treatment arms)	93	NA
Velasquez-Jones 1995	NA	Vancomycin 500 mg/L IP LD then 15 mg/L IP qid vs. vancomycin 30 mg/kg IP days 1 & 7; 10-day course	21	28
Different antibiotic IP				
Anwar 1995	NA	Vancomycin 250 mg IP LD then 25 mg IP bd + netilmycin 30–50 mg IP LD then 20–25 mg IP bd vs. imipenem 1 g IP bd; treatment until 5 days after dialysate cleared	56	NA
Bowley 1998	NA	Vancomycin 50 mg IP qid for 48 h then 25 mg IP qid vs. teicoplanin 50 mg IP qid for 48 h then 25 mg IP qid; 7-day course	12	5
De Fijter 2001	22	Cephradine 250 mg/L IP qid vs. ciprofloxacin 50 mg/L IP qid + rifampin 50 mg/L qid; 14-day course	98	14
Flanigan 1991	50	Vancomycin 25 mg/L IP vs. cephazolin 50 mg/L IP; 14-day course	263	14
Friedland 1990	28	Vancomycin 12.5 mg/L IP qid + gentamicin 4 mg/L bd vs. ciprofloxacin 20 mg/L IP qid; 10-day course	40	10

(*continued*)

Table 47.3 (*continued*)

Study ID	% of patients that were diabetic	No. of Interventions	Follow-up patients	(days)
Gucek 1997	NA	Vancomycin 2 g IP every 5–7 days + ceftazidime 1 g IP LD then 250 mg IP qid vs. cephazolin 500 mg IP LD then 250 mg qid + netilmicin 80–120 mg IP LD then 40 mg IP od; 14- to 28-day course	52	NA
Jimenez 1996	NA	Vancomycin IP + tobramycin IP vs. vancomycin IP + cefotaxime IP	47	NA
Khairullah 2002	NA	Vancomycin 1 g/L IP day 1 & day 5 or 8 + gentamicin 40 mg IP od vs. cephazolin 1 g IP LD then 125 mg/L qid + gentamicin 40 mg IP od; 14- to 21-day course	42	14–21
Lui 2005	NA	Cefazolin 1 g IP od + netilmycin 0.6 mg/kg IP od vs. cefazolin 1 g IP od + ceftazidime 1 g IP od; 14-day course	102	42
Leung 2005	39	Cefazolin 1 g IP LD then 250 mg IP qid + ceftazidime 1 g IP LD then 50 mg IP qid vs. imipenem 500 mg IP LD then 100 mg IP qid,	102	
Lupo 1997	NA	Cephalothin 2 g IV then 500 mg IP bd + tobramycin 120 mg IM LD then 10 mg IP qid vs. teicoplanin 400 mg IV LD then 40 mg IP qid + tobramycin 120 mg IM LD then 10 mg IP qid; 21-day course	65	NA
Wale 1992	NA	Teicoplanin 20 mg/L IP qid + aztreonam 250 mg/L IP qid vs. cefuroxime 125 mg/L IP qid; minimum 10-day course (at least 5 days from when dialysate cleared)	60	> 10 + 5[c]
Were 1992	NA	Vancomycin 50 mg IP bd + netilmicin 50 mg IP LD then 25 mg IP bd vs. cefuroxime 40 mg/L IP qid; treatment until 5 days after dialysate cleared	20	5[c]
Wong 2001	NA	Vancomycin 1 g IP days 1 & 7 + netilmicin 80 mg IP LD then 40 mg IP od vs. cefepime 2 g IP LD then 1 g IP daily; 10-day course	60	10
Antibiotic vs. nonantimicrobial procedure or nonantimicrobial procedure vs. placebo or other nonantimicrobial procedure				
Coban 2004	NA	Ampicillin-sulbactam 1 g IP tds + netilmicin 150 mg IP LD then 50 mg IP od vs. 320 mg IgG IP qid + antibiotics		
Eljersen 1991	NA	Vancomycin IP + netilmicin IP vs. rapid peritoneal lavage for 24 h + IP antibiotics	36	30[d]
Gadallah 2000	NA	Vancomycin-gentamicin vs. urokinase 5000 IU in 2.5 mL normal saline + antibiotics	80	
Innes 1993	NA	Placebo vs. urokinase	25	
Tong 2005	28	Cephazolin-netilmicin IP + placebo (20 mL normal saline) vs. cephazolin-netilmicin IP + urokinase 60,000 IU IP diluted in 20 mL of normal saline	88	28
Williams 1989	NA	Catheter removal and replacement vs. urokinase 5000 IU in 2 mL	37	90–360

Abbreviations: NA, not available; IP, intraperitoneal; PO, per oral; IV, intravenous, IM, intramuscular; od, once a day; bd, twice a day; qid, four times a day; IgG, immunoglobulin G; LD.

[a] Trials are grouped in alphabetical order and by type of interventions.

[b] Number of days from effluent clearing.

[c] Beyond total clearing of dialysate and a decrease in the dialysate white blood cell count <100/mm^3.

[d] After cessation of antibiotic treatment.

that each program weigh the benefits of vancomycin with the risk of emergence of resistant microorganisms.

Nystatin significantly reduced the risk of *Candida* spp. peritonitis in PD patients. The applicability of this finding is limited, given the relatively high occurrence rate reported in the control arm of the one large trial identified (8.5% over 2 years) [49]. However, in light of the high disease burden associated with fungal peritonitis and absence of adverse effects of nystatin, implementation of this practice, as recommended by the ISPD guidelines, appears to be of net clinical benefit.

Topical antiseptic agents were recommended in the previous version of the ISPD guidelines, but not in the current edition. Variations of this practice, along with use of other antimicrobial interventions, are not supported by any evidence, or else they have not been the subject of clinical trials. A meta-analysis of three RCTs

of topical povidone–iodine or powder sprays showed no benefit compared with nondisinfectant soap and water [37]. Moreover, although side effects were generally inadequately reported, one study observed that skin rashes occurred in 6% of patients following povidone–iodine application [50]. There is no evidence to support regular topical exit site disinfection with antibacterial soap or a medical antiseptic to keep the exit site clean and to diminish resident bacteria. Trials of UV germicidal chambers around the connection device [51] and anti-staphylococcal vaccine [52] also showed no significant effects of the intervention. There have been no controlled trials evaluating the effects of antibacterial soap.

Overall, although a number of trials have assessed the benefits of different antimicrobial interventions to prevent peritonitis in PD, the majority of trials enrolled few patients over relatively short

Table 47.4 Effects of antimicrobial agents in preventing peritonitis, exit site and tunnel infection, catheter removal or replacement, and all-cause mortality in PD.

Intervention[a]	Peritonitis		Peritonitis rate		Exit site and tunnel infection trials		Exit site and tunnel infection rate		Catheter removal or replacement		All-cause mortality

periods of follow-up, did not adequately assess harms, and did not fulfill widely accepted quality standards for reporting. Almost all trials evaluated in the systematic reviews failed to specify whether randomization allocation was concealed, outcome assessors were blinded, or data were analyzed on an intention-to-treat basis. These issues, together with the small sample sizes of all but three trials, reduce the strength of the conclusions that may be drawn at present. The possibility of a type 2 statistical error for some of the less frequently observed outcome measures (e.g. catheter loss) cannot be excluded; almost all analyses were consistent with both clinically important benefits and harms from the intervention, such was the imprecision of the estimates. The absence of statistical significance in the overall risk estimates provided by many trials means that we do not know whether the intervention is effective or that an intervention is definitely ineffective. Some studies, such as those involving prophylactic oral antibiotics, date back to the 1980s, when peritonitis rates were much higher than those observed more recently. Thus, the generalizability of

these studies to contemporary practice is questionable, although the likelihood that further trials will be carried out is low. Items that need to be considered when making a recommendation or suggestion about these interventions include the size and estimate of the effect, the likelihood that, if further studies were to be conducted, they would find different effects than those already published, and the trade-offs between potential benefits and harms. Table 47.7, below, presents a grading of the available evidence with relevant recommendations and suggestions for clinical care.

Table 47.7 Evidence ratings and recommendations for catheter-related interventions to prevent peritonitis and exit site and tunnel infection in PD.

Intervention	Existing systematic reviews[a]	Overall evidence rating[b]			Comment	Recommendation[c]			Comment
		High	Moderate	Low		I[a]	II[b]	III[c]	
Laparoscopy vs. laparotomy	●			●	3 RCTs, no heterogeneity, poor methodological quality		●		Moderate/imprecise effect size, low evidence base, no excess harms documented, higher likelihood of acceptance by patients
Standard insertion (resting and subcutaneous burying) vs. resting but no subcutaneous burying	●			●	3 RCTs, high heterogeneity, poor methodological quality		●		Moderate/imprecise effect size, low evidence base, no excess harms documented
Midline insertion vs. lateral insertion	●			●	2 RCTs, no heterogeneity, poor methodological quality		●		Moderate/imprecise effect size, low evidence base, no excess harms documented
Straight catheter vs. coiled catheter	●		●		8 RCTs no heterogeneity, 4 RCTs poor methodological quality			●	Undetermined effect, moderate evidence base, potential for increased harm
Y-set system vs. standard spike	●		●		10 RCTs little heterogeneity, 5 RCTs poor methodological quality	●			Large effect size, moderate evidence base, no excess harms documented, Y-set standard practice in several countries
Double bag systems vs. Y-set	●		●		4 RCTs high heterogeneity, 2 RCTs poor methodological quality		●		Moderate/imprecise effect size, moderate evidence base, no excess harms documented, double-bag standard practice in several countries

Favours Y-set   Favours standard spike

Figure 47.4 Y-set versus standard spike catheters: effects on peritonitis, peritonitis rate, and exit site or tunnel infection rate.

Catheter-related interventions for prevention of peritonitis

The only catheter-related measure that has been shown to reduce peritonitis rates in a systematic review is the use of disconnect systems rather than conventional spike systems [39]. The use of the Y-set compared to standard spike systems was associated with a significantly lower risk of peritonitis and peritonitis rate, but no differences in the risk and rates of exit site and tunnel infection, catheter removal or replacement, or all-cause mortality were found (Figure 47.4). One trial of 60 patients also showed a significant increase in the risk of technique failure with the Y-set [53]. These results support the recommendations of the BRA and CARI guidelines against the use of conventional spike connection systems. Although the ISPD and National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) clinical practice guidelines make no specific recommendations about connection methodology, spike and luer lock connect system usage has generally been declining in recent years. In the UK, the use of connect PD systems decreased from 22% in 1998 to less than 1% in 2002 [54]. A similar experience has been reported in Australia and New Zealand [55]. The double-bag systems are associated with a reduction in the risk of peritonitis compared to Y-set systems, although statistical significance has not been attained (Figure 47.5).

Other catheter-related interventions that have been the subject of RCTs and included in systematic reviews are surgical approaches (laparoscopy vs. laparotomy, standard insertion and resting vs. implantation and subcutaneous burying, and midline vs. lateral insertion), type of PD catheter (straight vs. coiled, single vs. double

cuffed, antibiotic impregnated vs. standard catheters), use of silver rings, immobilization devices, and use of the Ultrabag versus the Stay-safe set. None of these has been shown to significantly affect the rates of exit site and tunnel infections or peritonitis, but wide point estimates around the comparison of laparoscopy vs. laparotomy for insertion of PD catheters demonstrate a lack of statistical power [39]. Further trials in these areas should be encouraged.

A meta-analysis of eight RCTs comparing straight versus coiled catheters demonstrated a reduction in all-cause mortality associated with straight catheters. This result was largely unexplained, particularly in view of the similar rates of peritonitis, exit site and tunnel infections, and catheter removal or replacement observed with the two catheter types. Causes of death were not reported to clarify the reason for the result. Potential alternative explanations include a type 1 statistical error (most likely) or inadequate randomization, possibly due to suboptimal allocation concealment. This result should be interpreted with caution and may warrant further studies.

Several retrospective, observational studies have suggested that APD is associated with a reduced risk of peritonitis compared with CAPD and have speculated that this may reflect the reduced number of connections (and therefore opportunities for intraluminal contamination) involved with APD. However, interpretation of these findings is potentially confounded by the possibility of selection and recall biases. In the available Cochrane Review, only

two small, relatively short-duration RCTs of APD versus CAPD were identified and no differences in PD outcomes were observed, but the possibility of a type 2 statistical error could not be excluded [56,57].

As with antimicrobial preventative interventions, there is a relative paucity of quality RCTs in this area, and trial methodology has been generally poor. Many studies are small and often short in duration, so that the possibility of a type 2 statistical error for some of the less frequently observed outcome measures (e.g. catheter loss) cannot not be excluded. Moreover, evidence of trial heterogeneity was found in some analyses of peritonitis rates (such as for laparoscopy vs. laparotomy and twin bag vs. Y-set), which most likely reflected significant intertrial variability in duration of follow-up. These issues reduce the strength of the conclusions that may be drawn. However, the likelihood that further trials will be carried out in this area is relatively low, so clinicians need to make decisions based on these data alone. Table 47.8 presents a grading of the available evidence with relevant recommendations and suggestions.

Treatment of exit site and tunnel infections

Two trials comparing antibiotic regimens for treatment of exit site and tunnel infections have been conducted. In one, intraperitoneal vancomycin–oral rifampin were found to be equally effective as intraperitoneal vancomycin–oral trimethoprim-sulfamethoxa-

Table 47.8 Evidence ratings and recommendations for antimicrobial interventions to prevent peritonitis and exit site or tunnel infection in PD.

| Intervention | Existing systematic reviews[a] | Overall evidence rating[b] | | | | Recommendation[c] | | | |
		High	Moderate	Low	Comment	I[a]	II[b]	III[c]	Comment
Oral antibiotics vs. placebo/no treatment	●		●		6 RCTs high heterogeneity, 4 RCTs poor methodological quality	●			Moderate/imprecise effect size, moderate evidence base, potential for development of antibiotic resistance, no other excess harm documented
Nasal antibiotics (mupirocin) vs. placebo	●	●			3 RCTs no heterogeneity, 2 RCTs poor methodological quality	●			Large effect size, high evidence base, potential for development of antibiotic resistance, no other excess harm documented
Oral antifungal agents (nistatin) vs. placebo/no treatment	●	●			1 RCT, large sample size	●			Large effect size, high evidence base, no excess harm documented
Topical disinfectants (povidone-iodine) vs. placebo/no treatment	●		●		3 RCTs no heterogeneity, poor methodological quality	●			Moderate/imprecise effect size, moderate evidence base, low likelihood that intervention may cause harms, topical disinfection of catheter exit site represents standard practice in many countries
Germicidal devices for connectology	●		●		1 RCT, small sample size, poor methodological quality			●	Small/imprecise effect size, moderate evidence base
Vaccines vs. placebo/no treatment	●		●		1 RCT, small sample size, poor methodological quality			●	Small/imprecise effect size, moderate evidence, low biological plausibility of effect
Perioperative i.v. antibiotics vs. placebo	●		●		5 RCTs low heterogeneity, 3 RCTs poor methodological quality	●			Large effect size, moderate evidence, no excess harms documented and unlikely to cause harm
Nasal or topical mupirocin vs. placebo	●			●	1 RCT, small sample size, poor methodological quality			●	Small/imprecise effect size, low evidence

Abbreviation: i.v., intravenous.

zole (cure rates of 86% vs. 89%, respectively) [58]. Concerns about multidrug-resistant organisms limit widespread application of either of these regimens. The second trial found intraperitoneal clindamycin to be superior to oral clindamycin; however, this trial was conducted in the early 1990s, again limiting applicability to current practice [59].

Treatment of peritonitis

A large number of antibiotic regimens used in the treatment of peritonitis have been evaluated in RCTs. Only two antibiotic regimens were found to be superior in a systematic review [41];

however, in both cases the applicability to current practice was low. Meta-analysis of two trials comparing cephazolin and vancomycin found the latter to be superior at reducing treatment failure and relapse. This finding was strongly influenced by a large number of patients in one trial in which a low dose of cephazolin (25 mg/L) was used [60]. The other trial included in the meta-analysis used a cephazolin dose of 125 mg/L, as is recommended in the ISPD guidelines, and found the two agents to be equivalent [61]. Further, when all glycopeptide-based regimens were compared to first-generation cephalosporin-based regimens, no difference was found (Figure 47.6). Intraperitoneal

Figure 47.6 Glycopeptide versus first-generation cephalosporin-based intraperitoneal antibiotic regimens: effects on treatment failure, relapse, and catheter removal.

ciprofloxacin–rifampin was found to be superior to intraperitoneal cephradine in one trial [35]. The usefulness of this finding is limited by the use of monotherapy with a first-generation cephalosporin in one treatment arm, without any broad gram-negative cover, a practice which is now uncommon. Similarly, first-line use of ciprofloxacin and rifampin is restricted in many centers due to concern regarding the risk of emergence of multidrug-resistant organisms. Details on other antibiotic regimens tested in RCTs are reported in Table 47.6.

No currently available guidelines recommend specific antibiotic regimens, reflecting the paucity of available evidence; however, information regarding factors requiring consideration when selecting antibiotics has been provided in the guidelines. ISPD guidelines recommend that there should be center-specific selection of an agent(s) according to local causative microorganism and resistance patterns [36]. The impact of local microbial resistance on peritonitis outcomes was apparent in two trials comparing oral and intraperitoneal quinolone use. In both studies, response rates were low for both treatment arms (41.7% and 55.6% in the per oral group and 66.7% and 70.6% in the intraperitoneal group, respectively) [62]. Microorganism resistance to quinolones was the major cause of treatment failure, and previous exposure to quinolones was a risk factor for infection with resistant microorganisms. Similarly, the emergence of vancomycin-resistant enterococci is associated with use of broad-spectrum antibiotics [63,64]. CARI suggests avoidance of aminoglycosides where possible to avoid ototoxicity and nephrotoxicity. Decline in residual renal function with an aminoglycoside-based antibiotic regimens was assessed in one trial of 102 patients with peritonitis [65]. In this study there was no increased loss of residual renal function with a netilmycin-based regimen compared to ceftazidime use for gram-negative cover. Few trials evaluated ototoxicity, despite the

fact that this is a clinically relevant and frequently encountered complication.

The optimal route of antibiotic administration has been addressed in trials comparing oral and intraperitoneal administration [62,66–72] and comparing intravenous and intraperitoneal dosing [73]. One trial found intraperitoneal therapy to be superior to a regimen where the initial antibiotics were given intravenously, followed by oral antibiotics at day 4 if considered appropriate. This finding may relate to achievement of higher intraperitoneal antibiotic concentrations with intraperitoneal versus systemic dosing and early use of oral therapy; however, a meta-analysis of 10 trials found that oral dosing was equivalent to intraperitoneal dosing (Figure 47.7). This was demonstrated when the same drug was administered intraperitoneally and orally [62,67,74] and when oral

quinolone monotherapy was compared to intraperitoneal combination therapy.

The ISPD guidelines recommend adjustment of some drug doses in patients with residual renal function and high transporters to compensate for increased urinary and peritoneal clearance, respectively. RCTs performed to date have not compared different dosing regimens or stratified patients according to residual renal function. Small pharmacokinetic studies found no difference in drug levels or clearances in patients stratified according to glomerular filtration rate; however, there were very small patient numbers [75,76]. Further evaluation in this area is required.

Intermittent dosing (daily or less frequent) was equivalent to continuous dosing (with each exchange) in four trials [77–79] (Figure 47.8). The applicability of results from trials of intermittent

drug therapy in CAPD to APD is unclear. Drug half-lives are greater and clearance is more rapid in cycler dwells compared to noncycler dwells [80]. Pharmacokinetic studies of intraperitoneal antibiotic dosing suggest that therapeutic drug levels are achieved during 6-h dwells [75,76]; therefore, it is likely that a patient can remain on APD as long as there is at least a 6-h daytime dwell during which antibiotics can be administered.

Peritoneal lavage in conjunction with antibiotic treatment provided no additional benefit in one trial, and it appears to have no routine place in peritonitis treatment [33]. Urokinase had no

advantages over placebo in improving response rates or reducing relapse [32,81,82] and, when compared to early catheter removal, urokinase was clearly inferior [83] (Figure 47.9). Overall, urokinase appears to have no role in standard treatment regimens. One study of intraperitoneal immunoglobulin administration in conjunction with antibiotics found that the treatment group achieved biochemical and clinical parameters of improvement sooner and that the duration of antibiotic therapy was shorter [34]. However, the response rate was 100% in both groups with no relapses during a 3-month follow-up period, suggesting that use

Table 47.9 Evidence ratings and recommendations for interventions to treat PD-related infections.

Intervention	Existing systematic reviews[a]	Overall evidence rating[b]			Comment	Recommendation[c]			Comment
		High	Moderate	Low		I[a]	II[b]	III[c]	
Intravenous vs. intraperitoneal antibiotics	●		●		2 RCTs, small sample size, 1 RCT poor methodological quality	●			Moderate effect size, low evidence base, no harm demonstrated, likely to be more acceptable to patients, facilitates outpatient management
Oral vs. intraperitoneal antibiotics	●		●		10 RCTs, low heterogeneity, 5 RCTs poor methodological quality		●		Undetermined effect, large evidence base, high risk of resistant microorganisms with oral antibiotic regimens used
High-dose vs. low-dose antibiotics	●			●	Subset of 1 RCT, small sample size			●	Large effect size, low evidence base, moderate likelihood of harm
Intermittent vs. continuous intraperitoneal antibiotics	●		●		4 RCTs, low heterogeneity, 2 RCTs poor methodological quality		●		Undetermined effect, moderate evidence base, no harm demonstrated, greater acceptance by patients likely, applicability to APD and antibiotics with different pharmacokinetic properties unclear
Regimen A vs. regimen B intraperitoneal antibiotics	●		●		14 RCTs, small sample sizes, 9 RCTs poor methodological quality			●	Small, imprecise effect size, small evidence base, low applicability to current practice, no harm demonstrated
Regimen A vs. regimen B oral antibiotics	●		●		1 RCT, small sample size, poor methodological quality			●	Undetermined effect, low evidence base, no harm demonstrated
Peritoneal lavage vs. standard therapy	●			●	1 RCT, small sample size, poor methodological quality			●	Undetermined effect, low evidence base, no harm demonstrated
Urokinase vs. placebo or routine catheter removal/replacement	●		●		4 RCTs, high heterogeneity, 1 RCT poor methodological quality	●			Large effect size for catheter removal or replacement, moderate evidence base, no harm demonstrated
Intraperitoneal immunoglobulin vs. standard therapy	●			●	1 RCT, small sample size			●	Large effect size on laboratory parameters but no effect on clinical outcomes, no harm, biologically plausible

[a] If no existing systematic review, overall evidence rating will start at moderate.

[c] Recommendation based on efficacy, trade-offs between benefits and harms, quality of evidence, and availability of medication. I, recommend; II, suggest; III, no recommendation possible.

of immunoglobulin does not change overall patient outcomes. This, together with the expense and limited availability of immunoglobulin therapy, reduces the feasibility of this treatment as part of routine therapy at the present time.

There have been no clinical trials evaluating the role of routine early catheter removal in refractory peritonitis or of temporary transfer of patients from APD to CAPD. In the latter case the question of when to safely recommence APD has also not been addressed.

Surgical peritonitis refers to cases in which peritonitis arises from intra-abdominal pathology. This may manifest as polymicrobial peritonitis. Such cases are usually treated by laparotomy and catheter removal at the same time as the underlying pathology is addressed, followed by a course of broad-spectrum intravenous

antibiotics. There have been no trials addressing the treatment of this situation, and such trials are unlikely to be performed.

As with infection prevention trials, systematic reviews of peritonitis treatment trials are limited by the suboptimal methodological quality of many trials, in particular, inadequate randomization and concealment methods were common. Definitions of peritonitis, successful treatment, and relapse varied between trials, thereby reducing their comparability. Similarly, antibiotic doses were not consistent across studies. The follow-up period of most included trials was 28 days or less, meaning that several long-term outcomes of peritonitis treatment, such as technique failure and longer-term mortality, were not evaluated. Studies tended to focus on choice and route of antibiotic without consideration of other variables, such as total duration of therapy or drug dose. To date, there have been no RCTs of treatment for fungal peritonitis, a condition that is associated with almost 100% catheter loss and high levels of mortality. Reported trials often predate the current era of lower peritonitis rates, newer antibiotic therapies, and increased awareness of multidrug-resistant organisms, thereby potentially reducing the applicability of our meta-analyses or the individual trials' results. These aspects all need to be considered when making a decision about recommending or suggesting adoption of these interventions.

Conclusions

There is evidence from clinical trials to support a small number of effective interventions in prevention and treatment of PD-related infections and some evidence that other interventions, which are in current use, are not likely to be studied further nor to cause substantial harm. The recommendations and suggestions for clinical care that can be made based on currently available evidence are summarized in Table 47.7 to 47.9, below. Eradication of nasal *S. aureus* carriage with topical mupirocin reduces the risk of exit site and tunnel infections (but not peritonitis), and intravenous antibiotic administration prior to PD catheter insertion prevents the risk of early postoperative peritonitis. These strategies can be recommended. Concomitant use of oral nystatin with antibiotic therapy to reduce the occurrence of *Candida* peritonitis is recommended. Disconnect (twin bag and Y-set) systems are clearly superior to conventional spike systems for the prevention of peritonitis and should be recommended; however, there is no clear advantage of twin bag over Y-set systems, different catheter designs, implantation techniques, or APD.

Treatment of peritonitis should consist of antimicrobial therapy, but most antibiotic regimens for empiric treatment are similar in efficacy, so no specific regimen can be recommended. Available evidence shows intraperitoneal administration of antibiotics to be superior to intravenous administration, the intraperitoneal route is more likely to be acceptable to patients, and this mode of administration is therefore recommended. Oral quinolones and intraperitoneal regimens have equal levels of efficacy, but due to a general increase in community levels of quinolone-resistant

microorganisms, this therapy is not recommended. Intermittent therapy appears to be equivalent to continuous therapy; however, further trials involving patients on APD are required, and thus this therapy can be suggested but not recommended. In relapsing or resistant peritonitis, catheter removal, and not urokinase, is recommended. There are insufficient trial data to make recommendations about peritoneal lavage, intraperitoneal immunoglobulin, or different dosing regimens.

There remains a need in this area for well-designed, randomized controlled studies. The design of such studies should focus on adequate allocation concealment and blinding of outcome assessors. In many cases, blinding of participants and investigators is difficult due to overt differences in interventions; however, when possible this should occur. Blinded measurements of outcomes are always possible. Preventative strategies that would be particularly worth investigating are trials of laparoscopy versus laparotomy for catheter insertion, exploring effects on early peritonitis (less than 1 month from catheter insertion), and of straight versus coiled catheters. Current data for both of these have suggested possible differences that require substantiation. Trials in these areas should be adequately powered to detect relevant outcomes. Studies of topical Medihoney application to reduce infection rates would be valuable, as this is a readily available treatment that is likely to be associated with minimal harm. Further studies of peritonitis treatment should be designed with follow-up periods sufficient to allow evaluation of outcomes, such as ultrafiltration failure, technique failure, and all-cause mortality. Specific interventions to be addressed include duration of antibiotic therapy and intraperitoneal courses versus combined intraperitoneal–per oral courses. Stratification of patients into CAPD and APD would be beneficial given the increasing number of patients on the latter therapy.

8 Transplantation

48 Evaluation and Selection of the Kidney Transplant Candidate

Bryce Kiberd

Dalhousie University, Halifax, Nova Scotia, Canada

Introduction

Kidney transplantation improves quality of life and length of life and costs less than dialysis (Table 48.1) [1–4]. However, comparing outcomes for transplanted patients to the general dialysis or wait-listed population is not ideal, because there are survival and selection biases [5–7]. Less than half of patients on dialysis are considered for transplantation; <3% of dialysis patients more than 70 years old are on the transplant waiting list [6], and most older patients who are on the list will either die or be removed from the list before receiving a transplant [8]. The process of selection is an essential but problematic activity. Most guidelines have focused on evaluation, leaving patient selection to a center's discretion [9–13].

Organ allocation policies recognize the need to find a balance between conflicting goals [11–14]. Goals of selection include the following: 1) maximize patient and graft survival, 2) minimize disparities in waiting time, 3) minimize deaths while waiting, and 4) maximize opportunity. Achieving equality may reduce utility. Attempts to minimize deaths on the list by performing transplants in the elderly will limit the ability to maximize survival by transplanting in younger patients. These competing goals are the root of the difficulty in defining selection criteria. One compromise is to limit transplantation to patients with reasonable life expectancies who are likely to live beyond current waiting times [12].

Cardiovascular disease

Recommendations

All patients should undergo cardiac evaluation by history, physical, electrocardiogram, and chest radiograph. Further testing should be based on the initial assessment. Contraindications to

transplantation include progressive angina, recent myocardial infarction (<6 months), and diffuse coronary artery or valve disease that is not correctable.

Evidence

Because cardiac disease is prevalent and the major cause of excess mortality, evaluating the extent of the disease and implementing preventive strategies is reasonable [15]. Congestive heart failure and ischemic heart disease occur in 27% and 29% of incident dialysis patients, respectively, and both are associated with reduced likelihood of transplantation [16].

Potential transplant recipients with cardiac symptoms or active disease deserve further evaluation, as in the general population [17]. Many uremic patients are sedentary or have symptoms that are ascribed to anemia or poor general health. Screening the high-risk asymptomatic recipient may be useful. Because the transplant procedure meets the criteria for high risk, as it involves vascular surgery and fluid shifts, and most patients have at least intermediate clinical risk factors (diabetes mellitus, renal impairment, ischemic heart disease), further evaluation is within accepted guidelines [18]. There are data supporting routine evaluation in asymptomatic potential kidney transplant patients. A relatively old study in a small group of high-risk diabetic uremic patients showed that there were a greater number of cardiac end points in the medical treatment arm (calcium channel blockers and aspirin) than in the intervention arm (angioplasty or bypass surgery) [19]. The extent of routine revascularization in asymptomatic pretransplant patients undergoing preparation for listing has not been quantified well in the nondiabetic population or in a larger diabetic population. A major reason for uncertainty is that a large trial ($n = 510$) in nontransplant patients found preoperative invasive treatment did not improve survival after noncardiovascular surgery [20].

Patients older than 45 years or with diabetes mellitus, prior cardiac history, or other multiple risk factors may benefit from noninvasive testing. In a meta-analysis, noninvasive tests did predict later cardiac events and death with reasonable accuracy [21]. There is no consensus on what is the best noninvasive test. A number of studies have examined the accuracy of tests to detect coronary

Table 48.1 Survival advantages of kidney transplantation.

Age at transplantation (yrs)	gained with kidney transplantation (vs. dialysis)[a]		
	USRDS 2004 [3]	Gill *et al* [2][b]	Wolfe *et al.* [1][b]
0–14	29.5	17.2 (0–19 yrs old)	13.0 (0–19 yrs old)
15–19	22.1		
20–24	21.0	14.8 (20–39 yrs old)	17.0 (20–39 yrs old)
25–29	19.4

40–44	13.8	9.4 (40–59 yrs old)	11.0 (40–59 yrs old)
45–49	12.1		
50–54	10.5		
55–59	9.0		
60–64	7.5	6.2	4.0 (60–74 yrs old)
65–69	6.3	5.3	
70–74	5.2	3.7 (70–79 yrs old)	
75–79	4.7		

[a] Methods for calculating survival advantages differed for each study.
[b] For the Gill *et al.* and Wolfe *et al.* studies, some wider age ranges were evaluated than in the USRDS study.

artery disease (Table 48.2) [11, 21–30]. Because of the high pretest likelihood, some have argued cardiac catheterization is the best approach [31]. Routine cardiac catheterization in high-risk patients is performed in only a minority of US centers [32]. Given that the availability of tests varies among centers and that not all tests are appropriate for any one patient, the local cardiologist should guide test selection. Patients with advanced disease, low functional capacity, or who do not have circumscribed arterial lesions that are amenable to treatment are likely do poorly with, or without, a transplant. Multivessel disease was an exclusion criterion in 88% of centers in a recent European survey [33]. Preoperative invasive therapy is likely to be of limited value in patients

with asymptomatic single- or double-vessel disease that is not a proximal left anterior descending lesion and not associated with impaired ventricular function. Discussions of further indications for corrective surgery and the evidence in asymptomatic patients are beyond the scope of this article.

Guidelines recommend periodic reevaluation [34,35], but cardiac evaluation in asymptomatic patients after listing is not routinely practiced and subsequent invasive therapy is unlikely. Kasiske reported intervention (angioplasty or bypass surgery) in only 9% of patients screened, with similar rates in the rescreened [36]. In a preliminary medical decision analysis, rescreening diabetic patients would be cost-effective if screening identified a

Table 48.2 Noninvasive screening for coronary artery disease.

Study [reference]	Population	n	Test	Criterion (% extent of stenosis)	Sensitivity (%)
Reis [24]	Pretransplant	97	DSE	>75	92
Vandanberg [22]	Diabetes mellitus, pretransplant	41	Pharmacologic thallium	>75	62

Marwick [26]	Pretransplant	45	Pharmacologic thallium	>70	75
Worthley [27]	Pretransplant	50	Tachycardiac Stress	>70	87

Abbreviations: DSE, dobutamine stress echocardiogram; SPECT, single photon emission computed tomography.

significant proportion with covert disease who subsequently received invasive therapy that allowed them to remain listed and where covert disease was associated with higher mortality rates [37]. What studies do not report is the extent to which evaluation results in appropriate delisting decisions.

There is a trend away from preoperative surgery and toward the use of medical interventions to prevent cardiovascular disease [38,39], although use of medications, even in high-risk wait list patients, is low [40]. Although a recent randomized controlled trial failed to show the benefits of statin therapy in diabetic hemodialysis patients [41], many study subjects were unlikely to be transplant candidates, and another randomized control trial demonstrated the benefit of statins posttransplantation in this subgroup in a post hoc analysis [41,42]. Without evidence of harm, it seems reasonable to consider greater use of cardiovascular disease risk-reducing medications in patients waiting for kidney transplantation.

Patients with symptomatic cardiac valve heart disease should be treated as these patients are in the general population. Patients denied appropriate surgical correction because of reduced life expectancy or excessive risk should not be considered for kidney transplantation (unless done in conjunction with cardiac transplantation). Isolated uremic cardiomyopathy is not an absolute contraindication to transplantation [43,44].

Cerebral vascular disease

Recommendation
Ancillary testing for cerebral vascular disease may be required based on history. A stroke or transient ischemic attack (TIA) within 3 months is an absolute contraindication to transplantation.

Evidence
Stroke mortality is the third (8%) most common cause of death posttransplantation [45,46]. Mortality after a stroke is 50% at 3 months [46].

Patients with a stroke or TIA should be treated with control of blood pressure, antithrombotic therapy for atrial fibrillation, and antiplatelet therapy [47]. Statins may also lower the incidence of stroke [48]. The optimal waiting time to allow recovery from injury is unknown, but waiting 2–3 months [49], the period in which there is the highest risk of recurrence is recommended. The short-term stroke risk is 11% after a TIA, and so a patient with a TIA should be considered at the same risk as a patient with a completed stroke [50]. Guidelines for patients with symptomatic or asymptomatic carotid disease who might benefit from endarterectomy are available elsewhere [51].

Screening for cerebral aneurysms in autosomal dominant polycystic kidney disease is controversial because it is uncertain whether screening and treatment confers net clinical benefit compared with treatment of only symptomatic patients [52]. The prevalence of aneurysms is likely to be higher in patients with a family history of stroke [53]. Younger patients with asymptomatic aneurysms of >10 mm should be considered for intervention [54].

Peripheral vascular disease

Recommendations
Ancillary testing for peripheral vascular disease should be based on history or physical findings. Large uncorrected aortic aneurysm, severe occlusive iliac disease, active gangrene, or recent atheroembolic events are contraindications to listing.

Evidence
Peripheral vascular disease is present in about 15% of incident dialysis patients and is associated with increased mortality (hazard ratio, 2.4) [55]. The prevalence of peripheral vascular disease at the time of transplantation is about 5–6% and is also associated with reduced survival [2,56].

Recent practice guidelines recommend screening for abdominal aneurysms in men between 65 and 75 years of age who have smoked, with uncertainty about similarly aged men who have never smoked [57]. Large abdominal aneurysms of 5–5.9 cm have rupture rates ranging from 4 to 14%/year and those of >6.0 cm have rupture rates of greater than 20%/year with high subsequent mortality [58]. Patients who are not considered candidates for repair because of high comorbidity are not likely to be transplant candidates. Patients with severe vascular disease in the iliac arterial system should be identified in order to prevent inadequate flow to the newly transplanted kidney.

Pulmonary disease

Recommendations
All patients should undergo a history, physical, and chest radiograph. Ancillary testing may be required in symptomatic patients or those with an abnormal chest radiograph. Advanced irreversible pulmonary disease or frequent lower tract infections are contraindications to transplantation.

Evidence
Uncontrolled asthma, severe chronic obstructive pulmonary disease and/or pulmonary fibrosis or restrictive disease with a low forced expiratory volume in 1 s (FEV1) of <25% of predicted value, low PO_2 (<60 mmHg) on room air, or with exercise desaturation (SaO_2) of <90% were acknowledged by consensus to be absolute contraindications [10]. Patients with less respiratory compromise but likely to progress and those with frequent infections (>4 lower respiratory infections in the last year) were also felt to be noncandidates. Patients with these disorders, typically with a best FEV1 of <40% of normal, have high mortality rates, with 50% survival at about 6 years. Patients with a FEV1 of <25% of predicted have an even lower survival [59], and patients requiring home oxygen therapy have a 5-year survival as low as 30% [60]. The incidence and case fatality rate of pneumonia have decreased over time [61], but patients with frequent infections prior

Table 48.3 Possible cancer screening strategies for the potential kidney recipient.

Target organ	Test	Test frequency	Age (yrs) at screening
Bladder	Cytoscopy	Not routine	>50 and high risk
Breast	Mammography	Every 1–2 yrs	>40
Colorectal[a]	FOBT	Annually (FOBT)	>50
	Sigmoidoscopy	Every 5 yrs	
	Colonoscopy	Every 10 yrs

[a] Abnormalities detected by screening require additional tests.

to transplantation, in the absence of immunosuppression therapy, should be considered high risk.

Cancer

Recommendations

Selected patients should undergo cancer screening prior to transplantation. Patients with a past history of cancer will need further testing and an observation period for recurrence, and the advice of an oncologist prior to transplantation should be considered. Patients with advanced-stage cancers are not candidates for transplantation.

Evidence

Cancer is more common in end-stage renal disease patients than the general population [62]. Some cancers have mortality rates that exceed the dialysis mortality rate [63]. Transplanting patients with a high risk of cancer-associated mortality is not likely to improve outcomes.

The US Preventive Services Task Force has provided recommendations for screening specific cancers in men and woman in the general population [57]. Overall, colorectal, cervical, and breast cancer screening have the highest evidence. Other strategies, such as prostate cancer screening, are inconclusive although widely practiced. It is possible that detecting cancers through screening may do more harm to patients who might otherwise receive a transplant promptly. Table 48.3 gives a list of potential screening strategies. The evidence for referral to screening in the general population is different for screening to determine transplant eligibility. Avoiding transplantation in a cancer patient with limited life expectancy concerns more the prudent use of a scarce resource than a strategy to improve life expectancy.

In general, about 50% of cancers recur within <2 years, 33% between 2 and 5 years, and about 15% more than 5 years after the first cancer [11]. Published cancer recurrence rates are inaccurate due to selection bias. Data from the Israel Penn International Tumor Transplant Registry do not have a reliable denominator to accurately calculate rates [64]. Table 48.4 gives a list of the cancers and recommended waiting times, taking into account the evidence.

Table 48.4 Recommended transplantation wait times for specific cancers.

Cancer site or type	Wait time (yrs)
Breast	>5 (>2 for early disease)
Bladder	>2
Colorectal	>5 (>2 for Dukes stage A or B1)
Kaposi sarcoma	>2
Leukemia	>2 (limited data to make recommendation)
Liver	Unable to give recommendation
Lung	>2
Lymphoma	>2
Melanoma	>5 (>2 melanoma *in situ*)
Myeloma	Unable to give recommendation
Prostate	>2 (localized disease possibly shorter wait)
Renal/Wilm's tumor	>2 (>5 for large cancers; no wait for incidental of <5 cm)
Skin (non-melanoma)	0–2 (no wait for basal cell)
Testicular	>2
Thyroid	>2
Uterine or cervix	>2

Sources: Kasiske *et al.* 2001 [11] and European Best Practices Guidelines 2000 [13].

Published guidelines give more details on individual cancers [11–13].

Infections

Recommendations

Ideally, patients should be free of all active infections at the time of transplantation. Patients should be tested for immunity to varicella-zoster virus, Epstein-Barr virus (EBV), cytomegalovirus (CMV), and HIV. HIV-infected patients may be considered for kidney transplantation if they meet certain criteria.

Evidence

All guidelines recommend that patients be free of active infection. Infection is the second most common cause of death (21%) within the first year after transplantation [65]. Given that the early transplant period is the time of intense immunosuppression, the recommendations are reasonable and are unlikely to be tested in a clinical trial.

The prevalence of treatable occult dental disease, detected with routine screening by panoramic radiographs, and the consequences avoided compared with treating symptomatic patients have not been systematically evaluated. It is reasonable to refer patients with symptoms or obvious disease. In a European survey, 61% of centers referred all patients for dental consultation [33].

Mycobacterial infections may be more common in the end-stage renal disease population than in the general population [66]. Patients on dialysis may be anergic, and testing may underestimate true exposure. Administering two-step tuberculin skin testing may improve detection [67]. The risks and benefits of pretransplant

prophylaxis, early posttransplant prophylaxis, or watchful waiting are all acceptable but may depend on other risk factors [66].

Patients seronegative for varicella-zoster virus should be considered for vaccination pretransplantation, because this infection can be fatal in a transplant recipient [68]. Although donor–recipient CMV matching is not routinely performed, knowledge of donor and recipient status predicts posttransplant CMV infection. CMV disease is a potentially fatal infection, and chemoprophylaxis is very effective [69]. Evidence for screening for EBV is not as effective. Seroprevalence of EBV is high in adults, and donor–recipient matching is not performed. Naïve recipients are at greater risk for infection and posttransplant lymphoproliferative disease [70]. Surveillance strategies for EBV are under evaluation.

Patients with HIV have received solid organ transplants with success, and outcomes appear to be equivalent to the general transplant population, but HIV-infected patients who have received transplants are a selected group. Prospective studies are underway to better define which HIV-infected patients should be transplanted. Excellent results have been demonstrated in patients with undetectable plasma HIV viral loads for 3 months, a CD4+ T-cell count of more than 200 cells/μL for 6 months, and no history of opportunistic infection or neoplasm [71].

Liver disease

Recommendations

Patients should be screened for liver disease. Patients with overt liver disease or positive for hepatitis B or C virus should be referred to a hepatologist for assessment of the extent of disease, a discussion of prognosis, ongoing monitoring, and candidacy for specific treatment.

Evidence

The prevalence of hepatitis C-positive kidney transplant recipients in the USA is 6.8% [72], and the prevalence of hepatitis B surface antigen in the US dialysis population is <1% [73]. Liver failure is a significant cause of morbidity and mortality in hepatitis B and C patients. In a pooled analysis, hepatitis C antibody was a significant risk factor for death and graft failure (relative risk [RR], 1.8 and 1.6, respectively) [74], but in a recent UNOS registry analysis, hepatitis C patients had an increase in adjusted mortality of only 1.2 ($P = 0.04$) [75]. Patients that were hepatitis C positive had many characteristics associated with inferior survival, including higher rates of regrafts, cadaver donors, and longer duration of dialysis. Differences in patient selection for transplantation and treatment will more than likely change the natural history of these infections [76].

Because biochemical tests may not reflect the extent of disease, a liver biopsy is recommended in those without portal hypertension [77]. The biopsy results may direct therapy. Hepatitis C patients with chronic hepatitis can be considered for a course of pegylated interferon [78]. Hepatitis B patients with active viral replication can be considered for a course of lamivudine [79]. All of the

antiviral studies are small and lack hard end points. It is not clear whether patients with compensated cirrhosis are candidates for kidney-alone transplantation. At issue is whether kidney transplantation confers a survival advantage over the risk of progressive liver disease. Patients with decompensated disease can be considered for combined kidney–liver transplantation.

Gastrointestinal disease

Recommendations
Patients with a recent history or symptoms of gastrointestinal bleeding, peptic ulcer disease, biliary disease, or diverticulitis should be investigated and treated pretransplant. Patients without symptoms should not be screened.

Evidence
In a European survey, active peptic ulcer disease was a criterion for exclusion from transplantation in 57% of centers [33]. The incidence of early posttransplant gastroduodenal disease with prophylaxis is low, at about 3% [80]. *Helicobacter pylori* screening has not been recommended, since the association with adverse outcomes is weak.

The prevalence of asymptomatic cholelithiasis in the transplant population ranges between 5 and 10% [81]. Although the cumulative risk of symptomatic disease, morbidity, and mortality in the asymptomatic transplant candidate is unclear, there is no evidence that patients need to be screened or require surgery.

Complications of diverticular disease, such as perforation and obstruction, have high mortality rates but occur infrequently [82]. Asymptomatic disease is common, and guidelines do not recommend routine screening, but they do recommend surgical correction in immunocompromised patients even after a single episode of diverticulitis [83,84].

Systemic disease

Recommendations
Most systemic diseases should be quiescent prior to transplantation. Selected patients with primary hyperoxaluria can be considered for transplantation.

Evidence
All systemic diseases can recur. The major issues are measuring disease activity and the optimal timing of transplantation. Balancing the benefits of transplantation, the harms of ongoing dialysis, and risks of recurrence are difficult, especially in a recipient with a potential live donor.

Patients with primary hyperoxaluria have a poor prognosis, and many centers avoid transplantation in such patients [33]. A combined liver–kidney transplant potentially provides sufficient enzyme to correct disease and prevent recurrence [85], but studies have not shown a clear benefit for a combined procedure versus

kidney transplantation alone, which may reflect selection biases. Patients with large systemic oxalate burdens are at high risk of early graft loss and may do poorly with either of these options. Patients with a preemptive kidney transplant, or who are transplanted soon after dialysis is initiated, do well without a liver transplant.

Anti-glomerular basement membrane (anti-GBM) disease recurs in <10% of patients and has been associated with circulating antibodies at the time of transplantation [13,86]. Several guidelines recommend waiting until anti-GBM antibodies are undetectable and patients are off therapy for at least 6 months [11–13]. It is not likely that prospective information on the negative and positive predictive values of antibody levels for disease recurrence will be available.

Systemic lupus erythematosus recurs in <10% of transplant patients but may be higher if histopathological criteria are used, although graft loss is uncommon and outcomes are comparable to those in the general transplant population [87,88]. Practice guidelines recommend waiting until the disease is clinically and immunologically quiescent [11–13]. The evidence requiring a long delay prior to transplantation is limited and anecdotal.

ANCA-positive vasculitis patients have modest (up to 20%) recurrence rates posttransplantation [89]. Graft loss due to recurrent disease occurs in <10% and may occur late posttransplantation. ANCA levels do not predict disease recurrence posttransplantation. Most of the available data are from cases series, with little information from large registry analyses. Many practice guidelines recommend a period of observation off cytotoxic therapy. The length of wait has not been clearly established, and the time on dialysis does not impact disease recurrence [89].

Hemolytic uremic syndrome (HUS) recurrence rates may be high and overall survival reduced [90]. Risk of recurrence with epidemic HUS (toxigenic *Escherichia coli*) is uncommon. Nonepidemic HUS is associated with higher recurrence rates (>20%) [91]. Other proposed risk factors, including living donor, use of calcineurin inhibitors, older age, and shorter interval between onset and transplantation, have not been consistently reported. Up to 40% of familial cases and 20% of sporadic cases are linked to mutations in the factor H gene [92], but genetic screening is not readily available and is of uncertain value for predicting recurrence. The utility of repeated transplantation in this group needs to be demonstrated, as recurrence with graft loss is high [93].

Recurrent disease

Recommendations
Patients that lose their first transplant from recurrent focal segmental glomerulosclerosis and patients with Alport syndrome losing a transplant from *de novo* anti-GBM disease are at high risk of recurrence that may preclude retransplantation.

Evidence
No cause of primary kidney disease precludes kidney transplantation absolutely, and in most conditions a second transplant is

reasonable. However, focal segmental glomerulosclerosis has relatively high recurrence rates (20–50%) with subsequent graft loss [94]. The rate of progression of the primary disease, duration of pretransplant dialysis, and younger age may be risk factors, but their clinical predictive accuracy has not been quantified and is not likely to be used to deny kidney transplantation. Measuring recipient disease activity by permeability bioassay is not useful [95]. There are insufficient data to support pre- or posttransplant plasmapheresis prophylaxis [96]. Waiting until the patient is anuric or free of nephrotic-range proteinuria or proceeding by performing bilateral nephrectomy has also not been tested. The use of genetic testing is also currently unproven [97]. Retransplantation may be precluded in patients with early recurrence and a rapid rate of graft loss, because the disease may have a high rate of recurrence in subsequent transplants.

Alport syndrome is a hereditary deficiency of basement membrane collagen, and recurrence of disease is neither expected nor found. However, the disease is associated with an aggressive posttransplant anti-GBM disease in approximately 5% of patients which almost always results in graft loss [98]. Recurrence is high and may preclude a second attempt despite aggressive treatment.

Urological issues

Recommendations

A dysfunctional bladder or urinary diversion is not a contraindication to transplantation.

Evidence

Patients with known bladder problems or symptoms should be referred for urologic evaluation. Pretransplant correction of reflux reduces posttransplant urinary tract infections in children, but urinary tract infection is uncommon and so the clinical benefit of this intervention is uncertain [99]. All patients should have an adequate urinary reservoir to permit storage at a low pressure and a patent passageway with a reliable method of achieving complete evacuation [100]. There are a number of different urinary diversion procedures, but all have significant risk of recurrent infection [101]. Bladder augmentation has also been used in contracted and neuropathic bladders. Successful management with intermittent self-catheterization is an option. Newer modalities to treat hyper-reflexive bladders are being investigated [102]. Overall patient and graft survival do not appear to be adversely affected, and therefore corrected urinary problems should not limit eligibility [103,104].

Obesity

Recommendations

Obesity is not an absolute contraindication to transplantation.

Evidence

Although obesity is associated with some adverse outcomes, reporting has been inconsistent [11,105–107]. Patients with very high body mass indices (>36 kg/m^2) are at higher risk of death (RR, 1.34) and graft loss (RR, 1.39) [105]. Not all surgeons are willing to transplant the very obese, and this may be a limiting factor. There is no evidence that weight loss prior to surgery improves outcomes.

Compliance and adherence

Recommendations

Patients must understand the risks and benefits of transplantation and demonstrate adherence to therapy.

Evidence

Noncompliance is the second (28%) most common medical reason for patient exclusion [108] and was a definite exclusion in 61% of European centers surveyed [33]. In a US survey, 83% of clinicians assess compliance based on dialysis attendance [32]. Most centers have a policy on drug abuse. The period of abstinence required before eligibility varies considerably. Smoking, although discouraged, has not limited eligibility in most centers. Unfortunately, measuring and predicting noncompliance and sustained drug abstinence with accuracy is difficult, leaving centers to decide by local consensus.

49 Evaluation and Selection of the Living Kidney Donor

Connie L. Davis

Division of Nephrology, Department of Medicine, University of Washington School of Medicine, Seattle, USA

Introduction

Transplantation with a living kidney donor is the treatment of choice for end-stage renal disease (ESRD). Although the focus is often on the recipient regaining health, an equally important goal is making sure that the living donor will be able to maintain their own health after donation. Medical evaluation of the donor is aimed to detect medical abnormalities that would put them at risk for donor surgery or to develop ESRD. The evaluation also should exclude diseases (infection, malignancy) that may be transmitted to the recipient. Finally, the evaluation attempts to identify conditions where the removal of one kidney could increase the risk of disease progression or limit the delivery of optimal care. There have been no randomized controlled trials in the living donor population; all data are from single-center, retrospective, or more recently, prospective cohort trials. Few studies have included control groups, and those that did usually recruited control subjects from the general population, which may not be the most appropriate for comparison, as living donors should represent the healthiest members of society.

The overall evaluation process

Evaluation of the living donor starts with education about the donation process and a screening history by the living donor coordinator. Often the prospective donor will be asked to supply a copy of their most recent history and physical and laboratory examinations to the transplant center. Early in the evaluation process, the donor's blood type is ascertained to determine compatibility with the recipient. If this information, plus the screening interview, do not exclude donation, then the prospective donor undergoes a complete history and physical examination, laboratory testing, cross-matching, and finally renal imaging [1,2]. The

donor evaluation is completed with visits to the transplant social worker, psychologist, or psychiatrist (Table 49.1).

Medical evaluation of the living donor has been standardized based on two large conferences with broad representation from the transplant community [3]. However, some testing issues (e.g. type of urinary protein measurement, method of glomerular filtration rate [GFR] determination, anatomic testing method) remain to be established (http://www.bts.org.uk/) [3].

Immediate surgical risk: assessment of cardiopulmonary and coagulation systems

Cardiopulmonary disease

Cardiac evaluations include medical history, physical examination, electrocardiogram, and chest X-ray [4,5]. If these suggest ischemia, then a stress test (exercise or pharmacologic) should be performed. An individual with myocardial dysfunction should not donate, as kidney dysfunction is a common accompaniment to heart failure [6–8]. Coronary lesions requiring intervention should be treated and stable prior to donation. Careful assessment for renovascular disease is needed in those with coronary artery disease [9,10].

Valvular integrity is ascertained by questioning about past rheumatic fever, use of fenfluramine or phentermine, prosthetic valve placement, dyspnea, and cough. The possibility of valvular abnormalities should be particularly considered in family members of those with autosomal-dominant polycystic kidney disease [11,12]. Absolute contraindications to donation are symptomatic valvular disease, severe valvular disease even if asymptomatic, and valvular disease with abnormal cardiac function and/or ischemia [13]. Relative contraindications are the presence of a prosthetic valve and moderate regurgitant valvular disease with otherwise-normal echocardiographic findings.

Postoperative pulmonary complications are as prevalent as cardiac complications and contribute similarly to morbidity, mortality, and length of stay after noncardiac surgery. The probability of pulmonary disease should be determined through a history (cough, smoking, dyspnea), physical examination, and a chest

Table 49.1 Donor evaluation.

History: Look for/ask about
    Hypertension

        Breast
        Colorectal
        Lymph nodes
    Cardiovascular disease
Laboratory
    Urinalysis
    Electrolytes, liver panel
    Fasting blood glucose, lipid profile
    CBC with platelets, coagulation screen
    24-h urine, creatinine clearance, protein excretion or GFR (iothalamate clearance) and protein determination (or protein/creatinine ratio and urine albumin determination)
    Antiviral screening: HCV, HBV, HIV, EBV, CMV, HSV
    PPD (controversial in nonendemic areas), RPR
    EKG, chest X-ray
    PAP, prostate exam
    Age/family history determined
        ETT, ECHO
        Colonoscopy, ultrasound
        Mammogram/PSA
Anatomic evaluation per local expertise
    CT angiogram
    Multislice CT (96% accuracy compared to operative findings)
    MRI angiogram
    Standard arteriogram
    Digital subtraction angiography

radiograph [14]. If indicated by history and examination, pulmonary function testing, echocardiogram, and/or sleep studies should be performed [15]. In all cases, donors should be encouraged to cease smoking for at least 4–8 weeks before surgery to minimize the risk for pneumonia and wound complications [16,17]. Pulmonary contraindications to donation include cystic fibrosis, sarcoidosis, interstitial lung disease with fixed pulmonary hypertension and persistent hypoxemia, primary and secondary pulmonary hypertension, severe sleep apnea, severe chronic obstructive pulmonary disease, asthma complicated with status asthmaticus, and α_1-antitrypsin deficiency. Relative contraindications to donation are mild sleep apnea without a history of pulmonary hypertension, chronic hypoxia, or arrhythmias on bilevel or continuous positive airway pressure therapy [15,18].

Coagulation abnormalities

A history of venous thromboembolism should be ascertained. Only if present should a comprehensive coagulation profile be done, as these tests are expensive and are unlikely to change management [19–21]. Oral contraceptives and hormone replacement therapy are commonly used in the general population and may increase the risk for postoperative venous thrombosis [22,23]. In general it is advised that hormone replacement be withheld for at least 1 month prior to an elective surgery, although not all current data or reviews support this practice [22–27].

Mortality

Postoperative

Only recently has the United Network for Organ Sharing (UNOS) begun collecting information about short-term donor outcomes (Table 49.2). The mortality rate for living donor nephrectomy using a laparoscopic technique is 0.03% from surveys and single-center sources. Data from UNOS and the Social Security Death Master File on donors from October 1999 to October 2004 reveal a 0.04% 30-day mortality and a 0.09% 1-year mortality for kidney donors (Organ Procurement and Transplantation Network [OPTN] data as of April 2005). Several deaths have been due to failure of the clips placed on the remnant donor renal artery, resulting in massive hemorrhage, rather than an impaired cardiovascular state of the donor [28].

Long term

The underlying premise of living kidney donation is that the removal of one kidney does not impair survival or long-term kidney function in the donor. Reports of relatively homogenous northern European populations after nephrectomy by Narkun-Burgess (for trauma), Fehrman-Ekholm (for kidney donation), and Najarian (for kidney donation) suggest that live kidney donation is safe (Figure 49.1) [29–33]. A meta-analysis of outcomes in 3124 subjects with reduced kidney mass mostly due to kidney donation (60.5%) showed a 17.1 mL/min average decrease in GFR after nephrectomy but no progressive decline in renal function with time [34].

Table 49.2 Operative mortality in living kidney donors.

Figure 49.1 Survival of Swedish kidney donors compared to general Swedish population. The donors demonstrated superior survival [30].

However, the profile of donors has changed over time to include those with isolated medical abnormalities, such as essential hypertension, an increased body mass index (BMI), isolated hematuria, dyslipidemia, and stone disease. Follow-up has not been long enough to be confident that these various comorbid conditions will not adversely influence survival (Table 49.3). Furthermore, the UNOS/OPTN data combined with those of the Social Security Death Master File for those donating between October 1999 and

October 2004 reveals a 0.18% donor mortality rate (www.optn.org; OPTN data as of April 2005). Although cause of death is generally listed as unknown, one category of death is concerning: death due to accident, homicide, or suicide (OPTN/UNOS data as of April 2005). In particular, younger donors seem to be at increased risk for this outcome and need to be carefully evaluated psychologically for the risk of self-destructive behavior following donation [35,36] (National Center for Health Statistics 2003; www.cdc.gov/nchs/datawh/statab/unpubd/mortabs/gmwk210_10.htm).

Renal evaluation

GFR

Establishing baseline renal function is critical. Although serum/plasma creatinine, 24-h creatinine clearance and calculated clearances based upon the plasma creatinine have been used to determine GFR, they are not accurate enough for the purposes of living donation (http://www.bts.org.uk/) [37–39]. Similarly, although changes in cystatin C levels may be more predictive of changes in renal function than the serum creatinine, cystatin C is also not sufficiently accurate for estimating renal function in people with normal GFR [40–42]. Measuring the clearance of compounds such as ^{51}Cr-EDTA, [^{125}I]iothalamate, and

Source: Rule *et al.* 2004 [37].

[99]mTc-diethylenetriaminepenta-acetic acid (DTPA), or nonradiolabeled iohexol or iothalamate provides more accurate measurements of GFR [43–46]. Whatever measurement is used, the GFR must be interpreted in the context of age, gender, and body size and corrected for body surface area.

The threshold of normal kidney function has seemingly declined with time. Inulin clearance studies in 1950 reported the normal GFR was 130 mL/min/1.73 m^2 for young men and 120 mL/min/1.73 m^2 for young women [47,48]. An age-related decline in renal function of 10 mL/min/1.73 m^2 was noted after age 40, such that the GFR at age 80 was half that at age 40. More current studies have been performed using ^{125}I-labeled or cold iothalamate [37,47,49]. Gonwa *et al.* reported a slightly lower GFR of 102 ± 15 mL/min/1.73 m^2 for men and 114 ± 17 mL/min/1.73 m^2 for women age 21–30 years old, compared to data from earlier studies [49]. The GFR for men and women ages 51–60 was 84 ± 13 and 79 ± 15 mL/min/1.73 m^2, respectively. Rule *et al.* recently reported on the GFR of 365 potential kidney donors and found similar results to Gonwa's study (Figure 49.2) [37]. In general, living donors should be required to have a GFR that is average for their age (Table 49.4). Furthermore, because GFR declines with age, a donor's projected GFR at age 80 should be ≥40–50 mL/min/1.73 m^2 [50]. Most centers have chosen a GFR of 80 mL/min/1.73 m^2 to be the lower limit for donation [1-3] (see http://www.bts.org.uk/.).

Following donation, the average renal function has been shown to decrease by 27% compared to the predonation value (Table 49.5) [51]. The limitations of these studies include being single-center data, loss to follow-up (only about 50–60% of the original cohort), and that the ethnicity of those studied was almost uniformly white individuals. Furthermore, few studies report on the development of ESRD in prior living donors and again, usually only from white populations (Table 49.6). The concern is that ESRD may develop more frequently in those of other than northern European heritage. Additionally, donor characteristics are changing from what they were several decades ago. For instance, the average weight of the living donor has increased, concurrently with that of the general population [52]. Further study is needed in order to determine the true incidence and risks for renal function decline with a

preeminent focus on hyperfiltration and components of metabolic syndrome [53].

ESRD

Hartmann *et al.* reported that 7 of 1800 (0.4%) living donors developed ESRD [54] (Tables 49.6 and 49.7). More recent published data suggest that between 0.2–0.4% of donors of Northern European descent have developed ESRD (32). Ojo and Davis performed a preliminary evaluation of the Scientific Registry of Transplant Recipients (SRTR) and Centers for Medicare and Medicaid Services ESRD databases (OPTN/SRTR as of March 2005). The maximum incidence of ESRD was estimated to be 0.10% in white donors and 0.52% in black donors. The most recent data from UNOS/OPTN reports 121 living donors listed for kidney transplant: 35.5% female, 64.5% male (compared to 42% of all donors), 43% white, 42.1% black (compared to 13% of all donors), and 10% Hispanic (based upon OPTN data as of May 2006). Age at donation was between 18 and 34 years in 66.3%, 35–49 years in 27.6%, and 50–64 years in 6.1%. Duration between listing for transplant and donation and the age at donation varied (Table 49.7). The cause of ESRD was glomerular disease in 24.8%, diabetes in 10.7%, hypertension in 19%, vascular disease in 6.6%, tubular/interstitial disease in 5.8%, other in 5.8%, transplant failure in 5.8%, neoplasm in 4.1%, not reported in 0.8%, and unknown in 17.4%. When evaluating only those donating since 1994 and who had been placed on the kidney transplant wait list since 1996, the rate of ESRD over 12 years appears to be 0.02%. Again, 45% of donors who developed ESRD were black. In summary, most donors who developed ESRD were young at donation, more often black, and male. The length between donation and kidney failure is usually over 15 years, and conditions associated with metabolic syndrome appear to provide significant risk.

Ahmed *et al.* reported on 34 African American donors and compared the results to those of 23 Caucasian donors [55]. Although

Source: Based upon OPTN data, as of May 2006.

the serum creatinine was not different at donation between black and white donors, the number of donors with a serum creatinine that increased over 50% was higher in African American donors. Given that the risk of ESRD after donation appears higher than previously recognized (even if the absolute numbers are small), renal evaluation, especially of African American donors, needs to be undertaken with special care.

Proteinuria screening

Urine protein (β_2-microglobulin, immunoglobulin G [IgG]) and albumin excretion after nephrectomy was studied by Strandgaard *et al.* [56,57]. The fractional clearances of β_2-microglobulin, IgG, and albumin increased markedly immediately after nephrectomy and peaked within 3 days. By 2 weeks the excretion of albumin and IgG was normal, but that of β_2-microglobulin remained increased. In the long term, although a significant number of living donors excreted more than 150 mg/day of total protein, most of the protein was not albumin (Table 49.8) [57,58].

Urine protein excretion is associated with the development of ESRD and cardiovascular disease [59–63]. Even minimal albuminuria is associated with vascular disease development [61,62]. Interestingly, proteinuria in living donor studies has not generally been associated with decreased renal function, hypertension, or obesity [51,57,58,64,65]. However, studies have not been long enough in duration, nor large enough, to confidently exclude such associations. Additionally, the relationship between microalbuminuria and cardiovascular morbidity and mortality has not been investigated in donors (Table 49.9) [57]. Until these studies are completed it is prudent to measure both total protein and albumin excretion in living donors.

Urine collection should be timed to provide an accurate representation of albumin excretion. Urinary albumin excretion is higher during the day and with exercise, acute febrile illnesses,

excessive water consumption, and menstruation [66]. At least two first-morning specimens collected on different days, free of these confounders, should be obtained for protein and albumin creatinine ratios [67].

Routine donor kidney biopsy

Donor kidney biopsies have rarely been performed or correlated with donor outcome. Goecke *et al.* reported on donors who were biopsied at donation and clinically evaluated more than 10 years after nephrectomy [68]. Biopsies from 29 donors showed normal pathology in 13, chronic ischemic glomerular changes in 9, thick glomerular basement membrane in 2, thin glomerular basement membrane in 1, and IgA nephropathy in 4. Urinary sediment was abnormal at follow-up in 11 donors (9 with microhematuria). There was no association between the biopsy results and subsequent creatinine clearance or proteinuria. These results suggest that kidney biopsy at donation is not beneficial from the donor's perspective.

Hypertension

Hypertension is associated with microalbuminuria, kidney failure, and cardiovascular disease [69–71]. This relationship is particularly pronounced in those with mild kidney dysfunction (GFR <60 mL/min), a level of kidney dysfunction seen in some living donors in the years following surgery [72]. Although controversy surrounds the direct causal relationship between hypertension and kidney disease, the link is strong enough to consider hypertension as a risk for living kidney donors.

The Third National Health and Nutrition Examination Survey (NHANES III) evaluated the association between blood pressure and albuminuria in 9462 people without hypertension (BP of >140/90 mmHg) or diabetes. In this study those with high-normal blood pressure (130–139/85–89 mmHg) had a significantly increased odds of microalbuminuria compared to those with optimal blood pressure (<120/80; odds ratio, 2.13; 95% confidence interval [CI], 1.51–3.01) [73]. African Americans had the highest risk for microalbuminuria (OR, 1.30; CI, 1.04–1.64) compared to Mexican Americans and non-Hispanic whites. This finding was also illustrated in a longitudinal 15-year study of young (age 18–30 years at onset) adult blacks and whites where increases in blood

pressure within the normal range were associated with albuminuria many years later, especially in Blacks [74].

Blood pressure at the time of living donation has usually been normal, defined as ≤140/90 mmHg without antihypertensive treatment, rising to 10–40% postdonation (Table 49.10). However, even normotensive donors after nephrectomy may have decreased nocturnal blood pressure decline [75,76], secondary to a decline in renal function following surgery. Comparing the rates of hypertension in living donors to that of their nondonor siblings revealed similar degrees of hypertension [33]. Likewise, the prevalence of hypertension in living donors has been reported to be less than, the same as, or slightly increased compared to the general age-matched population [33,51,77].

A recent meta-analysis of all studies of more than 10 living donors in whom blood pressure was assessed at least 1 year after donation was recently reported [78]. Donors were compared with control groups of similar age, gender, and ethnicity. Although the authors reported significant limitations of the analysis, the conclusion of the study was that kidney donors may have a 5-mmHg increase in blood pressure within 5–10 years after donation over that anticipated with normal aging, consistent with the findings of an earlier meta-analysis by Kasiske *et al.* [51]. Finally, Saxen *et al.* compared blood pressure change in normotensive individuals who underwent unilateral nephrectomy for kidney donation ($n = 25$) or removal of renal cell carcinoma ($n = 7$) to binephric healthy controls [53]. Young kidney donors (average age, 35 years, range, 21–48) demonstrated a 7-mmHg increase in mean arterial pressure compared to the binephric control group. Older subjects (>55 years old) did not have increased blood pressure compared to control subjects over 55 years old.

Although there is no proven association between a predonation blood pressure and the development of ESRD, many of the donors who have reached ESRD have been reported to do so because of hypertension [79]. Furthermore, the prevalence of hypertension is increasing. The NHANES study found that hypertension was identified in 7.8% of individuals 18–39 years old, 30.6% of those 40–59 years old, and 64.5% of those ≥60 years old [80]. Thus, the evaluation for hypertension remains important, although the degree of risk for donors with hypertension and no abnormal urine microscopy, albuminuria, or decreased renal function has not been established [81].

Abbreviations: BP, blood pressure; NA, not available.

[a] Systolic blood pressure.

[b] Diastolic pressure.

At the Mayo Clinic, hypertensive donors were not found to have increased short-term morbidity [76], but these donors were all over age 50, Caucasian, had controlled blood pressure with an angiotensin converting enzyme inhibitor and hydrochlorathiazide, a normal GFR (by iothalamate clearance) for age, and no microalbuminuria at donation [76,82]. A study from India likewise found no short-term morbidity in 18 hypertensive donors, with a median follow-up of 30 months, except the need to increase antihypertensive treatment in two of the donors [83]. These and other studies of hypertensive donors also need to investigate the long-term implication of a blood pressure pattern that does not dip at night [84,85]. When living donors with hypertension are accepted, the estimated increase in transplantation is only about 2% [86].

The living donor evaluation should include blood pressure measurements by experienced health care providers on three separate occasions; verification of elevated levels should be undertaken with ambulatory blood pressure monitoring, as about 10–20% may be found to have normal blood pressure [1,76,87,88]. If elevated blood pressures are detected and the prospective donor is still under consideration, then in addition to the standard donor evaluation, an ECHO and ophthalmologic evaluation should be performed to look for secondary consequences of hypertension.

Hematuria

Isolated hematuria in a prospective donor necessitates consideration of thin glomerular basement membrane disease (TBMD) and glomerulonephritis (especially IgA nephropathy) as well as urinary tract infection, malignancy, renal cystic disease and nephrolithiasis [89,90]. Microscopic hematuria is a relatively common problem,

as demonstrated in a mass screening study in Japan, where 4% of adult men and 10% of adult women had microscopic hematuria [91]. Persistent microscopic hematuria was seen in approximately 20–40% of these individuals, with an overall risk of malignancy of approximately 4.8%, which increased with age and was more common in men [89,90]. TBMD accounts for approximately one-third of the hematuria in those without malignancy or other structural abnormality [92–94]. TBMD has been found in up to 5–9% of unselected (deceased) donor kidney transplant biopsies [95,96]. IgA nephropathy also accounts for approximately one-third of glomerular-derived microscopic hematuria [92–94]. Suzuki *et al.* found latent mesangial IgA deposition in 16% (82/510) of living donor allografts biopsied at implantation; one had proteinuria [97]. Hematuria was more pronounced in those with IgA deposition but not detected in all. Koushik *et al.* reported the evaluation of 14 kidney donors with persistent hematuria (>1/hpf) [98]. This represented 2.7% (14/512) of their prospective donors. Ten underwent biopsy. Two biopsies were normal, one had IgA nephropathy, four had TBMD, one had glomerulosclerosis, one had non-homogenous basement membrane abnormalities, and one had TBMD with early hypertensive changes. Two donor candidates had normal biopsies, and two with TBMD donated.

The real question in those with hematuria is, what is the long-term risk for kidney failure? How often do IgA deposition and TBMD indicate a risk for progressive renal disease? Unfortunately, Suzuki *et al.* did not have outcome data on the living donors with IgA deposition, some of whom had diffuse proliferative lesions (personal communication). Koushik *et al.* have 15-month follow-up on the two donors with TBMD; at the last report, these donors had not developed hypertension, proteinuria, or azotemia [98].

Isolated hematuria, however, is not necessarily benign. Nieuwhof *et al.* reported on a subset of subjects with greater than 6 months of microscopic hematuria but without extrarenal symptoms or anatomic abnormalities [92–94]. IgA deposition was found in 27, TBMD in 19, and 24 had normal histology. All were normotensive with normal renal function. Over a median of 12 years of follow-up (range, 9–15 years), the incidence of hypertension in those with TBMD exceeded that of healthy controls (35% vs. 8%). Renal function (inulin clearance) at follow-up was reduced in three of seven normotensive subjects with TBMD. Others have reported the development of ESRD in individuals with isolated TBMD including a kidney donor [99–103].

IgA deposition in the same study was associated, after a median follow-up of 11 years, with a higher rate of hypertension compared to controls [92,94]. Two of 27 went into histologic remission, and 12 showed disease progression, of whom 3 developed renal failure. Initial proteinuria over 1 g/day was associated with a high activity score and progression. IgA deposition may occur with TBMD, but without hearing or ocular alterations, and has an increasingly evident familial predisposition [104–106].

The investigation of hematuria in prospective donors includes urine culture, repeated urinalyses, urine protein and albumin measurement, and anatomical studies to determine the presence of cysts, nephrolithiasis, tumor, or vascular lesions. If the studies continue to reveal only hematuria, and if the donor accepts the risk and still wishes to proceed with donation, then a renal biopsy is indicated. If IgA nephropathy (proliferation, mesangial expansion) is discovered, the individual should forgo donation. However, the implications of isolated mesangial IgA without other manifestations of nephropathy are not known and this requires further study. Donation should be decided upon in the context of family history, absolute renal function, the presence of interstitial disease, and age. If TBMD is discovered, then it could be argued that only those over age 50 should donate, as they should have already manifested the risk for progressive kidney failure. Such donors, however, should have normal GFR for age, no albuminuria, and have a predictable family history of disease progression. Further research is needed before fully informed decisions can be made about accepting donors with TBMD [107,108].

Polycystic kidney disease

Testing prospective donors at risk for polycystic kidney disease (PCKD) must be 100% accurate. Ultrasound is 100% reliable for ruling out PCKD in individuals at risk who are age 30 or older, but the sensitivity is less in those under 30 years [109]. The resolution of computed tomography (CT) and magnetic resonance imaging (MRI) for small cystic structures is better than for ultrasound [110,111]. On average, ultrasound can detect cysts of 1.0 cm, CT with intravenous contrast can detect cysts of 0.5 cm, and heavily T2-weighted MRI can detect cysts of 0.3 cm in diameter. Therefore, wherever possible, linkage analysis should be performed in prospective donors at risk who are under age 30, but if genetic testing is not a possibility, CT and/or MRI may provide better sensitivity than ultrasound [112,113]. In the near future, more

specific gene tests for the diagnosis of PCKD will be available [114–118].

Nephrolithiasis

Nephrolithiasis is a relative contraindication for live kidney donation with urinary tract obstruction in a single kidney [1,2]. Those with a history of bilateral stones or stones demonstrating high rates of recurrence (cystine or struvite stones) should not donate [119]. Additionally, those with systemic disorders leading to high rates of recurrence, such as primary or enteric hyperoxaluria, distal renal tubular acidosis, sarcoidosis, inflammatory bowel disease, or other conditions causing nephrocalcinosis, etc., should not donate. However, an asymptomatic potential donor with a current single stone may be suitable if the donor does not have a high risk of recurrence, the current stone is less than 1.5 cm in size, and it is potentially removable during transplant [120]. One report of 10 such donors showed no recurrent stone formation over an average of 36.4 months of follow-up [121]. The evaluation of an asymptomatic donor with a single prior episode of nephrolithiasis should include measurement of serum calcium, creatinine, albumin, and parathyroid hormone, spot urine for cystine, a urinalysis and urine culture, a helical CT, stone analysis if possible, and a 24-h sample urine for oxalate and creatinine.

Other testing

Psychological evaluation

There has not been any standardization of the predonation psychological evaluation. Usually, the evaluation is completed by the transplant program social worker, but ideally, programs should also have a psychologist. All prospective donors should be queried about their concerns regarding coercion, transplant success, recipient survival, their reasons for donation [122,123], and their expectations of the donor experience. More detailed psychological evaluation is required for people inquiring about altruistic donation, because of high rates of depression and other psychiatric illness [124–126]. Because UNOS data show an increase in suicide and accidental death in young donors compared to the general population, young donor candidates should be evaluated for suicidal ideation and excessive risk-taking behaviors (UNOS data as of April 2005; National Center for Health Statistics).

Anatomic evaluation

The angiogram has been supplanted by the CT angiogram or magnetic resonance angiogram [127]. The overall accuracy of multirow detector CT angiogram to detect renal arterial anatomy compared to surgical findings is between 93 and 100% depending upon the number of channels used [128–130]. The overall accuracy of the magnetic resonance angiogram compared to angiography or surgically determined anatomy is 80–100% [131–133]. Venous anatomy has been confirmed to correlate with surgical findings in 95–100% with either technique ([129,130,132].

Other issues

Obesity

Obesity is associated with diabetes, cardiovascular disease, hyperfiltration, hypertension, nephrolithiasis, renal cell cancer, proteinuria, and chronic kidney disease [134–139]. Obese donors have a larger glomerular planar surface area, which correlates with donor weight and microalbumin excretion [140]. Obese donors also have more tubular dilatation and a trend toward more arterial hyalinosis. Further evidence for the association between obesity and kidney failure is demonstrated by the decrease in glomerular hyperfiltration, excessive renal plasma flow, and albuminuria with weight reduction [141].

Praga *et al.* described 73 subjects from Spain who underwent unilateral nephrectomy without known disease in the contralateral kidney [142]. Those with a BMI over 30 kg/m^2 at the time of surgery were found to develop proteinuria and kidney failure 10–20 years later. The average BMI in the obese group at nephrectomy was 31.6 kg/m^2, compared to 24.3 kg/m^2 in the nonobese group.

Of concern for the health of future kidney donors is that albuminuria has been demonstrated in up to 5.8% of obese teenagers (BMI, >35 kg/m^2), especially in association with hyperinsulinemia, impaired glucose tolerance, and hypertension [143,144]. Future donors may have a longer exposure to the metabolic syndrome than donors from previous eras and so may develop more renal and cardiovascular disease, nephrolithiasis, and cancer. Careful instruction about possible future health risks needs to be given to donors who are obese (or smoke). Education on healthier life choices and weight reduction programs should also be included in the plan for donation. In the future, selection of the donor may be aided by noting the distribution of fat in an obese donor candidate, because visceral adiposity is associated with harmful cytokine levels which may contribute to future renal disease [145].

Even with the apparent risks of obesity, many programs are accepting obese living donors. Heimbach *et al.* has prospectively evaluated obese donors over 12 months [52]. To date, the accepted obese donor has been found to have a higher baseline blood pressure, glucose level, and lipid levels than nonobese donors, although the levels are still within the high-normal range. So far, the obese donors have not had lower GFRs (by iothalamate clearance) or higher protein excretion rates compared to the normal BMI donors. The Swiss donor registry has likewise not yet noted a change in albuminuria in obese donors over 5 years from donation, although one donor has developed diabetes, hypertension, proteinuria, and kidney failure [146].

The risk of diabetes must be carefully considered in obese donors. Rizvi *et al.* reported the development of diabetes in 3.6% of 734 donors followed for 3 years on average (maximum follow-up, 18 years) [64]. Obesity was associated with the development of diabetes and hypertension. Ramcharan and Matas reported that 7.6% (19/250) of donors responding to their survey had developed diabetes over 20–37 years after donation [147]. Sansalone

et al. noted 1.2% of 162 donors developed type 2 diabetes within 4.5–11 years of donation [148].

Obesity increases the future risk of diabetes substantially. Even without overt obesity, those with a family history of diabetes or other associated risk factors should be concerned about their risk of developing the disease. As diabetes is a contraindication to live kidney donation, all prospective donors should be evaluated with a fasting blood sugar, and a 75-g 2-h oral glucose tolerance test should be performed if they have a fasting glucose between 5.55–6.66 mmol/L, a first-degree relative with diabetes, a history of gestational diabetes or delivery of babies over 4 Kgs, a blood pressure over 149/90, fasting triglyceride levels of 2.8 mmol/L, a BMI over 30 kg/m^2, a high-density lipoprotein level of 0.9 mmol/L, are less than 40 years old, or have a second-degree relative with diabetes.

Age

Age is associated with declines in GFR and increases in proteinuria and blood pressure. Older donors have been defined variably as those over the age of 50–60 years. No matter the age threshold, older donors have a lower GFR and higher blood pressure compared to younger donors [76,149,150]. However, as have all donors, they have been selected for a lack of proteinuria.

The rate of acceptance of older donors varies worldwide. In the USA, the number of living kidney donors over age 65 has been between 41 and 64/year since 1997 [83,151–153]. There has, however, been a steady increase in US donors between the ages of 50 and 64 (based upon OPTN data as of August 25, 2006).

Surgical complications, including death, have been rare in elderly living donors, with either open or laparoscopic procedures [151–157]. Following donation, the serum creatinine may be somewhat higher and GFR lower for older versus younger donors [152,157,158]. However, the single-kidney GFR in older donors increases by the same proportion (10–40%) as in younger donors [53,83,150,154,155,159]. Furthermore, no deterioration in renal function of elderly donors has been found for up to 7 years follow-up [155,156]. To date, based upon limited numbers and duration of follow-up, there has not been an increased risk of ESRD or cardiovascular mortality in older donors. In one report, 1 of 112 elderly donors died of pneumonia, 1 of a motor vehicle accident, and 1 of suicide [155]. In another report, 2 of 26 donors developed coronary artery disease 3 and 5 years after donation but were still alive [156]. How this compares to what they would have experienced without donation is unknown.

Renal vascular disease

Renovascular disease has been found in up to 10% of those undergoing donor evaluation [160]. Fibromuscular dysplasia (FMD) is found in about 2–4% of prospective donors [160–162]. In a study of 1862 renal angiograms performed in potential living donors, 71 demonstrated FMD [161]. The average age of the donor candidates with FMD was 50.8 years, and 75% were women. Thirty candidates who did not undergo nephrectomy were followed over a mean of 7.5 years, and 8 (26.6%) developed hypertension. Nineteen who

donated were followed for a mean of 4.4 years and 5 (26.3%) developed hypertension. This compared to 3 of 49 (6.1%) control subjects selected from the group of healthy age- and sex-matched controls without FMD who developed hypertension over 7.1 years of follow-up. Indudhara *et al.* followed 19 living donors who had FMD [163]. A total of 37 individuals with FMD had been considered for donation but 18 were rejected due to disease severity or the availability of another donor. Donors were older than those who did not donate (50.5 vs. 44.7 years) and had less severe disease; only one had bilateral disease. At a median follow-up of 4.5 years (range, 2 months–12 years), none of the donors had hypertension or increased serum creatinine levels. Of the 18 patients not undergoing nephrectomy, 11 were contacted and none had developed hypertension, proteinuria, or an abnormal serum creatinine. This study concluded that an evaluation for bilateral and distal branch disease should be performed prior to donor nephrectomy in an individual with FMD, and donors with severe and diffuse disease should not be selected for donation. The age of the prospective donor should also be considered, with the outcome in donors over age 50 more predictable and benign than in younger donors. Similar conclusions were drawn by authors of a paper reporting on three donors with FMD, none of whom developed hypertension within 21–115 months of follow-up [164]. However, given these sparse data, a donor with FMD may still progress and so require blood pressure monitoring and vascular imaging postnephrectomy. Recently, there was a report of a 41-year-old female donor who had such mild disease that it was not detected by spiral CT predonation, but within 1 year of nephrectomy she developed severe renal artery stenosis complicated by accelerated hypertension [165].

Atherosclerotic renal vascular disease should be considered a relative contraindication for living donation [166]. If renal atherosclerosis is present, the donor should be normotensive, have normal renal function, and have only unilateral disease [164,167]. Careful evaluation for coronary disease should be undertaken, given the significant correlation of renal atherosclerosis with coronary artery disease [10,168]. Likewise, investigations to determine the presence of peripheral vascular disease should be undertaken [169]. Donors with renal atherosclerosis should have regularly scheduled visits to assess blood pressure and vascular integrity following donation.

Malignancy and infection

A prior history of the following malignancies usually excludes live kidney donation: melanoma, testicular cancer, renal cell carcinoma, choriocarcinoma, hematological malignancy, bronchial cancer, breast cancer, or monoclonal gammopathy [3]. A prior history of malignancy may only be acceptable for donation if prior treatment of the malignancy does not decrease renal reserve or place the donor at increased risk for ESRD, does not increase the operative risk of nephrectomy, and if the specific cancer is curable and transmission of the cancer can reasonably be excluded. Consultation with an oncologist may be required.

An individual with an active infection that requires nephrotoxic treatments or which may be complicated by renal disease should not be a living donor. Some of these infections include HIV, hepatitis C, hepatitis B, recurrent urinary tract infections, endocarditis, and malaria [3]. Tuberculosis can cause renal dysfunction through obstruction. Transmission of the infection may also be fatal to the recipient. It is uncertain whether donors should be screened for tuberculosis using a tuberculin skin test. Recently, a paper from Mexico reported that if the potential living donor ($n = 217$) had a negative chest X-ray, urinalysis, and excretory urography, isoniazid treatment of the donor did not change the risk of transmission of tuberculosis or change the donor's rate of developing active tuberculosis [170]. This study should be validated by studies in other countries, but it does raise the question about the need for routine tuberculosis skin testing for living kidney donors.

Consent

During the medical evaluation there is an ongoing dialogue between the prospective donor and transplant team to ensure continued comfort with the decision to donate. Conversations are held to determine whether the donor understands the social and health implications of donation and whether there is evidence of coercion. This dialogue is the foundation of informed consent. The components of informed consent discussed with the donor include the impact of donation on their social and financial well-being, the short-term morbidity and mortality directly related to the surgery, the future risk of renal insufficiency and failure, the risk of *de novo* medical problems on kidney and overall health (i.e. hypertension, diabetes), and the risk of allograft failure in the recipient due to rejection, technical problems, recurrent disease, and/or comorbid medical problems [171,172].

50 Predictors of Transplant Outcomes

Krista L. Lentine[1], Robert M. Perkins[2], & Kevin C. Abbott[3]

[1]Saint Louis University Medical Centre, St. Louis, Missouri, USA
[2]Medigan Army Medical Center, Ft. Lewis, WA, USA
[3]Walter Reed Army Medical Center, Washington, DC, USA

Introduction

Graft and patient survival after kidney transplantation have traditionally been the outcomes reported. Detailed data from the USA are available in annual reports of the United Network for Organ Sharing [1] and the United States Renal Data System (USRDS) [2]. European data are available from the European Renal Association/European Dialysis and Transplant Association [3]. Recently, USRDS also listed incidence rates for cardiovascular disease after kidney transplantation. Two key outcomes form the assumption underlying kidney transplantation. Namely, kidney transplantation is associated with improved survival and quality of life compared to dialysis. Until recently, a survival advantage of kidney transplantation had not been widely accepted, and kidney transplantation was advocated primarily for improved quality of life. The first part of this chapter will review studies that have compared mortality between kidney transplantation and dialysis in general and among specific subgroups of patients. This survival advantage appears to be due to the reduced incidence of cardiovascular disease. In contrast, the incidence rates of infections and malignancies are not reduced and may even be higher after transplantation compared to dialysis.

Although short-term patient and graft survival rates have improved significantly in recent years, no comparable improvement in long-term survival rates has occurred, suggesting allograft rejection is not a valid useful surrogate outcome in clinical trials, and this highlights the importance of emerging infections, such as BK virus.

The importance of individual predictors of transplant outcomes has also changed over time. The importance of HLA matching has declined, and it is now recognized that HLA matching has different implications for black and white organ recipients. Some recent reports advocate deemphasizing HLA matching as a way to reduce

racial disparities in organ allocation [4]. Given the increasing mismatch between donor supply and demand, organs from older and higher-risk donors (extended criteria donors [ECD]) are being offered more frequently, particularly to older recipients, resulting in survival benefits to the recipient.

In contrast to the dialysis population, no large randomized trials comparing different interventions or the "dose" of therapy (as measured primarily by donor/recipient nephron mass) have been performed for kidney transplantation. Because almost all outcome data are observational, many of the selection criteria recommended for randomized clinical trials do not apply. Once a particular finding has been reported in registry data, follow-up reports are generally lacking. Therefore, identifying and pooling studies, a common practice among randomized clinical trials, does not apply as much to these observational studies. Additionally, some of the statistical methods commonly used in the studies, especially survival analysis and its many variations, may not be as familiar to clinicians and other health care providers as are the methods used in randomized clinical trials.

Definitions

To assess the major outcomes associated with kidney transplantation, the following questions were examined:

• Is kidney transplantation associated with reduced mortality compared to its alternative therapies, that is, hemodialysis and peritoneal dialysis?
• In what specific subgroups has a survival advantage of kidney transplantation over dialysis been shown?
• Are long-term outcomes associated with kidney transplantation improving?
• How reliable are surrogate outcomes for graft loss, such as allograft rejection or posttransplant serum creatinine levels?
• Have the predictive values of certain factors for graft loss, such as HLA matching or duration of dialysis prior to transplant, changed over time?

The quality checklist for observational trials is quite different and more extensive than for randomized controlled trials [5] and has not been used extensively in previous reviews.

Survival benefit of kidney transplantation

Three studies have compared adjusted mortality after kidney transplantation compared to remaining on the kidney transplant waiting list, that is, patients presumed to be of comparable health status. In the first and largest study, Wolfe *et al.* [6] estimated that the projected life remaining was 10 years for those on dialysis and 20 years for those who received kidney transplants, with a reduction in mortality of 68% for kidney transplant recipients compared to dialysis. This risk varied by time after transplant; early after transplant, mortality risk was actually increased (due to perioperative mortality, especially from cardiovascular disease and infections). Thereafter, mortality slowly declined; at 106 days incident risk was equal, and by 244 days cumulative survival was equal. The greatest relative improvement in survival was for patients with diabetes as a cause of end-stage kidney disease.

Studies in other countries (Canada [7] and Scotland [8]) have shown similar results, including the increased early risk of mortality after transplant and gradual lowering of mortality. The study from Scotland adjusted for comorbidities more completely.

Other studies showed a relative survival benefit of kidney transplantation for every subgroup identified, including patients with hepatitis C [9] or who were obese [10,11]. Still other studies showed that patients with presumed diabetes had improved survival with simultaneous kidney and pancreas transplant, compared to cadaveric kidney transplant alone; survival with a solitary living donor kidney was comparable to that of receiving a kidney and pancreas transplant [12]. Use of ECD kidneys, primarily from older donors and donors with certain high-risk characteristics defined as those associated with a relative risk of graft loss of ≥1.7 compared to "standard" kidneys, was also associated with improved mortality for elderly recipients [13]. A more recent study confirmed this finding and identified those subgroups most likely to benefit from ECD kidneys, namely, those with prolonged expected waiting times on dialysis, those with diabetes, and those over 40 years old [14].

Is long-term kidney allograft survival improving?

Short-term graft survival after kidney transplantation has increased progressively from 1988 to 1996 [15], but from 1995 to 2000 there was not a comparable increase in graft survival beyond 2 years [16] (Figure 50.1). The same authors compared actual Kaplan-Meier renal allograft half-lives to the projected half-lives from the same year and documented substantial disparities between projected and actual allograft half-lives [17]. Two other studies assessed change in serum creatinine and estimated glomerular filtration rate (eGFR) and concluded that the rate of decline in allograft function after transplantation has improved [18,19]. A different study demonstrated the relatively poor predictive value of serum creatinine in predicting allograft loss after transplantation [20]. Another study from the same group showed that, recently,
* Kaplan-Meier half-life based on time to 51.0% survial
** as published in NEJM (March, 2000).

Figure 50.1 Projected Half-Lives (white bars) of deceased donors kidney transplants (including re-transplants) vs. actual Half-Lives (dark bars).

rates of death attributed to cardiovascular disease and infection have decreased among wait-listed dialysis and transplant patients, whereas rates of death attributed to malignancy have not [21]. Thus, available observational data suggest that long-term kidney allograft and patient survival rates are improving.

Are traditional predictors of transplant outcomes becoming less reliable?

The results of national sharing of fully HLA-matched kidneys were reported in 2000 [22]. The UNOS allocation program has changed over time from an initial "six-antigen match" to any donor who had no HLA-A, -B, or -DR antigens that were not also detected in the recipient (referred to as no mismatches). That is, the recipient was matched for these HLA antigens, but may still have had antigens that were not present in the donor. Ten-year graft survival was 52% for HLA-matched kidneys versus 37% for non-HLA-matched kidneys (including any degree of HLA mismatch). The authors found that, apart from zero-mismatch kidneys, HLA matching had diminishing importance over time.

Another report did not show improved graft survival in transported organs that were fully HLA matched, but rather a significantly higher risk of graft failure in these organs compared with locally transplanted kidneys [23]. Yet another study showed that over four successive years (1994–1998), HLA had progressively less significant association with graft survival after kidney transplant than nonimmunologic factors [24].

If it is true that HLA matching now has little effect on outcomes, then removing HLA-B matching as a priority for the allocation of cadaveric kidneys could reduce existing racial imbalances by increasing the number of transplants in non-white patients, with only a small increase in the rate of graft loss [25]. Recipient race, especially being black, has been an independent predictor of increased risk of graft loss in US [26], but not European, transplant

Figure 50.2 The three general pathways to allograft deterioration: allograft rejection (acute and chronic), infection (with BK/polyomavirus specifically affecting the allograft), and calcineurin inhibitor toxicity. (From Rush 2006 [29], reproduced with permission.)

populations [27]. Whether recipient race is truly an independent risk factor for graft outcomes or this observation is confounded by socio-economic factors or other differences between populations and/or transplant practices between US and European centers is uncertain. Of note, the Veterans Administration Health Affairs System, in which most medications are provided without cost, similar in many ways to European health systems, found that for black recipients race was still an independent risk factor for graft outcome.

In summary, HLA matching is decreasing in relative importance as a predictor of outcomes, and its use in organ allocation is rapidly evolving.

Which surrogate or composite outcomes should be used in kidney transplantation?

The dwindling frequency and predictive usefulness of allograft rejection in kidney transplantation pose a vexing dilemma. One potential explanation for the lack of improvement in long-term outcomes despite reduction in allograft rejection rates could be due to a higher proportion of more severe, antibody-mediated rejection causing a disproportionate impact in the minority of allograft recipients it affects [28]. Another possibility is that enhanced immunosuppression has led to increased risk of calcineurin inhibitor-related nephrotoxicity and opportunistic infections, of which BK virus nephropathy in particular may lead to graft failure. Recent reviews suggest the two extremes of immunosuppression should both be given equal emphasis given their risks (Figure 50.2) [29]. This unfortunately would greatly reduce the utility of allograft rejection in clinical trials. The limited usefulness of serum creatinine or eGFR, or even renal histology, in predicting allograft failure has increased attention on other surrogate or composite markers for allograft survival, although there is no current agreement on which combination of markers should be used [30], a dilemma not unique to transplantation [31].

Conclusions

It will never be ethical or feasible to perform randomized, controlled trials comparing kidney transplantation versus dialysis. Prior to the publication of the seminal article of Wolfe *et al.*, transplant professionals could counsel prospective patients that they were likely to have an improved quality of life after kidney transplantation. A potential survival advantage was regarded as unproven, because previous studies had not adjusted for the considerable selection bias of deciding which dialysis patients should be enrolled on the kidney transplant waiting list. Dialysis patients enrolled on the waiting list have significantly lower risk of mortality, even when adjusted for other factors, compared to dialysis patients not selected for enrollment. This research group's use of wait-listed dialysis patients as the control group, in addition to their ability to study the entire population of US wait-listed patients and follow those who received kidney transplants for many years, provided convincing data for the medical community. Table 50.1 summarizes the findings from studies of patients on kidney transplant waiting lists.

Nevertheless, there remain important differences between waitlisted patients and those who receive kidney transplants, which was shown by the Scottish study and from the study of obese wait-listed patients. However, adjustment for these comorbid factors in that study actually strengthened the association of kidney transplantation with reduced mortality.

Current immunosuppressive practices after kidney transplantation have largely succeeded in reducing the incidence of the typical target end point, renal allograft rejection. The dilemma now is that reduced allograft rejection rates do not seem to correlate with improved long-term renal allograft survival. This may be due to the changing nature of renal allograft rejection itself, or to a greater frequency of infectious complications which may directly impact graft function. Given the difficulties in showing improvements in short-term renal allograft function, the future dilemma will be to determine which surrogate outcomes, or combination of surrogate outcomes, are appropriate to use in clinical trials. No consensus currently exists.

Infections after kidney transplantation

In this section we will focus on major infectious complications, namely, cytomegalovirus (CMV) and urinary tract infections (UTIs), that may affect patient and allograft survival after kidney transplantation, with attention to risk factors and proven management strategies. BK virus nephropathy is discussed in detail in chapter 26.

CMV

CMV is a DNA virus of the herpesvirus family (human herpesvirus 5). It is the most common viral infection complicating solid organ transplantation. Various incidence rates have been reported, depending on the definitions used (asymptomatic infection versus clinical CMV disease), the patient populations (CMV serologic

[a] The serostatuses of the donor (D) and recipient (R) are indicated (+ and −).

status of donor and recipient pretransplant), the induction and maintenance immunosuppressive regimens, and the use of prophylactic medications. Reported rates range from 8 to 63% [32–35]. The period from 1 to 6 months after transplantation, correlating with the most intense period of immunosuppression, is the highest risk period for CMV infection and disease.

Risk factors for posttransplantation CMV disease include CMV-seropositive donor status, use of antilymphocyte agents as induction therapy, and with more uncertainty, the use of mycophenolate mofetil (compared with azathioprine) as maintenance immunosuppression [36].

Allograft and patient outcomes by CMV serostatus, episodes of CMV infection, and episodes of CMV disease are outlined in Table 50.2. Based upon the results of several large retrospective cohort studies, donor seropositivity and donor and recipient seromismatching (D+/R−) reduce graft outcomes. Increased recipient mortality has been associated with CMV donor seropositivity as well as CMV infection.

Recommendations

Based on two meta-analyses, we recommend a prophylactic rather than preemptive antiviral strategy in recipients of kidney transplants for protection against CMV-related morbidity and mortality [39, 40]. Lack of evidence precludes designating a specific treatment after transplantation.

UTIs

UTIs are the most common form of bacterial infection following kidney transplantation and may affect allograft and patient outcomes directly with the infection itself and indirectly by possibly activating the rejection process [41].

In kidney transplant recipients not receiving prophylaxis, UTIs occur in 35–50%, predominantly in the first 6 months after transplantation [42]. Variability in rates reported may be explained by differences in the definition of UTI, methods of urine sampling, and the use or absence of perioperative and postoperative antibiotic prophylaxis [43]. Prophylactic therapy is associated with a

reduction of early UTI incidence of greater than 50%, although over half of all female recipients (and nearly half of male recipients) will still develop a UTI (as defined by medical claims) within 3 years after transplantation [44].

Although data are very weak, UTIs, regardless of timing of occurrence posttransplant, may negatively impact allograft and patient outcomes. Rice *et al.* recently reported in a prospective cohort study of kidney transplant patients with UTI that renal allograft injury (defined as a 20% or greater rise from baseline in peak serum creatinine within 24–48 h of positive urine culture) was significantly associated with P fimbriated *Escherichia coli* isolates (62% vs. 29%; $P = 0.03$) [45]. Although this study did not follow patients until graft failure or death, it suggests that a unique pattern of uropathogenic serotypes and adherence factors may contribute to allograft injury in kidney transplant patients with UTI in a manner quite unlikely to be influenced by other comorbid illnesses or other potential confounders. Muller *et al.* identified UTIs as a risk factor for chronic renal allograft rejection in a single-center, retrospective cohort analysis [46]. In a larger retrospective cohort study, Abbott *et al.* examined graft and patient survival after late-onset UTI (greater than 6 months posttransplant) [14]. The results of this study suggest that late-onset UTIs are not benign. However, both studies are retrospective and observational in nature and subject to ascertainment bias, in that urine cultures may be ordered more often in patients who are not doing well from any cause. The details and results of both of these studies are outlined in Tables 50.3 and 50.4.

Antibiotic prophylaxis for prevention of UTI is the topic of a Cochrane systematic review [47]. Few studies have been carried out using a randomized, double-blinded methodology, and none has yet shown whether antibiotic prophylaxis improves renal allograft survival or patient survival.

Management strategies

Given the morbidity and mortality associated with UTIs in the kidney transplant population, prevention is the primary management strategy. Prophylactic therapy (with either trimethoprim or

an oral fluoroquinolone) significantly reduces the incidence of UTIs.

Cardiovascular disease and posttransplantation outcomes

Rationale for cardiovascular risk assessment among transplant candidates and recipients

Given the high incidence and adverse effects of posttransplantation cardiovascular disease, the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) workgroup on chronic kidney disease concluded that kidney transplant recipients should be considered to be in the highest risk group for cardiovascular events, that is, coronary heart disease equivalent [48]. Although this emphasizes the severity of the problem, it does not reflect the heterogeneity of risk among the more than 115,000 patients currently living with kidney transplants in the USA [2] as well as those in other countries. Between 100,000 and 150,000 persons will be registered on the kidney transplant waiting list by 2010, and they will have unique cardiovascular risk management issues dictated by their need to maintain preparedness for transplant surgery [49]. Applying the most intensive screening and therapeutic strategies to all these patients is impractical, given limited health care resources, and may produce costs and treatment-related risks that outweigh benefits. This may be especially true

Table 50.4 UTI studies: results.

Study [reference]	Results
Muller *et al.* 1998 [46]	Significantly higher rates of UTI (after 3 yrs posttransplant) in patients with biopsy-proven chronic rejection
Abbott *et al.* 2004 [44]	Late UTI associated with death (AHR, 2.93; 95% CI, 2.22–3.85; *P* < 0.001) and graft loss (AHR, 1.85; 95% CI, 1.29–2.64, *P* < 0.05) Cumulative incidence of UTI at 3 yrs was 60% for women and 47% for men

Abbreviations: AHR, adjusted hazard ration; CI, confidence interval.

in subgroups of patients that are unlikely to have cardiovascular events. Methods for individualizing cardiovascular risk assessment among transplant recipients are needed.

Pretransplantation cardiac screening
Pretransplantation cardiovascular disease is a strong predictor of posttransplantation cardiac events [50–52]. It has been proposed that serial cardiac surveillance of transplant candidates on the waiting list may improve outcomes after transplantation. Consensus-based guidelines were developed that incorporate diabetes status, ischemic heart disease, peripheral vascular disease, results of non-invasive stress tests, and revascularization into an algorithm for suggested frequency of cardiac surveillance by stress echocardiography or combined resting echocardiography and nuclear stress imaging [53,54].

Clinical risk scores
Clinical prediction tools translate patient risk profiles into estimates of the absolute risk of an event during an observation interval and are useful for prognostication and for guiding the intensity of risk management. The most widely used tool for cardiac risk prediction in the general population, the Framingham Heart Score (FHS), estimates 10-year risk of new-onset coronary heart disease in stable persons based on age, cholesterol level, blood pressure, smoking history. and diabetes status [55]. Many FHS risk factors are prevalent among transplant recipients [50,56], suggesting that the FHS may predict coronary heart disease events after transplantation.

Performance of risk assessment strategies
Pretransplant cardiac screening
A recent American Transplantation Society survey reported wide variability among centers in the practice of cardiac surveillance of patients on the waiting list [49]. Few studies have examined outcomes associated with adherence to screening recommendations. Recently, a prospective, observational study of 604 transplant candidates in British Columbia found that surveillance based on ongoing clinical assessment resulted in fewer investigations (*n* = 171) than suggested by guidelines (*n* = 503) over a mean period of follow-up of 3.7 ± 1.8 years [57]. There was no difference in total

Table 50.5 Performance of the FHS for prediction of coronary heart disease events after kidney transplantation.

Study [reference]	Kasiske *et al.* 2000 [58]	Ducloux *et al.* 2004 [59]
Methods	Historical cohort	Historical cohort
Participants	1124 KTR at a single center	344 KTR at a single center
Years of transplant	1963–1997	NA
Sampling criteria	Allograft functional and free of heart disease at 1 yr after transplant	Serum creatinine ≤4.5 mg/dL and free of heart disease at 1 yr after transplant
Outcome measures	MI, coronary revascularization, or death due to IHD	MI, coronary revascularization, or angina with abnormal coronary arteriography
Observation interval	1 yr after transplant to death, loss to follow-up, or end of study (date not specified)	1 yr after transplant to death, loss to follow-up, or end of study (date not specified)
Performance of FHS	Underestimation of risk due to increased observed risk conferred by diabetes (HR in men 2.8, CI 1.7–4.5 vs. 1.5 in FHS; HR in women 5.4, CI 2.7–11 vs. 1.8 in FHS) and to lesser extent, age and smoking	Underestimation of risk; prediction of 16/27 (59%) observed coronary events

cardiovascular event rates after listing among subsets who did receive the recommended frequency of investigations (99 per 1000 person-years) and those who did not (67 per 1000 person-years), but potential selection biases in a retrospective study make it difficult to draw firm conclusions.

FHS and nontraditional factors

The FHS was developed for risk stratification of stable outpatients and has limited applicability in the prediction of peritransplantation coronary disease events precipitated by surgical stress. Several studies have shown limitations of the FHS even among stable kidney transplant recipients [58,59] (Table 50.5). Whereas individual Framingham factors are significantly associated with coronary risk among renal allograft recipients, effect sizes are altered such that risk estimates from the traditional algorithm are generally lower than the observed risk in this population. Features of this miscalibration include largest errors among those at highest risk, driven in part by underappreciation of diabetes-related risk.

A number of nontraditional risk factors and elements unique to kidney disease and transplantation have been linked with cardiovascular risk after transplantation, including C-reactive protein [59], hyperhomocysteinemia [59], duration of pretransplant dialysis [60], donor comorbidities [56], immunosuppressive drug regimen [61], viral infections [62], acute rejection [63], new-onset diabetes [64], and the quality and persistence of allograft function [51,52,65–71]. These factors are important considerations for the development of transplant-specific risk indices, but current clinical applications for risk stratification are uncertain. However, the relationship of the quality and maintenance of allograft function to cardiovascular risk is also important, because strategies for preservation of renal function may also reduce cardiovascular risk. A summary of the incidence and prognosis of congestive heart failure after kidney transplantation is provided in Table 50.6.

Recommendations

Kidney transplant recipients should be evaluated for traditional Framingham risk factors. These factors are markers of increased risk, but quantitative estimations of coronary risk after transplant are not possible using the general population FHS. Patients with graft dysfunction, and especially those with graft failure, should be considered at increased risk for diverse presentations of cardiovascular disease including ischemic heart disease, congestive heart failure, and arrhythmias.

Interventions for cardiovascular risk reduction
Dyslipidemia

Hyperlipidemia is a common and potentially modifiable metabolic abnormality among kidney transplant recipients [72]. Lipid-lowering therapy with HMG-CoA reductase inhibitors (statins) has repeatedly been shown to decrease cardiovascular events and mortality in the general population [73,74], suggesting that statin therapy may improve outcomes after kidney transplantation. The Assessment of Lescol in Renal Transplantation (ALERT) study is the only randomized controlled trial of an intervention designed to expressly target cardiovascular disease outcomes after kidney transplantation [75]. In this study, 2101 stable kidney transplant

recipients were randomly assigned to fluvastatin or placebo. Details of the trial and its findings are shown in Table 50.7. Statin therapy lowered lower-density lipoprotein cholesterol (average difference of 38 mg/dL), and there was a trend towards a reduction in the primary composite outcome, but this did not reach statistical significance. Secondary analyses suggest that fluvastatin may be associated with significantly fewer cardiac deaths or nonfatal myocardial infarctions [76], particularly when initiated early after transplant [77], and an open-label extension trial detected a significant reduction in the primary end point in the fluvastatin group by intention-to-treat analysis [78] (Table 50.7). Notably, there were no significant differences in patient or graft survival in the ALERT extension trial, suggesting a possible redistribution in causes of death.

Immunosuppressive regimen choice
Many immunosuppressive medications are associated with adverse effects on traditional cardiovascular risk factors, such as lipid levels, blood pressure, and glycemic control. Thus, modification of the immunosuppression regimen is frequently proposed as a strategy for cardiovascular risk reduction after transplant. The effect of immunosuppressive regimen on cardiovascular end points (except for all-cause mortality) has not been directly assessed in a clinical trial. A number of small studies have examined effects of drug conversion and withdrawal strategies on surrogates of cardiovascular risk, including blood pressure, lipid levels, and glycemic control,

but the actions of specific agents on individual surrogate end points preclude extrapolation to cardiovascular events.

Several studies have attempted to improve our understanding of differences in net cardiovascular risk conferred by calcineurin inhibitor choice using the FHS as a composite of surrogate factors. For example, an open-label comparison of tacrolimus versus cyclosporine, randomly allocated at transplantation with concomitant azathioprine and corticosteroids, found higher time-averaged glucose levels but lower total cholesterol and blood pressure in the tacrolimus arm over 6 months of observation; FHS was lower only among tacrolimus-treated men [61]. Late, open-label conversion of cyclosporine to tacrolimus in patients taking corticosteroids with or without an antimetabolite has been shown to reduce FHS (5.7± 4.3 to 4.8 ± 5.3 at 24 months postrandomization) [79], although early benefit was not present in statin-treated patients [80]. These analyses should be interpreted cautiously, given the aforementioned limitations of the FHS in kidney transplant recipients, in particular, underestimation of risk associated with diabetes [58] may bias the FHS in favor of tacrolimus, which is more likely to cause hyperglycemia and posttransplant diabetes [61,81].

Recommendations
Based on suggestive findings from the ALERT study, along with convincing studies of statin therapy in the general population, several national groups, including the NKF K-DOQI, recommend use of statins in transplant recipients with hypercholesterolemia

[72]. In parallel with recommendations of the Adult Treatment Panel III (ATP III) for high-risk members of the general population, the NKF suggests treatment to achieve a goal lower-density lipoprotein cholesterol of less than 100 mg/dL [82]. However, the ATP III and NKF guidelines were published before availability of newer lipid-lowering data, which suggest even lower levels may be beneficial in high-risk patients without kidney disease [83]. Additional studies are warranted to determine if aggressive lipid lowering may be beneficial for reduction of cardiovascular risk after kidney transplantation.

At present, there is insufficient evidence with respect to clinical outcomes to recommend adoption of particular immunosuppressive strategies for cardiovascular risk reduction. The immunosuppressive regimen should be individualized to manage competing risks of rejection versus drug side effect profiles, considering patient history and characteristics. Studies of the cardiovascular consequences of immunosuppression should consider the possibility of effect modification by cardiovascular drugs such as statins.

Summary

Observational data now strongly support the view that kidney transplantation offers a survival advantage for patients with chronic kidney disease in comparison with remaining on long-term dialysis. This advantage applies to all subgroups that have so far been investigated. This advantage in survival appears mainly related to reduction in cardiovascular disease, whereas infectious complications may not be reduced. Because of immunosuppression, kidney transplant recipients are at risk for infections not often seen in the general population. Emergent infections, such as BK virus infections, have become widely recognized and have had a

substantial impact on graft loss in the modern era, although no generally accepted guidelines for diagnosis and management have yet been published and no FDA accepted treatments are yet available. Infections generally assumed to have been relegated to the past, such as CMV and UTI, remain serious problems after kidney transplantation. Finally, although cardiovascular disease is less common after kidney transplantation than among long-term dialysis patients, cardiovascular disease is still more common than in the general population and remains the leading cause of death with graft function.

51 The Early Course: Induction, Delayed Function, and Rejection

Paul A. Keown

Departments of Medicine and Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada

Introduction

The success of kidney transplantation has increased dramatically, driven by innovations in biology, medicine, and surgery. Almost 40% of patients with chronic kidney disease in Canada and Australia and 30% of those in the USA are now maintained with a functioning transplant [1–3], although other developed countries such as Germany and Japan have lower transplantation rates (1 and 10%, respectively) due to societal, logistical, or economic factors [3,4]. Understanding of biological processes of graft injury and selective inhibition of key molecular steps in alloantigen response has been critical in this evolution [5–7]. Patient and graft survival now exceed 95% and 90%, respectively, during the first year, and over 80% of patients remain free from acute rejection [1–3]. Complications have diminished in frequency and severity; life-threatening bacterial, fungal, and viral infections are now uncommon; and there has been a corresponding improvement in both quality of life and overall cost-effectiveness [8–11].

The first 3 months posttransplant remain a critical period during which the graft is at risk of physiological and immunological injury, which may reduce long-term success [2]. Optimal care requires precise estimation of recipient risk, appropriate prophylaxis, accurate diagnosis, and speedy intervention to prevent graft injury. Potent biological immunosuppression is often used to complement conventional pharmacological maintenance immunosuppression to minimize the risks of delayed graft function (DGF) and rejection, whereas plasma exchange may be employed to remove antibodies against donor HLA antigens and mitigate severe humoral injury [12]. It is challenging to define optimal strategies for early transplant care, because formal randomized clinical trials are often lacking or do not explore all potential treatment options or therapeutic combinations. This chapter therefore summarizes the principal issues of induction therapy, DGF, and

rejection; it documents the current treatment guidelines and reviews the emerging evidence in each of these areas.

Definitions

Induction therapy
Induction refers to the use of potent immunosuppression administered around the time of transplantation to reduce the risk of acute rejection, minimize delayed graft function, and decrease subsequent renal toxicity by permitting a reduction in calcineurin inhibitors during the critical posttransplant period [12]. Induction therapy most commonly consists of a short course of polyclonal or monoclonal antibodies directed against discrete epitopes on the lymphocyte surface. It is normally administered in addition to routine maintenance therapy, which may be reduced, or individual agents may be withheld during this time to minimize specific drug toxicity or global immunosuppression.

DGF (Delayed Graft Function)
DGF is frequently defined as the requirement for dialysis in the first 7 days posttransplant, although this lacks both sensitivity (missing subjects with mild impairment not requiring dialysis) and specificity (including subjects requiring dialysis for other reasons, such as accelerated rejection) [13]. A more precise definition includes a urine output of less than 1200 mL/day, decline of serum creatinine of less than 10% in the first 2 days, or achievement of a functional threshold (e.g. serum creatinine less than 220 μmol/L or estimated glomerular filtration rate above 10 mL/min). However, calculation of creatinine elimination kinetics perhaps provides the most objective measure of early function [14].

Rejection
Graft rejection is classically divided into three categories. Hyperacute rejection usually presents within the first hours following graft implantation and is characterized by endothelial injury, vascular occlusion, and microvascular thrombosis of the graft [15]. It is now uncommon, occurring in <1% of patients, is caused by

preformed antibodies to donor transplantation antigens, and is resistant to conventional therapy, often leading to graft loss. Acute rejection occurs in around 10% of patients reported to the US Renal Data System (USRDS) [2] and typically presents from day 3 to 90 posttransplant, although it may occur later if immunosuppression is decreased due to comorbidity or noncompliance. Acute rejection may comprise both cell-mediated and antibody-mediated injury [15]; the former typically responds readily to conventional therapy, whereas antibody-mediated rejection is more resistant or refractory. Chronic rejection usually presents after the first year and has often been included in the confusing term "chronic allograft nephropathy," which is now discouraged [16]. The diagnostic features include specific histological changes in the glomeruli, interstitium, tubules, and vessels, diffuse C4d deposition, and circulating donor-specific antibody (DSA). Chronic rejection responds poorly to therapy.

Guidelines

Induction therapy

The European Best Practice Guidelines [15] provide recommendations for the use of induction therapy based on level A evidence (systematic reviews of randomized trials). These state that prophylactic immunosuppression with antibody may be administered to kidney transplant recipients as an optional initial therapy to reduce the number and severity of rejections during the first 3–6 months after transplantation, although benefits must be balanced against the risks of overimmunosuppression with increased susceptibility to opportunistic viral infection and posttransplant lymphoproliferative disease. They emphasize that induction therapy with polyclonal (ALG or ATG) or monoclonal (OKT3) antibodies administered during the perioperative period for a limited time (1–3 weeks) does not consistently improve graft survival at 3 years posttransplant in unselected recipients. Recipients with DGF, or recipients with low and high panel-reactive antibodies directed to HLA antigens may benefit from classical induction therapy with ALG, ATG, or monoclonal antibodies (OKT3), and these agents show equivalent efficacy. Finally, they noted that safe and effective prophylaxis has been achieved with high-affinity humanized or chimeric monoclonal antibodies (daclizumab and basiliximab, respectively), which target the interleukin-2 (IL-2) receptor.

DGF

Guidelines provide recommendations for the management of the donor and recipient during the perioperative phase to maximize organ quality and recipient volume status based on level B or C (observational) evidence .[15,17–19]. Central components of these include recommendations that management of the donor should be similar to normal intensive care, but the objectives are to support future function of renal, cardiac, and pulmonary grafts. A simplified goal for managing the donor may be to maintain a central venous pressure of 10 cm water, a systemic blood pressure of 100 mm/Hg, and a urine output of 100 mL/h. Preoperative dialysis

should not be performed routinely except for patients with heart failure or hyperkalemia, and preoperative hypovolemia should be avoided to prevent DGF. Caution should be used with marginal donors, including the elderly (>60 years), particularly those with prior hypertension, diabetes, or intrinsic renal disease, who have a calculated glomerular filtration rate of <60 mL/min. Such organs should preferentially be offered to older recipients (over 60 years) with a limited life expectancy and who provide informed consent to receipt of such an organ. The recipient should not be dialyzed routinely pretransplant, except for those with heart failure or hyperkalemia, and hypovolemia should be avoided to prevent DGF. Graft function should be monitored closely in patients with delayed function, vascular, and urological complications, drug toxicity and infection should be also excluded as causes, and surveillance biopsies should be considered [15].

Rejection

Formal guidelines provide recommendations for the detection of donor-specific anti-HLA antibodies, histological diagnosis, and treatment of rejection based on level B or C evidence [15,19–22]. A cross-match test must be performed pretransplantation on current serum using at least one method that detects complement-dependent antibodies, and a positive immunoglobulin G (IgG) cross-match is considered an absolute preclusion to transplant. Historical sera should also be tested, and a positive historical cross-match may increase the risk of rejection and indicate a need for more intensive immunosuppression [22] or be a contraindication in patients receiving a repeat transplant and in those with high panel-reactive antibodies [15]. Flow cytometry may be used to increase the sensitivity of antibody detection, although guidelines differ regarding the implication of a positive flow cross-match [15,19,22]. Posttransplant monitoring of DSA may be of value in the diagnosis or prognosis of rejection and should be monitored if possible, particularly at the time of biopsy [15,22].

Histological diagnosis and categorization of rejection is standardized in the Banff criteria, which are updated following each biennial meeting [16,21,23]. Criteria for hyperacute or accelerated acute antibody-mediated rejection and grades I–III acute rejection are defined in the 1997 criteria [23], whereas the characteristics of chronic rejection have been clarified and distinguished from other forms of chronic graft injury in the 2005 criteria [16]. Patients should be monitored routinely for evidence of graft dysfunction [15,19,22,24]. Acute rejection should be considered in patients with a rapid rise in serum creatinine of 10–25% over baseline, with or without a decline in urine output; graft biopsy should be performed to confirm rejection, and reporting should be standardized according to an internationally agreed-upon scheme [15]. High-dose intravenous methylprednisolone is recommended for treatment of the first acute rejection episode, and ATG is preferred to OKT3 for subsequent or severe episodes in light of their respective toxicities [15]. Alteration in baseline therapy and the use of plasmapheresis with or without intravenous immunoglobulin (IVIG) may be required in refractory cases [15,22]. Subsequent deterioration in graft function or new proteinuria should

be investigated fully to determine the cause, including chronic rejection, although no guidelines yet exist for therapy of proven benefit [19,22,25].

Available evidence

Not all key aspects of care in the early posttransplant period have been subject to appropriately powered and designed randomized clinical trials. Several systematic reviews and meta-analyses addressed those randomized controlled trials that have evaluated the use of induction therapy and the management of DGF and rejection, and many smaller high-quality studies have provided additional insight and guidance into these aspects of care. The key information derived from these studies is reviewed in the sections below.

Induction therapy

Systematic reviews of induction therapy performed by Gaston, Hardinger, Chapman, Kirk, Nashan, and colleagues chronicle the changing role of this therapy during the past decade [6,12,26–28]. In prior years, induction was employed principally for patients at high risk of immunological or physiological graft injury due to its cost, toxicity, and paucity of high-level evidence for benefit and cost-effectiveness in low-risk subjects [29–32]. However, it has experienced a resurgence with the availability of more consistent, safe, and effective biological preparations, and accumulating data show that induction therapy offers a significant reduction in the incidence of acute graft rejection following living or cadaver donor transplantation (Figure 51.1) [32].

The principal polyclonal antibodies employed today are equine-derived ATGAM, and rabbit-derived ATG-Fresenius and Thymoglobulin [33]. The last of these is the most widely used in North America, particularly in subjects who are sensitized, who are undergoing retransplantation, or who have DGF [31]. These agents have composite molecular actions, including ligation of surface epitopes, T- and B-lymphocyte deletion via tumor necrosis factor/Fas-mediated apoptosis, selective downregulation of gene expression, and the induction of $CD4^+$ $CD25^+$ FoxP3 regulatory cells [34–36]. Administration has varied from 1 to 10 days, although treatment for 5–10 days is now most common. Reported efficacy varies according to the product and the target population, so that evaluation of relative risk or benefit is complex. Studies have shown that Thymoglobulin is superior to ATGAM [37] in reducing the cumulative probability of acute graft rejection ($P = 0.001–0.004$). However, it did not improve graft or patient survival and significantly increased the risk of cytomegalovirus (CMV) and other viral infections, leukopenia, and other hematological complications compared with pharmacological immunosuppression ($P = 0.001–0.05$).

Two recent randomized studies suggest that ATG exerts a positive effect in low-risk kidney transplant recipients when calcineurin inhibitor therapy is delayed [38,39]. In the first study of 309 deceased donor graft recipients, patients randomized to receive ATG for 10 days followed by tacrolimus had significantly fewer biopsy-confirmed acute rejection episodes (15% vs. 30%; $P = 0.001$) than those treated with tacrolimus from the time of transplantation. However, patient and graft survival, DGF, and graft function 1 year posttransplant were similar between the groups, and viral and other infections were more common in the ATG group. The second study involved 555 deceased donor graft recipients. Patients randomized to receive ATG for 10 days followed by tacrolimus had a lower incidence of biopsy-proven rejection than those receiving ATG followed by cyclosporine or those commencing tacrolimus from the time of transplant (15% vs. 21.2% vs. 25%; $P = 0.004$ and 0.177) [39]. Again, cumulative

Figure 51.1 Trends in kidney transplant induction immunosuppression. (From Kaufmann *et al.* 2004 [45].)
Source: 2003 OPTN/SRTR Annual Report, Table 5.6a

patient and graft survival and mean serum creatinine levels were similar among the groups, and hematological and viral complications were higher in the ATG groups. The elevated risk in the cyclosporine-treated group may reflect imbalances in the number of patients with a prior transplant or increased PRA in this group [39].

The prophylactic use of Muromonab (OKT3) has declined substantially during the same period due to substantial toxicity and lack of demonstrable benefit [40,41]. Large-scale national and international studies show that the relative risk of posttransplant lymphoproliferative disease is increased by 1.5- to 2-fold in patients receiving Muromonab compared with no induction therapy [30,42–44]. Muromonab is now used in less than 1% of patients [45] and has been largely replaced by ATG in high-risk subjects or anti-CD25 antibodies in low-risk patients [32,46], although data showing differences in graft or patient survival are lacking [47]. Novel anti-CD3 molecules with differing isotypes or epitope specificities [48] are under investigation, but their benefit/toxicity ratio remains unproven.

Alemtuzumab (Campath-1H) is a humanized monoclonal antibody to CD52 that causes long-lasting depletion of human B and T cells. Alemtuzumab offers potential practical benefits over polyclonal depleting antibodies, with lower cost and simplicity of intravenous access. A systematic review by Morris *et al.* showed that despite increasing use, the level of evidence for its role in transplantation is limited [49]. Preliminary noncontrolled studies indicate that graft rejection, graft loss, mortality rates, and infectious complications are comparable or perhaps superior to patients receiving anti-CD25 monoclonals and conventional triple or quadruple therapy. The expectation of patient and graft survival exceeds 95% at 500 days [50], and steroid avoidance and minimization of long-term maintenance immunosuppression may be possible [51,52–55]. Two small randomized controlled trials confirmed that the incidence of acute rejection is not different from control therapy, although steroid-free and calcineurin-sparing protocols are possible [56,57]. Although there is a profound and long-lasting T-cell lymphopenia after administration of alemtuzumab, there is no apparent increase in infection, posttransplantation lymphoproliferative disease, or other side effects other than perhaps autoimmune disease. However, the limited studies available at present do not support early hopes of immune accommodation permitting withdrawal of maintenance therapy.

Basiliximab and daclizumab (anti-CD25) are monoclonal antibodies to the IL-2 receptor that bind selectively to the CD25 molecule, inhibiting high-affinity IL-2 binding to this structure and inhibiting the proliferative signals critical for lymphocyte activation. Basiliximab is a chimeric molecule that includes the complete variable region of the original anti-CD25 molecule, and it is normally administered on two occasions within the first posttransplant week. Daclizumab, a humanized molecule that includes only the hypervariable region of the murine antibody whereas the remainder is of human origin, exhibits slightly lower binding affinity and is given more frequently throughout the first 2 months [12,13]. Both have long terminal half-lives (2 weeks)

and deplete CD25 expression for an average of 45 and 90 days, respectively.

A number of meta-analyses have examined the efficacy and toxicity of these drugs [8,58]. The most extensive has been completed by Webster and colleagues, who included 38 current studies of anti-CD25 antibody use comprising 4893 subjects [59] (Table 51.1). The antibody was compared to placebo or no therapy in 16 studies (2682 subjects) and to another monoclonal or polyclonal antibody in 14 studies (1108 subjects). Two studies compared the antibodies directly, and the remaining studies examined other treatment comparisons or dosing strategies. Cyclosporine A was employed as maintenance immunosuppression in 32 studies, and tacrolimus was used in the remainder. Results were homogeneous among all studies with no discernable difference between the two anti-CD25 antibodies. Anti-CD25 therapy reduced the incidence of clinical acute rejection in the first 6 months by 34% (relative risk [RR], (Figure 51.2), 0.66, 95% confidence interval [CI], 0.59–0.74), biopsy-proven rejection by 36%, and steroid-resistant rejection by 49% (RR, 0.51; CI, 0.38–0.67). Graft loss (RR, 0.84; CI, 0.64–1.10) (Figure 51.3) and CMV infection (RR, 0.82; CI, 0.65–1.03) were also reduced at 1 year in patients receiving anti-CD25 therapy, although these did not reach statistical significance. On this basis, for every 100 subjects treated with these agents, 14 would be expected to avoid acute rejection and 8 to avoid steroid-resistant rejection [59].

Anti-CD25 antibodies were comparable in efficacy to other monoclonal or polyclonal antibodies, and no significant differences were evident for graft rejection or loss, CMV infection, mortality, or other principal outcomes [59] (Figure 51.4). Fever, leukopenia, thrombocytopenia, and overall adverse reactions were significantly lower in subjects receiving anti-CD25 therapy than other induction therapies. Basiliximab and daclizumab were compared directly in only two small studies comprising 82 subjects. Despite the limitations in sample size and study design, there was no difference in reduction of rejection risk between the two agents (RR, 0.67 [CI, 0.59–0.77] vs. RR, 0.66 [CI, 0.53–0.82]).

DGF

DGF occurs in approximately 4% of live donor recipients and 23% of deceased donor graft recipients (overall reported range, 2–50%) [2,13] and varies from mild impairment with slow recovery to persistent oliguric renal failure and graft loss [13,17,18]. DGF may result both from donor factors, which include donor source, age, renal function, comorbidity, clinical support, and surgical technique, and recipient factors, including surgical implantation, vascular competency, volume status, immunological sensitization, and immunosuppressive therapy [13]. Careful management of all of these is required to reduce immediate injury and ensure long-term success.

The European Expert Group has defined the ideal deceased (cadaver) donor as a previously healthy individual, aged 10–55 years, brain dead due to trauma or intracerebral bleeding, with no ongoing infection and excellent organ function [17]. However, the majority of donors no longer fulfill these criteria, and

Table 51.1 Clinical trials of anti-CD25 monoclonal antibodies following kidney transplantation.

Figure 51.4 Clinically diagnosed acute allograft rejection at 6 months after transplantation: anti-CD25 versus other monoclonal or polyclonal antibodies, stratified by antibody class. (From Webster *et al.* 2004 [59].)

the pressing shortage of deceased donor organs has expanded the sources and criteria for donor acceptance [60–62]. Cadaver donors now frequently include the elderly and those with vascular disease, long-term insulin-dependent diabetes, hypertension, or other risk factors that may impair renal function [17]. Non-heart-

Table 51.2 Proposed strategies to prevent ischemia–reperfusion injury and DGF.

Recipient fluid management
- Volume expansion with colloid or crystalloid
- Mannitol or furosemide

Vasodilatory agents
- Calcium channel blockers
- Prostacyclin
- Atrial natriuretic peptide
- Selective and nonselective endothelin receptor antagonists

Antioxidants
- *N*-Acetylcysteine
- Propionyl-l-carnitine
- Inhibitors of inducible nitric oxide synthetase

Biological agents
- Monoclonal antibodies to ICAM-I, LFA-1, and tumor necsrosis factor-α
- CTLA4 fusion protein
- Insulin-like growth factor 1

Source: Adapted from Perico *et al.* 2004 [13].

beating cadaver donors are used in centers equipped for this service [17], and expanded-criteria living donors are now being accepted in an increasing number of centers. There is good evidence that expanded-criteria donors with an adequate pretransplant kidney biopsy should be utilized but that the risk of physiological injury to the transplanted organ is increased and the probability of delayed or impaired function is increased [13,63].

There is little evidence that recipient dialysis modalities confer different risks for DGF, although there are trends towards superior function in patients receiving peritoneal dialysis and inferior outcome in those on home nocturnal dialysis [64,65]. These studies need to be confirmed but have potential importance only in cases where transplantation is imminent. Similarly, although immunological sensitization increases the risk of DGF, there is no evidence that desensitization techniques reduce this probability. Minimization of warm and cold ischemia times are critical in reducing ischemia–reperfusion injury (Table 51.2), and retrospective studies suggest that pulsatile perfusion may significantly reduce the risks of DGF, but the benefit if any remains to be proven in appropriately designed prospective studies [66].

Posttransplant initiatives to minimize DGF have been reviewed by Perico *et al.* [13]. Recipient hypovolemia or hypotension can affect the early function of the graft, and intensive support with crystalloid, colloid, or dopamine may be required [18]. Mannitol given just prior to reperfusion may improve early function by virtue of its antioxidant properties, but whether furosemide enhances glomerular filtration or simply increases urine volume is

Table 51.3 Banff diagnostic categories for renal allograft biopsies, 2005 update. (Solez et al, Am J. Transplant, 7, 518–526, 2007, table 2)

1. Normal

2. Antbody-mediated rejection

Due to documented anti-donor antibody ('suspicious for' if antibody not demonstrated; (may coincide with categories 3–61)

Acute antibody-mediated rejection

Type (grade)

  i. ATN-like-C4d+, minimal inflammation
  ii. Capillary-margination and/or thromboses, C4d+
  iii. Arterial-v3, C4d+

Chronic active antibody-mediated rejection[1]

Glomerular double contours and/or particular capillary basement membrane multilsyering and/or interstitial fibrosis/tubular atrophy and/or fibrous intimal thickening in arteriea, C4d+

3. Borderline changes: 'suspicious' for acute T-cell-mediated rejection

The category is used when no intimal arteritis is present, but there are foci of tubultis lt1, t2 or t3 with i0 or ill although the t2 t2 threshold for rejection diagnosis is not met (may coincide with categories 2, 5 and 6)

4. T-cell-mediated rejection[1] (may coincide with categories 2, 5 and 6)

Acute T-cell-mediated rejection

Type (grade)

  IA. Cases with significant interstitial infliltration t > 25% of parendhyma affected, i2 or i3 and foci of moderate tubulitis (i2)
  IB. Cases with significant interstitial infiltration t > 25% of parenchyma affected, i2 or i3 and foci of severe tututlitis (t3)
  IIA. Cases with mild to moderate intimal arteritis (v1)
  IIB. Cases with severe intimal arteritis comprising >25% of the lumical area (v2)
  III. Cases with 'transmural' arteritis and/or arterial fibrinoid change and necrosis of medial smooth muscle cells with accompanying hymphocytic inflammation (v3)

Chronic active T-cell-mediated rejection[1]

'Chronic alongraft arteriopathy' tarterial intimal fibrosis with mononuclear cell infiltration in fibrosis, formation of neo-intimal

5. Interstitial fibrosis and tubular atrophy, no evidence of any specific eticlogy[1]

Grade

  i. Mild interstitial fibrosis and tubular atrophy l < 25% of cortical areal
  ii. Moderate interstitial fibrosis and tubular atrophy 126–50% of cortical areal
  iii. Severe interstitial fibrosis and tubular atrophyloss l > 50% of cortical area)
(may include nor-specific vascular and glomerular aclerosis, but severity graded by tubulointerstitial features)

6. Other: Changes not considered to be due to rejection-acute and/or chronic the dagnosis given in Table 1); may coincide with categories 2–5

[1] Indicates changes in the updated Bani CE schema.

unclear. Randomized studies have shown that pretreatment of the donor or recipient with calcium channel blockers prior to grafting, or administration of these into the graft artery, may improve initial function. Evidence regarding the use of atrial natruretic peptide or its synthetic forms is conflicting, and additional studies are required. Similarly, although inhibition of free radical mediated injury by *N*-acetylcysteine or inhibitors of inducible nitric oxide synthetase is appealing, these approaches remain in the experimental domain [13]. Finally, neither modulation of key cell surface products, such as ICAM by enlimomab or of LFA-1 by odulimonab, or use of the growth factor insulin-like growth factor 1 have proven successful in this setting [13,67].

Two important changes in immunosuppression designed to optimize initial function include the increasing use of induction therapy and the transient or permanent avoidance of calcineurin inhibitors. These approaches are often employed in subjects at risk or in those with established graft dysfunction, although absolute evidence of benefit is still lacking. Small randomized studies have shown that the use of ATG is associated with improved early graft function [68], whereas the effect of anti-CD25 therapy remains uncertain, particularly since subjects at greatest risk of delayed function are often those at high immunological risk [13]. Calcineurin inhibitors may be withheld for the first 7–10 days [38,39,69] or replaced by nonnephrotoxic agents, such as mycophenolate mofetil or sirolimus [70]. Knight and colleagues suggested that the combination of ATG and sirolimus in high-risk patients and basiliximab and sirolimus in low-risk subjects is an effective combination for minimizing both DGF and acute rejection [71]. However, other reports indicate that sirolimus itself may cause direct renal tubular toxicity and promote or prolong delayed function of the graft, particularly when used in combination with a calcineurin inhibitor [72,73]. The most common therapeutic approach at present is therefore the use of an induction agent in combination with mycophenolate mofetil and the delayed introduction of a calcineurin inhibitor if this is to be employed for long-tern therapy until graft function is established.

Graft rejection

The Banff system (Table 51.3), first introduced in 1993 [74], provides a universal system for histological categorization of graft injury ranging from cellular infiltration to fibrosis and scarring, and attempts to incorporate new diagnostic and mechanistic understandings in order to provide a common framework for scientific and clinical evaluation. During the past decade, the focus has gradually shifted from cellular injury to mixed patterns or pure antibody-mediated rejection [20,21]. This is now recognized as perhaps the most important immunological threat to graft success [22,75–77] and is characterized by the combination of circulating donor-specific anti-HLA antibody, the deposition of C4d in the graft, and evidence of histologic injury and physiological dysfunction [22]. Innovations in management of graft rejection have been directed principally to the reversal and prevention of humoral injury.

Numerous treatments have been employed for graft rejection, depending on the time of presentation, clinical severity, histology, and comorbidity. Their efficacy may depend on the expression of antibody-mediated rejection across the spectrum from predominant cellular injury to mixed antibody-mediated rejection with high DSA titers to finally pure T-cell-poor antibody-mediated

rejection [76]. For example, Banff type I tubulo-interstitial cellular injury within the first 6 months of transplant usually responds to intravenous steroids and increased maintenance immuno-suppression, whereas Banff type II transplant endarteritis that is C4d negative often requires antilymphocyte antibody treatment [76]. Mixed patterns with C4d deposition are most commonly treated with a full course of depleting antilymphocyte agents, such as ATG, which can clear both cellular and humoral components.

A meta-analysis by Webster and colleagues examined the use of polyclonal or monoclonal antibodies for treatment or graft rejection [78]. This analysis revealed a total of 21 trials in 49 reports, although only 2 of these were conducted within the last decade (Table 51.4). Most were small, incompletely reported especially for potential harm, and did not define outcome measures adequately (Table 51.5). Fourteen of these trials encompassing 965 patients compared therapies for first rejection episodes. Eight of these compared antilymphocyte antibodies against steroids, two against other antibodies, and four against other therapies. Meta-analysis indicated that antibody was superior to steroid in reversing rejection (RR, 0.57; CI, 0.38–0.87) and preventing graft loss (death-censored RR, 0.74; CI, 0.58–0.95) (Figures 51.5 and 51.6) but there was no difference in preventing subsequent rejection (RR, 0.67; CI, 0.43–1.04) or death (RR, 1.16; CI, 0.57–2.33) at 1 year. Seven trials encompassing 422 patients investigated treatment of steroid-resistant rejection. There was no benefit of Muromonab CD3 over ATG (Table 51.6) or ALG in reversing rejection (RR, 1.32; CI, 0.33–5.28) (Figure 51.7), preventing subsequent rejection (RR, 0.99; CI, 0.61–1.59), or preventing graft loss (RR, 1.80; CI, 0.29–11.23) or death (RR, 0.39; CI, 0.09–1.65). However, Sun and colleagues have shown that mixed cellular and antibody-mediated rejection with circulating DSA and C4d deposition can also be reversed by intravenous steroids followed by conversion from cyclosporine to tacrolimus, or by an increase in the tacrolimus dose for those already on this medication, without ATG use [79]. More stringent studies are therefore required in this field.

The treatment of predominantly antibody-mediated rejection episodes with high-titer DSA and positive C4d, typically recognized as "pure or dominant antibody-mediated rejection" and associated with rapid deterioration in graft function, is extremely challenging. It increasingly incorporates the use of antibody removal with plasmapheresis and inhibition of new antibody formation via the use of IVIG acting through the Fc feedback loop [80,81]. Anti-CD20 (rituximab) monoclonal antibody may be used simultaneously to inhibit antibody formation systemically or within the graft [81], although few randomized studies are available to demonstrate the utility and safety of these procedures and no systematic or meta-analyses have thus far been published.

The AHG-CDC assay currently used to measure recipient sensitization and to define antibody specificity [22,82] lacks sensitivity, and the flow cytometry cross-match (FCXM) assay [83], which is more sensitive for detecting low levels of antilymphocyte antibodies [83–88], is widely employed as a key measure of sensitization. A positive FCXM has been proposed as a valid rationale to withhold transplantation, to augment immunosuppression, or to employ innovative strategies to reduce sensitization [22,82,89], but the prognostic value remains unclear [82]. Many reports have suggested that recipients with a positive FCXM, especially those at high immunological risk, experienced a greater incidence of acute rejection and early graft loss [20,90–93]. In contrast, other studies have shown negative results or indicated little incremental advantage of FCXM in terms of reducing acute rejection episodes and graft loss [20,94–96]. Prospective and blinded evaluation shows that the FCXM has little independent incremental predictive value compared with AHG-CDC, and positive and negative post-test probabilities for acute rejection or graft loss are low [97], perhaps reflecting the recognized lack of analytical specificity. Newer high-resolution solid-phase technologies using HLA antigens bound to microparticles offer both specificity and sensitivity [98] and may be a superior tool for both pretransplant screening and posttransplant monitoring [99].

Two principal methods have been employed for reducing DSA pre- or posttransplant, but comparison is difficult because of differences in diagnostic methodologies, degrees of sensitization, and patient risk factors [100]. The first employs high-dose IVIG to treat patients previously screened for responsiveness using an *in vitro* CDC assay with a panel of normal controls under conditions resembling those of the normal cross-match [101]. Patients in a randomized prospective placebo controlled study received 2 g/kg IVIG (or placebo) monthly for 4 months pretransplant and for a further 4 months after transplant. Panel reactive antibocties (PRA) levels declined by approximately 20% in the IVIG group by 4 months of treatment ($P = 0.0007$) and rose slowly thereafter to prior levels. The number of patients who could be transplanted was twice as high in the IVIG group ($P = 0.048$), time to transplant was significantly shortened ($P = 0.049$), and the number of repeat transplants performed was also increased. Graft failure occurred in 25% of IVIG recipients compared with 38% of controls, although the incidence of acute rejection was higher in the IVIG group ($P = 0.042$) [101]. Side effects were few and not sustained.

The second protocol employs four daily plasmapheresis sessions with low-dose IVIG for antibody reduction, often with rituximab [102]. In the comparative study, anti-HLA antibodies were determined by AHG-CDC, FCXM, and solid-phase single-antigen assays. The success of desensitization correlated with the baseline antibody level in each group: all patients with PRA titers of <1:4 had a negative cross-match compared with either protocols, while only 10% of those with titers of >1:32 achieved a negative cross-match. Overall, 38% of those receiving high-dose IVIG achieved a negative cross-match but 80% had acute rejection, whereas 84–88% of those receiving plasmapheresis and low-dose IVIG achieved a negative cross-match and 29–37% experienced rejection [102]. At the present time, it therefore appears that desensitization is possible in patients with antibody titers of <1:16 and that a combination of IVIG and plasma exchange achieves

Table 51.4 Use of antibodies for treatment of graft rejection: characteristics of patients, randomized treatments, and baseline immunosuppressive therapy.

Trial name	Antibody intervention (dose, duration)	Randomized comparator (dose, duration)	n	% Deceased donor	% 1st transplant	Background immunosuppression (initial; maintenance dose)	Follow-up (months)
Trials of antibodies for treatment of first rejection episode							
Antibody vs. steroid

this most effectively and may enable transplantation for patients otherwise denied this treatment.

Conclusion

A growing evidence base is now available to guide the management of patients during the critical first 3 months posttransplant. However, the numerous therapeutic options, treatment combinations, and dosing regimens remain challenging for clinicians, and the relatively limited number of high-quality and appropriately powered randomized and blinded clinical trials do not provide adequate evidence for all key decisions.

It now appears apparent that biologic induction immunosuppression increases the freedom from acute rejection and is increas-

ingly employed for this purpose, particularly in North America. Selection between polyclonal and monoclonal agents remains difficult but may be determined by safety and side effects. In general, for patients at low immunological risk, anti-CD25 antibodies offer an equivalent reduction in rejection risk to ATG but with a lower incidence of infection and adverse effects. Although the evidence is not clear for patients at high immunological risk, most centers will select ATG in preference to anti-CD25 agents for these subjects in order to maximize immunosuppression.

DGF remains problematic, particularly in sensitized recipients of grafts from extended criteria donors. In this setting, evidence suggests that biologic induction with delay in introduction of calcineurin inhibitors offers the greatest opportunity for early establishment of function, although the evidence base is not adequate to support this with a high degree of confidence. New approaches in which potent biological induction with depleting antibodies are

Figure 51.7 Treatment of acute steroid-resistant rejection with Muromonab versus other antibodies: recurrent rejection up to 12 months posttreatment. (From Webster *et al.* 2004 [59].)

used to permit the complete elimination of calcineurin inhibitors may provide an option to optimize early and long-term graft function, but such studies are still under way.

The incidence of classical acute rejection is declining with improved immunosuppression, and such rejection responds promptly to simple therapy with steroids or to secondary treatment with ATG. Strategies to reduce pretransplant sensitization to donor HLA antigens and to avoid the risk of hyperacute or accelerated rejection permit transplantation in settings previously considered impossible. The risks of severe antibody-mediated rejection following transplantation remain high in this setting, however, and may be treated with the same techniques of biological immunosuppression, intravenous immunoglobulin and plasmapheresis. The availability of new monoclonals directed at the B lymphocyte may play an important role in this setting and further reduce the risks of antibody-mediated rejection, which is currently one of the most important immunological barriers to successful transplantation.

Table 51.6 Summary of relative effects of Muromonab versus other antibodies for treatment of resistant rejection, within 12 months of treatment.

Outcome	No of trials	No. of participants	Relative risk (95% confidence interval)[a]	Heterogeneity	
				P[b]	I² %
Failure of acute rejection reversal	3	136	1.32 (0.33, 5.28)	0.35	5.4
Graft loss (death censored)	3	136	1.80 (0.29, 11.12)	0.17	43.6
Graft loss or death with a functioning graft	3	136	1.08 (0.38, 3.10)	0.26	26.3
Death	3	175	0.39 (0.09, 1.65)	0.97	0
Infection as a cause of death	2	76	0.68 (0.17, 2.65)	0.77	0
CMV	3	175	0.88 (0.60, 1.28)	0.51	0
Malignancy	2	115	2.09 (0.28, 15.66)	0.40	0
Fever , chills, malaise following drug administration	2	81	3.21 (1.34, 7.70)		
Serum creatinine (μmol/L)	3	120	10.04[c] (−16.68, 36.77)	0.35	4.6

Source: Webster *et al.* 2004 [59].

[a] Relative risk values of <1 (or WMD of <0) favor treatment with Muromonab CD3.

[b] *P* value for Cochran Q ?² test for heterogeneity.

[c] Value for serum creatinine is the weighted mean difference (and confidence interval).

52 Maintenance Immunosuppression

Yves Vanrenterghem

Department of Nephvosy Gasthuisberg, University of Hospital, Leuven, Belgium

Introduction

In the last decad the number of immunosuppressive agents used in solid organ transplantation has rapidly increased. Their modes of action and their specific nonimmune toxicities have been recently reviewed in detail by Halloran [1]. Because these immunosuppressive drugs interrupt different pathways of the lymphocyte activation cascade, combined use is preferred in order to increase their efficacy (suppressing rejection) and to limit their drug-specific toxicity. At present several new drug combinations have been tested in clinical trials, but often without adequately establishing dosing, efficacy, and safety [2]. This chapter will be limited to a description of the specific immunosuppressive drug combinations that have been evaluated in large-scale clinical trials with long-term follow-up.

When reviewing the literature on maintenance immunosuppressive therapy, several problems emerge. A first problem concerns the lack of a good definition of what exactly constitutes "maintenance" immunosuppression. In an overview of the evolution of immunosuppression between 1994 and 2004, and based on the OPTN/SRTR data, maintenance immunosuppression was defined as the therapy at the time of discharge [3]. In his review, Halloran coined the terms preadaptation maintenance therapy and postadaptation therapy, but without providing a clear definition of either [1]. Although it is common practice to reduce the daily dose of immunosuppressive agents with time after transplantation, very few authors have assessed the optimal maintenance dose in properly designed long-term studies. The concept of tailor-made immunosuppression, aimed at fulfilling the clinical requirements outlined by the individual patient profile, is becoming more popular, but the evidence-based allocation of an optimal protocol to a specific patient category remains limited [4]. In addition, most controlled trials analyzing the efficacy and safety of newer immunosuppressive drugs have had a short follow-up, often limited

to 1 year or less. Only a limited number of trials provide long-term follow-up data. Moreover, the study protocols of the latter often allow a change in therapy after the end of the study period, resulting in a substantial number of patients who are no longer on their allocated regimen. In his excellent review on immunosuppression for long-term maintenance of renal allograft function, Offermann correctly stated that most long-term data available in the literature are descriptive, retrospective, nonrandomized, and uncontrolled. He also stressed that, although registry data have the advantage of large numbers and long-term follow-up, with respect to immunosuppressive therapy, selection bias is often present or difficult to identify [5]. For all these reasons the proposed long-term efficacy and safety of maintenance immunosuppressive regimens are not always based on trial evidence.

Tacrolimus–mycophenolate mofetil–corticosteroids: the current standard of maintenance immunosuppression

After the publication of the first results of the European trial comparing cyclosporine A (CsA) with azathioprine (Aza) in combination with corticosteroids [6], most kidney transplant centers progressively switched to CsA and corticosteroids. The second calcineurin inhibitor (CNI), tacrolimus (Tac), was introduced in clinical practice following the publication of the results of the European and US randomized controlled trials comparing Tac with CsA [7,8]. After some initial reluctance to switch from CsA to Tac [9], over the last years Tac has become the CNI of choice in many kidney transplant programs. Based on figures from the 2005 OPTN/SRTR Annual Report, 93% of the renal transplant patients in the USA received CNIs as part of their maintenance therapy, and 72% of them are using Tac [3]. The reason why transplant physicians now prefer Tac is its higher efficacy (lower incidence of acute rejection and improved graft survival), even if compared to the newer microemulsion formulation of CsA, Neoral [10], and its more favorable risk profile. In the Margreiter study, as in previous studies comparing Tac with CsA, similar patient and graft

survival were seen, with a significantly lower incidence of acute rejections in the Tac-treated patients. The incidences of hypertension and hypercholesterolemia were also significantly lower in the Tac-treated patients. In contrast to prior studies, the incidence of diabetes mellitus, defined as the need for insulin for more than 30 consecutive days, was similar in both groups.

The question of whether the better short-term results with Tac also translate into improved late outcomes has to be answered with more caution. Both the US and the European trials comparing CsA and Tac have reported their 5-year results [11,12]. In the US trial the intent-to-treat analysis revealed similar patient and graft survival (79.1% vs. 81.4% and 64.3% vs. 64.6%). The rate of crossover was significantly higher among patients randomized to receive CsA therapy (27.5% vs. 9.3%; $P < 0.001$). Graft survival at 5 years was significantly better in the Tac arm when crossover due to rejection was counted as graft failure (63.8% vs. 53.8%; $P = 0.014$). The latter method of analysis may however have introduced a substantial bias. Tac use was also associated with significantly reduced requirements of antihypertensive and lipid-lowering medications, and Tac-associated insulin dependence was often reversible. In the European trial, patient and graft survival at 5 years were comparable. However, in the Tac-treated patients, the incidence of biopsy-confirmed chronic rejection was significantly lower (6.6% vs. 15.3%; $P < 0.01$) and the projected half-life was 15.8 years for the Tac patients versus 10.8 years for the CsA patients. In a registry analysis of more than 32,000 patients, chronic allograft failure at 4 years was similar for Tac and the microemulsion of CsA, whereas it was significantly higher in the patients treated with the original formulation of CsA [13]. In a subsequent study by the same authors, using a paired kidney analysis of the same SRTR database, a difference in risk for 5-year survival or graft loss could not be demonstrated, but renal function was superior for Tac at all time points [14]. In the single-center randomized trial from Cardiff, the 6-year graft survival was significantly higher in the 115 Tac-treated patients than in the 117 patients receiving CsA microemulsion (81% vs. 60%; $P = 0.0496$) [15].

With the exception of the first CsA European trial [6], the above-mentioned trials have always used CNIs in combination with anti-metabolites and corticosteroids. In the European Tac versus CsA trial, Aza was given for the first 3 months of the study and, where possible, discontinued thereafter. However, no data were provided on the exact number of patients who really stopped Aza [7]. In the US trial, Aza was administered throughout the entire study [8]. In the Margreiter study, Aza was also part of the immuno-suppressive therapy in both arms [10]. In the mid-1990s, three randomized double-blind clinical trials compared the efficacy and safety of a triple-drug combination of CsA, mycophenolate mofetil (MMF), and corticosteroids with a combination of either CsA, placebo and corticosteroids, or CsA, Aza, and corticosteroids [16–18]. As summarized in the pooled analysis paper, adding MMF in a daily dose of 2 or 3g significantly reduced the incidence of acute rejection from 40.8% in the placebo–Aza patients to 19.8% and 16.5% for the MMF 2-g and the MMF 3-g groups, respectively [19]. Due to the higher number of side effects in the 3-g

group, a preferred daily dose of 2-g was subsequently proposed. This favorable effect of MMF on acute rejection was also seen when MMF was added to Tac-based immunosuppressive regimens [20,21]. Whereas in the European trial a significant reduction of the incidence of rejection was also seen in the 1-g MMF arm, this effect could only be demonstrated in the 2-g MMF arm in the US study. There has been no good explanation for these different findings. The three pivotal trials showing the superiority of MMF over Aza were conducted with the old formulation of CsA. More recently, Remuzzi *et al.* conducted a multicenter, randomized trial comparing Aza and MMF in association with the new microemulsion formulation Neoral [22]. In this trial no advantage of MMF over Aza in terms of prevention of acute rejection could be found, but there was no change in clinical practice in most transplant centers [23]. Several analyses of large transplant registries have indeed indicated that the use of MMF decreases the risk of developing chronic allograft nephropathy [24], slows the decline of glomerular filtration rate [25], and improves long-term outcome even in immunologically high-risk patients, such as African Americans [26].

Maintenance immunosuppression without corticosteroids

Based on the well-known corticosteroid-sparing effect of CsA, soon after its more widespread use, several attempts were made to completely withdraw corticosteroids from maintenance immunosuppression. The proponents of withdrawal stressed the benefits of corticosteroid discontinuation, such as improved control of hypertension [27] and hyperlipidemia [28,29], the lower incidence of *de novo* diabetes mellitus [30], less frequent cataracts [31], better control of body weight [32], and better preservation of bone mineral density [33]. The opponents considered that the potential benefits, which seemed to be not sustainable [34], did not outweigh the increased risk of acute rejection. The latter conclusion was further strengthened by the results of a meta-analysis by Kasiske published in 2000 [35]. In the nine prednisone withdrawal trials ($n = 1461$), the proportion of patients with acute rejection was increased by 0.14 ($P < 0.001$) and the relative risk (RR) of graft failure was also increased (RR, 1.4). In seven of the nine trials CsA and Aza were used.

In two more recent prednisone withdrawal trials, MMF was used, but the difference in acute rejection between withdrawal and control groups was not different compared with the trials that did not use MMF. In the US study, in which corticosteroids were discontinued at 3 months, enrollment was stopped after 266 patients were randomized, because of excess rejection in the corticosteroid withdrawal group (21% vs. 4.4%) [36]. In the European trial, the withdrawal group not only stopped corticosteroids but also received only 50% of the corticosteroid dose during the first 3 months compared to the control group [29]. The greatest difference in the occurrence of acute rejection was seen in the first two posttransplant weeks. In the 3 months after withdrawal of corticosteroids,

only 4% of the patients without corticosteroids developed an acute rejection, versus 0.4% in the group maintained on corticosteroids. In addition, no difference in the incidence of rejection was seen in the subgroup of patients who had received induction with antithymocyte globulin (ATG). In a large European randomized study of patients treated with Tac–MMF–corticosteroids, a low incidence of acute rejection (6%) was seen after corticosteroids were stopped at 3 months [37]. At least from the two European trials, it can be concluded that withdrawing corticosteroids 3 months after transplantation is associated with a very low risk of acute rejection (4–6%) and that these rejections can easily be controlled. In other words, almost 95% of these patients can be successfully withdrawn from corticosteroids.

As the follow-up of these trials was short, no conclusions can be made whether corticosteroids withdrawal is also safe in the long run. Concerns about the long-term safety are at least partially based on the findings of a Canadian multicenter controlled trial published in 1992 by Sinclair [38]. In this trial, conducted between 1982 and 1985, patients were treated initially with CsA and steroids. At 3 months they were randomized either to stop steroids or to continue dual therapy. Although the early results were very promising, after 5 years the corticosteroid withdrawal patients had significantly worse graft survival ($P = 0.03$). Long-term data from other randomized controlled trials are lacking. In 2005, Opelz published the results of a large study that compared patients prospectively withdrawn from corticosteroids with controls selected from the Collaborative Transplant Study (CTS) registry [39]. Thus, this study was not a randomized trial, and unfortunately both kidney and heart transplant recipients were included. There were 1110 deceased-donor kidney recipients and 450 heart recipients included in the analysis. All patients were immunologically low-risk patients. Corticosteroids were withdrawn no earlier than 6 months posttransplantation. Each patient was matched with three patients from the CTS database. A comparison of 7-year outcome in the kidney transplant recipients (94% receiving cyclosporine; 97% Caucasian) showed a benefit of corticosteroid withdrawal versus corticosteroid continuation for graft survival (81.9% vs. 75.3%; $P = 0.0001$), patient survival (88.8% vs. 84.3%; $P = 0.0016$), and death-censored graft survival (91.8% vs. 87.9%; $P = 0.0091$). A total of 58.6% of the kidney transplant patients never required corticosteroids during follow-up. A 5-year outcome study of 589 kidney transplant recipients (transplanted in Minneapolis) showed comparable results after corticosteroid withdrawal [40]. In contrast to most earlier published studies, patients were already withdrawn from corticosteroids on postoperative day 6. All patients received induction with ATG and were maintained on dual therapy of either CsA–MMF or Tac–MMF.

Based on available evidence, it appears that corticosteroid withdrawal can be safely performed in almost 95% of immunologically low-risk patients. Antibody induction may have a protective role [29]. Whether very early (<7 days) withdrawal of corticosteroids may be even more successful must be confirmed by more studies [40,41].

Maintenance immunosuppression without CNIs

Since the introduction of CsA, it has been observed that kidney function in CsA-treated patients is worse than in patients treated with Aza and steroids [6]. It is now generally accepted that chronic CNI administration causes nephrotoxicity that is clinically and histologically difficult to distinguish from chronic allograft nephropathy, and although the number of studies is low, the same holds true for Tac [42,43]. Therefore, numerous investigators evaluated CsA withdrawal strategies, via a conversion from CsA to Aza or through withdrawal of CsA from an Aza-containing regimen. A constant finding in most of these conversion trials was a trend toward an improvement in renal function. However, the "price" for this was an increased risk for acute rejection. Both in 1993 and in 2000, Kasiske published a meta-analysis of randomized, controlled trials that examined CsA withdrawal [35,44]. The results of the meta-analysis published in 2000 included 13 studies that were completed before 1999 and indicated that CsA withdrawal was associated with a higher incidence of acute rejection (pooled mean difference, 0.11; $P < 0.0001$) but that CsA withdrawal did not adversely affect graft survival, even in studies with long-term follow-up (maximum follow-up, 96 months) [35]. Even after the publication of this meta-analysis, systematic withdrawal of CNIs did not become common practice in most transplant centers, mainly because of concerns about rejection after CNI withdrawal.

Since the more widespread use of MMF instead of Aza, new attempts have been made to withdraw CsA from MMF-based regimens. When CsA was withdrawn 6 months after transplantation, as was performed in two Dutch randomized multicenter trials, an incremental increase in acute rejection was observed, comparable with CsA withdrawal from Aza (e.g. 6.3% and 20.6%) [45,46]. Similar data were found in the French randomized trial in which CsA or MMF withdrawal 3 months after transplantation was compared [47]. Although in this trial all patients received induction with ATG, the probability of acute rejection was 18.5% in the CsA withdrawal group versus 5.6% in the MMF withdrawal arm. This study is one of the few that examined risk factors of acute rejection after CsA withdrawal. Borderline changes in the biopsy before withdrawal as well as a lower area under the curve exposure of mycophenolic acid at the time of withdrawal proved to be significant risk factors for acute rejection after CsA discontinuation. A withdrawal later after transplantation (at least 1 year posttransplantation) resulted in comparable results: the cumulative incidence of acute rejection or graft loss due to rejection 5 years after transplantation was significantly higher in the CsA withdrawal group (19%) versus the group maintained on CsA (5%) ($P = 0.01$) [48].

More recently, CsA withdrawal from regimens containing the mTOR inhibitor SRL has been advocated. Three randomized studies have analyzed the safety of CsA withdrawal from a CsA–SRL–steroid regimen. In the Rapamune Maintenance Regimen Trial, 430 of a total of 525 patients were randomly assigned at 3 months posttransplantation to one of two treatment arms (SRL–CsA–steroids or SRL–steroids) [49]. One of the main early findings

was a progressive increase of the calculated creatinine clearance after CsA withdrawal, compared to the group maintained on triple-drug therapy. However, a significant difference in the occurrence of acute rejection after randomization was seen (4.2% and 9.8% for the SRL–CsA–steroid and SRL–steroid arms, respectively; $P = 0.035$). In the 36-month report a trend toward a better graft survival was seen in the CsA withdrawal arm [50], a difference that became significant when analyzing the 48-month results [51]. Protocol biopsies performed at baseline, 12 months, and 36 months confirmed that early CsA withdrawal led to significantly less chronic allograft damage [52]. Apart from the rather high number of patients withdrawn from the study, the long-term conclusions of this study are limited by the fact that it became obvious that a combination of CsA and SRL in standard doses, as were initially used, is indeed nephrotoxic [53] and results in worse graft survival compared to the combination of CsA and MMF [54]. Similar results are seen with the combination of CsA and everolimus [55]. Two smaller CsA elimination trials confirmed the improvement of renal function after CsA withdrawal, but with a smaller risk of acute rejection than in the Rapamune Maintenance Regimen Trial [56,57]. A major limitation of these three SRL–CsA withdrawal trials is that only patients with a low to moderate immunological risk have been included. In addition, more widespread use of SRL has also revealed an increasing number of adverse effects not reported in the early trials [58]. On the other hand, the reduced risk of developing posttransplant *de novo* malignancies on SRL therapy, as recently suggested in an analysis of UNOS registry data, is an intriguing finding [59]. If confirmed in randomized trials, this may be a strong reason for more systematic withdrawal of CNI.

Finally, when trying answer the question of whether CNIs can or should be withdrawn from maintenance immunosuppressive regimens, the following should be kept in mind:

• Although in all studies CNI discontinuation is associated with an amelioration of renal allograft function, this has not resulted in better long-term graft survival. In the study by Abramowicz, graft survival was even worse [48]. Only in the Rapamune Maintenance Regimen Trial was better graft survival seen at 4 years, compared to a group of patients treated with a nephrotoxic maintenance regimen [49]. One of the reasons why improved long-term outcome is not seen may be that follow-up has not yet been long enough to detect a difference. Although it has been shown that 1-year serum creatinine is strongly correlated with long-term renal graft survival [60], the change in serum creatinine after CNI discontinuation is probably too small to have a significant impact on the long-term outcome.

• That chronic administration of CNIs may result in end-stage renal failure has clearly been shown in nonrenal solid organ allograft recipients [62,63]. From these reports it is clear that the development of end-stage renal failure is multifactorial, and the risk factors for developing end-stage renal failure are poorly understood [64]. The question as to what extent pure CNI-mediated nephrotoxicity is responsible for graft loss after kidney transplantation will at least for the moment remain unanswered because of a lack of long-term controlled trials. In Figure 52.1 the long-term
Figure 52.1 Actuarial graft survival (censored for death) in 340 patients transplanted between 1973 and 1982 with ATG-Aza-corticosteroids and in 872 patients transplanted between 1983 and 1992 with a CsA-based immunosuppressive regimen.

graft survival (censored for death) of 340 patients transplanted between 1973 and 1982 with an immunosuppressive protocol consisting of ATG–Aza–steroids in our unit is compared with that of 872 patients transplanted between 1983 and 1992 with a CsA-based immunosuppressive regimen. Although the use of CsA resulted in a significant improvement of the 1-year outcome, the slope of the two curves after the first year is similar, suggesting no deleterious effect of the long-term use of CsA. One of the reason for this finding may be the relatively low doses of CsA that have been used. As shown in Figure 52.2, the mean daily dose of CsA used at the end of the first year after transplantation has progressively decreased over the last 2 decades. The same trend can be seen for the mean daily dose at 10 years. That the dose of CNIs can be safely reduced to 50% of the doses normally used and is associated with improved renal function has been shown by Kuypers *et al.* in a small retrospective study [65]. These findings have now been confirmed by a large multicenter randomized trial [66]. It has also been shown that low doses of CsA in association with MMF lead to similar inhibition of
Figure 52.2 Mean daily dose of CsA used at the end of the first year after transplantation and at the end of the 10th year after transplantation.

calcineurin activity and cytokine production as conventional CsA exposure in maintenance immunosuppression [67].

During the last 2 or 3 years, new combinations of drugs, with or without CNIs, have been tested. It is beyond the scope of this chapter to review the results of these trials, because the trials are small, often from a single center, not controlled, and have too short follow-up to allow any conclusion as to their role as maintenance immunosuppression. In a few years maintenance immunosuppression may be become completely different from what we currently consider standard practice in most centers. For example, blocking T-cell activation at the signal 2 level by a selective costimulatory blocker such as Belatacept may be a good candidate [68].

[3]Department of Nephrology, Rikshospitalet, Oslo, Norway

Chronic allograft nephropathy (CAN) is the major preventable cause of late graft loss in kidney transplantation. Overall, death ("death with a functioning graft") constitutes about 50% of "graft failures," whereas CAN and recurrence of the primary kidney disease account for the remainder [1–3]. Graft loss due to premature cardiovascular death and CAN may be linked due to shared risk factors in kidney transplant recipients. Although short-term outcomes in kidney transplantation have improved over time, a significant proportion of grafts develop progressive dysfunction and fail within 10 years [1,2], and the balance of evidence is that long-term graft survival has not improved despite advances in immunosuppressive therapy [4–7]. Graft failure has major human and economic sequelae. In the USA, approximately 4700 patients with failed transplants restarted dialysis in 2002, representing about 5% of the total number of patients starting dialysis [7] and 2–3% of the transplant population. In our own experience in maintenance kidney transplant patients, there has been an annual rate of (death-censored) graft loss of 2.2%, of which 82% was considered to be due to CAN [3,8].

Definition

Historically, CAN has been defined as a combination of histological features that includes interstitial fibrosis, tubular atrophy, vascular intimal hyperplasia, fibrosis or hyalinosis, and transplant glomerulopathy. The histological changes are generally associated with variably reduced renal transplant function, although histological changes usually precede functional deterioration, and with hyperfiltration in the remaining nephrons [2]. The pathophysiological processes underlying CAN include both immunologically driven chronic rejection and nonimmune processes, such as hypertension and chronic calcineurin inhibitor (CNI) toxicity. Recurrence of native kidney diseases, such as certain types of glomerulonephritis (immunoglobulin A nephropathy, membranous nephropathy, and focal segmental glomerulosclerosis) or recurrence of diabetes nephropathy, are usually excluded from the diagnosis of CAN. Recent seminal studies from Australia, in which protocol biopsies were performed in patients who received kidney–pancreas transplants after a 10-year posttransplant follow-up, reported the prospective development of histopathological changes [9,10]. These reports demonstrated that chronic interstitial fibrosis and tubular atrophy emerge very early following transplantation and precede both arteriolar hyalinosis and fibrointimal thickening, as well as chronic glomerulopathy. The occurrence of CNI nephrotoxicity was also assessed and found in almost 90–100% at 10 years after transplantation in CNI-treated patients [9,10]. The authors concluded that CAN is a sequential multifactorial process in which clinical and subclinical rejection in the early stages contribute to interstitial fibrosis, tubular atrophy, and nephron loss that together constitute CAN. Later damage appeared to be predominantly associated with a histological pattern suggestive of CNI toxicity, defined as striped cortical fibrosis or new onset of arteriolar hyalinosis together with tubular microcalcification. It should be pointed out that, despite the progressive histological changes during the 10-year follow-up, there was only a 10–15% reduction in renal function in this series

The course of CAN

When describing the course and development of CAN, it is important to separate the early injury and its impact on early graft function from the subsequent deterioration of renal graft function [2,7,9]. Several factors determine early transplant function, including injury due to acute rejection (AR) episodes, ischemia and reperfusion damage, and preformed structural changes of the kidney related to donor age (and premorbid conditions, such as hypertension), plus thrombotic and other vascular damage in the perioperative period [7,9,10]. The donor source also influences the onset of function, where recipients of transplants from living donors exhibit better early function compared to recipients

from cadaveric donors. In the longer term many additional factors play an important role, determining the fate of renal transplant function. Such progression factors include the level of transplant function achieved in the early posttransplant period, hypertension, proteinuria, hyperlipidemia, cigarette smoking, and viral infections [2].

Immunological injury

Acute rejection episodes

A great number of studies have demonstrated that acute rejection episodes influence the future development of CAN, specifically, the features of chronic rejection. Thus, kidney transplant recipients without prior clinical acute rejection have a substantially longer graft half-life than patients with previous acute rejection [11]. The association between AR episodes and CAN appears strongest for acute vascular rejection, rather than tubulo-interstitial rejection episodes [12]. AR episodes followed by loss of graft function have a stronger negative impact on long-term outcome than those with functional recovery [13]. In our own long-term outcome study, treatment for previous AR episodes was a significant risk factor for graft loss in a univariate analysis, but poor graft function (a result of early AR, among other factors) was the dominant risk factor [8].

Subclinical rejection

Recently, a great deal of attention has also been paid to subclinical rejection and its impact on the future development of CAN

[14–16]. Subclinical rejection is defined as lymphocyte or monocyte infiltration in the graft without functional deterioration. This form of rejection damages the kidney through low-grade inflammation, which leads to gradual injury and destruction and remodeling of the functional unit of the kidney. Randomized treatment of subclinical rejection is reported to lead to improved long-term graft function [14].

Antibody-mediated rejection

In addition to T-cell-mediated rejection—and its influence on the future development of CAN—it has been recognized that the presence of HLA antibodies has a strong adverse impact on the development of CAN [17,18]. Posttransplant antibodies are significantly more common in CAN patients, their presence being associated with subsequent renal dysfunction and graft loss from chronic rejection [19]. Thus, anti-HLA antibodies both prior to and after transplantation are associated with development of CAN. Furthermore, C4d deposition (a marker of humoral rejection) has been found in more than one-third of late allograft biopsies [20], in particular localized to the peritubular capillaries and in cases with transplant glomerulopathy. Antibodies against non-HLA antigens, such as endothelial cell antigens, have been described in both kidney transplant recipients and recipients of cardiac allografts complicated by CAN or transplant arteriosclerosis, respectively [21–23] (Figure 53.1).

Another interesting aspect from a pathophysiological viewpoint is the relationship between oxidative stress-induced accelerated aging and cellular "exhaustion" and graft loss (replicative senescence). Many different types of injury, including oxidative

	Allo-immune response (HLA-MM; presensitization)	Innate immune response	Nonimmune reactivity

Primary Injury	• Acute cellular rejection
	• Humoral acute rejection (HLA-Ab)
		• Donor brain death

stress and aging, target the telomere, resulting in loss of telomere length and altered function of telomere binding proteins. In both experimental animals and explanted human kidneys, CAN is associated with telomere shortening, the determinants of which include donor age, perioperative ischemia–reperfusion injury, and posttransplant oxidative stresses, including acute rejection [24–26]. Pretransplant measurement of telomere length may provide a useful objective predictor for the subsequent development of CAN.

Clinical factors and progression of CAN

Ongoing pathophysiological stressors, such as hyperfiltration, proteinuria, hypertension, cigarette smoking, hyperlipidemia, and reactive oxidative species (ROS) production, have long been suggested as mediators of CAN, based upon circumstantial evidence. All are biologically plausible and have been reported individually to be related to future deterioration of transplant function and eventually graft loss. In the ALERT trial of 2102 long-term kidney transplant recipients, renal dysfunction and proteinuria were the two strongest, independent risk factors for future graft loss [3,8] and confirmed the findings from previous studies that proteinuria is a strong risk factor for CAN and future graft loss [27] (Figure 53.2). Proteinuria is a powerful risk factor for renal dysfunction in general and is dependent upon both glomerular leakage and impaired tubular reabsorption. Reabsorbed filtered protein is known to lead to an increase in interstitial chemoattractants, cytokines, and monocyte infiltration, which may cause additional interstitial and tubular damage and may contribute to CAN [28]. The tubular cell is both a focus of injury in CAN and a potential source of factors that contribute to interstitial cellular infiltration and fibrosis. Thus, uncontrolled ROS production from tubular cell mitochondria may also contribute to continued tubular injury and apoptosis, and both interstitial nitrothyrosine and ROS production are increased in CAN [29].

BK virus nephropathy

Polyoma virus infection is increasingly recognized as a complication in renal transplant recipients (RTR) [30–33]. Polyoma virus is widely prevalent in nature, and most people are exposed by adulthood. The BK virus by itself, in the background population, has low morbidity, long latency, and asymptomatic reactivation [34]. BK virus allograft nephropathy (BKVAN) emerged as a cause of renal allograft dysfunction in the mid-1990s, when more powerful immunosuppression was introduced. In recent years, routine posttransplant protocol biopsies have also detected BKVAN in the absence of serum creatinine elevation [16,35]. Virus replicates within tubules and forms intranuclear inclusions with focal interstitial mononuclear inflammatory cell infiltrates and tubulitis.
Figure 53.2 Schematic of the time relationship between factors contributing to development of CAN, renal function, and proteinuria in kidney transplantation.

BKVAN-induced nephropathy may lead to chronic graft dysfunction [30–35]. Renal interstitial inflammation with BKVAN cannot always be differentiated from acute rejection. Moreover, the final stage of chronic tubulo-interstitial scarring and atrophic tubules may resemble a nonspecific pattern of fibrosis and tubular atrophy. Thus, BKVAN-induced nephropathy may lead to chronic graft dysfunction.

CNI nephrotoxicity

Reports of Cyclosporine A (CsA) and tacrolimus (Tac) nephrotoxicity are increasingly common late after transplantation [9] and cannot be distinguished from each other based upon histology. CNI nephrotoxicity lesions include arteriolar hyalinosis, striped fibrosis, and tubular vacuolizations. Cyclosporine A-induced arteriolopathy is characterized by vacuolation and necrosis of smooth muscle and endothelial cells with hyaline deposits, considered to be the most characteristic marker of CNI nephrotoxicity [36–38]. Progressive arteriolar hyalinosis causes vascular narrowing and ischemic injury. Striped fibrosis of the cortex is usually regarded as the most pathognomonic sign of CNI nephrotoxicity [39], but tubular vacuolization may also occur as part of CNI nephrotoxicity. The progressive character of CNI nephrotoxicity is the reason for trials focusing on reduction or withdrawal of CNI in kidney transplant subjects with signs of CNI nephrotoxicity with or without deterioration of kidney transplant function.

Table 53.1 Prevention modalities in CAN: hypothetical, indicative, and evidence based.

Target	Action	Evidence[a]	Reference(s)
Primary Prevention			
Ischemia–reperfusion injury	Reduce ischemia time	I	40
	Antioxidant drugs, protective genes	H	41
Acute cellular rejection	Immunosuppressive treatment to prevent acute rejection	E	44, 45
	Prevention vs. acute rejection per se		
Humoral rejection	Pretreatment	I	43
(HLA and non-HLA Ab)	Removal of Ab by PP or immune absorption		
	Prevention neoformation of Ab		
	C IVIG		
	Rituximab		
	Cyclophosphamide		
Secondary prevention			
CNI toxicity (CONVERT, TRANCEPT, REFERENCE, and MODIFY studies)	Selection of CNI	H/I/N	47, 48/49, 50/51, 52
	Reduction or withdrawal of CNI ± mTORi	H/I	53–55, 58/56, 57, 69
	Reduction of withdrawal of CNI ± introduction of MMF	/I/	/49, 59–65/67, 68
Subclinical rejection	Corticosteroid treatment		
	Other rejection treatment		
de novo formation of HLA- or non-HLA Ab (CHR)	Removal of Ab	H	43
	Prevention of continued formation of Ab (IVIG, Rituximab, cytostatics)	H	43
Tertiary prevention (progression factors)			
Proteinuria	ACEi, ARB introduction	H/N	75–78/79
Hypertension	CCB; ACEi		
Hyperlipidemia	Statins	N	3
BK virus	Reduction or change of immunosuppression	H	70
	Leflunomide	H	71, 72
	Cidofovir		
Stressors and ROS excess (senescence)	Reduce stressors		
	Antioxidative measures		
	Remove nephrotoxic agents		

Abbreviations: Ab, antibody; IVIG, intravenous immunoglobulin; CCB, calcium channel blocker; PP, plasma pheresis

[a] Evidence categories: H, hypothetical; I, indicative (inadequate small clinical studies); E, solid evidence based upon controlled randomized trials; N, no effect.

Prevention and treatment

There is no specific intervention to prevent or treat CAN. The primary aim is to minimize exposure to risk factors for development of CAN. When CAN is established, the aim of disease management is to minimize exposure to risk factors for progression, including modification of immunosuppressive treatment, and to commence interventions for specific progression factors, such as proteinuria and hypertension. Lately, the focus has been on the differential effects of immunosuppressive agents with regard to nephrotoxicity, specifically, the reduction or withdrawal of CNI and their replacement with nonnephrotoxic agents, to limit the risk of AR (Table 53.1).

Primary prevention

Preventive measures include minimization of ischemia–reperfusion damage, prevention of AR episodes by optimal immunosuppressive treatment, and pretreatment of recipients with HLA antibodies. Registry studies have shown that delayed graft function, which is strongly related to the length of warm and cold ischemia preceding reperfusion, has a clear association with later development of CAN and subsequent graft loss [40]. Hence, there is a general consensus that shorter ischemia–reperfusion times lead to better long-term graft survival. With regard to drugs used for reduction of ischemia–reperfusion damage, very little has been achieved in clinical transplantation, although a number of compounds efficiently reduce the effects of prolonged ischemic injury in experimental animal models. One topical

approach is the use of gene transfer to upregulate protective genes [41].

Additional preventive measures include the pretransplant identification of sensitized patients and pretreatment of sensitized recipients, because of the strong association between presensitization and subsequent development of CAN or humoral-driven chronic rejection [42]. Various modalities have been used for pretreatment of sensitized patients, including either plasmapheresis combined with intravenous immunoglobulins or rituximab [43]. These treatment modalities have been shown to reduce the occurrence of acute antibody-mediated rejection episodes. The extent to which the frequency of chronic antibody-mediated rejection becomes attenuated by these treatment modalities remains to be seen, but early results are encouraging and long-term graft survival does appear to improve [42,43].

The most important means of prevention is effective immunosuppressive treatment to prevent acute cellular rejection. This can be considered as not only a preventive strategy but also as part of the long-term management of CAN, given that different immunosuppressive protocols affect the development of CAN via their contribution to nephrotoxic injury. In contrast with secondary treatment of CAN based upon diagnostic evidence (e.g. SWITCH studies, which will be covered below), studies that target early AR provide evidence on the effect of reduced AR on subsequent development of histological CAN and its functional sequelae [44,45]: the rate of decline of glomerular filtration rate (GFR) and/or differences in the development of CNI nephrotoxicity. Because CNI nephrotoxicity is an important component of CAN, many primary prevention studies have focused on reduction of CNI nephrotoxicity and reduction of early and late posttransplant graft dysfunction.

First, the choice of CNI, Tacrolimus or Cyclosporine A, together with the monitoring strategy (trough levels vs. blood levels at a given time point) have been examined in a number of clinical studies. Most of these studies were powered only to compare AR rates, and the effects on other end points, including graft function, rate of deterioration of GFR, or long-term graft survival must be viewed with this caveat. The impact of CNI choice has recently been reviewed [46]. The balance of evidence is that Tacrolimus is associated with lower rates of AR than Cyclosporine A (with conventional trough monitoring), although AR rates when C2 monitoring is used approach those of Tacrolimus. Given our understanding of the impact of AR on CAN, one would predict that Tacrolimus would be associated with less CAN. In one randomized trial [47], an increase in interstitial fibrosis was demonstrated with Cyclosporine A compared to Tacrolimus. In another small randomized study renal function was significantly better and the degree of interstitial fibrosis less in Tacrolimus-treated patients than in those treated with Cyclosporine A, and there was also an advantage with regard to graft survival [48]. Renal function should be considered a surrogate end point, but it is also one of the strongest predictors of future graft loss [2,8]. There are a few studies that have compared graft function in Tacrolimus-treated versus Cyclosporine A-treated patients. The findings from the recent SYM-

PHONY and DIRECT studies [49,50], which compared various therapeutic regimens containing Tacrolimus and Cyclosporine A, do tend to support the notion that Tacrolimus use leads to better early graft function, particularly when Tacrolimus is used with mycophenolate mofetil (MMF) and when low trough levels (3–7 nmol/L) are targeted. But these are all relatively small studies with short follow-up, provide little data on the long-term impact on CAN, and neither registry studies [51] nor biopsy-based studies [52] provide consistent support for one or the other CNI.

Another recent primary prevention approach has been to compare the use of CNI with mTOR inhibitors (sirolimus [SRL] or everolimus [EVL]), which are potent immunosuppressive and antiproliferative agents but without direct nephrotoxic effects. This class of compounds also seems to be useful in prevention of scarring processes and the development of intimal hyperplasia in blood vessels. Studies comparing SRL and Cyclosporine A as primary immunosuppressive agent [53–55] have demonstrated lower serum creatinine and higher GFR in SRL-treated patients. To what extent this would translate into a lower propensity for development of CAN is not known, but similar findings were made in another primary prevention study that compared renal transplant function in patients treated with Cyclosporine A and SRL, where Cyclosporine A was withdrawn after 3 months in a randomized fashion combined with increased doses of SRL [56]. Histological evaluation of biopsies taken during follow-up in a subgroup of this study also showed less interstitial damage or CAN in patients who withdrew from Cyclosporine A [57]. However, the interpretation of these data is clouded by the early combination of SRL with Cyclosporine A, a combination that is known to potentiate the nephrotoxicity of Cyclosporine A. Similar findings have been observed with EVL. Compared with Cyclosporine A alone, EVL alone or in combination with low-dose Cyclosporine A (40% of original dose) had beneficial effects on renal function [58]. Short-term reports have shown better renal function with "high-dose" EVL or moderate doses of EVL combined with a low dose of Cyclosporine A, compared to Cyclosporine A alone. However, there are no long-term data available at the present time.

Secondary prevention

The risk of AR decreases with time after transplantation. This observation provides an alternative two-phase strategy to limit AR by the early use of CNI followed by CNI minimization or withdrawal (to limit CNI nephrotoxicity and its contribution to CAN) by the introduction (or dose increase) of nonnephrotoxic agents, such as MMF or mTOR inhibitors. There is debate whether such a strategy should be part of the treatment protocol, at 3–6 months after transplantation, and preempt the development of histological or functional CAN. The latter approach has been studied in clinical trials. When MMF was used to allow CNI minimization or withdrawal in patients with declining renal function and biopsy-proven CAN, there was an improvement in renal function [59]. Subsequently, several other small studies demonstrated similar findings with improved renal transplant function upon reduction or withdrawal of Cyclosporine A, facilitated by substitution

by, or concomitant treatment with, MMF [60–65]. Most of these studies have been small, open studies. Also, there is a complex pharmacokinetic interaction between Cyclosporine A and MMF such that that high-dose Cyclosporine A reduces the exposure of MMF, whereas reduced Cyclosporine A increases the exposure to MMF and thereby the risk of MMF-related side effects. This is true to a lesser extent in the combination of Tacrolimus and MMF [66].

Withdrawal of CNI in stable maintenance renal transplant patients receiving CNI together with MMF and glucocorticoids improved renal transplant function, albeit with a slight increase in modest acute rejection [67].

Switch studies

An ongoing observational study (TRANCEPT) is capturing data in patients with declining renal function, with or without biopsy-proven CAN, for whom CNI have been reduced or withdrawn in parallel with introduction of MMF. An interim report made at the WTC 2006 [68] demonstrated a significant change in the slope of the calculated GFR at the time of the switch.

Other switch studies have been conducted in patients switched from CNI-based therapy to SRL (CONVERT trial). In the CONVERT trial, preconversion biopsies were made and transplant biopsies will also be performed by the end of the study. A total of 800 patients were recruited, but the group with low GFR (<40 mL/min) had to be stopped after only 70–80 patients, due to adverse side effects. A 1-year, interim analysis in patients who had preserved renal function (GFR, 40–70 mL/min) at inclusion reported potential benefits on renal function, provided that proteinuria was low, whereas patients with GFR below 40 mL/min that were converted to SRL experienced a high frequency of side effects without any improvement in kidney transplant function [69].

Combining mTOR inhibitors and CNI may lead to an enhanced form of nephrotoxicity unless the Cyclosporine A or Tacrolimus dose is reduced substantially (tentatively by two-thirds), apparently due to increased formation of ROS causing renal injury (unpublished data).

Another (ongoing) switch study is the ASCERTAIN study, in which stable RTR patients with GFR of 30–70 mL/min were randomized (total of 450 patients; three groups) to EVL with CNI minimization or elimination, or conventional CNI-based therapy. The study is targeting transplant function, biopsy scoring of CAN, and carotid intima media thickness. To date just over half the study population has been recruited; the study will be reported in 2008–2009.

Treatment of BK virus infection

The treatment of manifest BK virus nephropathy is problematic. The options are reduced immunosuppressive medication (with the associated risk of acute rejection), with or without concomitant virus therapy [34]. In a recent report, leflunomide was used as antiviral therapy, together with a reduction in immunosuppression, mycophenalate was discontinued, and Tacrolimus was given in a reduced dose. Marked reductions in viremia and viruria were observed. However, the seemingly beneficial effect of leflunomide

might have been secondary to reduced immunosuppression [70]. Cidofovir has also been used in the treatment of BKVAN, with mixed results [71,72]. Overall, the treatment modalities for BK virus nephropathy are hampered by a lack of randomized controlled studies, and the precise place of BKVAN as a component of CAN or as a separate entity remains to be resolved.

Treatment with nonimmunosuppressive agents

Since hypertension, both systemic and intraglomerular, is implicated in CAN, the use of angiotensin converting enzyme inhibitors (ACEi) and angiotensin II receptor blockers (ARB) is a logical therapeutic approach. These agents slow the decline in renal function in patients with diabetic and nondiabetic renal disease [73,74], and their beneficial effects on blood pressure and proteinuria in renal transplant recipients have been well-described [75–78]. Lin and colleagues demonstrated that patients treated with ACEi or ARB had a lower incidence and slower progression of renal insufficiency, together with a significant decrease in the combined end point of graft failure or death in patients receiving the ACEi or ARB. Campistol and colleagues found that patients with documented CAN had higher levels of transforming growth factor-β than a control group of 15 kidney transplant recipients with normal renal function and without CAN. Treatment with losartan caused a decrease in the transforming growth factor-β levels, which reached those of the control transplant recipients without CAN. However, the same study group recently presented the results of a randomized placebo-controlled study with losartan, which failed to shown any clinical benefit of losartan on CAN (AALOGRAFT) [79].

Statin treatment

The similarities between the pathophysiological processes underlying glomerulosclerosis and atherosclerosis suggest that statin therapy (and lipid lowering in general) may be a useful strategy. However, in the ALERT study, effective lipid lowering with fluvastatin, with 5–7 years follow-up in 2100 patients, had no impact on graft survival, rate of decline of function, or proteinuria. Thus, as monotherapy at least, statin treatment has no effect on CAN [3].

Overall impact of CAN

Although we have focused on the effects of CAN on the graft, there are additional considerations. Graft failure is associated with major increments in cardiovascular and all-cause mortality risks, reflecting the reverse of the published survival benefits of transplantation over dialysis (e.g. Wolfe) [80,81]. Thus, patients in the ALERT study who experienced graft loss had an overall doubling of cardiovascular and noncardiovascular event rates. In a mathematical modeling study by McLean and Jardine [82], graft failure was associated with a threefold increase in overall risk. The potential impacts of CAN and future reduction in CAN can only really be estimated. At the present time approximately 3% of all patients with functioning transplants return to dialysis per annum, representing about 5% of all those patients starting dialysis each year.

Slowing the rate of graft failure would increase the number of patients with functioning grafts and also the proportion of patients who die with a functioning graft. Those patients who return to dialysis will tend to be older and have a corresponding adverse impact on survival on the dialysis population. Thus, the overall benefit of reducing graft loss due to CAN is predicted to be an increase the proportion of patients with end-stage renal disease living with a functioning graft and a reduction in the proportion of patients on maintenance dialysis.

Summary and conclusion

CAN is a clinical diagnosis, the components of which are progressive deterioration in graft function, premature graft failure, and proteinuria, associated with histological changes of interstitial fibrosis, tubular loss and atrophy, and vascular and glomerular changes. It has two broad determinants, immunological, specifically the occurrence and severity of rejection episodes, and non-immunological, specifically hypertension, proteinuria, hyperlipidemia, and the nephrotoxic effects of immunosuppressive drugs. Despite our improved understanding of the mechanisms and natural history of CAN, therapeutic strategies have not been established. As a consequence of reluctance to change immunosuppression in patients with stable graft function, there are few data to support changing immunosuppression to prevent CAN; although CNI reduction or withdrawal under cover of increased MMF has proven benefits, these are marginal. The emerging importance of CAN is a reflection of the success in preventing AR and should now become the focus of clinical trials in transplantation.

9 Disorders of Electrolytes (Acute and Chronic)

54 Overview of Electrolyte and Acid–Base Disorders

L. Lee Hamm & Michael Haderlie

Department of Medicine, Tulane University School of Medicine, New Orleans, USA

Introduction to evidence-based electrolyte disorders section

Electrolyte and acid–base disorders are common. However, seldom has the diagnosis or the treatment of these conditions been evaluated using an evidence-based approach. The reasons for this can be readily discerned. The most common electrolyte and acid–base disorders are secondary to other identifiable underlying conditions or treatments and are not primary disorders. For example, hyponatremia commonly occurs in association with congestive heart failure; hypokalemia occurs with diuretic use, and metabolic acidosis occurs frequently with sepsis and lactic acidosis. The primary electrolyte and acid–base disorders are often of several distinct etiologies. Diagnosis and treatment vary by condition and thus the therapeutic approaches to each of these electrolyte or acid–base disorders cannot necessarily be lumped together. For example, treatment of metabolic acidosis from sepsis-induced lactic acidosis will differ dramatically from treatment for metabolic acidosis associated with chronic kidney disease (CKD). The usual treatment is also frequently directed predominantly at the primary underlying disorder, not the secondary electrolyte abnormality. Therefore, an evidence-based approach to most of the electrolyte and acid–base conditions has not been attempted to any significant extent.

Some electrolyte and acid–base disorders do occur as primary disorders. These are usually the result of renal tubular disorders, because the kidneys and specifically the tubular segments of the nephron are the main regulatory site of the electrolyte and acid–base composition of the body. However, all of these primary electrolyte and acid–base disorders that arise from abnormalities in renal tubular transport properties are unusual or rare (with perhaps a few exceptions), and are therefore also difficult to evaluate with typical evidence-based approaches. Another reason for the limited number of evidence-based studies evaluating the diagno-

sis and management of electrolyte and acid–base disorders is the widely held view that most clinical electrolyte and acid–base issues are adequately addressed by a solid understanding of their physiologic mechanisms and that this physiologic perspective provides a sufficient basis for determining the optimal strategies for their diagnosis and treatment. Diagnosis of these disorders is frequently simple and straightforward (although diagnosis of the underlying causes may not be); for example, to diagnose hypokalemia, one measures the plasma potassium, and the confidence levels for normal values are assessed routinely by clinical laboratories. Therefore, the electrolyte and acid–base disorders covered in this chapter are selective rather than comprehensive.

This chapter will briefly discuss metabolic acid–base disorders. Because much of the approach to acid–base disorders is covered in standard texts and reviews, the focus here will be on areas where some systematic contemporary evidence-based approaches have been provided. Respiratory disorders will not be covered in any detail here. Subsequent chapters will discuss other electrolyte disorders and renal stone disease.

Normal physiology of acid–base homeostasis

Homeostasis of the body's acid–base balance occurs by mechanisms that maintain the systemic arterial pH between 7.35 and 7.45. These mechanisms include ventilatory control of volatile carbon dioxide (CO_2), regulation of HCO_3^- by the kidneys, and moderation by various buffer systems, particularly blood and tissue proteins, bone, and the CO_2/HCO_3^- buffer system. The CO_2/HCO_3^- buffer system is especially important because its components can be directly adjusted independently in the body by the lungs and kidneys, respectively. The interrelationship of the components of systemic pH can be described by the Henderson-Hasselbalch equation: $pH = 6.1 + \log \frac{HCO_3^-}{PaCO_2 \times 0.03}$.

Normal physiologic processes generate large quantities of CO_2 (which can be considered a volatile acid) that are exhaled by the lungs. Failure of adequate excretion of CO_2, such as with severe

decompensated chronic obstructive pulmonary disease, causes respiratory acidosis. Excess excretion of CO_2, such as with hyperventilation, causes respiratory alkalosis. With normal metabolism, nonvolatile acids are also generated from dietary acids and as a by-product of normal metabolism; nonvolatile acids consume HCO_3, thereby decreasing pH and, thus, will cause metabolic acidosis if not excreted adequately. One role of the kidneys is to excrete this nonvolatile acid and in the process generate new HCO_3, which replaces that consumed by these nonvolatile acids. Under usual circumstances acid production and renal excretion are matched to maintain a plasma HCO_3 concentration of approximately 23–26 mM. The kidneys regulate plasma bicarbonate concentration by three main mechanisms. First, reabsorption of bicarbonate filtered by the glomeruli occurs in several sites along the nephron: the proximal tubule reabsorbs 70–80% of filtered HCO_3^-; the thick ascending limbs reabsorb another 10–15%; the collecting ducts reabsorb most of the remainder such that virtually no bicarbonate appears in the urine under normal circumstances. Second, the kidneys excrete acid into the urine and in the process generate bicarbonate. Finally, ammonium, NH_4^+, excretion into the urine also produces bicarbonate; NH_4^+ is produced in the proximal tubule via deamination of glutamine and is excreted into the urine by complex processes which depend to a significant extent on acidification of the urine. These processes work normally to maintain acid–base homeostasis; however, these same processes can create disturbances under certain conditions.

The lungs and kidneys together under normal circumstances mediate the physiologic compensatory responses to acid–base abnormalities (Table 54.1). Metabolic acid–base disorders can elicit an immediate compensatory response by altering respiration and the excretion of CO_2. Respiratory derangements also elicit a compensatory response with changes in the renal handling of bicarbonate; however, the renal response to respiratory acid–base changes takes several days to complete. Because these compensations are predictable for a given simple acid–base disorder, failure of compensation indicates another coexisting acid–base disorder. Predictable compensations to simple acid–base disorders were investigated many years ago and were used to create nomograms to diagnose acid–base disorders and to create common formulas used to predict their compensation. Such studies represented an initial evidence-based approach but are not detailed here because they are generally accepted.

Diagnosis of acid–base disorders

Acid–base disorders are commonly seen in clinical practice. Although the possibility of an acid–base disorder may be suggested by a patient's history and physical examination, the presence of an acid–base disorder is usually confirmed by abnormalities in arterial blood gas and/or electrolyte values. The calculated HCO_3^- from the arterial blood gas should closely approximate the measured HCO_3^- (or total CO_2) from the electrolyte panel. An abnormally low pH is an acidemia (either metabolic, usually with a low HCO_3^-, or respiratory, with a high pCO_2), and a high pH is an alkalemia. However, because two or more processes may be occurring simultaneously, possibly with opposite effects on pH, identification and recognition of processes in distinction from the pH, per se, are important. In this regard, calculation of the anion gap $[Na^+ - (Cl^- + HCO_3^-)]$, which represents the unmeasured anions in plasma, is also important in diagnosing specific acid–base disorders, even in the absence of changes in plasma HCO_3^- [1]. An elevated anion gap (normal, 6–11 mM in most laboratories) is usually associated with a metabolic acidosis, particularly if the level exceeds 20 mM [2,3]. However, an elevated anion gap may not be a sensitive indicator of lactic acidosis in critically ill patients [4]. In recent years some investigators have proposed a different approach to understanding acid–base disorders, the so-called Stewart approach [5,6], but no clear benefits to this approach have yet been proven.

Metabolic acidosis

There are many well-established causes of metabolic acidosis (Table 54.2). The mechanistic etiologies of metabolic acidoses include large endogenous or exogenous acid loads that consume plasma HCO_3^-, loss of HCO_3^- from the gastrointestinal tract or kidneys, and/or the failure of the kidneys to excrete acids accumulated as the normal by-products of metabolism. Clinically, however, metabolic acidosis is usually approached by first categorizing the condition as either a high anion gap acidosis or a normal anion gap (or hyperchloremic) metabolic acidosis. Those conditions causing a high anion gap metabolic acidosis include kidney failure, ketoacidosis (either diabetic or alcoholic), lactic acidosis, and intoxications. Four intoxications have been associated with

Table 54.1 Response to simple acid–base disorders.

Primary disorder	pH	pCO_2	HCO_3^-	Cl^-	Predicted response
Metabolic acidosis	Low	Low	Low*	↑ or →	$\Delta pCO2 (\downarrow) = 1.0\text{--}1.4 \times \Delta HCO_3^-$
Respiratory acidosis	Low	High*	High	↓	Acute $\Delta HCO_3^- (\uparrow) = 0.1 \times \Delta pCO_2$
					Chronic $\Delta HCO_3^- (\uparrow) = 0.25\text{--}0.55 \times \Delta pCO_2$
Metabolic alkalosis	High	High	High*	↓	$\Delta pCO2 (\uparrow) = 0.4\text{--}0.9 \times \Delta HCO_3^-$
Respiratory alkalosis	High	Low*	Low	↑	Acute $\Delta HCO_3^- (\downarrow) = 0.2\text{--}0.25 \times \Delta pCO_2$
					Chronic $\Delta HCO_3^- (\downarrow) = 0.4\text{--}0.5 \times \Delta pCO_2$

*Primary abnormality

Table 54.2 Causes of metabolic acidosis.

High anion gap
- Renal failure (severe)
- Lactic acidosis
  - L: tissue hypoxia, tumors
  - D: short bowel syndrome, mental status changes; not measured by routine lab
- Ketoacidosis: diabetic, alcoholic
- Poisonings
  - Salicylate (usually associated with respiratory alkalosis)
  - Ethylene glycol
  - Methanol
  - Acetaminophen-induced 5-oxoprolinuria (pyroglutamic aciduria)

Normal anion gap
- Diarrhea (loss HCO_3)
- Renal tubular acidosis
- Renal failure
- Ureterosigmoidostomy
- Carbonic anhydrase inhibitors (e.g. acetazolamide for glaucoma)
- Dilution with hyperchloremic solutions (e.g. saline)
- Pancreatic or biliary diversion
- Administration of inorganic acid or acid equivalents
- Ketoacidosis, well hydrated or excretion of Na^+ ketones

metabolic acidosis: salicylate, methanol, ethylene glycol, and recently acetaminophen [7,8]. Simple laboratory tests (i.e. serum creatinine, glucose, urine and plasma ketones, lactate, and toxicology screening) can usually distinguish among these possibilities.

Although renal failure and ketoacidosis are classically associated with an elevated anion gap, both conditions may also result in a normal anion gap acidosis. Metabolic acidosis with a normal anion gap often results from gastrointestinal loss of HCO_3^- (from diarrhea or conditions such as ureterosigmoidostomies) but may be secondary to renal tubular acidosis (RTA). RTA represents a group of disorders that present with normal anion gap or hyperchloremic metabolic acidosis with a normal blood urea nitrogen and creatinine. They are classified as proximal (type II) RTA, in which renal bicarbonate excretion is excessive, and distal RTA (types I and IV), in which distal H^+ secretion and/or ammonium ion excretion are impaired. Urine pH is high (more alkaline than is appropriate) in type I RTA but can be appropriately acidic in proximal (type II) RTA and type IV RTA. Both types I and II are rare, particularly in adults, and are usually secondary to some underlying cause that should be identified. Hypokalemia is a typical feature in types I and II and may be more of a clinical issue than the acidosis. In contrast, type IV RTA is characterized by hyperkalemia and also frequently by low renin and aldosterone. Type IV RTA is quite common in patients with moderate renal insufficiency, particularly CKD secondary to diabetic nephropathy. Other causes of normal anion gap metabolic acidosis include carbonic anhydrase inhibitors, dilution with hyperchloremic solutions such as saline, and pancreatic or biliary diversion procedures.

Consequences of severe acute acidemia (blood pH < 7.1–7.2) include predisposition to cardiac arrhythmias, venoconstric-

tion, characteristic increase in ventilation, central nervous system depression, decreased total peripheral vascular resistance, pulmonary edema, decreased blood pressure, reduced hepatic blood flow, and impaired oxygen delivery. Acidemia also suppresses myocardial contractility; however, inotropic function is typically normal because of catecholamine release induced by acidosis. These alterations in organ function can contribute to increased morbidity and mortality; however, the role of acidosis per se is not clear. In fact, some acutely beneficial effects of acidosis have been proposed [5]. Chronic acidosis is associated with bone resorption, growth failure in children, kidney stones from hypocitraturia and hypercalciuria, possibly accelerated renal fibrosis, and muscle wasting from protein catabolism.

Treatment of metabolic acidosis

The mainstay of treatment for metabolic acidosis is correction of the underlying condition [9–11]. An area of interest and some controversy has been whether alkali treatment is beneficial to patients, particularly those with acute acidosis. Acute infusions of sodium bicarbonate have the possible detrimental effects of volume overload, hyperosmolality, decreased ionized calcium, increased cellular production of acids and, paradoxically, decreases in cerebrospinal fluid pH and cellular pH [12,13]. Some specific entities which have received particular attention will be addressed. The controversy regarding the use of bicarbonate therapy in the treatment of severe acidemia centers on three clinical disease states: lactic acidosis, metabolic acidosis and hypercarbia associated with cardiac arrest, and diabetic ketoacidosis [11].

Lactic acidosis
Lactic acidosis is typically caused by tissue hypoxia (type A lactic acidosis) either from inadequate tissue circulatory perfusion or acute hypoxemia. Typical etiologies for inadequate tissue perfusion include sepsis, cardiogenic shock, and hypovolemic shock. Some malignancies, drugs (e.g. metformin and some antiretroviral agents in particular), and hereditary metabolic disorders have also been recognized to cause lactic acidosis. The diagnosis can be confirmed by an elevated lactate level, although the level may not correlate well with either the degree of acidosis or the change in anion gap.

Most patients with lactic acidosis are critically ill with profound acidosis a major component of their condition. Although treatment of the underlying condition is always attempted, treatment of the acidosis per se with alkalinizing agents would seem logical. However, infusion of sodium bicarbonate frequently fails to adequately correct the acidosis. No studies have shown a survival advantage. In addition, two small randomized controlled trials (24 patients total) did not find any hemodynamic improvement in treating lactic acidosis with sodium bicarbonate [14,15]. Dichloroacetate administration was found effective in animals, but a sizable clinical trial failed to show any hemodynamic improvement or survival benefit with this therapy despite an

improvement in pH [16]. Other buffers such as Carbicarb (a mixture of sodium bicarbonate and sodium carbonate) and TRAM [Tris(hydroxymethyl)-aminomethane] have been used in animal studies but have not been evaluated in suitable clinical studies in humans [13,17]. Lactic acidosis and acidosis associated with acute renal failure have also been treated in nonrandomized, noncontrolled studies with continuous hemofiltration methods with improvement found in several parameters, but rigorous controlled clinical studies have not been performed [18–22].

Guidelines on cardiopulmonary arrest (in which lactic acidosis is usually present) have progressively restricted the recommendation for sodium bicarbonate based on studies showing lack of benefit in many circumstances [23,24]. Similar to other findings noted above, a systematic review of controlled trials in preterm infants with metabolic acidosis also found insufficient evidence for the use of base infusion in this condition [25]; as in other conditions of acidosis, this indicates a paucity of adequate randomized controlled trials, not a finding that this treatment is not useful.

Acidosis in CKD

CKD with a glomerular filtration rate of less than 20–25% of normal is frequently accompanied by chronic metabolic acidosis. Acidosis is generally mild to moderate in degree, with plasma bicarbonate concentrations ranging from 12 to 22 mEq/L (mmol/L), with values rarely less than 12 mEq/L in the absence of an increased acid load [26]. The degree of acidosis generally correlates with severity of renal failure and usually is more severe at a lower glomerular filtration rate. The metabolic acidosis can be of the high anion gap type, although the anion gap can be normal or only moderately increased, even in patients with stage 4–5 CKD. Long-term adverse consequences have been associated with metabolic acidosis, including muscle wasting, malnutrition, bone disease and demineralization, impaired growth, abnormalities in growth hormone and thyroid hormone secretion, impaired insulin sensitivity, progression of renal failure, and exacerbation of β_2-microglobulin accumulation. In these cases of acidosis, administration of bicarbonate may be warranted; however, base therapy aimed at normalization of plasma bicarbonate concentration might be associated with certain complications, such as volume overload, exacerbation of hypertension, and facilitation of vascular calcifications. Whether normalization of plasma bicarbonate concentrations in all patients with CKD is desirable therefore requires additional study.

At present, although the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines recognize the possible negative effects of metabolic acidosis, it is recommended that plasma bicarbonate concentrations in patients with CKD, both before and after the initiation of maintenance dialysis therapy, be increased to 22 mEq/L, but not to completely normal values [27]. Epidemiological studies in hemodialysis patients suggest that normalization of serum bicarbonate levels is associated with a higher mortality rate than when the lower K/DOQI level is targeted. These studies do not permit exclusion of confounding that may account for an apparent favorable survival with mainte-

nance of a mild acidosis in hemodialysis patients. The argument against recommending full normalization of plasma bicarbonate concentrations is currently under further investigation.

Because controlled studies examining the impact of different levels of acidemia are yet to be reported, it is not clear whether complete normalization of plasma bicarbonate concentrations is necessary or desirable. However, compelling studies have shown that even the small acid load resulting from the metabolism of ingested foodstuffs can have a negative impact on bone and muscle metabolism, even when plasma bicarbonate concentrations are within the normal range. A systematic review of the literature on chronic metabolic acidosis in patients with CKD concluded that randomized controlled trials of correcting metabolic acidosis in predialysis patients and in children are lacking [28]; for dialysis patients, three small trials have provided evidence of protein and bone metabolism improvement with treatment of acidosis, but no large robust trials have been reported that have also evaluated the impact of correction of the metabolic acidosis on mortality and morbidity [28].

RTA type IV

Type IV RTA is also called hyperkalemic distal RTA. In this disorder, distal tubule secretion of hydrogen and potassium ions is abnormal. Of the types of RTA, type IV is the most common. It is an acquired disorder and is usually seen in patients with at least some renal insufficiency, often secondary to diabetic nephropathy. Drug-induced type IV RTA (e.g. from cyclosporine, tacrolimus, angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and aldosterone antagonists) is generally seen in patients who already have existing renal insufficiency. Patients who have hypoaldosteronism from pure adrenal abnormalities typically have normal or high renin levels, while patients with disorders associated with CKD typically have low renin levels. In type IV RTA, control of plasma potassium is often more of an issue than the acidosis. All patients should be instructed to maintain a low-potassium diet. In addition, offending drugs that may interfere with aldosterone action should be discontinued if possible. Fludrocortisone is also effective in patients with hyporeninemic hypoaldosteronism. Type IV RTA may respond to fludrocortisone therapy alone [29]; however, administration of a loop diuretic and/or a potassium-binding resin such as Kayexelate and/or oral bicarbonate is usually preferable [30,31], because fludrocortisone will often worsen the volume overload and hypertension that are frequently present in patients with CKD.

Treatment of other causes of metabolic acidosis

In ketoacidosis, similar to other causes of acute acidosis, studies have not shown a clear benefit from sodium bicarbonate administration [24,32,33]. Guidelines for children with diabetic ketoacidosis do not generally recommend bicarbonate, but there are areas where additional studies are needed [34,35]. Despite the lack of clear data in support of bicarbonate usage in acute organic

metabolic acidosis, many clinicians (including this author, in cases with adult patients) use relatively slow infusion of iso-osmolar sodium bicarbonate in some cases of severe acidosis [24].

Thiamine administration has been recommended by some, based on theoretical and anecdotal grounds in both the ketoacidosis and the lactic acidosis that arise in the presence of nucleoside analog reverse transcriptase inhibitors [36,37]. ʟ-Carnitine has also been tried for the latter condition [38,39].

In toxin-induced metabolic acidosis of the increased anion gap type, one of the relatively new aspects of treatment is the use of fomepizole for ethylene glycol and methanol intoxications [40,41]. The full benefits of this approach await validation in a large randomized controlled trial.

Metabolic alkalosis

Metabolic alkalosis and alkalemia are common and associated with significant morbidity [42]. The detrimental effects of alkalemia include neuromuscular irritability, arrhythmias, hypokalemia, central nervous system dysfunction, and decreased ventilatory drive. Metabolic alkalosis is usually caused by one of two conditions associated with volume and chloride depletion: 1) loss of gastric contents from vomiting or nasogastric suction, or 2) diuretic use (Table 54.3). In these conditions, the kidneys are unable to excrete the excess HCO_3^- because of the volume and chloride depletion; therefore, treatment with sodium chloride (and often potassium to correct simultaneous potassium deficiency) and/or discontinuation of diuretics is sufficient treatment. These conditions are characterized by, and can be confirmed by, the presence of a low urine chloride (usually less than 20 mEq/L) if diuretics have not been administered recently.

Table 54.3 Metabolic alkalosis: usual causes.

1 Chloride responsive (associated with volume depletion; urinary chloride <20, unless recent diureticse; usually normal or low blood pressure; low K^+; secondary increases in aldosterone)
- Vomiting or nasogastric suction
- Diuretics
- Rarely, congenital chloride diarrhea, cystic fibrosis, chloride-free infant formula
2 Chloride-resistant (associated with excess mineralocorticoids; urinary chloride > 20)
- Hypertension, mineralocorticoid excess (or similar biological action)
  - Secondary hyperaldosteronism (e.g. RAS)
  - Primary hyperaldosteronism (e.g. adenoma or Cushing's)
  - Licorice
  - Genetic forms of hypertension (Liddle's syndrome, etc.)
- Normal or low blood pressure, salt wasting, secondary increase in aldosterone (Bartter's or Gitelman's syndromes)
3 Hypokalemia: usually contributes to categories 1 and 2; severe ↓K^+ alone can rarely cause metabolic alkalosis
4 Posthypercapnic metabolic alkalosis
5 Renal insufficiency with alkali administration (e.g. milk alkali syndrome)

A second category of metabolic alkalosis is associated with elevated urinary chloride (greater than 20 mEq/L) and hypertension; these are frequently associated with syndromes of mineralocorticoid excess, such as in primary hyperaldosteronism or Cushing's syndrome. Little's syndrome (with severe hypertension caused by abnormal sodium channels in the collecting duct) and renal artery stenosis can appear similar. Two conditions, Gitelman's syndrome and Bartter's syndrome, are associated with inherited tubular abnormalities of sodium chloride reabsorption, and patients frequently have metabolic alkalosis, hypokalemia, and elevated aldosterone but have normal or low blood pressure. These conditions mimic diuretic abuse with either thiazide diuretics or loop diuretics, respectively.

Occasionally, metabolic alkalosis can result from severe potassium deficiency alone or from alkali administration in the setting of renal insufficiency; a subcategory of the latter is the milk alkali syndrome. Metabolic alkalosis can also result after chronic hypercapnia (with compensatory increases in plasma HCO_3) has been treated acutely, so-called posthypercapnia metabolic alkalosis.

Treatment of metabolic alkalosis is directed at the primary abnormality, as suggested above. Decreasing acetate administration in parenteral nutrition solutions and decreasing gastric acid removal (when nasogastric suction is ongoing) with proton pump inhibitors or H-2 blockers may be useful adjuncts. Occasionally, administration of acetazolamide, a carbonic anhydrase inhibitor, can be useful in facilitating urinary excretion of HCO_3 [43,44]. Under unusual circumstances, metabolic alkalosis can be treated with acidifying agents or with hemodialysis.

Contemporary evidence-based approaches to either the diagnosis or the treatment of metabolic alkalosis have not been performed.

Summary

Available evidence-based trials of the diagnosis and optimal treatment of acid–base disorders are scarce. Thus, current practice relies almost entirely on an approach based on physiologic reasoning. New evidence from higher-quality observational studies and some small randomized controlled trials evaluating outcomes with treatment of various types of metabolic acidosis with sodium bicarbonate have demonstrated that basing therapeutic recommendations on a physiologically based logic might prove inadequate. Thus, sodium bicarbonate infusion may correct an acid pH without obvious improvements in survival or morbidity. Additional randomized clinical trials are indicated to help determine the optimal mode and magnitude for acid–base treatment strategies. Some of these strategies might involve administration of buffer, and others might be directed at correcting the underlying renal tubular transport abnormalities responsible for generation of the acid–base disorder. In the latter case, an understanding of the renal tubular pathophysiology of these acid–base disorders should lead to the generation of new hypotheses regarding treatment and inform the design of clinical trials.

Similar limitations in the corpus of clinical trials evidence are found when attempting to construct evidence-based recommendations for the diagnosis and management of electrolyte disorders, especially those due to renal tubulopathies. The best evidence that informs the management of disorders of water, sodium, and potassium are reviewed in the next two chapters. Tubular transport disorders also play a key role in abnormalities of renal divalent cation handling and pathogenesis of renal stone disease. An evidence-based approach to the diagnosis and treatment of renal stone disease will be reviewed in chapter 57.

55 Hyponatremia

Chukwuma Eze & Eric E. Simon

Section of Nephrology and Hypertension, Department of Medicine, Tulane University school of Medicine, New Orleans, LA, USA

Introduction

Hyponatremia represents a decrease of blood sodium relative to water. This review will concentrate on disorders in which the serum osmolality is concomitantly reduced (hypotonic hyponatremia) in the adult population. We will concentrate on clinical evidence pertaining to the setting and risk factors for hyponatremia and its treatment. We will not discuss in detail the diagnosis, differential diagnosis, or pathophysiology.

In the vast majority of cases, hyponatremia is causally associated with elevated antidiuretic hormone (ADH) levels and an impaired ability to excrete water. In the case of hypovolemic patients, ADH levels are elevated as a physiologic response to severe intravascular volume depletion. Many of the patients with clinical euvolemia and hyponatremia have the syndrome of inappropriate ADH secretion (SIADH), and others have thiazide diuretic-induced hyponatremia or psychogenic polydipsia (which may also be associated with elevated ADH levels). Those hyponatremic patients with obvious volume expansion include patients with CHF and cirrhosis who also have elevated ADH levels.

Clinical manifestations

Symptoms of hyponatremia are potentially due to two factors: the decrease in osmolality with resulting brain edema and the hyponatremia per se. Symptoms are variable, depending on the blood sodium level, the rate of onset, severity, age, comorbidities, etc. The tolerance of severe levels of hyponatremia, especially when it has developed over days and weeks, is due to brain adaptations. Our knowledge about the consequences and adaptations to hyponatremia are necessarily derived from animal studies and are crucial to understanding the effects of hyponatremia and the

consequences of treatment. With the acute development of hyponatremia, water leaves the extracellular space down its concentration gradient into the intracellular space, causing cell swelling. The brain, encased by the cranium, is particularly prone to the effects of swelling. Because of the constraints of the skull, the brain is limited to about a 10% increase in volume before death from brain herniation ensues [1]. The onset of hyponatremia is countered by brain adaptations, notably, the loss of solutes. The loss of solutes from the intracellular space attenuates the intracellular accumulation of water, limiting cerebral edema. Initially, electrolytes including potassium are lost. In rats, significant electrolyte loss is observed as early as 6 h and is essentially maximal by 24 h after the onset of hyponatremia [2,3]. Within 24 h there is also loss of non-electrolyte osmols, such as myoinositol, which continues for about 48 h. In part because of the loss of these electrolytes and organic molecules, slowly developing hyponatremia is often well-tolerated. At some point, these adaptations are exceeded and overt symptoms ensue. Symptoms referable to hyponatremia include altered sensorium, lethargy, headache, nausea, dizziness, vertigo, falls, and muscle cramps. More severe manifestations include seizures, noncardiogenic pulmonary edema, respiratory arrest, brain stem herniation, and death. The onset of severe symptoms, such as seizures, whether during acute or chronic hyponatremia, signifies critical brain edema and constitutes a medical emergency. With chronic hyponatremia, because the brain has adapted by loss of osmols, rapidly raising the serum sodium concentration back to closer-to-normal levels may have adverse effects, such as central pontine myelinolysis (CPM). It is believed that the loss of brain solutes makes the brain susceptible to intracellular dehydration during rapid correction of hyponatremia. Studies in rats and dogs have demonstrated this phenomenon. On the other hand, complete correction of the blood sodium is not required to alleviate the hyponatremia-induced elevated pressures in the brain to noncritical levels [1]. Thus, the optimal treatment of hyponatremia needs to take into account these experimental observations and theoretical considerations.

Due to brain adaptations, overt symptoms are generally not encountered in patients with chronic hyponatremia until the serum

sodium has fallen below 125 mEq/L, and often lower concentrations are observed in patients without symptoms. However, some patients have overt symptoms with serum sodium concentrations over 120 mmol/L (see, for instance, Figures 2 and 3 in reference 4). Many of these patients with symptoms at higher sodium levels have acute or subacute hyponatremia. In acute hyponatremia, frank cerebral edema has been documented in experimental animals.

Whether patients with chronic hyponatremia and moderately depressed blood sodium levels have truly normal central nervous system (CNS) function is questionable. Patients with psychogenic polydipsia were found to exhibit neurologic deficits when hyponatremic that were not clearly related to the underlying psychosis [5]. Even more convincingly, a recent study in patients with SIADH found neurological abnormalities, including gait disturbances, present even in mild hyponatremia, a symptom that may contribute to the increased incidence of falls observed in the hyponatremic patients [6]. Similarly, correction of hyponatremia with a vasopressin antagonist resulted in an improvement in self-reported changes in sensorium [7].

Incidence, morbidity, and mortality

General hospital setting

Hyponatremia is a common clinical condition. The incidence depends on the clinical setting and the definition of hyponatremia. Normally, serum and plasma sodium levels are identical, with the lower limit of normal defined as 136 mmol/L. Two large prospective studies have helped define the frequency and etiologies responsible for hyponatremia. Anderson *et al.* prospectively examined patients admitted to a university hospital and carefully delineated the incidence of and the likely etiologies for the hyponatremia in this hospital cohort [8]. The incidence and prevalence of hyponatremia, defined as a plasma sodium concentration of less than 130 mEq/L, were 1.0% and 2.5%, respectively. Two-thirds of these patients developed hyponatremia after admission to the hospital. Hyperglycemia, a cause of nonhypotonic hyponatremia, was present in 16%, laboratory error in 5%, and severe kidney failure in 9%. The remainder had hypotonic hyponatremia. Of these, 19% were hypovolemic, 17% had edema, and 34% were clinically normovolemic. Most of the latter group were thought to have SIADH and, overall in those in whom it was measured, 97% of patients with hypotonic hyponatremia exhibited elevated ADH levels. Severe hyponatremia, defined as a plasma sodium concentration of less than 120 mEq/L, was seen in 12% of the hyponatremic patients.

A recent study from Singapore [9] examined plasma samples obtained from both hospital and clinic settings. In the hospital setting, the incidence of serum sodium of <126 mEq/L was 6.2% and for levels <115 mEq/L the incidence was 1.2%. Similar to the Anderson *et al.* study, more than half of the patients who developed severe hyponatremia (serum sodium, <126 mEq/L) did so after hospitalization. The incidence of severe hyponatremia in the hospital was about 20 times that seen in a community care

setting. The prevalence of hyponatremia increased progressively with age, starting at age 40. A retrospective analysis suggested that patients admitted to an intensive care unit have an even higher incidence of hyponatremia of 30% [10].

Mortality associated with hyponatremia may be from associated conditions causing the hyponatremia or the hyponatremia itself via its CNS effects. Mortality varies depending on the setting. Observational studies that have permitted quantification of the mortality risk associated with hyponatremia in various clinical circumstances were summarized by Lee *et al.* [11] and will not be repeated here in detail. Hospitalized patients with a blood sodium of less than 120 mEq/L show a 20–50% mortality. A recent study by Hoorn *et al.* [12] addressed the incidence and causes of hyponatremia in 5437 hospitalized patients. Severe hyponatremia (plasma Na of ≤125 mEq/L) was seen in 3% of patients in whom plasma sodium was measured (54% of total admissions). These patients were followed as a cohort. About equal numbers of these patients had developed severe hyponatremia in the hospital versus presenting with hyponatremia on admission. Symptoms attributable to hyponatremia per se were found in 36% of this cohort (27 patients). Mortality was 19% (76 patients) for patients with severe hyponatremia, a finding that is consistent with the previous studies cited. However, only half of the patients who died were felt to have had symptomatic hyponatremia antemortum. Thus, how much of the morbidity and mortality was attributable to the observed hyponatremia is unknown, but hyponatremia probably played a role in at least 19 patients, including three of the deaths. The risk factors identified in these observational studies for the development of severe hyponatremia in the hospital setting included prescription of thiazide diuretics and ADH-stimulating drugs, surgery, and the administration of hypotonic fluids.

Nursing home patients

A combined retrospective and prospective study of nursing home patients found a high prevalence of hyponatremia (<135 mEq/L) of 18% compared to an age- and gender-matched control population prevalence of 8% [13]. Of the nursing home patients in this study, 53% had at least one episode of hyponatremia during a 1-year period. However, hyponatremia did not confer excess mortality. The high mortality (17%) in the patients exhibiting hyponatremia was no different from normonatremic patients (21%). Thus, it is difficult to assign a precise mortality risk to hyponatremia in such a nursing home population per se versus an increased mortality risk attributable to their underlying diseases. Nevertheless, clinical observations as well as observational studies examining the effects of treatment versus no treatment (albeit not in a controlled manner) are supportive of the view that symptomatic hyponatremia causes death and other adverse outcomes. This causal link will be discussed further in the section on treatment, below.

Psychogenic polydispsia

The entity of hyponatremia in patients with psychiatric illness has been reviewed by de Leon *et al.* [14]. There is a high incidence of

psychogenic polydipsia, especially in patients with schizophrenia, which generally precedes episodes of frank hyponatremia. Overall, patients with schizophrenia have a 3–5% incidence of hyponatremia. Those who develop hyponatremia are generally found to have impaired water excretion due to elevated ADH levels despite volume expansion and excessive water loads. The elevated ADH levels are in turn usually attributable either to medications or to the psychosis itself [15]. The hyponatremia and/or its correction may be life-threatening [16] but may also contribute to more persistently impaired CNS function [5].

Postoperative

Arieff presented disturbing clinical vignettes describing young, otherwise-healthy women who underwent surgery and in the subsequent postoperative period were found to have severe hyponatremia and severe neurologic abnormalities [17]. The majority of these patients subsequently experienced respiratory arrest followed by permanent neurologic impairment or death. In the postoperative period, multiple mechanisms impair free water excretion and stimulate ADH, including volume depletion, drugs, and pain. Especially if hypotonic fluids are administered, hyponatremia may result. The true incidence of postoperative hyponatremia is unknown and likely varies between centers depending on the awareness of the anesthesia and surgical staff of the dangers of hypotonic fluid administration (either as dextrose in water [which is effectively water after metabolism of dextrose] or as hypotonic irrigation solutions). The incidence of postoperative hyponatremia (plasma sodium of <130 mEq/L) as reported for 1986 from the University of Colorado was 4.4%, with a mortality rate of 4.2% (two patients); mortality was significantly higher than that for normonatremic surgical patients (0.2%) [18]. However, no symptoms of hyponatremia were present in these two patients. Importantly, 94% of the patients with hyponatremia were given hypotonic fluids. This suggests that this complication is largely preventable.

Over a 14-year period at the Mayo Clinic, 290,815 female patients between 15 and 50 years of age underwent surgery. Eleven (0.004%) patients had metabolic encephalopathy, new-onset seizures, or CPM in association with hyponatremia. None had cardiac arrest, as was reported in the series reported by Arieff. The authors concluded that the incidence of this entity is extremely low though nevertheless important.

Hyponatremia after transurethral resection of the prostate deserves further comment. During the procedure, irrigation with large volumes of fluid commonly containing glycine, but no sodium, has been used routinely in the past. Absorption of this hypotonic fluid results in increased glycine levels and hyponatremia. The use of sodium-containing irrigants is precluded by the electrical conduction of electrolyte solutions during the use of electrocautery. Newer methods should make this practice obsolete [19].

Cerebral salt wasting

Excessive urinary loss of sodium in association with CNS disease resulting in hypovolemia and hyponatremia was first described in 1950s. The recognition of the syndrome of cerebral salt wasting (CSW) has reemerged in recent years [20]. The pathophysiology of CSW is unclear, but elaboration of a natriuretic hormone(s) such as brain natriuretic protein has been proposed. The resulting volume depletion leads to elaboration of ADH and impaired ability to excrete water. The high ADH levels and the difficulty in assessing volume status have often led to the confusion of this entity with SIADH. For instance, uric acid levels, usually high in volume depletion, are low in SIADH because of volume expansion. They are also low in CSW, perhaps due to the elaboration of a natriuretic and uricosuric hormone [21]. Renin and aldosterone levels may also be low in CSW due to decreased neural input to the kidney from the brain. Most of the cases of CSW have been described after subarachnoid hemorrhage, but CSW has been seen in a variety of other CNS diseases and injuries. The existence of this entity has been supported by balance and hemodynamic studies which have tended to rule out SIADH; the true incidence of CSW is not known. As the treatment of hyponatremia in other settings such as SIADH involves water restriction, the distinction between CSW and SIADH is critical: water restriction in CSW would only exacerbate the volume depletion and not address the need for volume repletion.

Marathon runners

Hyponatremia has long been described during prolonged exercise. New studies have defined the incidence and risk factors in marathon runners. Runners have been advised to drink before they are thirsty. A popular method of running marathons is to walk through every water stop for about 1 min, often spaced every mile, and drink plenty of fluids during the walking segments. Marathons have become increasingly more popular in recent years, attracting many slower runners. Almond *et al.* [22] prospectively studied runners in the Boston Marathon. They enrolled 766 runners, although only 488 gave a blood sample at the end. Thirteen percent had serum sodium levels of ≤135 mmol/L, with three at <120 mmol/L (0.6%). Factors that predicted hyponatremia after multivariate analysis were body mass index (BMI; both high and low), longer racing time, and weight change (gain) during the marathon (with a surprising number of runners, both with and without hyponatremia, actually gaining weight). The type of fluid intake did not influence the prevalence of hyponatremia. This and other studies have led to new recommendations for fluid intake during marathons [23]. However, it should be pointed out that not all runners develop hyponatremia. A study of finishers of the 2003 Boston Marathon showed that among those 140 runners who had collapsed, 6% were hyponatremic and 69% were normonatremic, while 25% were actually hypernatremic [24].

HIV/AIDS

Hyponatremia has been found with a high frequency in persons with AIDS and AIDS-related complex. In a 3-month prospective study of 259 admissions with 212 patients, Tang *et al.* [25] noted hyponatremia (serum sodium of <135 mmol/L) during 38% of hospitalizations. Hyponatremia was present on admission in more

than half of these episodes. The majority of episodes were in eu-volemic patients and were attributed to SIADH, with most of the rest attributable to hypovolemia of a gastrointestinal etiology. Hyponatremia in this setting was associated with longer admissions and increased mortality.

Drugs

Drugs are an important cause of hyponatremia and, as indicated above, contribute to hyponatremia in psychogenic polydipsia. Selective serotonin reuptake inhibitors used for depression are an important class of drugs that produce hyponatremia in a relatively large percentage of patients. A retrospective analysis of 845 patients aged 65 years or over showed an incidence of hyponatremia, defined as a plasma sodium of <130 mmol/L, of approximately 0.5% [26]. More recently a prospective study of 75 patients revealed a 12% incidence of hyponatremia defined as a plasma sodium of <130 mmol/L [27]. Most had no or mild symptoms, such as nausea and fatigue, but one patient became confused. The appearance of hyponatremia was generally seen during the first 2 weeks of treatment and was more common in those with lower baseline plasma sodium levels and lower BMIs.

Thiazide diuretics are associated with hyponatremia. The actual incidence is not clear. Because of the large number of patients treated with diuretics, they are an important cause of hyponatremia. In a series of 1000 consecutive hospitalized patients, severe hyponatremia (plasma sodium of <129 mmol/L) occurred in 9.1% of the patients on diuretics versus 5.7% of those not treated with diuretics [28]. Diuretic-induced hyponatremia is more common with thiazide than loop diuretics and when it occurs it often appears within 2 weeks of starting therapy [29]. Thiazides may cause volume depletion in some patients with stimulation of ADH secretion. However, in others there is apparent SIADH with features of volume expansion, such as low uric acid levels. Stimulation of thirst also appears to be an important component of thiazide-induced hyponatremia. Risk factors for thiazide-induced hyponatremia, analyzed in a case–control study, include advanced age and low BMI [30].

The drug Ecstasy has also been implicated in acute hyponatremia by stimulating ADH levels and thirst [31]. The incidence for this is unknown.

Desmopressin is used to correct bleeding diatheses from von Wildebrand factor deficiency and, as expected, can cause hyponatremia, although the true incidence of desmopressin-induced hyponatremia in this setting is unknown. Larger numbers of adults are treated with desmopressin to treat nocturia. Rembratt *et al.* [32] compiled information on 632 patients from three trials. The incidence of hyponatremia in this population was high, averaging 15%, with 3% of all treated patients having at least one sodium reading of <125 mmol/L. Risk factors for the development of hyponatremia included low body weight, age of ≥65 years, and low basal serum sodium levels [32]. These findings imply that elderly patients with low baseline sodium should not be treated with desmopressin.

Cirrhosis

Hyponatremia in cirrhosis results from neuro-hormonal activation, including a nonosmotic vasopressin release. In the hospitalized cirrhotic patient population, the prevalence of hyponatremia, defined as a serum sodium level of <130 mEq/L, is about 30% [33,34]. There is a near-uniform association with ascites in these series, with infections and diuretic use also contributing. Borroni *et al.* reported a mortality of 26% in the hyponatremia cohort; elevated bilirubin (>2 mg/dL) and serum urea (>43 mg/dL) were independently correlated with mortality [34]. Mortality was even higher (48%) in the group with severe hyponatremia (serum sodium of <125 mmol/L). Studies have not shown an independent association of hyponatremia with adverse clinical outcomes. It is yet to be established whether hyponatremia is an independent risk factor for death rather than a confounder, that is, a comorbid event associated with other independent risk factors for death.

Congestive heart failure

CHF is associated with neuro-hormonal activation with stimulation of the renin–angiotensin system, the sympathetic nervous system, and arginine vasopressin. These result in a defect in water excretion and increase in thirst. Hyponatremia in CHF portends a poor prognosis. In the 1980s Packer and colleagues [35] found that the presence of hyponatremia predicted mortality in patients with CHF. In 203 patients with severe CHF, median survival for those with a normal serum sodium (>137 mmol/L) was 373 days, versus only 164 days for those with hyponatremia [35]. Treatment with angiotensin converting enzyme inhibitors improved the hyponatremia [36,37]. Packer *et al.* also showed in a retrospective analysis that treatment of CHF with angiotensin converting enzyme inhibitors was associated with decreased mortality in the hyponatremic patients [35]. As described below, vasopressin antagonists may also decrease mortality in hyponatremic patients.

Treatment

Before treatment is contemplated, a plasma osmolality measurement is generally needed to verify the presence of hypotonic hyponatremia, although exceptions such as hyponatremia in marathon runners exist. Despite the use of ion-specific electrodes, falsely low serum sodium values are still encountered.

Hyponatremic encephalopathy

The overriding issues regarding the proper treatment of hyponatremia are the rapidity and magnitude of correction of acute and chronic hyponatremia. Unfortunately, there are no randomized, controlled trials (RCTs) that have addressed these issues. Further, many of the studies that evaluated treatment strategies have included both patients with acute and patients with chronic hyponatremia and have at times not distinguished between these two fundamentally different patient groups. Furthermore, these studies have described a variety of methods of correction of hyponatremia (or no correction). Definitions of acute and chronic

hyponatremia vary between studies. The studies are typically small. And, most importantly, the methods of correction are usually interrogated without comparisons to a control treatment strategy, making bias very possible. Often the patient undergoing the experimental treatment is compared to historic controls or to contemporary patients who have not been enrolled in an RCT. For instance, patients with severe underlying diseases might not be treated aggressively and may be included in the control group for comparison to patients treated aggressively. The rates of correction are not always comparable between studies, and overall rates may mask periods of treatment in which rates of correction were either faster or slower than the reported mean. Thus, the treatment of hyponatremia remains controversial, with insufficient data from RCTs to fully inform therapy. The controversy can be summarized as follows. If a symptomatic patient is corrected slowly, permanent neurologic sequelae may ensue, and some have argued that rapidly correcting sodium is safe and effective in avoiding these sequelae. On the other hand, it has been argued that slow correction leads to better outcomes and that overly rapid correction also often leads to permanent neurologic sequelae, especially demyelinating lesions, such as CPM or osmotic demyelinating syndrome.

As there are no controlled trials, a careful evaluation of the reported studies (Table 55.1), in conjunction with clinical reasoning dictated by pathophysiologic principles, may allow for reasonable conclusions about treatment in the absence of more robust clinical trials evidence. Some of the studies (mostly retrospective cohorts) have divided patients into arbitrary correction rate groups (expressed either as milliequivalents per liter per hour or as a cumulative magnitude of correction over a time interval, such as 24 h) and then have reported the incidence of complications. Other studies (nested case–control study design) have divided the patients into those with complications versus those without and then compared their rates of correction.

In 1982 Ayus et al. [38] presented a case series of seven selected cases of severe hyponatremia who were corrected rapidly and who experienced no neurologic sequelae. Only two of the cases were clearly acute. All were treated at a relatively rapid rate, yet none had neurologic sequelae. The authors reviewed the literature up to that time (case reports and small case series) and suggested that those patients who were treated rapidly (>1 mEq/L/h) generally (11 of 12) recovered without sequelae, whereas those who were treated more gradually (13 patients) all had neurologic sequelae. Similarly, Worthley [39] reported that four of five patients with acute hyponatremia treated rapidly did well. One 47-year-old woman exhibited neurologic sequelae after a seizure in the postoperative period, but effects of treatment could not be ruled out as a cause of her neurologic symptoms. Ashouri [40] presented eight elderly patients with severely symptomatic, diuretic-induced, hyponatremia who were treated with hypertonic saline at a moderately rapid rate. All were said to have recovered without sequelae, although one patient could conceivably have had CPM. It was not stated if these cases were selected or consecutive. None of these three studies examined different rates of correction, and all were small.

In what remains one of the largest series of symptomatic hyponatremia (64 patients), Sterns [41] in a retrospective analysis reported that treatment of 26 patients (25 chronic, 1 acute) with hyponatremia at a rate of <0.55 mmol/L/h to a level of 120 mmol/L resulted in no sequelae. Although none of the 7 patients with acute hyponatremia who were treated at a rate higher than this had sequelae, 7 of 27 with chronic hyponatremia who were treated at the higher rate were reported to have had neurologic sequelae, including CPM. None of these seven were corrected to frankly hypernatremic levels, and most were corrected to hyponatremic levels. However, all seven patients were corrected at a rate of >12 mmol/L/day.

Ayus et al. [42] advocated a more aggressive approach to treatment in a combined prospective observational study and retrospective study of cases of CPM and also a literature review. Thirty-three patients, studied prospectively, were treated at a rapid rate and had no neurologic sequelae. The magnitude of correction at 24 h (20 ± 1 mEq/L/h) was higher than the rate reported by Sterns. In those patients who were selected because they had CPM, the magnitude of correction of 37 ± 3 mEq/L at 41 ± 3 h was higher than in those patients who had no sequelae (21 ± 1 mEq/L at 48 h). Similarly, data gleaned from the literature for patients with demyelinating lesions showed a higher magnitude of correction (27 ± 2 mEq/L at 39 ± 4 h) than in patients without sequelae. Both groups with CNS events had a higher magnitude of correction (both $P < 0.01$) at 24 h than those without CNS events, although the actual levels were not stated. The authors concluded that patients could be safely corrected rapidly but only if the magnitude of the correction was kept to less than 25 mEq/L at 48 h. Although 25 mEq/L at 48 h is similar to 12 mEq/L at 24 h, much of the controversy actually stems from this difference. In the study by Ayus et al. the magnitude of correction at 24 h was higher than that in Sterns [41] and to an extent that was associated with neurologic sequelae in the Sterns study.

Brunner et al. [43] prospectively studied 13 hyponatremic patients admitted from the emergency room. Three of 13 developed CPM. The rate of correction in these patients with CPM was significantly higher than those who had no sequelae. One of the patients with CPM had acute hyponatremia after transurethral resection of the prostate. Although his serum sodium on admission at 133 mmol/L was only mildly decreased, the magnitude of correction was 40 mmol/L in the first 24 h.

Cheng et al. [44] examined retrospectively severe hyponatremia in a large psychiatric hospitalized population. The nurses were trained to recognize the potential of psychogenic polydipsia and, when suspected, action was taken promptly. Therefore, the 13 patients with seizures were all considered to have acute hyponatremia. Treatment varied from hypertonic saline to water restriction. (Note that patients with psychogenic polydipsia often have a large spontaneous water diuresis). All recovered uneventfully after a rate of correction averaging 1 mmol/L/h. Tanneau et al. [16], however, found complications after treatment of hyponatremia in patients with psychogenic polydipsia. They examined retrospectively 24 separate episodes in 12 patients with hyponatremia and

a Number with complications.
b All patients considered rapid.
c Derived from Table 1.
d One patient had early seizure and permanent neurologic damage.
e 4 patients who died were excluded from analysis; correction to 120 mEq/L.
f Prospectively looked at patients with follow-up CT; those without CT (excluded patients) had no clinical evidence of neurologic damage. Retrospectively analyzed those with demyelinating lesions on CT or autopsy. Literature review included those with neurologic damage in which rate of correction was described.
f2 Initial correction rates.
f3 All corrected by <25 mmol at 24 h except two with acute hyponatremia.
f4 P vs. prospective group.
g Acute vs. chronic not explicitly stated; we assume those that presented to the hospital were chronic and those that developed hyponatremia in the hospital were acute.
g2 Overall rate at 24 h. During the first 8 h, 1.4 ± 0.8 vs. 2.8 ± 0.72 in those with CPM.
g3 Any persistent CNS complications (excluding 2 patients with preexising CNS abnormalities)
h 27 episodes of seizures in 13 patients.
i Calculated from 24-h data in Table 55.3; rate in first 12 h was 1.26 ± 0.1 mM/h.
j 68 patients including 14 of the authors' own in whom data on rate of recovery could be determined.
k Death or CPM; includes patients from Ref. 40.
l 24 episodes.
l2 All 5 with complications developed hyponatremia at home and therefore may have not been acute.
m Abstracted from Fig 1, which includes only treated patients. Only 1 was acute (evidently in the rapid treatment group).
n Prospective but selected.
n2 Taken from the means in Table 2.
n3 Patients were treated with sodium chloride only after respiratory insufficiency.

Table 55.2 Evidence ratings and recommendations for treatment of acute symptomatic hyponatremia.

Intervention	Existing systematic reviews[a]	Overall evidence rating[b]					Comment	Recommendation[c]			Comment
		High	Moderate	Low	Very low			I	II	III	
Rapid vs. slow correction	Yes		✓				Prospective and retrospective studies; no RCTs	✓			Controversial; rapid correction until severe symptoms controlled, not to exceed 8–12 mM in first 24 h; avoid overcorrection
Hypertonic saline	No		✓				Prospective and retrospective studies; no RCTs	✓			Current gold standard for severe symptomatic hyponatremia; may combine with diuretics
V-2 receptor antagonists (avoid)	No		✓				No data for acute hyponatremia	✓			Avoid; data for only chronic hyponatremia; rate may be too slow for acute hyponatremia

[a] If no existing systematic reviews, overall evidence rating starts at moderate.

[b] High for RCT with precise estimates, adequate allocation concealment, blinding of participants and investigators, use of intention-to-treat analysis, and loss to follow-up <20%; moderate if RCT but estimates imprecise, potential for type 1 or 2 statistical error, unclear allocation concealment, no intention-to-treat analysis; low in all other cases; judgment also accounts for directness of findings.

[c] Recommendation or suggestion is based upon whether further research is likely to change confidence in estimate of effect; assessment accounts for trade-offs between benefits and harms, translation into clinical practice, uncertainty about baseline risk of population of interest, and quality of evidence. I, recommend; II, suggest; III, no recommendation possible.

Table 55.3 Evidence ratings and recommendations for treatment of chronic symptomatic hyponatremia.

Intervention	Existing systematic reviews[a]	Overall evidence rating[b]				Comment	Recommendation[c]			Comment
		High	Moderate	Low	Very low		I	II	III	
Slow vs. rapid correction	Yes		✓			Retrospective and observational studies; no RCTs		✓		Trend toward more neurologic sequelae with rapid vs. slow correction
Hypertonic saline vs. normal saline	No			✓		No comparative studies		✓		Most studies have used hypertonic saline; avoid normal saline in SIADH
V-2 receptor antagonists (avoid)	No			✓		No studies in symptomatic patients		✓		Avoid; no data available; may be too slow for initial correction
Urea	No			✓		Small uncontrolled trials			✓	Experience too limited to recommend
Water restriction alone (avoid)	No			✓		No controlled studies		✓		Avoid unless spontaneous water diuresis begins; poor outcomes in patients with severe symptoms corrected at very slow rates such as with water restriction alone

a If no existing systematic reviews, overall evidence rating starts at moderate.

b High for RCT with precise estimates, adequate allocation concealment, blinding of participants and investigators, use of intention-to-treat analysis, and loss to follow-up <20%; moderate if RCT but estimates imprecise, potential for type 1 or 2 statistical error, unclear allocation concealment, no intention-to-treat analysis; low in all other cases; judgment also accounts for directness of findings.

c Recommendation or suggestion is based upon whether further research is likely to change confidence in estimate of effect; assessment accounts for trade-offs between benefits and harms, translation into clinical practice, uncertainty about baseline risk of population of interest, and quality of evidence. I, recommend; II, suggest; III, no recommendation possible.

Table 55.4 Evidence ratings and recommendations for treatment of chronic asymptomatic hyponatremia.

Intervention	Existing systematic reviews[a]	Overall evidence rating[b]				Comment	Recommendation[c]			Comment
		High	Moderate	Low	Very low		I	II	III	
Slow vs. rapid correction	No		✓			No systematic studies in asymptomatic patients; ample animal data	✓			If asymptomatic, no role for rapid correction
Water restriction	No		✓			Few RCTs; used as comparison group for vasopressin antagonists		✓		May prevent further decline in serum sodium; usually ineffective in correcting hyponatremia due to increased thirst
V-2 receptor antagonists	No		✓			Several RCTs using vasopressin antagonists		✓		Oral agent (tolavaptan) showed significant sustained improvement in hyponatremia; not yet approved for use
Demeclocycline vs. lithium	No			✓		One small nonrandomized study		✓		Demecocycline is superior to lithium; avoid in liver dysfunction
Urea	No			✓		Small-sized uncontrolled; case reports			✓	Well-tolerated with few side effects; limited clinical experience

[a] If no existing systematic reviews, overall evidence rating starts at moderate.

[b] High for RCT with precise estimates, adequate allocation concealment, blinding of participants and investigators, use of intention-to-treat analysis, and loss to follow-up <20%; moderate if RCT but estimates imprecise, potential for type 1 or 2 statistical error, unclear allocation concealment, no intention-to-treat analysis; low in all other cases; judgment also accounts for directness of findings.

[c] Recommendation or suggestion is based upon whether further research is likely to change confidence in estimate of effect; assessment accounts for trade-offs between benefits and harms, translation into clinical practice, uncertainty about baseline risk of population of interest, and quality of evidence. I, recommend; II, suggest; III, no recommendation possible.

serum sodium concentrations of ≤115 mmol/L. Five patients suffered neurologic sequelae. The overall rate of correction was 1.9 mmol/L/h. In those with no sequelae, the magnitude of correction over the first 24 h was significantly lower than those with adverse events (15.5 ± 5.1 vs. 21.8 ± 3.9 mmol/L). Of note, however, was the finding that all of the patients with sequelae developed hyponatremia at home. Therefore, it is likely that some or all of those with sequelae did not have acute hyponatremia.

Sonnenblick *et al.* [29] analyzed retrospectively 14 patients with diuretic-induced hyponatremia and sodium levels of <115 mmol/L. Using definitions of rapidity of correction similar to Sterns (less than or greater than 0.6 mmol/L/h), they found that 8% of those in the slower correction rate group had sequelae (death or demyelinating syndrome) versus 37% in the more rapid rate group. Looking at the data by magnitude of correction at 24 h, those with a correction of <20 mmol/L in the first 24 h had an 11% complication rate, compared to a 32% complication rate in those corrected by >20 mmol/L.

In one of the earliest prospectively assembled cohorts, Ellis [45] evaluated a large number of patients (184) with sodium levels of ≤120 mmol/L. Patients who recovered without complications had a rise in sodium of 8.2 mmol/L in the first 24 h, whereas those who developed complications were corrected on average by 12.1 mmol/L. Figure 4 of that paper allowed an evaluation of the effects of magnitude of correction on the complication rate. In those corrected by less than 10 mmol/L at 24 h, 1 of 100 patients had neurologic sequelae attributable to treatment, whereas in those corrected to ≥10 mmol/L, 9 of 58 developed complications. Thus, these studies support an even more cautious approach than that suggested by Sterns. However, as with all of these studies, the patients were not randomized to the different treatment groups. Although the majority of the patients had chronic hyponatremia, the results were not factored for acuity of the baseline hyponatremia. One could postulate that the rate that emerged from the prospective cohort of Ellis was too slow for patients with acute hyponatremia. If the cutoff rate were set at 14 mmol/L/24 h, then 7.7% (1 patient) who were corrected faster than this rate had an adverse neurologic sequela, versus 6.2% of those corrected at a slower rate. Thus, although the author supports a slower rate of correction, alternative interpretations are possible.

Ayus and Arieff [46], in a prospective observational study, examined the outcomes of postmenopausal women with hyponatremia defined as a serum sodium of <130 mmol/L (higher than the other studies cited). Postmenopausal women were studied because they were felt to have a "lower risk" than premenopausal women. All of the patients treated initially with water restriction alone developed complications, whereas none of the cohort corrected at a faster rate (averaging 0.8 mmol/L/h) exhibited neurologic sequelae. The latter group had an average rise in their serum sodium of about 14 mmol/L at 24 h. In those treated with water restriction only, the rise in plasma sodium after 24 h was only about 3 mmol/L. Twenty-two patients were seen by the authors after they had already had a respiratory event. They were then further corrected more rapidly at 0.8 mmol/L/h, but the neurologic sequelae persisted in 14 patients despite the correction. The authors concluded that prompt treatment at fast rates, prior to a respiratory event, is critical. The data support the view that symptomatic patients represent an emergency that must be corrected with saline, as those who ultimately experienced adverse events had an extremely low rate of correction. However, the data do not adequately address the optimal speed for this rapid correction, as the numbers of patients studied were low and the patients were not randomized.

The most recent study, by Nzerue *et al.* [47], examined 168 patients admitted to a tertiary care hospital with sodium levels of ≤115 mmol/L. Those with no observed sequelae were corrected at a higher rate than those with complications. The sodium at 48 h was 127 mmol/L in those without complications and 118 mmol/L in those with complications. The authors concluded that rapid correction is better. However, most of the patients in this study had acute hyponatremia (82%), yet the rate of correction in those with sequelae was minimal. This again supports the view that symptomatic hyponatremia should be corrected with saline, but the study did not adequately address the optimal rate of correction.

Based on these studies, general guidelines have been suggested to maximize the potential for recovery while avoiding CPM [48–51]. However, case reports have continued to be presented which describe CPM in patients despite correction at relatively low rates [52–55]. Patients with preexisting malnutrition and/or potassium depletion appear to be at particular risk of CPM [56]. It has been postulated that these patients are unable to reaccumulate brain osmols during correction of hyponatremia, making them particularly vulnerable to brain dehydration.

There are no studies that have examined the specific mode of treatment of acute symptomatic hyponatremia, and guidelines are largely based on theoretical arguments. The studies cited above used a variety of methods of treatment. In the euvolemic symptomatic patient, hypertonic saline is recommended because saline may aggravate hyponatremia, especially in patients with SIADH. The administration of normal saline to patients with SIADH can actually decrease the serum sodium, as the patients may excrete the sodium while reabsorbing the water because of inhibition of aldosterone and elevated levels of ADH. However, there have been no controlled studies comparing directly saline and hypertonic saline. Furosemide has been used to lower urine osmolality, but its role has not been systematically evaluated. Furosemide does not consistently lower urine osmolality below plasma and thus normal saline could theoretically aggravate hyponatremia even in the face of furosemide treatment. Furosemide would of course be useful in the hypervolemic patient to prevent further volume overload. ADH antagonists have no role at this time in the acute treatment of hyponatremia because they have not been studied for this indication and because the studies so far suggest that the rate of correction would be too slow. Urea has been used in symptomatic hyponatremia but experience is limited [57].

Chronic asymptomatic hyponatremia

Patients with chronic hyponatremia, because of physiological compensation, are often relatively asymptomatic from a CNS

standpoint despite critically low serum sodium levels. There are no studies that have directly addressed what course of treatment should be undertaken. There is general agreement that such patients should not be treated "aggressively" and that water restriction is the preferred mode of treatment to allow for the slow correction of the serum sodium to a more acceptable range. There is general agreement that saline plays no role in the immediate or long-term treatment of chronic hyponatremia. On the other hand, there are no studies demonstrating that water restriction is actually effective in the long term. Theoretically, all patients should improve with water restriction, but thirst will often overcome the patient's ability to adhere to the prescribed water restriction. One of the few studies that examined the effects of water restriction showed that a 1-L/day restriction in patients with cirrhosis did not improve their hyponatremia (although hyponatremia did not worsen, either) [58]. Alternative therapies to promote water excretion by inhibiting ADH activity have not been systematically evaluated. The toxicity of lithium has made its use problematic. Doxycycline is preferred to lithium because of generally lower toxicity but is not devoid of toxicity, and long-term therapy with doxycycline has not been evaluated. The presence of liver dysfunction has been shown to increase doxycycline toxicity and the risk of kidney failure [59]. Thus, its use in cirrhotic patients with hyponatremia is contraindicated. Urea appears to be safe and effective, but experience is limited to case reports by one group of investigators who have used urea in cases of SIADH [60,61], cirrhosis [62], and psychogenic polydipsia [63]. New ADH antagonists are currently being evaluated.

Prospective randomized trials have now been performed to examine the effects of the treatment of hyponatremia with ADH antagonists in cirrhosis [7,58,64], CHF [7,64,65], and SIADH [7,64,66]. Short-term clinical trials have demonstrated that ADH antagonists are effective in correcting promptly the hyponatremia under these clinical circumstances. In CHF they have also been shown in a retrospective analysis to decrease overall mortality [67]. There have been, however, few long-term studies to evaluate the effectiveness of these antagonists in improving mortality or significant long-term morbidities under these conditions. The efficacy of the oral V2 antagonist tolvaptan has been studied with both short-term and long-term RCTs, and the short-term outcome results are encouraging; the long-term results are more disappointing. In short-term use (6 and 30 days) in patients with heart failure, cirrhosis, and SIADH, the effects were sustained over the month of the study without serious adverse effects. In those patients with severe hyponatremia there was a measurable subjective improvement in CNS symptoms [7]. In only 4 of 225 patients treated with tolvaptan did the rate of correction of the presenting hyponatremia possibly exceed the recommended rate for chronic hyponatremia (>0.5 mmol/L over the fist 24 h). Thus, these agents may ultimately prove to be effective in controlling symptomatic hyponatremia and perhaps may ultimately improve mortality. With regard to this latter outcome, the results of a large RCT with long-term follow-up investigating the use of tolvaptan in patients with CHF were negative. Konstam and coworkers, reporting on the results

of the EVEREST trial, an event-driven masked RCT with 4133 patients, observed that treatment of patients hospitalized for CHF with tolvaptan for at least 60 days did not result in significant improvement in long-term morbidity and mortality (median observation period, 9.9 months) [68]. Another somewhat smaller RCT (120 patients each in two arms) evaluating tolvaptan's effects on left ventricular end-diastolic volume in heart failure noted in a post hoc time-to-event analysis that patients assigned to the tolvaptan arm demonstrated improvement long-term outcomes for the composite outcome of mortality and CHF hospitalizations [69]. The long-term effectiveness of tolvaptan in managing the hyponatremia of SIADH and cirrhosis and the potential benefits of tolvaptan treatment on mortality and morbidity attributable to chronic hyponatremia in these disease states have not been unambiguously demonstrated by the currently published clinical RCTs.

Summary of recommendations for various entities

Acute hyponatremia

Acute hyponatremia warrants immediate correction. The studies cited above suggest that if the patient develops hyponatremia rapidly, correction can be rapid without significant sequelae. However, if the time over which hyponatremia has developed is unknown, it seems prudent to be more cautious, as some physiologic adaptation may have already occurred. In this latter case, a relatively rapid rate of correction (1–3 mmol/L/h) for a few hours will decrease brain edema and alleviate the immediate prospect of brain herniation. Then, the rate of correction should be slowed so that the total rise is no greater than 12 mmol in the first 24 h. Protocols for the administration of hypertonic saline can be found elsewhere [50]. It should be noted, however, that the specific recommendations noted here are based exclusively on observational studies and may need to be changed substantially if and when any robust evidence from randomized clinical trials emerges. The investigation of the new ADH antagonists might provide an ideal opportunity to re-examine all aspects of treatment strategies for acute and chronic hyponatremia rigorously using more robust clinical RCT approaches.

The following comments are for some specific settings in which this occurs.

• *Psychogenic polydipsia with hyponatremia:* Even after presenting with severe symptoms attributable to hyponatremia, most patients with psychogenic polydipsia appear to recover uneventfully. Once these patients stop drinking copious quantities of fluids, they usually excrete a relatively dilute urine. If the patient has acute hyponatremia (which usually means the condition has developed under observation in the hospital), it can be corrected quite rapidly without sequelae. However, if the time to development is unknown, the study by Tanneau *et al.* [16] suggests that these patients should be treated as if they have chronic symptomatic hyponatremia and, thus, extremely rapid correction should be avoided.

• *Postoperative hyonatremia:* Reports from Arieff, Ayus, and colleagues [17,70] have provided compelling evidence that the presence of severe hyponatremia with symptoms postoperatively constitutes a medical emergency and requires prompt administration of hypertonic saline at rates suggested above. Again, complete correction may not be desirable, but rather should be tempered to account for any adaptation that may have occurred by the time the entity was discovered.

• *Endurance athletes:* Hyponatremia occurring in marathon runners or in triathletes can all be assumed to be acute. If discovered in the medical tent, hypertonic saline should be rapidly administered (a bolus of 100 ml of 3% saline has been suggested [23]). Such rapid correction should pose no risk based on the acuity. It is likely that complete correction acutely will have no additional adverse consequences, but no studies have addressed this issue.

Chronic hyponatremia
Chronic hyponatremia with symptoms
Patients with severe hyponatremia and symptoms require correction. Of those patients who are volume depleted, there are no studies comparing modes of treatment or rates of correction. Normal saline is considered customary treatment for correction of the volume depletion, but the optimal rate of correction of plasma sodium that might result from administration of normal saline has not been determined. The best available evidence supports the recommendation that a rate of correction similar to that for all patients with chronic symptomatic hyponatremia be used. As pointed out by Adrogue and Madias [50], correction of hypovolemia will inhibit ADH secretion, resulting potentially in a more dilute urine and potentially in correction at too rapid a rate. Thus, some authors have suggested that administration of hypotonic fluids may actually be required to slow the rate of correction in this setting.

In euvolemic patients, hypertonic saline is the preferred method of correction for symptomatic chronic hyponatremia, as many of these patients will have SIADH, and administration of normal saline has been associated in some observational studies with actual initial worsening of the hyponatremia (see above). The data reviewed above do not allow a definitive recommendation of the rate or magnitude of correction. At this time, we would recommend that, in general, a rate of about 0.5 mmol/L/h and no greater than 8 mmol total in the first 24 h. However, if the patient has more severe symptoms, such as seizures, a faster initial rate of 1–2 mmol/L/h for 2–3 h might be indicated, as this rapid initial rate of correction might be more likely to relieve deleterious cerebral edema. The rate might then be slowed so the total correction would not exceed 8 mmol in the first 24 h.

The available literature does not allow a definitive recommendation that would prevent all complications in all patients. We have recommended a rate of about 0.5 mmol/L/h and no greater than 8 mmol total in the first 24 h. This rate might result in neurologic sequelae if the patient subsequently has seizures or respiratory arrest. On the other hand, a more rapid rate would increase the risk of demyelinating disease. Again, guidelines for the administration of hypertonic saline to achieve these recommended rates of correction can be found elsewhere [50].

In the hypervolemic patient with CNS manifestations, the same considerations apply as for the clinically euvolemic patient. The use of ADH antagonists rather than hypertonic saline would seem especially suited to this group of patients, who already have an increase in extracellular fluid volume. However, the studies to date have not addressed the use of ADH antagonists for treatment of symptomatic hyponatremia. With the current level of experience, the rate of correction is not completely predictable and may be too slow when a patient exhibits CNS symptoms, and thus hypertonic saline with furosemide is currently considered preferable.

Chronic asymptomatic hyponatremia
Many patients with SIADH, cirrhosis, and heart failure are asymptomatic. Current best evidence, in the absence of any clinical RCTs, supports the recommendations that these patients be treated initially with water restriction. Demeclocycline can be considered for patients without liver failure who fail fluid restriction, but long-term toxicity is possible. The use of ADH antagonists will likely prove useful, but no studies to date have addressed their long-term efficacy, safety, and cost.

56 Potassium Disorders

John R. Foringer, Christopher Norris, & Kevin W. Finkel

Division of Renal Diseases & Hypertension, University of Texas Medical School, Houston, USA

Introduction

Potassium (K^+) is the major intracellular cation, with 98% of body K^+ being located in cells [1]. It has two major physiological functions. First, it participates in the regulation of metabolic processes such as protein and glycogen synthesis [2]. As a result, disturbances in K^+ concentrations can lead to impaired cellular function. Second, the ratio of intracellular to extracellular K^+ concentration is a major determinant of the resting membrane potential across the cell wall [3]. Therefore, alterations in the K^+ concentration can result in potentially fatal cardiac arrhythmias and muscle paralysis.

The mechanisms of K^+ distribution, absorption, and excretion are tightly regulated, because small changes in the serum concentration of K^+ can be potentially fatal. The various factors that affect K^+ balance are listed in Table 56.1. Knowledge of these variables can be useful in both diagnosis and treatment of K^+ disorders. Although it is intuitively obvious that treatment for K^+ disorders is the administration or enhanced removal of the cation, depending on the presence of hypokalemia or hyperkalemia, respectively, few data are available from controlled clinical trials to inform the safest or most effective treatment regimens. We review the available data here to provide the best-evidence approach to the treatment of K^+ disorders.

Hyperkalemia

Hyperkalemia is a common clinical occurrence in both the inpatient and outpatient settings. Because it is often asymptomatic, life-threatening cardiac arrhythmias or muscle paralysis can be the first manifestation. Management of hyperkalemia requires exclusion of rare causes of pseudohyperkalemia, review of an electrocardio-gram (ECG) to gauge the cardiac consequences of hyperkalemia, and institution of appropriate therapy.

Clinical features

Clinical signs of hyperkalemia are essentially limited to muscle weakness and cardiac arrhythmias. Muscle weakness has been attributed to reduced resting membrane potential. This change, by inactivating sodium (Na^+) channels, leads to decreased membrane excitability and impaired neuromuscular conduction [4]. Muscle weakness predominates, and ascending paralysis may ensue [5,6]. Usually, trunk and respiratory muscles are spared, so that the paretic effects of hyperkalemia are rarely life-threatening. Muscle weakness usually appears when serum K^+ levels exceed 7 mEq/L. However, in patients with hyperkalemic periodic paralysis, symptoms can occur at much lower concentrations [7].

The most important effect of hyperkalemia is on the myocardium. By lowering the resting membrane potential, hyperkalemia decreases cardiac conduction velocity and increases the rate of repolarization [8]. The progressive disturbance in cardiac conduction can be detected by changes in the ECG as the serum K^+ concentration increases [8–10]. Mild elevations of the serum K^+ concentration produce symmetric peaking of the T wave (tenting), particularly in the precordial leads. More advanced changes include lengthening of the PR interval, widening of the QRS complex, reduction in the P wave amplitude, and eventual atrial arrest. Severe hyperkalemia produces a sine wave pattern due to a greatly widened QRS complex, high T waves, and loss of P waves. Any of these patterns may be signs of impending ventricular fibrillation and sudden cardiac death and should trigger immediate and aggressive treatment.

Neither the serum K^+ concentration nor the ECG pattern is a perfect means of assessing the risk to the patient. The correlation of absolute K^+ levels with ECG findings is dependent on a number of factors, including rate of increase and patient sensitivity. Therefore, progression of hyperkalemia from mild to lethal arrhythmias is unpredictable, and any ECG changes should be treated as a medical emergency.

Causes of hyperkalemia

The differential diagnosis of hyperkalemia can be simplistically expressed as pseudohyperkalemia, excessive input, decreased output, and cellular redistribution, as shown in Table 56.2.

In pseudohyperkalemia, the K$^+$ concentration is artifactually high. Spurious causes of hyperkalemia include marked thrombocytosis (platelet count >1,000,000), severe leukocytosis (white

blood cell count >200,000), and hemolysis during blood drawing [1]. When a high K$^+$ level in a patient is reported on the laboratory slip as hemolyzed, it is imperative to check an ECG while awaiting a repeat test to rule out the need for emergent treatment. Patients may experience potentially fatal arrhythmias while awaiting a repeat K$^+$ level because the sample was reported as hemolyzed.

Excessive administration of K$^+$ is a rare cause of hyperkalemia in otherwise-healthy subjects. Because the kidneys are capable of excreting large quantities of K$^+$, hyperkalemia usually results from the presence of an additional factor that interferes with kidney excretion of K$^+$, such as a decreased glomerular filtration rate (GFR), hypoaldosteronism, or medications such as converting enzyme inhibitors or K$^+$-sparing diuretics. Commonly, cell lysis from hemolytic anemia, rhabdomyolysis, tumor lysis syndrome, and crush injuries results in severe hyperkalemia where the quantity of K$^+$ released into the plasma overwhelms the capacity of the kidneys to excrete the load [11,12].

The majority of cases of hyperkalemia are due to a defect in renal K$^+$ excretion in the presence of ongoing unrestricted intake. The impaired renal K$^+$ excretion is typically due to decreased GFR or to aldosterone deficiency. It should be noted that because the kidneys are so efficient at eliminating K$^+$, the GFR should be ≤15 mL/min before renal failure is considered the sole cause of hyperkalemia. Medications such as K$^+$-sparing diuretics, cyclosporine, Bactrim, converting enzyme inhibitors, and nonsteroidal agents also impair the renal excretion of K$^+$. Finally, because K$^+$ excretion is dependent on urinary flow and distal nephron Na$^+$ delivery, severe volume depletion itself can result in hyperkalemia.

Redistribution hyperkalemia is caused by K$^+$ transiently leaving cells, thereby raising the serum K$^+$ concentration. Total body K$^+$ need not be elevated for hyperkalemia to develop. Because the majority of total body K$^+$ is located in the intracellular compartment, relatively small shifts into the extracellular space can cause large increases in the plasma K$^+$ concentration. Insulin deficiency or resistance, by decreasing the activity of the Na$^+$,K$^+$-ATPase, results in K$^+$ efflux from the cell's interior [13,14]. Hyperosmolality may be associated with hyperkalemia [15,16]. The increase in extracellular osmolality leads to cell shrinkage, resulting in an increased intracellular K$^+$ concentration driving K$^+$ exit. β-Adrenergic antagonists, by blocking renin-stimulated angiotensin II production, can also produce hyperkalemia [17].

Metabolic acidosis is often cited as a cause of redistribution hyperkalemia. However, this is a much more prominent effect of mineral acidosis (hydrochloric acid, ammonium chloride) than the more clinically relevant organic acidosis (lactate, ketoacidosis) [18]. Mineral acids are largely dissociated and cause intracellular acidosis by electrogenic proton uptake, resulting in membrane depolarization and a favorable gradient for K$^+$ exit [19]. In contrast, organic acids are incompletely dissociated and relatively permeable across cell membranes, so that their diffusion has minimal effect on the membrane potential [18,20,21]. However, the effect of acidosis on K$^+$ concentration is more complex than simply the type of base. Acidosis stimulates the H$^+$,K$^+$-ATPase in the collecting duct, resulting in increased K$^+$ reabsorption [22]. Renal

Table 56.3 Treatment of hyperkalemia.

Agent	Mechanism	Onset	Duration	Caution(s)	Evidence
Calcium gluconate 10 mL, 10% solution (1 g) i.v., over 5–10 min	Temporarily antagonizes cardiac effects of hyperkalemia	1–3 min	30–60 min	May induce digitalis toxicity; precipitates with bicarbonate	No clinical trials; based on animal data and case series; likely very effective
Regular insulin 10 units i.v. with 50 ml 50% glucose	Temporarily translocates K^+ into cells	10–20 min	4–6 h	Hyperglycemia and hyperosmolality with worsening hyperkalemia	Good evidence based on multiple RCTs
β_2-Agonists (10–20 mg nebulized albuterol)	Temporarily translocates K^+ into cells	30 min	2–4 h	Tachycardia and coronary ischemia	Good evidence based on RCTs; not effective in 20–30% of patients
Sodium polystyrene sulfonate, 60 g p.o. or retention enema	Na^+–K^+ exchange in colonic fluid	1–2 h	4–6 h	Precipitation of fluid overload; colonic necrosis with enema and sorbitol	Little or no evidence of efficacy in acute hyperkalemia beyond that seen with diarrhea from simple cathartics
Sodium bicarbonate 1 ampule (50 mEq) i.v. over 5–10 min	May cause temporary transcellular shift in face of acidosis	Variable	Variable	Hypernatremia; hypocalcemia with seizures; volume overload	Little or no evidence of effectiveness in multiple studies; consider in patients with severe acidosis
Hemodialysis	Diffusive or convective K^+ removal	Immediate	Until dialysis completed	Arrhythmias if removal too rapid	Definitive means of potassium removal; no RCTs

Abbreviations: i.v., intravenous; p.o., per os (by mouth).

secretion of K^+ is also inhibited by acidosis: intracellular acidosis decreases the probability of open collecting duct K^+ channels and ammoniagenesis inhibits K^+ secretion in the collecting duct as well [23,24].

Treatment

Treatment of hyperkalemia is directed by its severity, presence or absence of ECG changes, and underlying cause. Therapies are divided into those that immediately minimize cardiac affects of hyperkalemia, those that transiently reduce plasma K^+ concentration by causing intracellular relocation, and those that remove K^+ from the body.

Although dialysis is the most effective means of removing K^+, it should never be considered as first-line therapy for life-threatening hyperkalemia because it typically entails delays in its application (venous access and equipment or personnel availability). Rather, medical therapy as a temporizing measure is the treatment of choice. However, the medical management of hyperkalemia remains controversial and is based on relatively few clinical trials. As reported in a recent systematic review for the Cochrane Database, no studies on the treatment of clinically relevant hyperkalemia have reported mortality or cardiac arrhythmia outcomes [25]. Reports have focused on serum K^+ levels only and appeared to be studies of convenient patient samples with modest hyperkalemia and some degree of renal impairment. Furthermore, the changes in K^+ concentration were reported in several different ways, limiting the number of studies from which data could be combined

in a systematic review. The evidence for the various treatment options of hyperkalemia are described below and summarized in Table 56.3.

Calcium (Ca^{2+}) gluconate chloride

Intravenous Ca^{2+} administration antagonizes the effects of hyperkalemia on the myocardial conduction system and myocardial repolarization. Administration of Ca^{2+} is the most rapid method for treatment of hyperkalemia and is effective in patients with normal serum Ca^{2+} concentrations [26].

Interestingly, although all modern review articles and chapters on hyperkalemia recommend intravenous Ca^{2+} administration, there are no published clinical trials on the topic. Often, no reference at all is cited for the recommendation. Most data are derived from electrophysiological studies of the canine heart or case reports in humans on the effectiveness of Ca^{2+} administration [27]. This is not to say that Ca^{2+} is not effective or should not be given, because much anecdotal clinical experience demonstrates its usefulness, and withholding treatment for patients with hyperkalemia-induced arrhythmias would be unethical. Rather, it merely demonstrates how clinical practice is often based on experience for which rigorous clinical data are limited.

Insulin

Insulin rapidly stimulates K^+ uptake by cells, primarily hepatocytes and myocytes [28]. Ten units of regular insulin are administered intravenously, usually with glucose to avoid hypoglycemia.

The effect of insulin on serum K^+ levels is seen within 10–20 min and lasts for 4–6 h [29].

In several clinical trials, insulin administration, either alone or in combination with other agents, consistently lowered the plasma K^+ concentration compared to placebo [30,31]. The reduction in K^+ concentration observed was in the range of 0.65–1.0 mEq/L. Delayed hypoglycemia was common (up to 75% of patients) if less than 30 g of glucose was administered with the insulin [32].

β_2-Agonists

Nebulized or inhaled β_2-agonists have been proven effective in the treatment of hyperkalemia in most, but not all, clinical trials [33]. In general, inhaled β_2-agonists are effective within 30 min and the duration of action is 2–4 h. In two studies, however, 20–30% of patients were unresponsive to β_2-agonists [32,34]. Most studies used a 10-mg dose, although one study showed that a 20-mg dose was more effective at 2 h in lowering K^+ [35]. A frequent error when administering β_2-agonists is underdosing with the agent. For hyperkalemia, the dose is close to 10 times the nebulized dose for bronchospasm. In two studies, the combination of β_2-agonists with insulin was more effective than treatment with insulin alone [28,32]. In summary, β_2-agonist administration is an effective method of transiently lowering the serum K^+ level but should always be combined with insulin and/or glucose because of the lack of response seen in some patients.

Bicarbonate

The treatment of hyperkalemia with bicarbonate has typically been studied as part of other multiple interventions. Four studies examined the efficacy of bicarbonate, and all failed to show any reduction in the K^+ concentration at 1 h [36]. In the only randomized trial of it use, bicarbonate had no significant effect on plasma K^+ concentration in the first 60 min after administration [37]. However, these trials did not include patients with severe acidosis and hyperkalemia. Therefore, it may be reasonable to consider bicarbonate administration as an adjunct therapy to both insulin and β_2-agonists when treating hyperkalemia in the face of concomitant metabolic acidosis, but clear clinical trial evidence to support this strategy is lacking. Furthermore, administration of bicarbonate to susceptible patients may potentially cause hypertension, pulmonary edema, hypernatremia, and tetany.

Sodium polystyrene sulfonate (Kayexalate)

Sodium polystyrene sulfonate (Kayexalate) is a resin that exchanges Na^+ for K^+ in the gastrointestinal tract, thereby removing K^+ from the body when the resin is excreted as stool. This is in contradistinction to the mechanism of action of insulin, β_2-agonists, and bicarbonate, which transiently lower the K^+ concentration by promoting cellular uptake without lowering the total body K^+ burden. In general, 1 g of resin removes 1 mEq of K^+ in exchange from 2–3 mEq of Na^+. Therefore, edema, hypertension, and rarely pulmonary edema can occur. Kayexalate can be administered either by mouth or via rectum with a retention enema. Sorbitol is of-ten added to the resin when taken orally to facilitate excretion, but sorbitol should be avoided with enemas because such use has been associated with intestinal necrosis and perforation [38]. Animal models suggest that sorbitol may be the causative agent by precipitating mucosal dehydration.

Resin binders are routinely recommended for treatment or prevention of hyperkalemia, and the reported rate of K^+ removal is slow, requiring almost 4 h for full effect. However, there exist few trials that have actually assessed the efficacy of sodium polystyrene resin [36]. Two reports are commonly cited in support of the use of resins [39,40]. However, in those studies, multiple doses were used, sometimes for a number of days, and the effect on plasma K^+ was noted after 1–5 days. In two studies in healthy subjects, the exchange resin was no better than the cathartics sorbitol or Na^+ sulfate alone [41,42]. Finally, in patients on dialysis, the exchange resin was no more effective in increasing stool K^+ loss and lowering serum K^+ levels than cathartics alone [41].

Hemodialysis

Hemodialysis is the definitive and most effective means of K^+ removal from the body. The plasma K^+ concentration falls rapidly in the first hour of dialysis, and if a low K^+ bath is used, plasma levels can fall by 1.2–1.5 mEq/L/h [31]. Potassium levels may rebound after hemodialysis has finished, and it may take several hours for it to reach its stable postdialysis plateau [43]. Also, temporizing agents such as insulin, β_2-agonists, and bicarbonate by translocating K^+ out of the plasma may decrease the total amount of K^+ removed during dialysis [44]. Hemodialysis is indicated for severe hyperkalemia after temporizing measures have been instituted, although there have been no clinical trials comparing hemodialysis to medical therapy alone. Peritoneal dialysis and continuous venovenous dialysis are effective in chronic hyperkalemic states, but the rate of removal is too slow to recommend their use in severe acute hyperkalemia.

Summary

The standardized treatment of severe hyperkalemia has been described in numerous books and reviews, yet is based on limited clinical data. Based on the limited available evidence we recommend the following for the management of hyperkalemia:

1 An ECG should be obtained and pseudohyperkalemia should be ruled out.

2 Calcium gluconate chloride should be administered intravenously with any ECG changes.

3 Intravenous insulin with glucose is the treatment of choice to transiently lower K^+ concentrations.

4 β_2-Agonists should be given in conjunction with insulin, but never alone.

5 Bicarbonate is likely ineffective in most cases. It may be a consideration in patients with severe metabolic acidosis.

6 Exchange resins do not appear to be reliably effective in lowering serum K^+ levels in acute hyperkalemia and are associated with intestinal necrosis when sorbitol is used in a retention enema. If

used, multiple doses are likely necessary and sorbitol should be avoided.

7 Hemodialysis is the definitive method for net K^+ removal from the body.

Hypokalemia

Clinical features

Clinical signs of hypokalemia are similar to those of hyperkalemia, with muscle weakness and arrhythmias predominating. The severity of symptoms tends to correlate with the level and duration of hypokalemia. Typically, there are no symptoms unless the plasma K^+ level is less than 3 mEq/L or there is a sudden drop in the extracellular K^+ concentration. Arrhythmias can develop with plasma K^+ greater than 3 mEq/L when there is another predisposing factor.

Muscle weakness is uncommon if the K^+ level is greater than 2.5 mEq/L as long as the decrease in K^+ concentration has not been sudden [45]. The weakness is ascending in character and can involve the gastrointestinal muscles, leading to ileus, abdominal distention, anorexia, nausea, and vomiting [46]. The respiratory muscles are rarely involved, resulting in respiratory failure and need for mechanical ventilation. Patients may experience cramps, paresthesias, tetany, tenderness, atrophy, and rhabdomyolysis.

Cardiac arrhythmias that can result from hypokalemia include atrial and ventricular premature beats, sinus bradycardia, paroxysmal atrial or junctional tachycardia, atrioventricular blocks, ventricular tachycardia, and ventricular fibrillation [45]. Changes on the ECG associated with hypokalemia are depression of the ST segment, diminished amplitude of the T waves, and increased amplitude of the U waves [47]. Other factors may contribute to the development of arrhythmias, including concomitant use of digoxin, cardiac ischemia, hypomagnesemia, and increased β-adrenergic activity [48,49].

Hypokalemia can adversely affect renal function. Chronic hypokalemia impairs urinary concentration, leading to symptoms of nocturia, polyuria, and polydipsia. Chronic hypokalemia can also cause hypokalemic nephropathy with vacuolar lesions in the proximal tubular epithelium. These changes are initially reversible with potassium repletion, but if persistent, interstitial fibrosis, tubular atrophy, and cyst formation may ensue [50–54].

Causes of hypokalemia

Potassium homeostasis is maintained by potassium intake and excretion or cellular shifts between the extracellular and intracellular fluid compartments. The differential diagnosis of hypokalemia can be separated into spurious hypokalemia, redistribution hypokalemia, renal and extrarenal K^+ loss, and inadequate intake. Hypokalemia due to inadequate intake is rare secondary to the kidney's ability to avidly conserve K^+. Marked leukocytosis (white blood cell count, >100,000) can cause pseudohypokalemia if the sample sits at room temperature and the white blood cells take up

the K^+. Therefore, the differential diagnosis of true hypokalemia primarily involves the loss of K^+ or its redistribution.

Transcellular redistribution of K^+ usually occurs in the face of normal total body K^+ levels. Metabolic alkalosis can result in redistribution as K^+ shifts into cells. It has been suggested that an increase in the pH by 0.1 will decrease the K^+ concentration by 0.3 mEq/L. Respiratory alkalosis has a minor effect on cellular shifts of K^+. Increased Na^+,K^+-ATPase stimulation with medications such as $β_2$-agonists, theophylline, dobutamine, dopamine, and insulin results in net cellular K^+ uptake and hypokalemia.

Hypokalemia results most commonly from excessive K^+ loss. This loss can be renal or extrarenal, the latter from either the gastrointestinal tract or the skin. Secretory diarrhea causes loss of K^+ with bicarbonate. Nasogastric suction and vomiting lead to hypokalemia by loss of K^+ in gastric contents and renal losses associated with metabolic alkalosis. Associated hyperaldosteronism with volume depletion exacerbates the hypokalemia induced by vomiting. Cutaneous losses of K^+ occur with sweating. Exuberant exercise may produce up to 12 L/day of sweat with a K^+ concentration of approximately 9 mEq/L.

Renal loss of K^+ is the most common reason for hypokalemia. Medications like loop diuretics and penicillin derivatives (nonreabsorbable anions) promote K^+ loss.

Hypomagnesemia can lead to hypokalemia through reduced Na^+ absorption by the thick ascending limb of Henle, resulting in K^+ wasting. Cisplatin is a common cause of magnesium wasting with resultant hypokalemia. Magnesium repletion is essential to the correction of hypokalemia.

Mineralocorticoid excess classically presents with hypokalemia associated with elevated aldosterone levels and hypertension. Primary aldosteronism is generally caused by aldosterone-producing adenomas of the adrenal glands. Liddle's syndrome has features of hyperaldosteronism but aldosterone levels are normal. These findings are attributable to mutations in the epithelial Na^+ channel in the cortical collecting duct that result in increased Na^+ reabsorption causing a hypokalemic metabolic alkalosis with volume expansion and hypertension. Bartter syndrome, on the other hand, is a renal tubulopathy that presents with hypokalemia, metabolic alkalosis, and normal blood pressure secondary to salt wasting and is due to one of several defects that result in impaired salt reabsorption in the thick ascending limb. Hyperreninemia is present with secondary hyperaldosteronism. A more complete list of the causes of hypokalemia is found in Table 56.4.

Treatment

The goal of therapy for hypokalemia is to prevent life-threatening complications. If there is any evidence of muscular weakness or ECG changes, repletion should be instituted immediately. The amount of K^+ given as well as the route of administration is variable and depends on the etiology of the hypokalemia and the clinical situation (Table 56.5). Care must be taken not to give excessive K^+ to a patient with hypokalemia. Therapy should not only

include the correction of total body K^+ depletion but reduction of ongoing K^+ losses and correction of the underlying disorder.

Oral K^+ replacement

With a K^+ concentration of >3.0 mEq/L, treatment with oral K^+ is usually sufficient. The plasma K^+ concentration will typically increase by 1–1.5 mEq/L after 40–60 mEq of oral K^+. This rise is somewhat transient, as most K^+ will eventually move into the cell interior [55,56]. A repeat measurement of the plasma K^+ concentration 4 h later can determine if further supplementation is necessary.

Replacement with potassium chloride (KCl) is best suited for conditions involving metabolic alkalosis with hypokalemia. Many times there is an associated hypochloremia. The KCl can appropriately replace the deficit, whereas other forms, such as K^+ with bicarbonate or citrate, can worsen the alkalosis and thereby accentuate the concomitant renal K^+ loss [57,58]. On the other hand, in renal tubular acidosis with hypokalemia, such formulations are better choices. Repletion by increasing consumption of foods high in K^+ is generally less effective than oral medicinal K^+ replacement for hypokalemia associated with chloride depletion [46].

Intravenous K^+ replacement

In patients who cannot take oral K^+, are undergoing treatment which will cause rapid intracellular shift of K^+, or have life-threatening arrhythmias or weakness, intravenous KCl replacement is used for treatment of hypokalemia. Conventional practice limits intravenous K^+ repletion to 10 mEq/h through a peripheral venous catheter or 20 mEq/h through a central venous catheter. The concentration of the KCl replacement solution is limited to 20 mEq/100 mL. The reasons given for this are to avoid infusion pain, sclerosis of the vein used for infusion, and arrhythmias that can result from higher concentrations or rates of infusion of KCl. However, studies have reported successfully giving 40–100 mEq/h of KCl to patients with paralysis or arrhythmia [59–62]. There can be ECG changes consistent with those of hyperkalemia or even complete heart block when giving greater than 80 mEq/h of KCl, so this rate of repletion should be reserved for life-threatening situations [63]. Arrhythmias have been successfully treated with intravenous solutions containing a K^+ concentration of 200 mEq/L [62,64,65]. Replacement fluids with such high concentrations are reserved for patients with volume overload.

Potassium-containing replacement fluid is typically made with saline. Dextrose-containing solutions can lead to a transient decrease in the plasma K^+ concentration due to an intracellular shift of K^+ from dextrose-stimulated insulin release. This is an important consideration in a patient with severe hypokalemia [46,66].

Certain patient groups often develop hypophosphatemia and hypokalemia. These include patients treated for diabetic ketoacidosis with insulin, patients recovering from severe malnutritional states (refeeding syndrome), and patients receiving continuous dialysis treatments. Mild to moderate phosphate deficits (serum phosphate concentration of 1.27–2.48 mg/dL) can be safely corrected with 15 mmol K^+ phosphate intravenously. In more severe hypophosphatemia ($\leq$1.24 mg/dL), 30 mmol K^+ phosphate has been used safely, although repeated doses were required for normalization of phosphate levels [67].

Magnesium (Mg^{2+}) repletion

Refractory hypokalemia can be a result of hypomagnesemia [68]. Correction of hypokalemia in the face of hypomagnesemia

Table 56.5 Treatment of hypokalemia.

Agent	Indications	Rate, dosage	Caution(s)	Evidence for rate of replacement
Oral K^+	Non-life-threatening hypokalemia; K^+ >3 mEq/L	Based on K^+ deficit and ongoing losses; 40–60 mEq, raise K^+ by 1–1.5 mEq/L	Large doses and sustained release forms can lead to gastric irritation	No randomized trials; based on case studies, likely to be accurate
i.v. K^+	K^+ <3 mEq/L; life-threatening arrhythmia or muscle weakness; inability to take oral medications	10–20 mEq/h, up to 100 mEq/h if life-threatening arrhythmia	Arrhythmia risk if >80 mEq/h; risk of hyperkalemia with overcorrection	No randomized trials; based on cohort and case studies; good evidence to limit to 60 mEq/h for most situations to avoid inducing arrhythmias
Magnesium repletion	Hypokalemia with associated hypomagnesemia	Replete Mg^{2+} prior to K^+ repletion		No randomized trials; based on reviews and *in vitro* data, likely to work
K^+-sparing diuretics	Hypokalemia resistant to treatment	Start with low dose and titrate as needed	Monitor for hyperkalemia if concomitant use of ACE inhibitors or K^+ replacement	No randomized trials; based on cohort and case series, likely to work

Abbreviations: i.v., intravenous; ACE, angiotensin converting enzyme.

requires repletion of Mg^{2+} prior to K^+ repletion for the reasons mentioned above.

K^+-sparing diuretics

In certain conditions, including primary hyperaldosteronism, chronic diuretic therapy, and Gitelman's syndrome, continued urinary loss of K^+ is limited by development of chronic hypokalemia leading to K^+ retention by the kidneys. Repletion of K^+ will paradoxically diminish this renal K^+ retention and result in incomplete correction of hypokalemia. In these conditions, it is often necessary to use a K^+-sparing diuretic in addition to K^+ supplementation [69–71]. The K^+ concentration should be monitored to avoid hyperkalemia in patients on K^+ supplementation, particularly in the presence of diabetes or chronic kidney disease.

Summary

Although a common problem, there are few data from rigorous clinical trials on the appropriate treatment of hypokalemia. Based on this limited evidence, we recommend the following:

1 Rule out spurious or pseudohypokalemia.

2 Review patient's medication list for a causative agent and discontinue if present.

3 Determine if hypokalemia is due to redistribution versus true K^+ loss or depletion.

4 With severe hypokalemia with a $[K^+]$ of <3 mEq/L, life-threatening arrhythmia, or muscle weakness, give intravenous K^+ until $[K^+]$ is >3 or symptoms resolve. Then, continue to replete the K^+ deficit with oral K^+. Hypokalemia due to redistribution requires significantly lower doses of K^+ than does hypokalemia due to loss.

5 Intravenous K^+ should be given at a rate of 10–20 mEq/h in most instances. In the presence of life-threatening arrhythmia due

to hypokalemia, 80–200 mEq/h of K^+ can be given. Caution should be taken with rates over 80 mEq/h.

6 With $[K^+]$ of >3 mEq/L, oral K^+ replacement should be used unless the patient is unable to take oral medications.

7 The choice of K^+ preparation should be based on associated conditions, such as acidosis, alkalosis, and hypophosphatemia.

8 Addition of foods high in K^+ to the diet is generally less effective than administration of oral K^+.

9 If concomitant hypomagnesemia is present, give Mg^{2+} to correct the deficit prior to correction of hypokalemia.

10 K^+-sparing diuretics may be added to K^+ supplementation to treat conditions with resistant hypokalemia.

57 Metabolic Evaluation and Prevention of Renal Stone Disease

David S. Goldfarb

Nephrology Section, New York Harbor VA Medical Center; Department of Urology, St. Vincent's Hospital, and
New York University School of Medicine, New York, USA

Introduction

The field of kidney stone prevention is marked by a relative paucity of high-grade data suitable for inclusion in a textbook promoting evidence-based medicine. The reasons for this scarcity are not clear, as kidney stones are quite prevalent. For example, stones affect as many as 6–15% of American men and 2–7% of American women [1]; this gender ratio is relatively consistent in other countries. Worldwide data suggest an overall prevalence of 1–5% in Asia, 5–10% in Europe, and as high as 20% in Saudi Arabia. Epidemiologic studies in the USA, Italy, Japan, and elsewhere have suggested an increasing prevalence worldwide [1–3]. The reasons for these increased rates remain speculative, although new epidemiologic data have begun to elucidate possible explanations [4].

This chapter will focus on the evaluation of stone formers and the measures taken to prevent stone recurrence. Topics that will be considered only briefly here are the urologic aspects of stone disease, including the differential diagnosis of renal colic, the management of renal colic, and the surgical management of ureteral stones.

Urologic aspects of stone disease

Many studies have clearly demonstrated the superiority of computerized tomography (CT) without contrast as the preferred diagnostic test in the evaluation of patients with suspected renal colic, repeatedly surpassing intravenous pyelography and ultrasound [5,6]. In a study of 97 patients with renal colic, CT had a sensitivity of 94% and a specificity of 97%; the corresponding

values for intravenous pyelography were 52% and 94%, whereas ultrasound yielded values of 19% and 97% [6].

Microhematuria is neither sensitive nor specific for stones. Using helical CT as the "gold standard" for the presence or absence of stones shows that 33% of patients with stones had ≥ 5 red blood cells/high-power field (RBC/field) and 11% had none [7]. Of patients without stones, 24% had more than 5 RBC/field and 51% had more than 1 RBC/field.

The differential diagnosis and immediate, urgent management of acute presentation with a renal stone have been reviewed elsewhere [8]. Nonsteroidal anti-inflammatory drugs are generally preferred to opiates in the management of renal colic, as they have been shown more effective for pain relief in randomized controlled trials and cause less sedation and vomiting [9,10]. Several randomized controlled trials have demonstrated the efficacy of tamsulosin in promoting spontaneous passage of ureteral stones [11]. Nifedipine and steroids have also been shown to be effective compared to control therapy [12]. No evidence supports administration of intravenous fluids to patients with renal colic to promote stone passage; fluids are appropriate only to replete extracellular fluid volume deficiencies in patients who have experienced significant volume loss from nausea or vomiting.

The American Urologic Association and the European Association of Urology have promulgated guidelines regarding the management of ureteral stones, although these have not been updated recently [13,14]. The choice between extracorporeal shock wave lithotripsy, ureteroscopy, and percutaneous nephrostolithotomy depends on stone composition, size, location, and the experience of the treating urologist. A recent retrospective study suggested an increased risk of diabetes and hypertension in patients undergoing extracorporeal shock wave lithotripsy in those treated with a brand of lithotriptor, the Dornier HM3, which is used much less commonly today [15]. Confounding that may have accounted for the observed association could not be excluded from this retrospective analysis. Newer lithotriptors are less powerful and may be associated with less damage to the kidney and pancreas, although no prospective data are available to confirm their relative greater safety. Obesity, hypertension, and diabetes have all been associated

with an increased risk of stone formation, so whether lithotripsy truly has a causal effect on these findings through as-yet-unknown mechanisms is questionable.

Guidelines on evaluation and management of stone formers

Two sets of guidelines, one a consensus statement from the National Institutes of Health in the USA and one from the European Association of Urology, regarding medical evaluation and treatment of patients with stones have been issued; neither can be considered up to date, however [14,16]. It is disappointing that the relative scarcity of randomized, controlled trials in the field means that neither set of guidelines is far from current practice. Neither set concentrated on distinguishing superior trials or evaluating varying levels of evidence.

Evaluation of stone formers

Stone disease is highly recurrent. After presenting with renal stones, guidelines recommend that patients undergo an evaluation for any associated conditions and assessment of their risk for stone recurrence [16]. These guidelines are founded on the biological reasoning that for the individual patient, management and prevention of stone recurrence can be based on a solid physiologic understanding of the unique factors in the individual that are responsible for the stone formation. The overall utility of the recommended comprehensive evaluation of the patient with renal stones has not been evaluated with rigorous randomized controlled clinical trials.

Epidemiologic data have consistently shown an association of animal protein intake with more stones [17], and urinary risk factors for stone formation worsen with diets with more animal protein intake and lower quantities of fruits and vegetables [18,19]. Prospective epidemiologic studies have also shown that men and women with the highest dietary calcium ingestion (mostly via dairy products) have the lowest associated prevalence of stones [17,20]. Both obesity and diabetes are now recognized as important risk factors for stones [21,22]. Occupations that expose people to hot environments are associated with stones [23], and stones are more frequent at geographically lower latitudes [1]. Many medications are associated with stones, including poorly soluble drugs like indinivir and high-dose sulfa antibiotics, carbonic anhydrase inhibitors like topiramate and acetazolamide, and contributors to increased urinary calcium, such as calcium supplements and vitamin D [24]. A family history of stones should be sought, as the heritability of the risk of stones is high, as indicated by a 56% concordance for stones in a study of twins after excluding the influence of a common environment and diet [25]. The genes responsible for the hereditary contribution have not yet been determined. Family history of kidney disease may reveal stone-associated conditions, such as polycystic kidney disease or renal tubular acidosis. Patients

with a variety of bowel diseases that may influence urine mineral, citrate, oxalate, and uric acid composition and patients with gout are affected more frequently by stones [26,27].

The guidelines recommend that stones or fragments be submitted to analysis at least once for each patient for determination of composition by X-ray crystallography or infrared spectroscopy.

Patients should have serum chemistries determined and urinalysis performed. Patients with hypercalcemia (or high-normal serum calcium values) should have primary hyperparathyroidism ruled out by measurement of parathyroid hormone [28]. Sarcoidosis should also be considered in the differential diagnosis. A finding of a high urine pH or pyuria should lead to urine cultures and consideration of struvite stones. Low serum bicarbonate concentrations with a concomitant alkaline urine pH of 6.0 or higher should raise the possibility of renal tubular acidosis (RTA). If imaging of the kidneys has not been obtained, all patients should have at least a renal ultrasound (a sensitive study for screening kidneys for stones, but insensitive for ureteral stones [see above]) to document the presence or absence of additional stones; polycystic kidney disease can simultaneously be eliminated from consideration as well.

Twenty-four-hour urine collections to determine urinary risk factors for stone recurrence and for assignation of preventive treatments are generally reserved for patients with recurrent stones and for children after their first stone episode [16]. One should also consider evaluating patients with large stones or stones requiring urologic intervention. Urine collections are usually performed on patients' *ad libitum* diets. Analytes should include components of stone salts, urine volume, and pH, as well as measures revealing dietary intake of sodium, potassium, and protein. Based on urine composition, supersaturation of crystal-forming phases can be calculated by the laboratory, so that changes in multiple urinary variables can be translated into a single number correlating with stone risk.

Stone composition also correlates with urinary supersaturation. For patients with hypercalciuria, protocols used to classify the etiology of the abnormality and then treat based on the results of this classification are currently not recommended.

Calcium stones

The prevention of calcium stones, whether these stones are predominantly calcium oxalate or phosphate salts, can consist of fluid therapy, as discussed following, manipulation of diet, or pharmacologic therapy. Nonspecific preventive measures, detailed on the next page, are directed at all calcium stone formers, while more specific therapies are directed at specific abnormalities as revealed in the urinary variables determined from a 24-h urine collection. The most common urinary variable abnormality seen in calcium stone formers is hypercalciuria, often defined as >4 mg (0.1 mmol) of calcium/kg body weight/day. However, like blood pressure, urine calcium excretion is a continuous variable, and attempts to define an upper limit of normal may be artificial. Hypercalciuria in most cases remains an idiopathic disorder, with a likely genetic

contribution that has not yet been well defined. Hypercalciuria may be exacerbated by increased renal sodium excretion.

Citrate is an inhibitor of calcium crystallization and of crystal aggregation. Hypocitraturia, defined variously as <250–500 mg (1.3–2.6 mmol)/day, is another relatively common abnormality associated with calcium stone formation and is often caused by increased acid loads, such as ingestion of animal protein, diarrhea, or RTA with hypokalemia or with metabolic acidosis of any cause. Hypocitraturia is often idiopathic as well.

Hyperoxaluria is defined as more than 40 mg (about 0.4 mmol) urinary oxalate/day. Both dietary and metabolic components contribute, and the relative proportions appear to vary among individuals. Hyperuricosuria is a risk factor for calcium stones because uric acid causes "salting out" of calcium oxalate. It is most often encountered in patients with greater ingestion of animal protein.

Nonspecific prevention of stone recurrence

The only Cochrane review currently available regarding prevention of stone recurrence examined the benefit of increasing fluid intake [29]. There has been only one randomized, controlled trial in which patients with calcium stones were randomly assigned to two groups, only one of which was told to increase fluid intake [30]. In the increased-fluid group, 12 of 99 patients had a stone recurrence within 5 years, compared to 27 of 100 in the control group ($P =$ 0.008). The former group increased 24-h urine volume from 1.1 to 2.6 L at 5 years whereas the control group, with a urine volume on study entry of 1.0 L, did not demonstrate a significant change in urine volume at any point during the study.

The Cochrane review considered this one study inadequate because of small numbers, short follow-up, and some questions about the randomization [29]. The review calls for additional research and states that "no conclusions can be drawn on increased water intake for the primary and secondary prevention of urinary calculi." This is not a practical assessment. It seems very unlikely, given the clear role of fluid intake in lowering urinary supersaturation, as well as the safety, low cost, and experience with the intervention, that additional research will be forthcoming. Whether fluid intake is effective in preventing noncalcium stones has not been tested, although the potential benefit of the therapy that is supported by epidemiological observations can be stressed, especially for patients with cystinuria.

Diet
The evidence that diet contributes to stones is summarized above and elsewhere in other publications [31]. A relative paucity of randomized controlled trials however means that many recommendations are based on epidemiologic data or on measurement of urinary chemistries after dietary manipulation. On the basis of this evidence, prevention regimens should include increased fluid intake and a diet that includes moderate but not low calcium intake and reductions in the intake of salt, oxalate, and animal protein.

Table 57.1 Composition of the "normal" calcium diet for prevention of stone recurrences in patients with hypercalciuria.

Component	Amount
Calcium	1200 mg (30 mmol)
Total protein	93 g
From meat or fish	21 g
From milk or milk products	31 g
From bread, pasta, and vegetables	41 g
Sodium chloride	50 mmol
Oxalate	2.2 mmol
Potassium	120 mmol
Phosphorus	49 mmol
Magnesium	14.5 mmol
Lipids	93 g
Carbohydrates	333 g
Fiber	40 g
Calories	2540 kcal
Water in foods	1550 mL

Source: Borghi *et al.* [32].

The only positive controlled trial of diet reported to date randomized men with hypercalciuria and recurrent calcium stones to one of two regimens [32]. One consisted of restrictions in calcium intake to 400 mg (10 mmol)/day; the other recommended a "normal" calcium intake of 1200 mg (30 mmol)/day and restricted animal protein (52 g) and salt intake (50 mmol) (details are shown in Table 57.1). Both groups were advised regarding oxalate restriction. At 5 years, the group on the higher-calcium, low-salt, low-animal protein diet had a reduction in stone recurrence by nearly 50% compared to the group on the low-calcium diet (Figure 57.1). The putative effect was attributed to the effect of calcium ingestion in reducing urinary oxalate while sodium restriction limited urinary calcium excretion, although mediation of the observed benefit through protein and salt restriction independent of calcium supplementation could not be excluded. Although bone mineral density was not measured, one would anticipate that the group in this study that had the higher calcium intake would have had less demineralization than the other group. It is worth mentioning that the "normal" 1200-mg calcium intake is higher than many people in Western societies usually ingest. For those who are lactose intolerant and other abstainers from dairy intake, lactose-free products or orange juice fortified with calcium are alternatives.

Given the evidence that obesity and diabetes are associated with stones, one might expect that weight loss would be associated with stone prevention, but this hypothesis has not yet been tested. Increasing ingestion of fruits and vegetables, after reduction of animal protein intake, is associated with increased urinary volume and citrate excretion and reductions in uric acid excretion [19]. It is anticipated that these changes alone might lead to a reduced occurrence of stones. Weight loss should be accomplished via well-rounded calorie-restricted diets and not via high-protein regimens such as the Atkins or South Beach diets [33]. A diet shown
Figure 57.1 Kaplan-Meier estimates of cumulative incidence of recurrent stones, according to assigned diet: low calcium vs "normal" calcium, restricted animal protein, salt, and oxalate [32]. The relative risk of a recurrence in the group assigned to the low-calcium diet was 0.49 (95% confidence interval, 0.24–0.98; $P = 0.04$). to be effective in the management of hypertension (from the Dietary Approaches to Stop Hypertension [DASH] study) might be a preferred, albeit untested, method of preventing stones and improving bone health [34].

Medications

Pharmacologic therapies for which randomized controlled trials are available and with demonstrated efficacy for prevention of recurrent calcium stones are thiazides for hypercalciuria, potassium citrate for hypocitraturia, and allopurinol for hyperuricosuria.

Thiazides

Thiazide diuretics have consistently been shown in randomized controlled trials to reduce stone recurrence in patients with hypercalciuria. Their action in the distal tubule is associated with decreased urinary calcium excretion. Table 57.2 summarizes the clinical studies. A meta-analysis of the five studies summarized in Table 57.2 plus one other of short follow-up concluded that thiazides were effective [35]; risk reduction was 21.3% compared with no treatment or placebo. The term "thiazides" here includes the thiazide-like drugs chlorthalidone and indapamide. Thiazides are associated with hypokalemia, which in turn can reduce urinary citrate excretion. Their use is therefore often accompanied by potassium citrate supplements. Triamterene, which is often used to reduce urinary potassium losses when thiazides are used to treat hypertension, is poorly soluble in the tubular fluid of the distal nephron, has been reported to form radiolucent renal stones composed of the medication, and is therefore contraindicated in stone

Table 57.2 Randomized controlled trials[a] of "thiazides" for prevention of stone recurrence.

Study ID [reference]	Drug(s) (dose)	Control	No. of patients	Follow-up (mos)	% Recurrence in controls	% Recurrence in treated group	P value	Comment
Borghi [18]	Indapamide[b] (2.5 mg)	Not treated	50	36	42.8	15.8	<0.02	A third arm with allopurinol and indapamide had no greater effect than indapamide alone
Ettinger [63]	Chlorthalidone (25 or 50 mg)	Placebo	73	36	45	16 (25 mg), 13 (50 mg)	<0.05	"Recurrence" includes stone growth
Laerum [64]	HCTZ (25 mg) + KCl (8.0 mEq b.i.d.)	Placebo	50	36	48	22	0.05	
Ohkawa [65]	Trichlormethiazide (4 mg)	Not treated	175	26	NA	NA	<0.05	Recurrence rates were not given, but rates of stone formation were lower in active thiazide group than in control
Robertson [66]	Bendroflumethiazide (2.5 mg) + KCl (14.8 mEq)	Not treated	22	36–60	NA	NA	<0.05	Small preliminary report; full report not published; recurrence rates not given, but rates of stone formation were lower in active thiazide group compared to control; two other arms, one with allopurinol and one with orthophosphate, had no effects compared to placebo

Abbreviations: HCTZ: hydrochlorothiazide; b.i.d., twice a day; NA, not available.

[a]Studies with less than 2 years of follow-up and those reported only as abstracts are not included.

[b]Indapamide is a nonthiazide diuretic with similar activity.

Table 57.3 Randomized controlled trials of other pharmacologic interventions for prevention of calcium stone recurrence.

Intervention [reference]	Indication	Control (n)	Duration (mos)	% Recurrence (intervention vs. control)	Stone formation rate/patient-yr (intervention vs. control)	Statistical significance
Potassium citrate, 30–60 mEq/day (n = 18) [36]	Hypocitraturia	Placebo (20)	36	28 vs. 80	0.1 ± 0.2 vs. 1.1 ± 0.3	P < 0.001
Potassium/magnesium citrate, 42 mEq; potassium, 21 mEq; magnesium, 63 mEq (n = 16) [37]	Calcium stones	Placebo (25)	36	12.9 vs. 63.6	NA	RR reduction, 0.16 (95% CI 0.05–0.46)
Allopurinol, 100 mg t.i.d. (n = 29) [38]	Hyperuricosuria (excluding hypercalciuria)	Placebo (31)	24	31.0 vs. 58.1	0.12 vs. 0.26	P < 0.05

Abbreviations: t.i.d., three times a day; RR, relative risk; CI, confidence interval.

formers; amiloride or spironolactone are preferred as potassium-sparing diuretics in this population. The thiazides' antihypertensive effects, their long history of efficacy in systolic hypertension, especially in the elderly, and their association with increases in bone mineral density and reduction in fracture rates make thiazides the first-line therapy in patients with stones who are also affected by these other conditions. Young and otherwise-healthy stone formers will also benefit, with minimal reductions in blood pressure in most normotensive individuals. The hypocalciuric effect is greater in patients who succeed in reducing sodium intake.

Citrate

For patients with hypocitraturia, potassium citrate supplementation was shown to prevent stone recurrence in one randomized controlled trial [36] (Table 57.3). A preparation of potassium and magnesium citrate, not commercially available, was also effective for patients with calcium stones, irrespective of urinary citrate excretion [37]. Sodium citrate is associated with increased urinary calcium excretion and should be avoided.

Allopurinol

The effect of uric acid on precipitation of calcium oxalate led to a positive randomized controlled trial of allopurinol for prevention of recurrent calcium stones in patients with hyperuricosuria [38] (Table 57.3). Small and therefore inadequate studies in patients without hyperuricosuria showed no benefit.

Other therapies

A variety of other therapies have been tested in randomized controlled trials, and these have not demonstrated efficacy. Other customary therapies have not been tested in well-designed trials. There is currently no evidence supporting the use of cellulose phosphate, sodium phosphate, or orthophosphate. Magnesium may be effective *in vitro* in preventing crystallization of calcium salts, but no human data exist to show that it is effective *in vivo*; it may, however, be indicated in patients with bowel dis-ease, who often have hypomagnesiuria. Reduction of urinary oxalate, whether through dietary restriction, calcium supplementation, or other oxalate binders, has not been shown to prevent stone recurrence.

Calcium phosphate stones

The therapies recommended for the prevention of recurrent calcium phosphate stones have not been studied in randomized controlled trials. Calcium phosphate, usually in the form of hydroxyapatite, is frequently a minor component of calcium oxalate stones, but only about 15% of calcium stones are composed of more than 50% calcium phosphate [39]. A major determinant of calcium phosphate crystal formation is higher urine pH.

Two diagnoses should be considered in patients with predominant calcium phosphate stones: RTA and primary hyperparathyroidism. Distal RTA (or type I RTA) is associated with an increase in urine pH, which is the major reason why the associated stone composition is often calcium phosphate. The diagnosis of incomplete RTA is made when serum bicarbonate is normal but urinary pH is high and citrate excretion is low. Although not required for diagnosis, defects in urinary acidification are usually found in response to testing with ammonium chloride. A defect in acidification can also be suspected if the apparent level of ammonium excretion estimated from the urinary anion gap is low. The accompanying metabolic acidosis, with or without decreased serum bicarbonate, is associated with hypocitraturia. Hypercalciuria and osteoporosis are also often present as a result of acidosis-induced stimulation of osteoclast activity and inhibition of renal calcium reabsorption [40]. Nephrocalcinosis is often seen on abdominal radiography or ultrasound. Treatment with bicarbonate or citrate to raise serum bicarbonate and urinary citrate excretion appeared to reduce stone recurrence in uncontrolled observational studies of RTA and incomplete RTA [41,42]. Potassium bicarbonate or citrate preparations are preferred to sodium salts to minimize

hypercalciuria. Citrate supplementation is complicated by an ensuing increase in urinary pH which could theoretically worsen calcium phosphate precipitation. Treatment with thiazides to lower urinary calcium excretion might make citrate supplementation safer in patients whose hypercalciuria persists despite successful treatment of acidosis and might contribute to increasing bone mineral density.

The effects of parathyroid hormone (PTH) to increase intestinal absorption of calcium via stimulated synthesis of 1,25-dihydroxy-vitamin D and to mobilize directly both calcium and phosphate from demineralizing bone contribute to calcium phosphate stone formation. Calcium oxalate stones occur as well. The diagnosis should also be suspected in women or patients with a family history of stones or parathyroid disease. PTH should be measured in patients with high-normal or high values of serum calcium; serum ionized calcium is a more sensitive test. As many as one-third of patients with hyperparathyroidism and calcium stones may be normocalciuric, suggesting that other factors may contribute to stone formation. The therapy is surgical parathyroidectomy, although stone recurrence after gland removal is surprisingly high [43]. For those patients in whom surgical therapy is contraindicated due to coexisting morbidities, thiazides may reduce urinary calcium but increase serum calcium concentration. The calcimimetic agent cinacalcet lowered serum PTH levels in a placebo-controlled randomized trial, but a clear beneficial effect on urinary risk factors was not demonstrated [44], and cinacalcet is currently not approved for this indication.

Struvite stones

Struvite stones, constituting 10–15% of all urinary tract stones, result from urinary tract infections with organisms that produce the enzyme urease, which catalyzes the conversion of urea to CO_2 and ammonia [45]. Ammonia alkalinizes the urine, and pH values of 7.5 or more result. Such values are rarely seen, even with renal tubular acidosis or vegetarian diets: high urine pH should always lead to obtaining a urine for bacterial culture. Struvite precipitates at these high pH values; the crystals are composed of calcium phosphate (in the form of carbonate apatite) and magnesium ammonium phosphate (leading to their alternative name of "triple-phosphate" stones). These stones are often large and can form staghorn calculi, stones which extend into multiple calyces of the kidney pelvis. (Staghorn calculi may be composed of any stone-forming crystal: cystine, calcium oxalate, calcium phosphate, and uric acid). Affected patients are often, but not always, those with recurrent infections associated with spinal cord injury such as a neurogenic bladder, chronic bladder dysfunction from other causes such as multiple sclerosis, and other disorders treated with chronic indwelling catheters.

The therapy of struvite stones is surgical removal, either via ureteroscopy or percutaneous nephrostolithotomy [46]. Extracorporeal shock wave lithotripsy should be tried only for relatively small stones in normal urinary tracts. Nonsurgical therapy is as-sociated with sepsis or deterioration of kidney function, which may eventually require treatment by nephrectomy [47], especially in patients with end-stage renal disease in whom a kidney transplant is anticipated. Long-term, low-dose suppressive antibiotics, such as nitrofurantoin or sulfamethoxazole–trimethoprim, may be appropriate when stones have been completely eradicated by surgical therapy, but this strategy has not been the subject of any long-term randomized controlled trials.

Although the urease inhibitor acetohydroxamic acid has been shown to effectively reduce urinary ammonia levels and stone growth, its use should be reserved for patients with significant contraindications to endourologic surgery or who have failed surgical eradication [48–50]. The incidence of side effects reported in the clinical trials was significant, with relatively high proportions of patients taking the drug withdrawing from these studies [50]. These studies predate the current technology of endourology and effective stone removal, so that the relevance of the drug for stone disease management currently is less clear.

Patients with struvite stones and chronic infection often have metabolic abnormalities which may be responsible for causing calcium stones, which in turn contribute to initiation of infection and struvite formation [51]. Metabolic evaluation with 24-h urine collection after complete stone removal is recommended, although whether specific treatment based on the measured metabolic abnormalities will reduce struvite stone recurrence is unknown.

Uric acid stones

Uric acid is the major constituent of about 5–10% of stones; recent evidence demonstrates that uric acid stones make up a much larger proportion of stones among diabetics and obese patients [52,53]. There have been no randomized controlled trials of prevention of uric acid stones. The pathophysiology of uric acid stones and the therapy that arises from an understanding of this pathophysiology are relatively clear and effective, respectively [54]. There are three major factors that account for increases in urinary uric acid supersaturation: low urine volume, hyperuricosuria, and low urine pH [55]. The latter is by far the most important variable affecting uric acid supersaturation. As the pK of uric acid is 5.6, at low urine pH (5.5 or less) most uric acid is in the poorly soluble, protonated form and thus crystalluria and stones may result. At higher urinary pH (6.0 or more) most uric acid is in the dissociated, ionic, and therefore highly soluble form, and crystals will dissolve and stones are therefore unlikely. The amount of uric acid in the urine is much less important: with a low pH, even relatively little uric acid in the urine can result in stones, whereas at higher urine pH even relatively greater degrees of hyperuricosuria are not associated with stone formation.

Because low urine pH is a major cause of uric acid stones, conditions associated with more acidic urine are frequently implicated. Chronic bowel diseases, such as ulcerative colitis, Crohn's disease, chronic diarrhea, and ileostomy are often causative [26]. These

bowel disorders may also be associated with low urine volume as the result of stool salt and water losses. Increasing body weight is also associated with decreasing urine pH [56]. Diabetes is associated with a higher prevalence of stones in general [22] and a higher proportion of uric acid stones than seen in the general population [52]. The link between obesity, diabetes, and low urine pH resulting in uric acid stones may be due to a reduction in renal ammoniagenesis associated with insulin resistance.

Hyperuricosuria may be idiopathic or result from excessive ingestion of animal protein (poultry, fish, beef, eggs, lamb, etc). About 20% of patients with gout are overproducers of uric acid and have hyperuricosuria. However, even patients with gout and lesser values for uric acid excretion may have low urine pH, resulting in an increased risk for uric acid stones. These patients' gout-associated uric acid stones may be the result of the low urine pH associated with their higher body mass index or diabetes rather than gout per se, although even after correction for body mass, gout is associated with a greater risk of stones [27]. Less frequently, hyperuricosuria is the result of hematologic disorders, such as polycythemia vera, lymphoproliferative disorders, or abnormalities in uric acid metabolism, such as Lesch-Nyan syndrome. Hyperuricosuria can also arise from uricosuric drugs, such as probenecid or high-dose salicylates.

The major implication for therapy in patients with uric acid stones is that alkalinization of the urine is far more likely to be successful than therapy with the xanthine oxidase inhibitor allopurinol. Significant reductions in uric acid excretion achieved by allopurinol will be associated with continued stone production if urinary pH is not raised. If alkalinization is successful, reduction of uric acid excretion is not very important. Alkalinization is most often achieved with potassium citrate in varying doses, from 20 to 40 mEq once or twice a day. Potassium citrate is preferable to sodium citrate, as the sodium excretion may be associated with increased calciuria, although hypertension and hypervolemia or pulmonary congestion are less likely than with sodium chloride supplementation. Citrate salts may be better tolerated than sodium or potassium bicarbonate, but they do cause gastrointestinal symptoms in some patients, especially elderly patients. Sodium bicarbonate, however, is the cheapest form of alkalinization therapy. Allopurinol is reserved for patients with significant hyperuricosuria (more than 800–900 mg/day) in whom alkalinization is not easily achieved. Such patients may be those who become hypertensive or hypervolemic with sodium salts, hyperkalemic with potassium citrate, or have more marked metabolic acidosis due to chronic diarrheal conditions, such as that seen in some patients with ileostomies. Patients with these bowel disorders have continued intestinal losses of base and may, therefore, exhibit persistently lower serum bicarbonate concentrations that interfere with achieving bicarbonaturia and urinary alkalinization. Alkalinization of the urine throughout the day should be the goal for patients with stones in place, in whom stone dissolution may be possible. Once-a-day, or even every-other-day, orally administered alkalinization is often adequate for purposes of prophylaxis only, as demonstrated in a single anecdotal series [57].

Reduction in animal protein intake may be useful in reducing uricosuria and mitigating the metabolic acid load that contributes to the low urine pH. Increased ingestion of fruits and vegetables can be associated with increases in urine volume and urinary pH as well [19]. However, the benefit of protein restriction may be insignificant in patients with obesity and diabetes. Although specific therapy for such patients has not yet been investigated, such patients may have a lesser impact from protein restriction and might benefit more from weight loss and exercise to prevent the onset of diabetes.

Acetazolamide, a carbonic anhydrase inhibitor, causes diminished reabsorption of bicarbonate in the renal proximal tubule. Urinary alkalinization results and could be associated with dissolution of uric acid stones or prevention of stone recurrence. However, its use is accompanied by metabolic acidosis (superimposed on patients who often already have a degree of acidosis) and hypokalemia, making it less desirable for chronic use. The drug is reserved for patients who have difficulties with potassium and sodium citrate or bicarbonate.

Cystinuria

Cystinuria is responsible for 1% of all stones. There have been no randomized controlled trials of treatment for recurrence of stones in patients with cystinuria. The condition is the result of an autosomal recessive mutation in one of the two components of the proximal tubule's major cystine transporter. There have been advances in the collection of urine and assays for cystine that might change management of the disease. Urine collections for cystine should be alkalinized in order to solubilize precipitated cystine and avoid underestimating the excretion of cystine [58]. A solid-phase assay has recently been developed to avoid interference of thiol drugs with cystine measurements and could yield more accurate measures of cystine excretion and solubility [59]. Validation of the utility of this technique is not yet available.

Prevention of recurrent cystine stones has four components: fluids, diet, urinary alkalinization, and thiol medications. Patients should maintain high urine volumes, at least 1 L/250 mg of cystine (about 1 mmol)/day. The diet should have limited intake of animal protein, which contains methionine, the metabolic precursor of cystine [60], and of salt, the excretion of which is accompanied by more urinary cystine [59]. It should be noted that the experimental literature demonstrating an effect of dietary restriction of protein and salt does not include stones as an end point but does include changes in urinary cystine excretion. Protein restriction may also be useful in causing a degree of urinary alkalinization and reducing the amount of citrate supplementation required to achieve a higher urinary pH. Urinary alkalinization to pH 7.0 or more significantly increases cystine solubility; potassium citrate is preferred to the sodium preparation.

Thiol drugs containing a sulfhydryl group can break the disulfide bridge of cystine and form two molecules of cysteine bound to the drug; cysteine and cysteine-drug complexes are

more soluble than cystine. Available drugs include tiopronin (α-mercaptopropionylglycine), D-penicillamine, and a less-effective agent, captopril. The drugs are associated with improvements in cystine solubility, but their efficacies in preventing stones have been demonstrated only in relatively small anecdotal series, rather than in controlled trials [61,62].

Themes Across Renal Disease and Renal Failure

58 Growth, Nutrition, and Pubertal Development

Lesley Rees

Consultant Paediatric Nephrologist Great Ormond St Hospital for Children NHS Trust, London, UK

Phases of normal growth and influence of renal disease

Normal growth can be divided into four phases: prenatal, infantile, childhood, and pubertal. Each growth phase has different determinants, but growth is most affected during periods when it is the most rapid.

Prenatal phase

Growth *in utero* is more rapid than at any other time; around 30% of final height (FH) is achieved by birth. Intrauterine growth retardation (IUGR) has a profound effect on postnatal growth: children remain small and catch-up is rare. Kidney disease is a risk factor for IUGR. An adverse environment *in utero* impairs kidney development and makes the kidneys more vulnerable to damage from a range of pathological processes [1–5]. An increased incidence of IUGR has also been demonstrated in children with nephrotic syndrome and is associated with increased risk of relapses and steroid resistance [6–8].

Infantile phase

The extremely rapid prenatal rate of growth gradually decreases from >25 cm/year at birth to an average of 18 cm/year at 1 year of age and 10 cm/year at 2 years of age. One-half of adult height is achieved by the age of 2 years. This phase is highly dependent on nutrition: 170 Kcal/day are stored in new tissue in the newborn term infant, falling to 50–60 Kcal/day at 6 months, 30–40 by 1 year, and 20–30 by 2 years. Maintenance of normal growth is very difficult in young children with chronic kidney failure (CKF). Poor feeding and vomiting are common, and urological malformations, the most common cause of CKF in infancy, may result in sepsis, further aggravating the feeding problems or necessitating investigation and treatments with associated periods of fasting [1,9–14].

Childhood phase

Growth during the childhood phase becomes more dependent on the growth hormone (GH)–insulin-like growth factor 1 axis. GH is secreted in pulses, particularly at night, and this secretion is important for its actions. The growth rate decelerates throughout childhood until the onset of sex hormone production. Prolonged slowing of growth, in association with lack of development of secondary sexual characteristics (prepubertal deceleration), often causes concern and is a complication of long-term steroid therapy [15,16]. Growth will not resume until the onset of puberty.

Pubertal phase

Acceleration of growth during puberty is dependent upon the co-ordination of GH and sex steroid production, which, together with nutrition and general health, modify the genetic growth potential. Rising sex steroid concentrations stimulate GH production by increasing the amplitude of GH secretory pulses. Together, they have an anabolic effect on muscle mass, bone mineralization, and body proportions. Rates of growth may reach as high as 12 cm/year. The pubertal growth spurt will not take place until the appearance of secondary sexual characteristics. In girls this occurs early, soon after the onset of breast development; in boys it occurs later, after the onset of penile and pubic hair development and not until the testes have grown to 10–12 mL. Growth rates should therefore be interpreted with knowledge of the corresponding pubertal stage. Pubertal development and growth may be affected by CKF and steroid therapy [15–18].

Prevalence, severity, and natural history of growth disorders in chronic kidney disease

Steroid-sensitive nephrotic syndrome

The main potential impediment to growth in steroid-sensitive nephrotic syndrome is the steroid treatment rather than the disease itself. However, despite multiple courses and sometimes prolonged treatment, the majority of studies have shown little reduction in long-term growth potential. In 1985, the first report

demonstrated that, although growth was suppressed while taking steroids, those who had completed growth had a mean height standard deviation score (HtSDS) of −0.22 [19]. In the most recent report, median final HtSDS was normal, at −0.4 [20]. Although obesity and reduced appendicular lean mass are relatively common, these too resolve by adulthood [20,21].

Use of steroid-sparing agents results in improved growth. Children with severe growth impairment treated with cyclophosphamide demonstrated dramatic catch-up: HtSDS increased from −2.29 to −0.43 [22]. Similar results were shown in 12 children following treatment with alkylating agents: growth rate increased from 4.3 to 8.7 cm/year [23]. Studies of GH secretion have demonstrated that normal pulsatility is lost during steroid treatment [24] and recovers after its cessation [15]. Normal growth has been demonstrated in children prescribed cyclosporine A or tacrolimus [25].

It is likely that children with more severe renal disease have the most growth retardation. The mean duration of prednisone treatment and the average cumulative dose, especially when given for >6 months/year at a dose of >0.2 mg/kg/day, have been shown to be major predictors of poor growth outcome [26,27].

Another factor that may confound accurate interpretation of studies is the age at administration of steroids. Prepubertal growth may be unaffected: 21 prepubertal children grew normally on a mean yearly cumulative doses of prednisone of 6300, 3459, 2677, and 2081 mg/m^2 at the first, second, third, and fourth years, respectively [28]. Children taking steroids during the pubertal phase may have delayed development of secondary sexual characteristics and therefore delayed onset of the growth spurt. This causes a fall in HtSDS, which may be particularly pronounced, especially in those on long-term steroids [29], but growth continues for a longer time and ultimate height may not be affected [15,16]. This effect is greater in boys and in patients treated in the immediate prepubertal period, rather than those who are already established in puberty when steroids are started. Those who were on prednisolone after the age of 9 years in girls and 11 years in boys were at higher risk for height loss [27]. The FH of boys on steroids from 12 to 16 years of age and of girls from 10 to 14 years of age were −2 standard deviations (SD) below target height, but if steroids were withdrawn by the age of 14 years in boys and 12 years in girls, FH was within the normal range [30].

Chronic kidney failure

Prenatal and infantile phases
Many infants are already growth-retarded by the time they are first seen in a pediatric nephrology service, with losses as high as −1.68 SD from birth (−5 SD/year) [31]. HtSDS is below the normal range in most studies [1,9–14]. Approximately one-third of the fall in HtSDS occurs during fetal growth and one-third occurs during the first 3 months of life, accompanied by a similar fall in head circumference [32–34]. Infants who grew well continued with

catch-up in early childhood [13,31]. As well as IUGR, a proportion of infants have comorbidities and associated syndromes which may in themselves affect growth. Although one-half of those with a glomerular filtration rate (GFR) of <35 mL/min/1.73 m^2 showed catch-up growth, many that grew poorly had IUGR [1].

Childhood phase
By the childhood phase, many patients with CKF that developed in infancy are growth-retarded, with growth paralleling the percentiles but not catching up [31,34,35]. Growth seems to be affected with even mild CKF, and these observations have changed little since 1996, when mean HtSDS was −1.5 in 1725 patients, to 1998, when HtSDS was −1.4 (with one-third of values greater than −1.88) in 3863 patients, and −1.4 in 2001 with 4666 patients aged <20 years and with GFR of <75 mL/min/1.73 m^2 [36–38]. More severe CKF has a greater effect on HtSDS: 321 children aged 1–10 years with congenital CKF divided according to GFR above versus below 25 mL/min/1.73 m^2 had HtSDS of −1.65 and −2.79, respectively (mean, −2.37) [35]. HtSDS may decline progressively, falling from −1.6 to −2.1 over 3.5 ± 3.3 years in 22 patients aged <14 years with a GFR of 32.6 ± 24.8 mL/min/1.73 m^2 [39]. However, this has not been found in all studies. In one study, improvement of +0.3 SD occurred over 2 years in 99 children with a median GFR of 22 mL/min/1.73 m^2 and HtSDS of −1.73 [40]; a smaller study had similar findings [41].

Pubertal phase
The pubertal phase is a phase of rapid growth and is another period when loss of height potential can occur. Early studies in children with severe CKF demonstrated that puberty was delayed by approximately 2.5 years in both sexes, with an irreversible decline in HtSDS [42], but others have reported normal pubertal progression and growth [31,34,43].

Dialysis

Many studies have combined children of all ages and dialysis modality (peritoneal dialysis [PD] and hemodialysis [HD]): of 651 patients aged <18 years, 266 (41%) had an HtSDS of less than −1.88 [44], and 57% of over 200 on PD had retarded growth [45]. Growth retardation is reported to occur less frequently with continuous ambulatory PD than with continuous cycling PD or HD (changes in HtSDS, −0.55, −1.69, and −1.80, respectively, over 6–12 months) [46], although this effect was most noticeable in older children [47].

Infantile phase
Reports vary considerably, but generally infants with chronic kidney disease either show no improvement or have worsening growth retardation without nutritional support. No change in HtSDS has been reported (−2.51 to −2.74) in 15 children <2 years old treated

with continuous ambulatory PD [48]. Deterioration in HtSDS occurred in 17 infants on PD [49], and a decline in HtSDS by −0.29 SD/year has also been reported, along with a significant improvement between the first (−0.50) and the second (−0.23) years, in 22 children starting PD in infancy [50]. Good growth with nutritional support has been reported in some, but not all, studies (Table 58.1).

There are fewer studies of growth in infants on HD. In those ages 0–1 and 2–5 years at the start of HD and/or PD, HtSDS was −1.99 and −2.05, respectively, falling to −2.46 and −2.32 at 1 year and −2.06 and −2.00 at 2 years [51]. There have been two studies of HD, one reporting no change from HtSDS −1.6 in 18 infants on HD for up to 2 years [52], and the other reporting an HtSDS of −3.59 in 10 infants weighing <10 kg, only one of whom showed any improvement in HtSDS over a mean duration of 8.5 months [53].

Childhood phase
Reports on growth in the childhood phase vary, from improvement from −2.13 to −1.66 in 34 patients on PD for 6 months [54], to no change over 1 year [55,56], to a declining HtSDS from −1.71 to −1.86 at 1 year and −2.12 at 2 years in children on PD or HD aged 6–12 years (51).

Pubertal phase
Puberty may be delayed with poor growth [57]. HtSDS fell from −1.97 to −2.36 in 94 adolescents on HD for 3 years [58], from −1.39 to −1.59 at 1 year, and to −1.83 at 2 years in those on PD or HD [51].

Posttransplantation

Mean (range) HtSDS values at the time of transplantation for all ages have been reported to be −2.11 (−5.05 to −0.27), improving to −1.50 (−3.67 to −1.27) at 7 years posttransplant in 85 children [59] and −2.20 improving to −2.0 at 1 year in 64 children but with no further increases in years 2 and 3. Overall, more than 40% had values that remained less than −2 SD [60]. Some, but not all, studies show growth posttransplant to be superior to growth on dialysis, particularly in younger children [47,61,62]. However, comparison is difficult because, as well as age at transplant, growth is influenced by pretransplant height deficit (the greater the height deficit the greater the catch-up), which is in turn influenced by time of diagnosis and duration of dialysis [61]. Several studies have demonstrated the importance of GFR [61,62]: each increase in serum creatinine of 90 μmol/L (1 mg/dL) is associated with −0.17 SD [63]. Immunosuppressive regimens, especially steroid administration, affect growth (see below).

Infantile phase
Children under 2 years old have the greatest improvement in HtSDS, with gains of +1 SD overall [63] and +1.4 SD in six in-fants [64] and −3.2 to −1.6 and −1.4 at 5 and 10 years of age, respectively, in 30 infants [65]. One study showed no change from −1.1 SD over 7 years [66].

Childhood phase
Improvement in growth diminishes throughout childhood: 47% of children <6 years old at the time of transplant and 22% aged >6 years gained 1 SD [63]; height deficit was reduced by one-third in those receiving transplants before 5 years compared to an increase of up to 22% in older children [67]. HtSDS changed from −2.1 to −1.0 at 1 year, to −1.1 at 5 years, and to −0.14 at 10 years in 54 children who received transplants before age 5 years [68]; from −2.0 to −1.8, −1.5, and −1.5 at 1, 2, and 5 years posttransplant in 39 children <6 years of age [69]; and from −1.71 to −1.14 at 1 year and −0.55 at 5 years in 20 children <8.5 years of age [13]. Growth rates improved from 4.9 to 8.0 cm/year (+0.6 SD) within 2 years and increased FH by 1.3 SD [61].

Pubertal phase
Onset of puberty may be delayed but is in accordance with bone age. In 68 patients, mean chronological age and peak height velocity were 14.6 ± 1.9 and 13.3 ± 1.9 years and 6.6 ± 1.6 and 6.5 ± 2.9 cm/year in boys and girls, respectively. Menarche was attained at 15.9 years, and the duration of pubertal development was within normal limits [57]. Steroids may contribute to this delay [17]. HtSDS increased by 1.3 SD and 0.7 SD until FH occurred in children who received transplants before and after the start of puberty, respectively, although pubertal height gain was reduced by 20% [61]. HtSDS increased from −1.8 to −1.6, −1.5, −1.0, −0.7, and −0.6/year over five consecutive years in 54 adolescents [70]. Total pubertal height gain was greater in younger children, in those transplanted before the onset of puberty, and in those with better graft function [61,70].

Obesity posttransplantation
Obesity occurs in up to 13% of children with renal transplants and is associated with young age, male gender, short stature, duration of dialysis, and the number of grafts received [71,72]. Obesity may not be more common than in the normal population and is strongly related to the body mass index (BMI) of the mother [60].

Final height

FH is less than −2 SD in up to 47% of patients [57,61,73–75], with a mean of −2.01 in boys and −1.4 in girls among 60 patients not on recombinant human GH (rhGH) [75]. Conservative management is associated with a better FH than for those on renal replacement therapy (−1.15 vs. -2.1) [75]. FH was not reached until 20.2 ± 1.8 years in boys and 18.8 ± 2 years in girls [57,75], with a gain of +0.87 and +0.3 SD, respectively, after the age of 18 years [75]. Young age at start of dialysis and at transplant, short stature at transplant [60,73], and graft function [60] predict FH.

Table 58.1 Effects of dietary supplementation, specialist input by a dietician, and tube feeding on growth.

Study [reference]	No. of patients	Age (yrs)	GFR (mL/min/1.73 m²)	Diet	No. with nasogastric/no. with gastrostomy	Duration (mos)	Growth
Improvement in growth							
Ledermann 1999 [11]	26	0–2	29 with GFR of 6–26, 6 on PD	100% EAR calories for CA, 100% RDA protein for Ht age with protein supplement for PD	20/9 8 Nissen	24	WtSDS −3.1 to −1.7 at 1 yr, −1.4 at 2 yrs, HtSDS −2.9 to −2.2 to −2.1

Norman 2004 [85]	25	2–16	51–75	Intensive input from dietician and supplementation if EAR energy and RNI micronutrients <80%	0/1	24	All on supplements increased Ht and Wt SDS. No change in HtSDS if GFR >50. HtSDS +0.1 SD, correlation between intake and ΔHtSDS if GFR <50
	21		25–50				
Guillot 1980 [86]	3	<3		Energy 116% EAR, protein 84%	3/0	4–37	2 improved growth, 1 did not
Brewer 1990 [88]	14	3days to 3.1	PD	>90% RDA for energy for height age, 3–4 g/kg protein	13/0	3–33	Increase in HtSDS and WtSDS in 11
No change in growth rate							
Shroff 2003 [52]	18	0.5–2	HD	100% EAR calories for CA, 100% RDA protein for Ht age with protein supplement for PD	9/8	0.3–26	No change in HtSDS or WtSDS

(*Continued*)

Table 58.1 (*Continued*)

Study [reference]	No. of patients	Age (yrs)	GFR (mL/min/ 1.73 m²)	Diet	No. with nasogastric/ no. with gastrostomy	Duration (mos)	Growth
Reed 1998 [80]	7	0.6 ± 0.7	Mean 17 (<30)	Energy based on median Wt for CA	7/0	18.6 ± 4.5	HtSDS −0.9 to −1.1, WtSDS −0.4 to −0.2
Coleman 1999 [87]	13	0.2–8.5	PD	5.9 and 3.1 dietician contacts/mo	1/7	36	HtSDS from −1.2 to −1.14 and WtSDS from −1.32 to −0.73
Initial decline then normalization of growth							
Van Dyck 1999 [12]	15	<1	Creatinine > 1mg/dl in 1st yr	1.8–2.2 g protein/kg/day (EAA supplements 20% of protein in first year), energy 120% EAR	0/0	36	Drop in first 3 months, stable after, Ht SDS −1.96, WtSDS-1.37
Abitbol 1993 [78]	12	0.25–2	<70	100% RDA energy, >140% protein	9/3	Up to 24	Ht and WtVel lowest (−2SD) by 6 months and Ht and WtSDS by 12 months of age, then stable at −2SD
Ramage 1999 [81]	8 7	<2.5 >2.5	PD	Aiming for 100% RNI calories or greater if no response	0/12	12	Decline in HtSDS arrested No change
Deterioration in growth							
Ellis 2001 [79]	137	<5	PD/HD	Not specified	Equal at <2yrs, 29%/57% at 2–5yrs	Until age 6 yrs	WtSDS −0.77 at start, −2.04 at 1 yr, HtSDS −1.75 and −2.89 without supplements, Wt SDS −1.33 and −1.70 and HtSDS −1.76 and −2.88 with supplements respectively

Abbreviations: Vel, velocity; CA, chronological age; EAR, estimated average requirement; RDA, recommended dietary allowance; RNI, recommended nutrient intake; Ht, height; Wt, weight.

Table 58.2 EAA supplements and growth.

Study [reference]	No. of patients	GFR (mL/min/1.73 m²)	Diet	Duration (mos)	Outcome
Jones 1980 [97]	7	Severe CKF	Protein RDA for Ht age, half as EAAs	6–8	Improved nitrogen balance but no increase in HtSDS
Jureidini 1990 [94]	10	Severe CKF	Low protein and EAAs	36	Increase in Ht and WtVel
Mir 2005 [95]	20	<50	0.6 g/kg protein and ketoacids	30	HtSDS from −1.93 to −1.37
Zachwieja 1994 [96]	10	HD	AAs 0.25 g/kg body weight i.v. with dialysis	2 of 3	No improvement in plasma AAs

Abbreviations: RDA, recommended dietary allowance; Ht, height; i.v., intravenous; Wt, weight; Vel, velocity.

Available guidelines

The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative has published guidelines for the nutritional management of children with kidney disease [76], including methods of assessment of nutritional status, management of acid–base status, role of urea kinetic modeling, interval measurements for assessment of nutritional status, energy, protein, vitamin, and mineral intakes, dietetic input, nutritional supplements, and use of rhGH. British Renal Association standards cover the role of the pediatric dietician and nutritional recommendations for energy, protein, and phosphate [77].

Evidence for benefits of interventions on nutrition and growth

Nutrition
Dietary supplementation, input by a dietician specialist, and nasogastric or gastrostomy feeds
The benefits of supplemental feeds in CKF and dialysis patients have been studied in case series and cohort studies [11–14,52,78–88] (Table 58.1). All but two studies focused on children younger than 2 years of age, who would be expected to benefit most from intensive nutrition. In eight studies there was an improvement in HtSDS [11,13,14,82–86,88], in three studies there was an initial decline followed by normalization of growth [12,78,81], in three studies there was no significant change [52,80,87], and in one study there was a decline in HtSDS [79]. Six studies included older children. Of these six, three showed an improvement in growth [11,83,85], two showed no change [81,87], and one showed a decline in HtSDS [79]. The normal age-related requirements for energy and protein seem to be needed for growth improvement, with an increased protein allowance for children on PD and a smaller supplement for those on HD to allow for losses in dialysate. The benefits of intervention by a dietician were demonstrated in two studies, but it is likely that none of the studies could have been achieved without provision of dietetic input.

Administration of nutritional supplementation was by nasogastric tube or gastrostomy in all but one study. Complications were not specified but are known to occur primarily in children on PD. Postgastrostomy, there is an early risk for peritonitis, but this resolves. There is an increased risk of exit site infection and catheter removal from infection when the gastrostomy tube is inserted after PD has started, a risk that may be reduced if open rather than percutaneous surgery is used. Paraoesophageal hernias have been reported [89,90]. Successful track closure on removal and normal feeding posttransplant are the usual outcomes [91,92].

Essential amino acid supplements
Serum essential amino acids (EAAs) may be low in CKF, particularly during PD [93]. It has been suggested that a low-protein diet supplemented with EAAs might ensure adequate intake and reduce protein toxicity, thereby benefiting growth. The small cohort studies available have been inconclusive [94-97] (Table 58.2).

Amino acids-containing PD solutions
Excessive glucose absorption and also dialysate AA and protein losses contribute to malnutrition during PD. It has been suggested that using an AA dialysate might both decrease glucose load and replace AA losses. However, although AAs are absorbed in proportion to the concentration difference between dialysate and plasma [98,99], there is no evidence for long-term nutritional benefit with the more costly AA-based dialysis solutions than the standard glucose-based solutions [100] (Table 58.3). Equivalent amounts of urea and creatinine are removed by both methods. With AA solutions, normoglycemia is maintained although ultrafiltration is variable [101–103]. It may be that using a combination of glucose and AA solutions increases protein synthesis [104]. There have been no adverse effects reported.

Intradialytic parenteral nutrition
Losses of AAs occur into the dialysate during HD, depending on their plasma concentrations and molecular weights. Studies of intradialytic parenteral nutrition have shown an increase in body weight but not serum albumin. No complications have been

Table 58.3 AA-containing PD solutions and growth.

Study [reference]	No. of patients	Dialysis	Dialysate	Duration	Outcome
Canepa 1990 [98]	7	CAPD	1% AA exchange compared to glucose 1.36%	1 exchange	Rise in plasma AAs proportional to amount of AA in dialysate; amount of AA absorbed 66% after 1 h, 86% after 4 and 6 h; loss of 116 ± 69 μmol/kg body wt with glucose
Hanning RM 1987 [99]	8	CAPD	AA-based dialysate	1 exchange	Absorption of 70–73% of AAs peaking at 1 h and varied with concentration difference; levels at pre-exchange at end of cycle
Canepa 1991 [100]	8	CAPD	First morning exchange of 1% AA dialysate	12–18 mos	No improvement in any plasma or anthropometric parameter of nutrition; plasma urea increased; plasma EAAs improved but intracellular pool did not
Qamar 1994 [102]	7	CAPD	AA or dextrose dialysate	3 mos, crossover	No nutritional benefit from AA dialysis
Qamar 1999 [103]	7	CCPD	AA or dextrose dialysate	3 mos, crossover	During AA, appetite, calorie, and protein intake improved and total body nitrogen increased in one-half of children; plasma albumin did not change; fasting AAs were comparable to baseline; plasma urea was higher
Canepa 2001 [104]	10	CCPD	3:1 ratio of glucose to AA	8 infusions	Glucose absorption was 33.7%, AA 55.2%; plasma AA levels high but plasma urea did not increase

Abbreviations: CAPD, continuous ambulatory PD; CCPD, continuous cycling PD.

reported, but the studies conducted have been very small [105–108] (Table 58.4).

Dialysis adequacy

Increasing dialysis dose might be expected to benefit appetite, nutrition, and growth, and this has been found in some studies [109–111], but it needs to be balanced against increasing dialysate albumin losses during PD [112] and increasing AA losses during HD [113] (Table 58.5). This may be possible with careful attention to diet. PD causes an influx of glucose, which can contribute to obesity. High transporter status was associated negatively with HtSDS and positively with BMISDS in 51 children on PD. Large dialysate volumes also increase BMISDS [114]. For HD it is not clear if there

is a maximum optimum dose. Studies of daily HD, which is likely to offer the most benefit, have been promising [115].

Residual renal function increases clearance and growth. HtSDS improved from −1.78 to −1.64 over 1 year of PD in 12 patients with RRF but declined from −1.37 to −1.90 in 12 patients without residual renal function. Weekly Kt/V was not different, and only the native kidney Kt/V and creatinine clearance correlated with growth, suggesting that clearance obtained by PD cannot be equated with that obtained by native kidneys [116]. Eleven of 20 patients on PD with a minimum Kt/V of 2.1, daily protein intake of 3.25 g/kg/day, and HtSDS of −2.3 improved their HtSDS by 0.55, whereas in the other 9 it declined by −0.50. Variables affecting growth were nitrogen balance and residual Kt/V [117].

Table 58.4 Intradialytic parenteral nutrition and growth.

Study [reference]	No. of patients	Intradialytic (HD) treatment	Outcome
Abitbol 1984 [105]	3	AAs added to dialysate in increasing concentrations	Zero flux of AA nitrogen when 22 mg/100 ml of AA additive in the dialysate; increase in plasma non-EAAs but not of EAAs
Krause 2002 [106]	4, malnourished	8.5% AA solution, 10–15% dextrose, 20% fat emulsion for 7–12 weeks	Oral intake improved; Wt did not improve during treatment, but did subsequently; albumin did not change
Goldstein 2002 [107]	3, malnourished adolescents	70% dextrose, 15% AAs, 20% lipids, 6 weeks	Wt improved but not albumin
Orellana 2005 [108]	9 with >10% Wt loss and <90th percentile of ideal body Wt	Thrice weekly for 3–22 mos	In six patients, BMI and PCR increased, serum albumin did not change

Abbreviations: Wt, weight; PCR, protein catabolic rate.

Table 58.5 Dialysis adequacy and growth.

Study [reference]	No. of patients	Age (yrs)	Duration (mos)	PD/HD	Kt/V	CrCl mL/1.73 m^2/URR	Outcome
Holtta 2000 [109]	10 11	<5 >5	9	CCPD	3.1 3.2	59 78	Catch-up growth in 62%, better than Kt/V 1.7 and CrCl >40 (historical)
Marsenic 2001 [110]	15	14.5 ± 3.8	38 sessions	HD	<1.3–>1.6	URR 85%	nPCR lowest if <1.3, no improvement when >1.6
Tom 1999 [111]	12	0.6–14	4–81	HD	>2.0 and high dietary intake	URR >85%	+0.31 SD/yr, normal pubertal growth
Brem 2000 [112]	23 30	14.3 ± 3.6 10.6 ± 4.7	18	HD PD	Review, noninterventional		No association with albumin; inverse correlation with albumin, particularly if Kt/V >2.75
van Hoeck 2003 [113]	8	2–12	1 week crossover of NIPD ± daytime icodextrin		Kt/V increased from 1.99 to 2.54	CrCl increased from 35 to 65	No change in plasma albumin or PD losses, increased AA losses but no change in plasma AAs

Abbreviations: CCPD, continuous cycling PD, peritoneal dialysis; NIPD, nocturnal intermittent peritoneal dialysis; URR, urea reduction ratio; nPCR, normalized protein catabolic rate.

rhGH

The efficacy of rhGH in CKF and posttransplantation has been the subject of a Cochrane review [118]. Fifteen randomized controlled trials involving 629 children were identified [119–131]. Ten trials compared rhGH with placebo or no treatment [119–127] (Table 58.6). rhGH at 28 IU/m^2/week resulted in a significant increase in HtSDS at 1 year (weighted mean difference, 0.78 SDS, 95% confidence interval, 0.52–1.04) and a significant increase in height velocity at 6 months (weighted mean difference, 2.85 cm/6 months; 95% confidence interval, 2.22–3.48) and 1 year (weighted mean difference, 3.80 cm/year; 95% confidence interval, 3.20–4.39) [118]. Results were independent of pubertal stage or treatment modality (CKF, dialysis, or transplant). The frequencies of reported side effects were similar for the rhGH-treated group and the controls. There was no further improvement in subsequent years of treatment. It is not certain whether rhGH therapy improves FH, but data from cohort studies suggest that it does [118]. The remaining five trials compared two different doses of rhGH: four trials compared 28 IU/m^2/week with 14 IU/m^2/week in CKF [129–131], dialysis [129–131], and posttransplant [130–132] patients. The group treated with 28 IU/m^2/week showed a 1.34-cm/year (0.55–2.13) increase in height velocity compared to those given 14 IU/m^2/week. However, increasing the dose to 56 IU/m^2/week showed no further benefit over 28 IU/m^2/week [131].

Alternate-day steroids and steroid withdrawal posttransplantation

Better growth occurs in children on alternate-day versus daily steroids, with no detriment to graft function [133–136] (Table 58.7). However, this may be confounded by selection bias of patients with better graft function to the alternate-day regimen [135,136].

Some have recommended no steroids or steroid withdrawal, and relevant studies have been reviewed recently [137,138]. Steroid withdrawal over 2–12 months was associated with improved growth in six of seven studies [139–145] but again, selection bias applies. The same is true for patients managed with steroid-free immunosuppression [138,146,147].

Deflazacort is derived from prednisolone and is said to have equivalent immunosuppressive effects to prednisolone and prednisone but with less toxicity. It was shown to improve growth and body composition after kidney transplantation when used in an equivalent dose to prednisolone in four studies by the same group [148–151]. However, a blinded controlled trial over 1 year in 40 patients with steroid-sensitive nephrotic syndrome showed no benefit on growth [152].

Effect of height on long-term outcome

Malnutrition and poor growth are associated with increased morbidity and mortality. Patients <18 years of age initiating dialysis with hypoalbuminemia are at a higher risk for death: in 1723 children, each decrease in serum albumin of 10 g/L was associated with a 54% higher risk of death, which was independent of other potential confounding variables [153]. An HtSDS less than −2.5 at dialysis initiation is associated with poor school attendance, more time in the hospital, and a twofold higher risk of death [154,155]. Each decrease in HtSDS or Ht velocity by 1 SD was associated with a 14% or 12% increase in risk for death, respectively. A U-shaped association between BMI and death, with low and high BMIs associated with an increased risk for death, has been demonstrated [156].

Table 58.6 Effects of rhGH on growth versus placebo or no treatment.

Study [reference]	No. of patients	Type of patients	Experimental intervention (rhGH dose)	Control intervention	Ht velocity, cm/yr (SD), with 1 yr of rhGH [treated (T) vs. control (C)]	ΔHtSDS[a] (SD) with 1 yr of rhGH [treated (T) vs. control (C)]
Fine 1994 [119]	82	Predialysis, prepuberty	28 IU/m^2/wk s.c. for 24 mos	Placebo injection s.c. for 24 mos	T: 10.7 (3.1); C: 6.5 (2.6)	T: 1.01 (0.94); C: −0.08 (0.96)
Fine 2002 [120]	52	Posttransplant, pre-/early puberty	28 IU/m^2/wk s.c. for 12 mos	No treatment	T: 8.59 (2.46); C: 4.23 (1.92)	HtSDS, T: −2.58 (1.04); C: −2.99 (0.88)
Ghio 2002 [121]	21	Posttransplant, prepuberty	30 IU/m^2/wk s.c. for 12 mos	No treatment	T: 6.48 (3.44); C: 4.60 (4.46)	
Guest 1998 [122]	85	Posttransplant, pre-/early puberty	30 IU/m^2/wk s.c. for 12 mos	No treatment	ΔHt: 3.60 (2.29); velocity: 0.40 (2.46)	T: 0.30 (1.11); C: 0.00 (1.30)
Hokken-Koelega 1991 [123]	16	Predialysis, prepuberty	28 IU/m^2/wk s.c. for 6 mos	Placebo injection s.c. for 6 mos	T: 5.2 (1.2); C: 1.5 (0.4) (over 6 mos)	
Hokken-Koelega 1996 [124]	11	Posttransplant, pre-/early puberty	28 IU/m^2/wk s.c. for 6 mos	Placebo injection s.c. for 6 mos	T: 1.4 (0.5–2.6); C: 0.8 (0.6–1.8) per 6 mos	T: −3.0 (−7.6 to −1.2); C: −2.6 (−3.6 to −2.1) (per 6 mos)
Kuizon 1998 [125]	14	Dialysis, prepuberty	28 IU/m^2/wk s.c. for 6 mos	No treatment	T: 6.30 (2.94); C: 3.60 (1.41)	HtSDS, T: −1.36 (0.59); C: −2.18 (1.05)
Maxwell 1998 (2 trials) [126]	22	Transplant, pre-/early puberty	28 IU/m^2/wk s.c. for 12 mos	No treatment	Change in Ht: 4.90 (2.26); velocity: 0.00 (1.85)	T: 0.88 (1.17); C: −0.20 (0.67)
Powell 1997 [127]	69	Predialysis, prepuberty	28 IU/m^2/wk s.c. for 12 mos	No treatment		T: 0.80 (0.50); C: 0.00 (0.30)
Sanchez 2002 [128]	23	Transplant, prepuberty	28 IU/m^2/wk s.c. for 12 mos	No treatment	T: 8.00 (2.10); C: 4.80 (1.70)	HtSDS, T: −1.09 (1.00); C: −2.80 (1.00)

Abbreviation: s.c., subcutaneous.
[a]For three studies, the HtSDS is shown, rather than the change in HtSDS.

Table 58.7 Effects of alternate-day steroids posttransplantation on growth.

Study [reference]	No. of patients on daily/no. on alt.-day steroids	Steroid regimen	Outcome
Broyer 1992 [133]	18/17	Randomized to daily or alternate day for 1 yr; all on alternate day in second year	1st yr, −0.29 SD on daily, +0.49 SD alternate day; 2nd yr, +0.29 SD and +0.52 SD
Feldhoff 1984 [134]	15/15	15 switched to alternate day matched with 15 on daily	Increase in HtVel in the 2nd but not the 1st yr
Kaiser 1994 [135]	24/31	31 switched to alternate day, but daily group had worse graft function and higher dose	+0.94 SD alternate day, −0.86 SD daily
Jabs 1996 [136]	1664/337	Not known how regimen selected	HtSDS up to 24 mos +0.5 SD on alternate day and +0.1 SD on daily

Abbreviation: Vel, velocity.

Table 58.8 Evidence table for all interventions on growth.

Intervention	SR[a]	Evidence rating[b,c] High	Moderate	Low	Comment	Recommendation[d] I	II	III	Comment
rhGH									
rhGH vs placebo or no treatment	+	•			10 RCTs (395 patients); variable quality; consistent results		•		Small benefit; height increase 3.80 (3.13–4.59) cm in 1 yr; harms of daily injections; high cost
rhGH 28 vs 14 IU/m²/wk	+		•		5 RCTs (129 patients); variable quality; consistent results			•	Height increase 1.34 (0.55–2.13) cm in 1 yr; high cost
Oral nutritional supplements/dietetic input/nasogastric or gastrostomy feeds									
Composite intervention in <2 yrs of age	—			•	10 case series (169 patients); generally consistent results		•		Benefit of improved/stable growth exceeds reported harms
Composite intervention in >2 yrs of age	—			•	9 case series (232 patients); inconsistent results			•	Uncertain benefit; few reported harms
AA supplements/intradialytic parenteral nutrition									
EAA supplements	—			•	4 case series (47 patients); inconsistent results			•	Uncertain benefit; growth reported in 3 of 4 studies; no evidence on harms; expensive
Amino acid vs glucose PD solutions	—			•	6 observational studies (47 patients); inconsistent results			•	No demonstrated benefit; no difference in harms; growth reported in 2 of 6 studies; expensive
Intradialytic parenteral nutrition	—			•	4 case series (19 patients); inconsistent results			•	Uncertain benefit; no difference in harms; growth reported in 3 of 4 studies; expensive
Dialysis adequacy									
Increase in dialysis adequacy	—			•	5 case series (109 patients); consistent results			•	Uncertain benefit; no harms reported; growth reported in 2 of 5 studies
Alternate-day steroids/steroid withdrawal posttransplant									
Alternate-day steroids	—		•		1 RCT (35 patients) and 3 case series (2086 patients); consistent results		•		Increased HtSDS; no increase in harms; patient selection bias
Steroid withdrawal or no-steroid regimen	—			•	7 observational studies (237 patients); consistent results			•	Improved HtSDS; no increase in harms; patient selection bias

[a]Systematic review of randomized controlled trials (RCTs).

[b]Evidence rating based on study design, study quality, consistency, and directness of results. [c]No intervention was rated with a high evidence rating.

[d]Recommendations based on trade-offs between benefits and harms, quality of evidence, translation of evidence into practice in a specific setting including availability of medication, and any uncertainty about the baseline risk of the disease in the population. I, recommend; II, suggest; III, no recommendation possible.

Conclusions

Short stature is common in children of all ages who have renal disease and it has an important influence on outcome. Results of potential interventions to improve growth are summarized in Table 58.8. Adequate nutrition is vital, particularly in the first 2 years of life but also in older children. Feedings often need to be administered by nasogastric or gastrostomy tubes and require dietetic input for prescription adjustment. There is no evidence of benefit from EAAs orally, AA-based PD solutions, or intradialytic parenteral nutrition. Dialysis prescription is likely to affect growth, but the ideal dose is unknown. The use of the lowest possible alternate-day steroid dose offers the best chance of good growth posttransplantation. One year of rhGH may improve growth by 4 cm/year for all treatment modalities and may improve FH. All these interventions have a very low complication rate.

59   Hypertension, Cardiovascular Disease, and Lipid Abnormalities in Children with Chronic Kidney Failure

Elke Wühl & Franz Schaefer

Division of Pediatric Nephrology, Center for Pediatric and Adolescent Medicine, University of Heidelberg, Im Neuenheimer Feld 430, 69120 Heidelberg, Germany

Introduction

Cardiovascular complications are the major cause of the excessive morbidity and mortality observed in adults with chronic kidney disease (CKD). Significant cardiovascular disease (CVD) occurs also in children with CKD and is the leading cause of death in young adults with childhood-onset end-stage renal disease (ESRD) [1,2]. Even in the pediatric age range, where cardiovascular mortality is extremely low, 25% of deaths in ESRD are attributable to CVD [3]. This increased cardiovascular risk appears to be related to increased exposure to general risk factors, such as hypertension and dyslipidemia, as well as to conditions specifically associated with uremia, including abnormal mineral metabolism, chronic inflammation, oxidative stress, and anemia. This section reviews the current strategies to prevent, detect, and treat cardiovascular complications and disease progression in children with CKD.

Hypertension

CKD is the most prevalent cause of arterial hypertension in the pediatric population, accounting for at least three-fourths of cases requiring pharmacological therapy [4]. This is in striking contrast to adults, in whom primary (or essential) hypertension predominates. The fraction of children with secondary hypertension decreases throughout childhood, whereas the prevalence of essential hypertension increases. Within the pediatric CKD population, the prevalence of hypertension is 20–50% in CKD stages II–IV, 50–80% in dialyzed patients, and up to 80% in kidney allograft recipients [5–8].

Multiple factors contribute to the high prevalence of hypertension in this population. Sympathetic hyperactivation is a key feature of CKD, which appears to occur very early in the course of CKD. The renin–angiotensin system (RAS) is activated in most pe-

diatric nephropathies. Salt and fluid overload and functional nitric oxide deficiency due to accumulation of the circulating nitric oxide synthetase inhibitor asymmetric dimethyl-arginine contribute to hypertension in advanced CKD. Hypertensiogenic effects of calcineurin inhibitors and glucocorticoids play a major role in immunosuppressant-dependent nephropathies and after kidney transplantation.

The measurement and interpretation of blood pressure (BP) in pediatric patients is complicated by the marked physiological changes in body dimensions and cardiovascular dynamics that occur across childhood. Hence, the assessment of BP in children and adolescents should follow standardized measurement procedures and use appropriate normative BP data sets.

Measurement of BP in children and selection of appropriate normative data

BP measurements should be performed according to the guidelines of the National High Blood Pressure Education Program Working Group [9] after 5 min of rest, with the child sitting in an upright position (infants supine). An appropriate cuff with an inflatable bladder width of at least 40% of the upper arm circumference and a bladder length of 80–100% of arm circumference should be used. There is still no consensus on the preferred measurement device. Although the automated oscillometric technology is rapidly gaining popularity, the *Fourth Report* [9] still recommends auscultation, reasoning that most available reference values are based on this method and suggesting that oscillometric measurements above the 90th percentile should be repeated with auscultation. For auscultatory measurements, systolic BP is defined by the onset of tapping Korotkoff sounds (K1), and diastolic BP is defined by the disappearance of Korotkoff sounds (K5). However, elevated BP values must be confirmed on repeated visits or by ambulatory BP monitoring (ABPM) before classifying a child as hypertensive [9].

ABPM has become recognized in recent years as a new diagnostic reference standard for the investigation of hypertension in adults and children alike. The large number of BP measurements

obtained outside the office setting largely eliminates the "white coat effect" and also diurnal BP variability [10–13]. ABPM is superior to casual BP measurements in predicting cardiovascular outcomes in adults [14]. Although ABPM is technically feasible in children aged 3 years and older, the major drawbacks of this method are the logistic challenges associated with returning the device after use and the sophisticated biostatistical workup of the readings. Manual home BP monitoring is becoming a popular partial alternative to ABPM, avoiding the "white coat" setting, and a valuable way of actively involving patients in disease management [15]. However, the pediatric use of home BP measurements is hampered by the lack of comprehensive normative data. From a practical viewpoint, the greater sensitivity of BP measurements in the clinic (clinic BP) justifies its use in screening examinations, whereas ambulatory and home measurements show greater specificity and are therefore especially suited to confirm a suspected diagnosis of hypertension [16].

In adults, cardiovascular risk is a function of BP, even below the arbitrary cutoff levels that define hypertension. This has led to a steady lowering of the recommended BP levels in adults over the last few decades [17]. Pediatric studies linking BP to cardiovascular outcomes are lacking. Therefore, the pediatric definition of hypertension is based on the BP distribution in the general pediatric population from birth to age 18 years and is dependent on height, age, and gender. Although early reports regarded children at the 95th BP percentile as high-normal, the most recent guidelines [9], reflecting the trend in adult hypertension research, label BP values between the 90th and 95th percentiles or any value above 120/80 mmHg (whatever BP threshold is lower, irrespective of age) as prehypertensive. Systolic or diastolic BP values exceeding the 95th percentile are labeled as hypertensive (stage 1: systolic or diastolic BP in 95th to 99th percentile +5 mmHg; stage 2: systolic or diastolic BP in >99th percentile +5 mmHg).

The most comprehensive and commonly used pediatric normative data sets for auscultatory casual BP have been published by the National High BP Education Program for North America [9] and by de Man *et al.* for European children [18]. Reference data for casual oscillometric BP measurements are available for North American children [19,20]. For ABPM measurements, normative data have been provided both for oscillatory [21,22] and for auscultatory [23] ABPM measurements. No normative data exist for home BP measurements in children oscillatory normative BP data are available [24].

Efficacies of strategies for prevention and treatment of hypertension in children

In children with mild hypertension or essential hypertension, non-pharmacological treatment (therapeutic life-style modifications, including diet, exercise, and stress reduction) might be successful in lowering BP. Although difficult to achieve, weight loss is effective in lowering BP in overweight children [9,25]. Although restriction of sodium in salt-sensitive adults is beneficial in those with hypertension [26], evidence for a direct relationship between sodium intake, diet, and BP in children is less conclusive, based on a meta-analysis of 37 pediatric studies [27].

In case of resistance to therapeutic life-style modification, and in most children with secondary hypertension, pharmacological treatment is required. The goal of antihypertensive treatment in children is reduction of BP below the 95th percentile unless concurrent conditions (such as CKD or diabetes) are present, in which case BP should be lowered at least below the 90th percentile (or <120/80 mmHg, whichever BP level is lower). Whether even stricter blood pressure control to levels below the 50th percentile will be of additional benefit in those children is the subject of the current ESCAPE trial [28].

Pharmacological treatment should be initiated with a single agent. Drug classes acceptable for use in children include angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), β-receptor blockers, calcium channel blockers, and diuretics [9]. Although most antihypertensive drugs marketed for adults have been used in children, few drugs have been proven effective and safe in children and received explicit regulatory authority approval for pediatric use to date (US Food and Drug Administration-approved drugs include, by class: ACE inhibitors benazepril, enalapril, fosinopril, and lisinopril; ARBs irbesartan and losartan; the β-receptor blocker propranolol; the Ca channel blocker amlodipine; and diuretics furosemide and hydrochlorothiazide). Recent clinical trials stimulated by the Best Pharmaceuticals for Children Act in the USA and emerging similar legislation in Europe are about to expand the number of drugs with pediatric dosage information.

In dialyzed children, dry weight [29] and dialysis prescription [30] must be frequently adapted to avoid fluid overload-induced hypertension. In pediatric kidney transplant recipients, modification of immunosuppressive medication, including calcineurin inhibitor and steroid withdrawal, may result in improved BP control [31].

The evidence ratings of recommendations for preventive strategies and treatment of hypertension in children with CKD are summarized in Tables 59.1 and 59.4. Because no systematic reviews exist for the treatment of hypertension in children, the overall evidence rating is only moderate. Life-style modification and diet failed to demonstrate a significant beneficial effect on hypertension in children with CKD. Data on steroid withdrawal in children with a transplanted kidney suggest a beneficial effect of steroid-free immunosuppressive regimens on BP. There is evidence that Ca channel blockers, ACE inhibitors, and ARBs are effective and safe in lowering BP in pediatric renal hypertension. Considering their superior side effect profile and in accordance with data in adults, ACE inhibitors and ARBs should be preferred over Ca channel blockers as first-line antihypertensive agents in children with CKD.

CVD in children with CKF

Left ventricular hypertrophy (LVH) is second only to age as the most powerful predictor of cardiovascular events in adults. The best noninvasive assessment of cardiac mass is the estimation of

Table 59.1 Evidence ratings and recommendations for treatment of hypertension in children with CKD.

Intervention	Existing systematic pediatric reviews	Overall evidence rating[a]		Comment	Recommendation[b]			Comment
		Moderate	Low		I	II	III	
Therapeutic life-style modification	No		●	No evidence from pediatric CTs; some evidence from adult RCTs			●	No conclusive data from children with CKD
Reduction of salt intake, dietary intervention	No	●		Pediatric meta-analysis, Cochrane review from adult studies		●		Data from pediatric meta-analysis inconclusive
Efficacy of antihypertensive agents								
β-blockers	No	●		One short-term study in 11 children with CKD; evidence from adult RCTs	●			Consistently effective in lowering BP
Ca^{2+} channel blockers	No	●		Moderate evidence from pediatric CTs (4 trials, 150 CKD patients); evidence from adult RCTs	●			Consistently effective in lowering BP
ACE inhibitors and ARBs	No	●		Good evidence from pediatric CTs (9 trials, >600 CKD patients)	●			Consistently effective in lowering BP and proteinuria
Superiority of RAS antagonists in treating CKD-related hypertension	No	●		High evidence from adult RCTs	●			Equally effective in lowering BP, additional reduction of proteinuria
Other interventions								
Adjustment of dry weight (CKD 5)	No	●		Limited evidence from pediatric CTs; evidence from adult studies	●			Favorable outcome under intensified dialysis regimen and dry weight adjustment
Steroid withdrawal in transplant patients	No	●		Limited evidence from pediatric data; evidence from adult RCTs	●			Pediatric RCT underway

Abbreviations: RCT, randomized controlled trial; CT, clinical trial.

[a]Evidence rating based on study design, study quality, consistency, and directness of results. No intervention was rated with a high or a very low evidence rating.

[b]Recommendations based on trade-offs between benefits and harms, quality of evidence, translation of evidence into practice in a specific setting including availability of medication, and any uncertainty about the baseline risk of the disease in the population. I, recommend; II, suggest; III, no recommendation possible.

left ventricular mass (LVM) by echocardiographic standardized measurements. Age, height, weight, gender, and BP each exert an independent influence on LVM in children [32]. Using the Devereux formula indexed to height (in meters) to the power of 2.7 will partly correct for the influence of body dimensions and age [33–35]. Controversy exists about the cutoff levels of LVM to define LVH in children. The *Fourth Report* [9] suggests using the adult level (i.e. 51 $g/m^{2.7}$), but this is very conservative, because the 95th percentile of LVM in children is approximately 38 $g/m^{2.7}$ and the adult 97th percentile of 51 $g/m^{2.7}$ is far above the 99th pediatric percentile [36]. Although studies linking LVM to CVD in children are lacking, it appears reasonable to define, in analogy to BP limits, any LVM above the 95th percentile as significant LVH to be considered for intensified antihypertensive treatment. An LVM index of 38–51 would indicate mild to moderate LVH, and an index above 51 would indicate severe LVH.

LVH is the most common identifiable cardiac alteration in ESRD, affecting approximately one-third of children with CKD

stages II–IV [36–38] and up to 80% of dialysis patients [2,39–41]. Notably, in children with mild to moderate CKD, LVM is only weakly inversely correlated with glomerular filtration rate (GFR), and LVH is common, even in patients with minimal impairment of renal function. In children after kidney transplantation, LVH often persists despite improved renal function [42,43]. Both concentric and eccentric changes in left ventricular geometry are common, independent of the level of residual renal function [36,40]. The increase of LVM in children with CKD is associated with an impairment of intrinsic left ventricular contractility [44].

The factors associated with LVH are similar to those observed in adults with CKD. Hemoglobin is inversely correlated with LVM [36,40] and LV function [44]. The role of hypertension in LVH in children with CKD is still unclear. BP was correlated with LVM in children with severe LVH on dialysis, but not in a large cohort of children with stage II–IV CKD [36,40]. Hyperparathyroidism is correlated with LVH in adults [45,46] as well as in children [47,48]. Moreover, an association of LVH and abnormal LV geometry with

increased C-reactive protein levels has suggested a role of occult inflammation in the pathogenesis of LVH in CKD [36].

An increase in carotid artery intima media thickness (IMT), as measured by high-resolution ultrasound, is considered an early marker of arteriosclerosis and a sensitive predictor of cardiovascular events both in the general population and in adult dialysis patients [49,50]. Increased carotid IMT has also been demonstrated in children who are considered at risk for CVD due to hypertension, obesity, or hyperlipidemia. Increased IMT that develops in the course of CKD is associated with stiffening of the large arteries, an abnormality that is related directly to an increased load to the left ventricle and impaired peripheral blood flow [51]. In children and adolescents with CKD on dialysis and after kidney transplantation significant increases of carotid IMT are detectable. The degree of vascular pathology depends on the level of renal dysfunction and is most marked in patients on dialysis [1,52–54]. The morphological changes are associated with an increased stiffness of large arteries. After correcting for BP, the total duration of dialysis, cumulative intake of calcium-containing phosphate binders, and time-integrated plasma parathyroid hormone levels are predictive of the alterations in carotid IMT and elasticity [47,52], strongly suggesting causative roles of the excessive calcium–phosphate load on dialysis and/or vascular actions of parathyroid hormone in CKD-associated arteriopathy .

Efficacies of strategies for prevention of CVD in children

The multifactorial etiology of CVD in CKD requires a multifaceted preventive strategy. The cardiovascular protective efficacies of individual preventive measures are supported by variable levels of evidence.

Anemia is associated with increased LVM and decreased cardiac function [55]. Thus, in concordance with the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines on management of renal anemia in children, maintenance of normal hemoglobin levels should be aimed for by early initiation of erythropoietin and iron therapy [56]. However, correction of anemia does not result in complete regression of LVH in adults, and full correction is associated with increased all-cause mortality [57,58].

In patients on dialysis, optimization of dry weight and reduction of interdialytic weight gain in hemodialysis may reduce volume effects on the cardiovascular system and, in addition, volume-dependent hypertension and activation of the RAS might be lessened.

Hypertension should be controlled adequately (see above), aiming for a BP target below the 90th percentile. A meta-analysis of more than 100 studies in adults yielded a moderately strong relationship between BP reduction and LVM regression [59]. Drug class-specific mechanisms may contribute to LVH regression beyond BP normalization. In a meta-analysis of 80 trials comparing the effects of different classes of antihypertensives on LVM in

adults, ACE inhibitors and ARBs exerted an additional beneficial effect on the prevention or regression of CVD [60].

In children with mild to moderate CKD, complete normalization of BP by ACE inhibition and the addition of other antihypertensive agents, if required, caused regression of LVM into the normal range in the vast majority of patients presenting with LVH (ESCAPE trial, unpublished data), despite the fact that a correlation between BP and LVM has been observed only in children with ESRD but not in stage II–IV CKD [2,36,40].

Calcium–phosphorus ion product and parathyroid hormone levels are correlated with carotid IMT and cumulative calcium-based phosphate binder intake with vascular morphology and function [47,52]. Hence, tight control of calcium–phosphorus metabolism with maintenance of normal calcium and phosphorus balances and prevention or correction of hyperparathyroidism is probably essential to improve the cardiovascular status of children with CKD. In adult dialysis patients the use of calcium-free phosphate binders largely halted coronary artery calcification, whereas progressive calcium deposition was seen in patients receiving calcium-based phosphate binders [61].

Renal function is correlated with carotid IMT, arterial function, and LVH. Uremic toxins and/or the state of microinflammation associated with failing kidney function may play a direct role in morphological and functional changes of the vascular wall and the myocardium. Therefore, renoprotective pharmacotherapy and correction of renal function by kidney transplantation may also be effective measures to prevent cardiovascular disease in CKD patients. Successful kidney transplantation led to partial regression of the CKD-associated carotid arteriopathy in children within 1 year of observation [62].

Progression of CKD toward end-stage renal failure is common and occurs irrespective of the underlying renal disease. There is clear evidence that hypertension and proteinuria are independent risk factors for progressive CKD in adult patients [63–65]. Dietary protein intake did not affect the rate of CKD progression substantially in seven randomized controlled clinical trials of adult nondiabetic nephropathies. However, a recent Cochrane review that combined these trials showed that reduction of protein intake delays the need for renal replacement therapy [66], most likely by reducing the accumulation of nitrogenous waste products. In a randomized controlled trial in children with CKD, prospective institution of a low-protein diet did not affect the rate of GFR loss, but proteinuria and hypertension were independent predictors of disease progression in the secondary data analysis [67].

Blockade of the RAS by ACE inhibitors and more recently, ARBs, has become the pharmacotherapy of first choice in children as in adults with CKD. Besides lowering BP effectively, RAS antagonists substantially reduce proteinuria. Several trials in adults with various acquired nephropathies have confirmed the initial evidence from animal models that RAS antagonists exert a specific renoprotective effect that exceeds the general beneficial effect of BP control [68–73]. The magnitude of the advantage of RAS antagonists over other antihypertensive agents is still under debate [74].

Limited published information is available regarding renoprotection in children with CKD. Small uncontrolled studies showed stable kidney function in children post-hemolytic uremic syndrome during long-term ACE inhibition [75], stable GFR during 2.5 years of losartan treatment in children with proteinuric CKD [76], and attenuated histologic progression in children with immunoglobulin A nephropathy receiving combined RAS blockade [77]. The ongoing ESCAPE trial has demonstrated efficient BP and proteinuria reductions by ramipril in 400 children with CKD [28]. The long-term antiproteinuric and renoprotective efficacies of ACE inhibition will become clear after completion of this 5-year trial in 2008 and analysis of the data.

There is evidence that the RAS is incompletely suppressed by ACE inhibition alone, and the possibility of partial secondary resistance has been suggested ("aldosterone escape," or compensatory upregulation of ACE-independent angiotensin II production) [78,79]. Therefore the combination of an ACE inhibitor and an ARB may be favorable if proteinuria persists or increases despite ACE inhibition at maximally tolerable doses. This concept has been proven in adults [80,81]; however, pediatric data are not available to date.

Aldosterone antagonists also lower BP by RAS suppression. Whereas the use of spironolactone is limited by endocrine side effects, the new aldosterone antagonist eplerenone has minimal affinity for progesterone and androgen receptors. Apart from the risk of hyperkalemia, reported side effects are similar to placebo [82]. Combined therapy of eplerenone and an ACE inhibitor increased patient survival in adults with congestive heart failure [83]. However, combination therapy appears limited in CKD patients due to the potentiated risk of hyperkalemia [84,85].

A summary of the evidence ratings for prevention strategies in CVD in children with CKD is given in Tables 59.2 and 59.4. Data on prevention of pediatric CVD are limited. However, there is evidence from adult studies that normalization of BP (by RAS antagonists), an optimized dialysis regimen, and adequate treatment of CKD-related diseases (anemia, hyperparathyroidism, malnutrition) might prevent CVD in CKD patients. This evidence may be extrapolated to children.

Lipid abnormalities in pediatric kidney disease

Epidemiological studies have identified dyslipidemia as an independent risk factor for CVD. Kidney disorders are often associated with dyslipidemia, and some evidence suggests that dyslipidemia is an independent risk factor not only for CVD but also for progressive chronic kidney failure [86].

Dyslipidemia in adults is defined by total cholesterol of >240 mg/dL (>6.24 mmol/L), low-density lipoprotein (LDL) cholesterol of >160 mg/dL (>4.16 mmol/L), triglyceride levels of >200 mg/dL (>2.28 mmol/L), or high-density lipoprotein (HDL) cholesterol of <40 mg/dL (>1.04 mmol/L) [87]. In contrast, dyslipidemia in children is defined by cholesterol or triglyceride levels exceeding the 95th percentile for age and gender [88].

The dyslipidemic pattern differs between the major renal disease entities [88]. In nephrotic syndrome, marked hypercholesterolemia or combined hyperlipidemia is present in the majority of children and adults with active disease [89–92]. The alterations are mainly caused by lipid transport protein imbalances resulting from urinary protein loss and exaggerated hepatic *de novo* synthesis of lipoproteins. All apolipoprotein B-containing lipoproteins [i.e. VLDL, LDL, and lipoprotein(a), abbreviated Lp(a)] are increased. Persistent hyperlipidemia in nephrotic syndrome has a pro-atherosclerotic effect and contributes to CVD not only in adults [93] but also in children [94]. In CKD the degree of dyslipidemia parallels the degree of renal function impairment. Chronic renal insufficiency commonly progresses to ESRD, and there is relatively little information about the CVD risk associated with chronic renal insufficiency as an entity distinct from ESRD. Underlying mechanisms of uremic dyslipidemia include insulin resistance [95], hyperparathyroidism [96], malnutrition, acidosis [97], and impaired catabolism of triglyceride-rich lipoproteins by decreased activity of lipoprotein lipase and hepatic triglyceride lipase [98,99], whereas lipoprotein synthesis appears to be unaltered. In line with findings in adults, children with CKD have elevated serum triglycerides, whereas total cholesterol is close to normal. Hemodialysis does not seem to alter the pattern of dyslipidemia associated with CKD, whereas peritoneal dialysis contributes to an elevation of total cholesterol with a further increase in hypertriglyceridemia [88], probably due to further increased insulin resistance secondary to continuous glucose absorption from the dialysis fluid. In hemodialysis patients the use of heparins may acutely disturb the action of lipoprotein lipase. Whereas early analyses suggested less marked lipid alterations by low-molecular-weight heparins compared to conventional heparin in dialysis patients [100], this was not confirmed in later studies [101]. Due to the heparin interference, lipid patterns in hemodialysis patients should be assessed prior to a hemodialysis session.

After kidney transplantation, glucocorticoid administration leads to elevated cholesterol and triglyceride levels. Calcineurin inhibitors are associated with increased total cholesterol and apoB-associated cholesterol (including HDL cholesterol), whereas total triglycerides and HDL levels are less affected [102]. The dyslipidemic effect appears less marked in patients receiving tacrolimus compared to cyclosporine. The recently introduced mTOR antagonists dose-dependently induce hypertriglyceridemia and an increase of LDL cholesterol and apoB lipoproteins [103].

Efficacies of strategies for prevention and treatment of lipid abnormalities in children

The broad spectrum of factors influencing lipid metabolism in CKD demands a multifaceted prevention and therapeutic approach. General measures to prevent dyslipidemia in CKD patients include prevention or treatment of malnutrition and correction of metabolic acidosis, hyperparathyroidism, and anemia, all of which may contribute to dyslipidemia [97,104,105]. In addition, extrapolating from evidence in the general population, therapeutic

Table 59.2 Evidence ratings and recommendations for treatment of CVD in children with CKD.

| Intervention | Existing systematic pediatric reviews | Overall evidence rating[b] | | | Recommendation[c] | | | |
		Moderate	Low	Comment	I	II	III	Comment
LVH and vascular alterations[a]								
Normalization of BP	No	●		Limited data from one pediatric RCT; evidence from adult RCTs	●			Adequate BP control recommended in general; BP reduction associated with regression of LVH
Superiority of RAS antagonists	No	●		Limited data from one pediatric RCT; evidence from adult RCTs	●			Extrapolated from findings in adults; pediatric RCTs lacking
Adjustment of dry weight (CKD 5)	No	●		Limited data from pediatric CTs; evidence from adult studies	●			Extrapolated from findings in adults; pediatric RCTs lacking
Optimization of dialysis regimen (CKD 5)	No	●		Limited data from pediatric CTs; evidence from adult studies	●			Extrapolated from findings in adults; pediatric RCTs lacking
Adequate control of hyperparathyroidism	No	●		Limited data from pediatric CTs; evidence from adult studies	●			Extrapolated from findings in adults
Calcium sparing by use of Ca^{2+}-free phosphate binder (Sevelamer)	No	●		No data from pediatric CTs; high evidence from adult RCTs	●			Extrapolated from findings in adults
Correction of anemia	No	●		Limited data from pediatric CTs; evidence from adult RCTs	●			Inconsistent effect of correction of hemoglobin level on LVH
Treatment of malnutrition and hypalbuminemia	No	●		Limited data from pediatric CTs; evidence from adult studies	●			Extrapolated from findings in adults
(Early) kidney transplantation	No	●		Evidence from pediatric and adult studies	●

[b]Evidence rating based on study design, study quality, consistency, and directness of results. No intervention was rated with a high or a very low evidence rating.

[c]Recommendations based on trade-offs between benefits and harms, quality of evidence, translation of evidence into practice in a specific setting including availability of medication, and any uncertainty about the baseline risk of the disease in the population. I, recommend; II, suggest; III, no recommendation possible.

life-style modifications (diet, exercise, weight reduction) are recommended for adults and children with CKD-related dyslipidemia [106]. In children who have received transplants, dietary interventions have lowered lipid levels at least in the short term [107]. However, the lipid-lowering effect of life-style modifications in CKD patients is small. Nonetheless, diet and physical exercise may exert beneficial effects on cardiovascular health independent of those on dyslipidemia. Dietary supplementation of fish oil effectively improved lipid profiles in a small cohort of children receiving renal replacement therapy [108].

In adult patients with nephrotic syndrome, a variety of lipid-lowering drugs has been tested, including statins, fibrates, bile acid-binding resins, and probucol. Simvastatin and lovastatin were effective and well-tolerated in a limited number of children with nephrotic syndrome treated for months to years [109,110]. Triglycerides and cholesterol were reduced by approximately 40% after 6 months of simvastatin treatment in a small cohort of younger children with steroid-resistant nephrotic syndrome in whom dietary advice had influenced lipid levels only marginally [109]. Probucol is also effective in children with nephrotic syndrome, but it caused QT prolongation in 4 of 22 patients in an uncontrolled prospective trial [111].

Because large trials for primary and secondary prevention of CVD in the general adult population provide a clear rationale for treatment of dyslipidemias, especially with statins, this treatment has also been proposed for adults with CKD. Statins effectively

lower cholesterol and triglyceride levels in CKD patients by up to 30% [106]. This is suggestive of a beneficial effect on CVD, and most studies have demonstrated significant CVD risk reduction [112–114]. However, a recent large randomized prospective trial in hemodialyzed adults with diabetic nephropathy [112] showed no significant effect of statin therapy on overall patient mortality despite significant reduction of lipid levels. A pooled analysis of 30 completed clinical trials [113] analyzing the efficacy and safety of fluvastatin in adult patients with mild to severe chronic kidney failure suggested a reduction of cardiac death and nonfatal myocardial infarction. However, treatment did not reduce the rate of coronary intervention procedures. Fluvastatin treatment in adult kidney transplant recipients also resulted in a nonsignificant reduction in CVD [114]. However, no conclusive data are available on the overall mortality risk reduction in CKD patients. Future and ongoing trials need to clarify whether statin therapy is beneficial not only to cardiac but also to overall mortality in patients with different stages of CKD and at what stage of disease the initiation of treatment should be recommended.

Statin therapy may have beneficial effects on renal disease progression, not only by their lipid-lowering effects but also by lipid-independent (pleiotropic) effects. Statins inhibit signaling molecules at several points in inflammatory pathways. Anti-inflammatory effects and improved endothelial function are thought to be partially responsible for CVD risk reduction and improved renal function [115]. Furthermore, there is also evidence for synergistic effects of statins and RAS inhibitors on prevention of kidney disease progression [116]. In younger children statins are used reluctantly, as the impacts of HMG-CoA reductase inhibitors on nutrition, growth, and pubertal maturation have not been fully elucidated yet. Therefore, the K/DOQI recommendations restrict statin treatment to children >10 years old with LDL levels of >160 mg/dL (>4.16 mmol/L) and non-HDL cholesterol of >190 mg/dL (>4.94 mmol/L) while on dialysis [106].

In adolescents statins are safe and effective [109,110,117], and several smaller studies in children with CKD have provided some evidence that statin treatment may be safely used in younger children as well. However, long-term data on efficacy in pediatric patients are still missing, and safety information on use of statins in children is not conclusive. Rhabdomyolysis and hepatic dysfunction appear to be potential side effects and occur in up to 5% of treated children [88,118].

Although bile acid resins are safe to use in children with CKD of all ages without dose adjustment, adherence to therapy is often poor due to a high incidence of adverse effects, including constipation, abdominal discomfort, flatulence, nausea, and vomiting. Moreover, application of bile acid sequestrants may interfere with cyclosporine treatment. Thus, additional information is required before statins or other lipid-lowering agents can be recommended for use in children or adolescents with CKD-related hyperlipidemia.

The evidence ratings for preventive strategies and treatments of dyslipidemia in children with CKD are summarized in Tables 59.3 and 59.4.

Table 59.3 Evidence ratings and recommendations for treatment of dyslipidemia in children with CKD.

Intervention	Existing systematic pediatric reviews	Overall evidence rating[b]		Comment	Recommendation[c]			Comment
		Moderate	Low		I	II	III	
Diet, therapeutic life-style modifications	no	●		some evidence from pediatric data evidence from adult RCTs	●			Recommended for all children with dyslipidemia [112]
Lipid-lowering treatment	no	●		limited data from pediatric CTs evidence from adult RCTs		●		Long-term effect of treatment in adults with CKD inconclusive
Statins	no	●		limited data from pediatric CTs evidence from adult RCTs		● (adolescents)	● (children)	No conclusive data on risks or benefits in children with CKD stages II–IV; recommended for CKD stage V adolescents only
Steroid withdrawal in Tx patients	no	●		evidence from CTs in pediatric Tx; evidence from adult RCTs		●		Pediatric RCT underway

Abbreviations: Tx, transplanted; RCT, randomized controlled trial; CT, clinical trial

[a]If no existing systematic review, overall evidence rating will start at moderate.

[b]Domains that are considered include study design, study quality, consistency, and directness of findings. No studies received an evidence rating of high or very low.

[c]Domains that are considered include trade-offs between benefits and harms, translation into clinical practice, uncertainty about baseline risk of population of interest, and quality of evidence. I, recommend; II, suggest; III, no recommendation possible.

Table 59.4 Summary of pediatric trials on the treatment of hypertension, CVD, and dyslipidemia in children with CKD.

Intervention	Study [reference]	Design	Conclusions and comments
Hypertension			
Reduction of salt intake, dietary intervention	Simons-Morton & Obarzanek 1997 [27]	Pediatric meta-analysis (25 observational studies, 12 intervention studies including 8 RCTs).	Studies with methodological problems included; results from observational studies and RCTs suggest that higher sodium intake is related to higher BP in children and adolescents; overall data not conclusive
Efficacy of antihypertensive agents			
β- blockers	Bachmann 1984 [119]	Prospective, open-label study, propranolol vs. chlorthalidone in 11 hypertensive CKD children treated for 4-6 wks	Propranolol effective in lowering mean BP by 22.3 mmHg
Ca²⁺ channel blockers	Silverstein et al. 1999 [120]	Retrospective, cross-over study comparing safety and efficacy of nifedipine vs.amlodipine in 24 pediatric kidney transplant patients	Nifedipine and amlodipine equally effective in lowering BP; nifedipine treatment associated with higher incidence of side effects (headache, flushing, dizziness, gingival hyperplasia; 91.7% of patients)
	Von Vigier et al. 2001 [121]	Open-label study in 43 CKD children treated with amlodipine for 16 wks.	Amlodipine effective and rather well-tolerated (BP lowering by 17/10 mmHg; side effects: edema, flushing, or headache; in 6 patients)
	Flynn et al. 2004 [122]	Randomized, double-blind, placebo-controlled study in 268 hypertensive children (25% CKD) (4-week dose response, 4-week withdrawal of either placebo or amlodipine.	Amlodipine effective in lowering BP in a dose-dependent manner
	Flynn 2005 [123]	Retrospective evaluation of amlodipine monotherapy > 6 months in 33 children (24 CKD patients)	Small study suggesting good tolerability and efficacy of amlodipine (sustained BP lowering by 8 mmHg)
ACE inhibitors	Mirkin & Newman 1985 [124]	Prospective, open-label clinical trial on efficacy and safety of captopril in 73 children treated for 3–12 months.	ACE inhibition consistently effective in lowering or normalizing BP and lowering proteinuria in children with CKD; effect on renal disease progression remains to be shown
	Callis et al. 1986 [125]	Retrospective observational study in 42 children with ESRD treated with captopril for 18–78 mos.	
	Wells et al. 2002 [126]	Prospective, randomized, double-blind, placebo-controlled multicenter trial in 110 children (50% CKD); 2-wk dose response, 2-wk either enalapril or placebo withdrawal study	
	Proesmans & Van Dyck 2004 [127]	Retrospective analysis of 10 children with CKD and Alport syndrome.

Steroid withdrawal in kidney transplant patients	Höcker *et al.* 2004 [31]	Retrospective case-control study on the safety and efficacy of steroid withdrawal in 20 renal transplant children (mean follow-up 46 mo)	Decrease of mean arterial BP SDS by 45%.
LVH, vascular alterations			
Normalization of BP	ESCAPE trial (unpublished data)	Prospective, randomized, open label study on the effect of intensified BP control on left ventricular hypertrophy and function in CKD children	Normalization of BP resulted in decrease of prevalence of left ventricular hypertrophy in children with CKD stage II-IV.
Optimization of dialysis regimen (CKD 5)	Fischbach *et al.* 2004 [30]	Prospective, single-center observational, trial on the effect of daily on-line hemodiafiltration (6 x 3 h/week) in 5 children	Intensified dialysis resulted in BP reduction, reduced size and improved function of left ventricle.
Dyslipidemia			
Diet, therapeutic life-style modification	K/DOQI 2003 [106]	K/DOQI guidelines	
	Goren *et al.* 1991 [108]	Prospective, open-label study on the effect of 8 weeks of daily oral fish oil supplementation on serum lipid levels in 16 ESRD patients (age 7–8 years).	No change of cholesterol levels, 27% decrease of triglyceride levels, improvement of atherogenic serum lipoprotein profile.
Lipid-lowering treatments			
Statins	K/DOQI 2003 [106]	K/DOQI guidelines	
	Coleman & Watson 1996 [109]	Single center observational study on the efficacy and tolerability of diet prior to and under statin treatment (mean dose 10mg/d) in 7 children with steroid resistant nephrotic syndrome, aged 1.8 to 16.3 years.	41% reduction of cholesterol, 44% reduction of triglycerides at mo 6, sustained effect at mo 12. No clinical side effects.
	Sanjad *et al.* 1997 [110]	Single center, prospective, observational study on the effect of statin treatment for 1 to 5 years in 12 infants and children with steroid resistant nephrotic syndrome.	40% reduction of cholesterol, 44% reduction of LDL cholesterol and 33% reduction of triglyceride levels. No side effects reported
	Butani 2005 [132]	Prospective open-label study on the effect of 12-month statin therapy on lipid status in 17 pediatric renal transplant recipients.	Significant decline in total cholesterol, serum triglycerides, LDL- and also HDL-cholesterol. Increase of prevalence of hypercholesterolemia from 31% pretransplant to 0% after 1 year.
	Argent *et al.* 2003 [133]	Prospective, open-label study in 9 pediatric renal transplant patients on the effect of atorvastatin.	41% reduction of cholesterol and 44% reduction of triglycerides. No adverse side affects on allograft function.
Probucol	Querfeld *et al.* 1999 [111]	Prospective, open-label, multicenter study on the effect of probucol on hyperlipidemia, proteinuria and glomerular filtration rate in 14 children for 8 to 24 weeks.	Positive effect of probucol on lipid profile (decrease of cholesterol 25%, HDL 24%, VLDL 27%, triglycerides 15%).
Steroid withdrawal in kidney transplant patients	Vidhun & Sarwal 2005 [134]	Review of 20 prospective trials on steroid free immunosuppression in children and adults (7 pediatric studies, 237 children) after renal transplantation.	Advantage on lipid profile in 3 pediatric studies.
	Sarwal *et al.* 2001 [135]	Prospective, open label study of complete steroid avoidance in 10 pediatric kidney recipients (age 5-21 years) compared to 37 matched historical controls.	No hypertension and no hypercholesterolemia in the steroid free group (significant difference vs. controls).

Life-style modification and diet are generally recommended in adults and children with dyslipidemia, irrespective of the underlying disease. In children who have undergone kidney transplantation a few studies suggest a beneficial effect of steroid-free immunosuppression on dyslipidemia.

Also, there are only a few studies on the efficacy of lipid-lowering drugs in children. There is some evidence that statins are effective in lowering serum lipid levels in children and adolescents with CKD. However, safety data in children are limited and not conclusive. To date, official treatment recommendations (K/DOQI) restrict the use of statins to adolescents with ESRD.

Conclusions

CVD is a common problem in children with CKD, starting as early as in the second decade of life. Therefore, treatment strategies aiming for CVD risk reduction are mandatory and should consider therapeutic life-style modifications (healthy diet, physical activity, maintenance of normal weight, abstinence from smoking) and correction of uremia-related risk factors. BP should be lowered below the 90th percentile using drugs controlling the RAS, proteinuria should be minimized, and renal anemia, metabolic acidosis, and mineral metabolism should be corrected. Whether correction of dyslipidemia results in improved cardiovascular and kidney survival remains to be shown.

Although there is evidence that treatment regimens established in adults are also safe and effective in children, further studies in pediatric patients with CKD are necessary to confirm these findings.

60 Bones Across Kidney Disease and Kidney Failure

Mary B. Leonard

Department of Pediatrics, The Children's Hospital of Philadelphia, and Department of Biostatistics and Epidemiology, University of Pennsylvania School of Medicine, Philadelphia, USA

Introduction

Renal osteodystrophy is a multifactorial and widespread disorder of bone metabolism in chronic kidney disease (CKD). As renal failure progresses, ensuing abnormal parathyroid hormone (PTH) secretion results in deterioration of trabecular microarchitecture, thinning of cortical bone, and increased cortical porosity [1]. Despite widespread use of phosphate binders and vitamin D therapies, hip fracture rates in young adults on dialysis are 100-fold greater than in healthy controls [2]. Significantly greater vertebral and extremity fracture rates have also been demonstrated in pediatric solid organ transplant recipients compared with healthy controls [3]: the age- and sex-adjusted hazard ratios for vertebral fractures were 61.3 (95% confidence interval [CI], 40.7–92.4) compared with over 200,000 population-based controls.

Throughout childhood and adolescence, normal bone mineral acquisition results in gender-, maturation-, and site-specific increases in bone density and dimensions. Children with CKD have multiple risk factors for impaired bone development, including abnormal mineral metabolism, secondary hyperparathyroidism, poor linear growth, delayed development, malnutrition (including vitamin D insufficiency), decreased weight-bearing activity, and immunosuppressive therapies. The impact of these threats to bone health may be immediate, resulting in fragility fractures, or delayed, due to suboptimal peak bone mass accrual. The signs and symptoms of renal bone disease seen in adults, such as subperiosteal resorption, osteosclerosis, fractures, and muscle weakness, may also complicate CKD in childhood. In addition, the effects of abnormal bone and mineral metabolism on endochondral ossification during growth result in complications in the epiphyseal region that are unique to children with CKD. These complications include linear growth failure, slipped epiphyses, and skeletal deformities resembling vitamin D deficiency rickets.

Histomorphometry of renal osteodystrophy in children

Renal osteodystrophy encompasses a heterogeneous group of disorders. The most common form is high-turnover disease due to secondary hyperparathyroidism, phosphate retention, hypocalcemia, reduced renal 1α-hydroxylation of 25(OH)-vitamin D to generate $1,25(OH)_2$-vitamin D (calcitriol), skeletal resistance to the actions of PTH, and decreased numbers of calcium-sensing receptors and vitamin D receptors in the parathyroid gland [4]. Therapies to increase serum calcium, decrease phosphate, and reduce PTH levels have resulted in decreased severity of hyperparathyroidism; however, these therapies are associated with low-turnover disease (adynamic bone disease) [5]. Table 60.1 summarizes published bone biopsy studies in children on dialysis, illustrating the greater prevalence of adynamic bone in the more recent series. Nonetheless, high-turnover bone diseases (osteitis fibrosa and mild lesions of secondary hyperparathyroidism) still frequently complicate pediatric CKD [6,7].

PTH assays and bone turnover in pediatric CKD

Numerous studies suggest that patients with end-stage renal disease (ESRD) require PTH levels well above the normal range (10–65 pg/mL) to maintain normal bone turnover. This peripheral resistance to the effects of PTH is due, in part, to downregulation of the PTH/PTHrP receptor [8]. The presence of circulating PTH fragments and the potentially antagonistic effects of the 7–84 PTH fragment may also contribute [9]. The prediction of bone turnover based on PTH levels is further complicated by the fact that the state of skeletal resistance to PTH progresses with further declines in renal function. That is, PTH levels that predict normal bone turnover in pediatric patients on dialysis are associated with high-turnover bone disease in patients in the earlier stages of CKD [10].

Table 60.1 Bone histomorphometry and PTH levels in children and adolescents on maintenance dialysis.

Study [reference], country	Year	*n*	Dialysis	Histomorphometry	PTH levels and bone turnover
Salusky [95], USA	1988	44	PD	• 39% osteitis fibrosa • 25% mild high turnover • 11% adynamic bone • 9% osteomalacia • 16% normal	• Bone formation rates correlated positively with PTH levels and negatively with bone aluminium content
Salusky [12], USA	1994	55	PD	• 50% osteitis fibrosa • 9% mild high turnover • 22% adynamic bone • 19% normal	• Serum PTH >200 pg/mL and calcium <10 mg/dL: 85% sensitive and 100% specific for identifying low-turnover disease • Serum PTH <200 pg/mL: 100% sensitive and 79% specific for identifying high-turnover disease; specificity increases to 92% using combined criteria of PTH <150 pg/mL and calcium >10 ng/dL
Yalcinkaya [7], Turkey	2000	17	PD	• 47% high turnover • 29% adynamic bone • 24% mixed turnover	• Serum PTH >200 pg/mL: 100% sensitive and 66% specific for identifying high-turnover disease • Serum PTH <200 pg/mL: 100% sensitive and 92% specific for identifying low-turnover disease
Ziolkowska [6], Poland	2000	51	PD or HD	• 24% high turnover • 27% adynamic bone • 2% osteomalacia • 10% mixed turnover • 37% normal	• In patients with normal bone turnover, 69% had PTH level of 50–150 pg/mL • Serum PTH <150 pg/mL: 100% sensitive and 33% specific for identifying low-turnover disease • Serum PTH >200 pg/mL: 75% sensitive and 95% specific for identifying high-turnover disease

Abbreivations: PD, peritoneal dialysis; HD, hemodialysis.

PTH levels discriminate moderately well between low- and high-turnover renal osteodystrophy in children and adults on dialysis. Multiple studies have been performed using intact PTH assays to diagnose high-turnover bone disorders and distinguish them from low-turnover disorders in adults [11]. The sensitivity and specificity of PTH levels in the discrimination of biopsy-proven low- and high-turnover disease have been examined in three series of children on maintenance dialysis [6,7,12]; the results are summarized in Table 60.1. The 1994 study by Salusky *et al.* suggested that combined consideration of the serum calcium and serum PTH levels improves the sensitivity and specificity of the assays [12].

PTH is a single-chain polypeptide of 84 amino acids. The studies described above were based on "intact-PTH" sandwich radioimmunometric assays. However, these assays also measure large PTH fragments, namely, 7-84 PTH [13]. These N-terminal-truncated PTH fragments may inhibit the action of PTH by blocking binding to its receptor, PTHR1, in bone cells [14,15]. In contrast, the newer-generation PTH assays only measure the 1-84 molecule [16]; however, the utility of these PTH assays has not been established. In a longitudinal study of 51 pediatric dialysis patients, the intact PTH (1-84 plus 7-84) and 1-84 PTH assay results were highly correlated ($R = 0.98$) [17]; however, there was substantial intra- and interpatient variability in the ratio of the 1-84 frag-

ment to intact PTH level. One study in adults suggested that a 1-84/7-84 PTH ratio of less than 1.0 predicted biopsy-proven low-turnover bone disease [18]. Other investigators have been unable to confirm these findings in adults [19–21]. In children, a bone biopsy study in 33 peritoneal dialysis patients demonstrated that intact PTH and 1-84 PTH levels were highly correlated ($R = 0.89$), and the bioactive 1-84 fragment did not correlate with bone formation any better than conventional intact PTH. Furthermore, the 1-84/7-84 PTH ratio did not distinguish between high- and low-turnover disease. The identification of more specific, non-invasive measures of bone turnover remains an area of active investigation.

Although the advantages of new-generation PTH assays and ratios in predicting bone turnover in children remain unproven, a recent study suggested that the 1-84/7-84 PTH ratio was positively correlated with improvements in height *Z*-scores [22]. Among 162 children and adolescents with estimated glomerular filtration rates (GFR) of less than 60 mL/min/1.73 m^2, there was no relationship between PTH concentration and change in height *Z*-score over an average interval of 1 year. However, the 1-84/7-84 PTH ratio was lower in dialyzed patients ($P = 0.003$) and in those with worsening renal function ($P < 0.05$), and there was a positive correlation between the 1-84/7-84 PTH ratio and the change in height *Z*-scores ($R = 0.2$; $P = 0.01$).

Treatment of renal osteodystrophy in children

Phosphate binders

Diminished phosphorus filtration and excretion result in hyperphosphatemia in the majority of children and adults with CKD, contributing to the progression of secondary hyperparathyroidism and renal osteodystrophy. Recent observational studies in adults have demonstrated an association between hyperphosphatemia and increased cardiovascular morbidity in adult dialysis patients [23–25]. Therefore, adequate control of serum phosphorus is a cornerstone of CKD management. Strategies to reduce serum phosphorus levels include restriction of dietary phosphorus, dialysis, and oral phosphate binders. After the recognition that aluminum hydroxide was associated with encephalopathy and osteomalacia, calcium salts emerged as the primary phosphate binder. Calcium carbonate controls phosphorus; however, its effectiveness may be limited by hypercalcemia, especially when administered with vitamin D. Calcium acetate binds approximately twice the amount of phosphorus per amount of calcium absorbed, compared with calcium carbonate [26]. Concerns regarding the potential role of calcium loading in the progression of cardiovascular calcification have resulted in increased use of noncalcium, nonaluminum phosphate binders. Of note, increased intima media thickness of the carotid arteries has been observed in children and adolescents with CKD and correlated with the mean past serum calcium–phosphorus product, the cumulative dose of calcium-based phos-

phate binders, and the time-averaged mean calcitriol dose [27]. Other studies have confirmed that the occurrence of vascular calcification in children and young adults with childhood-onset CKD was associated with the cumulative intake of calcium-containing phosphate binders, serum phosphorus levels, and the calcium–phosphorus product [28–30].

Sevelamer hydrochloride is a novel, nonaluminum, noncalcium phosphate-binding polymer. As recently reviewed by Coladonato [31], clinical trials in adults comparing sevelamer with calcium-containing phosphate binders have produced conflicting results. The open-label Treat-to-Goal study demonstrated no differences in the final calcium–phosphorus product; however, sevelamer was associated with attenuation of coronary and aortic calcification [32]. In contrast, the double-blind Calcium Acetate Renagel Evaluation trial showed that calcium acetate more effectively lowered serum phosphorus and calcium–phosphorus product than did sevelamer.

Calcium-containing phosphate binders effectively reduce serum phosphorus levels in children and are the first-line treatment in pediatric CKD [33,34]. However, calcium-containing phosphate binders are also associated with hypercalcemic episodes in children. Two randomized clinical trials comparing sevelamer and calcium-containing phosphate binders have been reported in children [35,36]. The studies are summarized in Table 60.2. Briefly, Pieper *et al.* conducted a multicenter, randomized, open-label, crossover study comparing the efficacy and safety of sevelamer versus calcium acetate in children with CKD [35]. Salusky *et al.*

Table 60.2 Phosphate binders in children and adolescents with CKD.

Study [reference], year	Study design (duration)	Interventions	Primary outcome	*n*	CKD	Results
Pieper [35], 2006	Randomized open-label, crossover trial (8 wks per arm)	Sevelamer vs. calcium acetate	Serum phosphorus	40 randomized; 18 completed the trial	11 on HD 6 on PD 1 pre-ESRD	• Equivalent reduction in serum phosphorus levels in sevelamer and control groups (−1.5 ± 1.6 vs. −1.7 ± 1.7 mg/dL) • Greater incidence of hypercalcemia (*P* < .001) with calcium acetate • Total cholesterol (−27%; *P* < 0.02) and low-density lipoprotein cholesterol (−34%; *P* < 0.005) decreased significantly with sevelamer
Salusky [35], 2005	2 × 2 factorial, randomized control trial (8 mos)	Sevelamer vs. calcium carbonate + oral doxercalciferol vs. calcitriol	Bone histology (all patients had high turnover at baseline)	42 randomized; 29 completed	PD	• Equivalent reduction in bone formation rates in sevelamer and control groups (−53 ± 11% vs. −49 ± 7%) • Serum calcium and Ca–P product increased with calcium carbonate (*P* < 0.001) • Hypercalcemic episodes more frequent with calcium carbonate (*P* < 0.01)

Abbreviations: HD, hemodialysis; PD, peritoneal dialysis.

conducted a multicenter, randomized trial comparing sevelamer and calcium carbonate in children on peritoneal dialysis with bone biopsy evidence of secondary hyperparathyroidism [36]. These two trials demonstrated that treatment with either sevelamer or calcium-containing phosphate binders resulted in equivalent control of the biochemical and/or skeletal lesions in CKD. Sevelamer, however, was associated with less hypercalcemia, thereby potentially increasing the safety of treatment with active vitamin D sterols.

Vitamin D

Impaired calcitriol synthesis is one of the major factors that contributes to the pathogenesis of renal osteodystrophy. In adults with moderate CKD, several placebo-controlled trials demonstrated that calcitriol therapy was associated with reduction in PTH levels and improvement in bone biopsy results without compromising renal function [37–39]. Early case series of daily oral calcitriol in children reported reductions in PTH levels with variable healing of skeletal lesions [40,41]. Details for these case series and the studies described below are provided in Table 60.3.

Prospective studies in adults showed that intermittent oral calcitriol was just as effective as daily dosing in reducing PTH levels and bone formation rates [42,43]. A case series of intermittent oral or intraperitoneal (i.p.) calcitriol therapy in 14 children on peritoneal dialysis [44] and a randomized clinical trial comparing intermittent oral versus i.p. calcitriol in 33 children with biopsy-proven high-turnover disease [5] demonstrated improvements in skeletal lesions. However, both studies reported that a substantial proportion of subjects on intermittent therapy developed adynamic bone.

It has been suggested that intermittent calcitriol therapy, combined with calcium-containing phosphate binders, may adversely affect chondrocyte activity in the epiphyseal growth plate, with a consequent reduction in linear growth. Schmitt *et al.* conducted a randomized study in 24 prepubertal children with CKD, comparing the effect of daily versus twice-weekly oral calcitriol therapy [45]. The degree of growth suppression and change in height Z-scores were comparable between groups; however, growth velocity was positively associated with PTH levels. Similarly, Kuizon *et al.* examined changes in height Z-scores in 16 children treated with intermittent calcitriol therapy [46]. The largest reductions in height Z-scores were seen in patients who developed adynamic bone lesions. In contrast, a retrospective cohort study of 99 children with CKD (GFR of <41 mL/min/1.32 m^2; median GFR, 22) and an overall mean change in height Z-score of +0.3 indicated that catch-up growth can occur with PTH levels in the high normal range during treatment with 1-α-calcidiol and calcium supplements [47].

In 2005, Greenbaum *et al.* reported the results of a double-blind, placebo-controlled study of the safety and efficacy of intravenous calcitriol for the treatment of secondary hyperparathyroidism in children on hemodialysis [48]. Although a greater proportion of children in the calcitriol group had substantial reductions in PTH levels compared with the placebo group, the incidences of elevated calcium–phosphorus product, hyperphosphatemia, and hypercalcemia were significantly higher in the calcitriol group.

Therapy with calcitriol is associated with hypercalcemia and hyperphosphatemia, which may limit its use and may contribute to vascular calcification. Milner *et al.* conducted a retrospective chart review of postmortem evidence of soft tissue and vascular calcification in 120 children with ESRD [49]. Soft tissue calcification was found in 72 patients (60%), and 36% had systemic calcinosis. Vitamin D therapy showed the strongest independent association with calcinosis, and the probability of calcinosis was higher in patients receiving calcitriol compared with dihydrotachysterol and vitamin D$_2$ or D$_3$.

New vitamin D analogs have been developed to minimize intestinal calcium and phosphorus absorption while suppressing PTH levels. These include 22-oxacalcitriol in Japan and 19-nor-1,25-dihydroxyvitamin D$_2$ (paracalcitol) and 1α-hydroxyvitamin D$_2$ (doxercalciferol) in the USA. Prospective comparisons against calcitriol are very limited, and the skeletal response to the new active vitamin D sterols remains to be determined. However, data in adults suggested that 19-nor-1,25-dihydroxyvitamin D$_2$ was associated with greater survival in those on hemodialysis compared with calcitriol [50]. In addition, recent studies of 1α-hydroxyvitamin D$_2$ [51] and 19-nor-1,25-dihydroxyvitamin D$_2$ [52] suggest that these agents lower PTH levels with few episodes of hypercalcemia. Finally, a recent study in 29 children suggests that oral 1α-hydroxyvitamin D$_2$ given thrice weekly is as effective as calcitriol in reducing PTH levels and improving the skeletal lesions of secondary hyperparathyroidism in children treated with peritoneal dialysis [36].

The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) clinical practice guidelines for bone metabolism and disease in children with chronic kidney disease future [53] provide multiple algorithms for calcitriol therapy, based on CKD stage, serum 25(OH)-vitamin D levels, subject weight, and serum calcium, phosphorus, and PTH levels.

Glucocorticoid-induced osteoporosis in pediatric CKD

Glucocorticoids are widely used in the treatment of kidney disease (e.g. nephrotic syndrome and renal transplantation) and impact bone formation and resorption. Glucocorticoids inhibit osteoblasts, thereby reducing bone formation [54]; the growing skeleton may be especially vulnerable to these effects. Although decreased bone mineral density (BMD) has been described in pediatric disorders requiring glucocorticoids and a population-based study reported increased fracture risk in children requiring repeated courses of glucocorticoids [55], some of the detrimental bone effects attributed to glucocorticoids may be due to the underlying inflammatory disease. For example, inflammatory cytokines that are elevated in chronic disease, such as tumor necrosis factor alpha, suppress bone formation and promote bone resorption through mechanisms similar to glucocorticoid effects [56].

Table 60.3 Vitamin D therapy in children and adolescents with CKD

Study [reference], year	Study design (duration)	Intervention(s)	Primary outcome(s)	n	CKD	Results
Chesney [40], 1978	Case series (up to 26 mos)	Daily oral calcitriol	Serum PTH	6		• Serum PTH levels decreased and lesions of rickets improved
Goodman [41], 1991	Case series (12 mos)	Daily oral calcitriol	Bone histology	33	PD	• Severe osteitis fibrosa failed to improve but lesions of mild secondary hyperparathyroidism improved
Goodman [44], 1994	Case series (12 mos)	Intermittent oral or i.p. calcitriol	Bone histology	14	PD	• Osteitis fibrosa resolved in 10 of 11 cases • Bone formation decreased in all patients • 6 patients developed adynamic bone
Salusky [5], 1998	Randomized controlled trial (12 mos)	Thrice-weekly i.p. vs. oral calcitriol	Bone histology, serum calcium and PTH	46 randomized; 33 completed	PD	• Equivalent improvements in bone histology • 33% developed adynamic bone • Serum calcium levels higher and reductions in PTH greater in subjects treated with i.p. calcitriol (both $P < 0.0001$)
Kuizon [46], 1998	Case series (24 mos)	Intermittent calcitriol over 12 mos vs. daily therapy during prior 12 mos	Growth	16 prepubertal	PD	• Height Z-scores decreased from -1.8 ± 0.32 to -2.0 ± 0.33 ($P < 0.01$) during intermittent calcitriol therapy • Greater growth deficits in children with adynamic bone after 12 mos intermittent treatment • Change in height Z-scores correlated with serum PTH ($r = 0.71$; $P < 0.01$) during intermittent calcitriol therapy
Schmitt [45], 2003	Randomized controlled trial (12 mos)	Daily vs. twice-weekly oral calcitriol	PTH and growth	24	PD	• PTH decreased significantly in both groups; magnitude of change did not differ between treatment arms • Equivalent change in height Z-scores in daily and intermittent groups (-0.18 ± 0.34 vs. -0.05 ± 0.52) • Growth velocity positively associated with PTH levels
Greenbaum [48], 2005	Randomized controlled trial (12 wks)	Thrice-weekly intravenous calcitriol vs. placebo	$\geq$30% decline in PTH from baseline	47	HD	• Greater proportion of patients in calcitriol group had two consecutive $\geq$30% decreases in PTH than placebo group (52% vs. 19%; $P = 0.03$) • Incidences of elevated Ca–P product and hypercalcemia higher in calcitriol group (both $P = 0.01$)
Salusky [36], 2005	2 × 2 factorial, randomized control trial (8 mos)	Thrice-weekly oral doxercalciferol vs. calcitriol + sevelamer vs. calcium carbonate	Bone histology (all patients had high turnover at baseline)	42 randomized; 29 completed	PD	• Doxercalciferol and calcitriol equally effective in reducing PTH levels and improving skeletal lesions of secondary hyperparathyroidism

Abbreviations: PD, peritoneal dialysis; HD, hemodialysis.

Childhood steroid-sensitive nephrotic syndrome (SSNS) provides a clinical model of chronic glucocorticoid therapy in the absence of significant persistent underlying disease activity. The nephrotic state is clinically quiescent as long as high-dose glucocorticoid therapy is continued. Unfortunately, SSNS relapses in the majority of children when the glucocorticoids are reduced, resulting in protracted, repeated courses of glucocorticoids. The standard prednisone dose for relapses is 2 mg/kg/day [57], far exceeding the 5 mg/day considered a risk factor for glucocorticoid-induced osteoporosis in adults [58]. Although SSNS relapses are

associated with transient increases in cytokines, these abnormalities promptly resolve with remission [59]. Therefore, SSNS serves as a clinical model without significant sustained systemic inflammatory involvement to examine the effects of glucocorticoids on the growing skeleton.

Leonard *et al.* examined spine and whole-body bone mineral content (BMC) by dual-energy X-ray absorptiometry (DXA) in a cross-sectional study of 60 children and adolescents with established SSNS and 195 healthy controls. The SSNS subjects had received an average of 23,000 mg of glucocorticoids over a 4-year interval. SSNS subjects had significantly decreased height ($P = 0.008$) and increased body mass index (BMI) Z-scores ($P < 0.001$), compared with controls. The prevalence of obesity in the control group was 16%, consistent with the 15.5% prevalence of obesity in children and adolescents nationwide [60]. In contrast, 38% of the subjects with SSNS were obese. Spine BMC, adjusted for bone area, age, sex, Tanner stage, and race, did not differ significantly between patients and controls ($P = 0.51$). The authors documented that obesity, in otherwise-healthy children, was associated with significant increases in whole-body, hip, and spine BMC and bone size [61,62]. Therefore, the models were adjusted for BMI Z-score. In the adjusted model, spine BMC was 4% lower in SSNS subjects than controls (ratio, 0.96; CI, 0.92–0.99; $P = 0.01$). Whole-body BMC, adjusted for height, age, sex, Tanner stage, and race, was 11% higher in SSNS subjects than controls (ratio, 1.11; CI, 1.05–1.18; $P < 0.001$); however, the addition of BMI Z-score to the model eliminated the association with the SSNS (ratio, 0.99; CI, 0.94–1.03; $P = 0.55$). These data suggested that intermittent treatment with high-dose glucocorticoids during growth was not associated with significant bone deficits relative to age, bone size, sex, and maturation in SSNS. Glucocorticoid-induced obesity was associated with increased whole-body BMC and maintenance of spine BMC.

Other studies have examined DXA BMD in SSNS. Gulati *et al.* reported that children in India with nephrotic syndrome had low BMD for age [63]. However, this study included children with steroid-resistant nephrotic syndrome and did not include controls. Furthermore, the DXA reference data used in this study have been shown to overestimate the prevalence of osteoporosis in boys [64], and 80% of the nephrotic syndrome subjects in the Gulati study were boys.

A recent study in the UK examined BMD using DXA and quantitative computed tomography (QCT) in 34 young adults with a history of childhood nephrotic syndrome. The mean height and BMI Z-scores were -0.45 ± 0.92 and 1.62 ± 1.53, respectively. DXA BMD Z-scores in the spine and hip were not reduced compared to controls. There was a significant reduction in QCT distal radial trabecular volumetric BMD (mean Z-score, -0.95 ± 0.99). However, the distal radial total volumetric BMD Z-score (0.00 ± 0.95) was normal. A more recent study using DXA hip structural analyses software [65] demonstrated that childhood SSNS was associated with significantly increased bone dimensions (periosteal circumference) and bone mass in the cortical shaft of the femur [66]. Therefore, one interpretation of these studies is that

trabecular BMD is decreased and cortical bone mass is increased (secondary to obesity) in SSNS. The fracture implications of these alterations are not known.

Finally, Bak *et al.* recently reported the results of a randomized prospective study of the effects and prophylactic role of calcium plus vitamin D treatment on bone metabolism in 40 children with SSNS [67]. All patients received prednisolone treatment (2 mg/kg/day for 4 weeks followed by alternate days at the same dose for 4 weeks). The patients were randomized into treatment (vitamin D at 400 IU plus calcium at 1 g daily) and nontreatment groups. Spine BMD was measured by DXA and decreased significantly during prednisolone therapy in both the treatment and nontreatment groups; however, the percentage decrease in BMD was significantly lower in the treatment group (4.6%) than in the nontreatment group (13.0%). Future studies are needed to determine the long-term effects of calcium and vitamin D in SSNS.

Quantitative assessment of bone status in children

Classification of bone health and relation to fracture risk

DXA is widely accepted as a quantitative measurement technique for assessing skeletal status. In elderly adults, DXA BMD is a sufficiently robust predictor of osteoporotic fractures that it can be used to define the disease. The diagnosis of osteoporosis in adults is based on a T-score, the comparison of a measured BMD result with the average BMD of young adults at the time of peak bone mass [68]. In contrast, children are assessed relative to age or body size, and the results are expressed as a Z-score. Despite the growing body of published normative data utilizing DXA in children, there are no evidence-based guidelines for the definition of osteoporosis in children. Fractures occur commonly in otherwise-healthy children, with a peak incidence during early adolescence, around the time of the pubertal growth spurt [69]. Several studies have compared the DXA BMD of normal children and adolescents with forearm fractures to that of age-matched controls without fractures. Most studies [70–74], but not all [75,76], found that mean DXA BMD was significantly lower in children with forearm fractures than in controls.

DXA has several limitations that can be pronounced in the assessment of children. These include difficulties in scan acquisition due to limitations in the bone edge detection software for children [77,78], difficulties in the interpretation of DXA results in children with variable body size, body composition, and skeletal maturation, and limited reference data [64]. A significant limitation of DXA is the reliance on measurement of areal rather than volumetric BMD. DXA provides an estimate of BMD expressed as grams per anatomical region (e.g. individual vertebrae, whole body, or hip). Dividing the BMC within the defined anatomical region (in grams) by the projected area of the bone (in square centimeters) then produces the "areal BMD" (in grams per square centimeter). This BMD is not a measure of volumetric density (grams per cubic centimeter) because it provides no information about the

depth of bone. Bones of larger width and height also tend to be thicker. Because bone thickness is not factored into DXA estimates of BMD, reliance on the areal BMD inherently underestimates the bone density of short people. Despite identical volumetric bone density, a child with smaller bones will appear to have a mineralization disorder (decreased areal BMD). This is clearly an important artifact in children with chronic diseases, such as CKD, that are associated with poor growth [79].

A recent study highlighted the importance of these limitations [80]: among children referred for enrollment in a pediatric osteoporosis protocol based on low DXA spine BMD, 80% had at least one error in interpretation of the DXA scan. Ultimately, only 26% retained the diagnosis of low BMD.

Limitations of DXA in CKD

DXA has additional important limitations in patients with CKD; these limitations were recently reviewed for children undergoing kidney transplantation [81]. Trabecular and cortical bone behave differently in response to increased PTH levels: trabecular bone mass increases and cortical bone mass decreases [1]. The two-dimensional posterior–anterior DXA projection of the spine captures the largely trabecular vertebral body, as well as the superimposed cortical spinous processes. However, the lateral projection allows one to distinguish between the vertebral body and posterior elements. A study in adults with primary hyperparathyroidism illustrated the limitations of DXA in the setting of increased PTH [82]: the mean spine BMD on the posterior–anterior projection

Table 60.4 Evidence ratings and recommendations for interventions to improve bone metabolism in children with CKD.

| Intervention | SR[a] | Evidence rating[b] | | | | Recommendation[c] | | | |
		Moderate	Low	Comment	I	II	III	Comment
Phosphate binders								
Calcium carbonate	−		●	2 case series (15 and 63 subjects)	●			Calcium carbonate reduces serum phosphorus in children with CKD
Sevelamer vs. calcium acetate	+	●		1 RCT (40 subjects enrolled, 18 completed the crossover trial)		●		Equivalent reduction in phosphorus levels and Ca–P product in the two groups; calcium acetate associated with more frequent hypercalcemic episodes
Sevelamer vs. calcium carbonate	+	●		1 RCT (42 subjects enrolled, 29 completed the trial)		●		Equivalent reduction in skeletal lesions of secondary hyperparathyroidism in the two groups; calcium carbonate associated with greater calcium, Ca–P product, and more frequent hypercalcemic episodes
Vitamin D therapy								
Oral daily calcitriol	−		●	2 case series (6 children with CKD; 33 children on PD)			●	PTH levels improved; severe osteitis fibrosis persisted or progressed in some subjects
Oral intermittent calcitriol	−		●	2 case series (14 and 16 children on PD)			●	Nearly half developed adynamic bone; may be associated with poor growth
Oral daily vs. oral intermittent calcitriol	+	●		1 RCT in 24 children on PD			●	Comparable growth velocity and decreases in PTH
Intermittent oral vs. intraperitoneal calcitriol	+	●		1 RCT in 46 children on PD		●		Equivalent improvements in bone histology (33% adynamic bone), but calcium levels were higher and reductions in PTH levels were greater in subjects treated with i.p. calcitriol
Intravenous calcitriol vs. placebo	+	●		1 RCT in 47 children on HD		●		Calcitriol reduces PTH levels but is associated with hypercalcemia and hyperphosphatemia
Intermittent oral doxercalciferol vs. calcitriol	+	●		1 RCT (42 subjects enrolled, 29 completed the trial)		●		Doxercalciferol and calcitriol equally effective in reducing PTH levels and improving skeletal lesions of secondary hyperparathyroidism

Abbreviations: RCT, randomized controlled trial; PD, peritoneal dialysis; HD, hemodialysis.

[a]Systematic review of randomized controlled trials.

[b]Evidence rating based on study design, study quality, and consistency and directness of results. No intervention was rated with a high evidence rating.

[c]Recommendations based trade-offs between benefits and harms, quality of evidence, translation of evidence into practice in a specific setting including availability of medication and any uncertainty about the baseline risk of the disease in the population. I, recommend; II, suggest; III, no recommendation possible.

was normal, but the lateral scan revealed increased BMD in the predominantly trabecular vertebral body and decreased BMD in the cortical spinous processes. Clearly, because trabecular and cortical bone behave differently in response to increased parathyroid activity and DXA does not distinguish between renal osteodystrophy effects on the two types of bone, DXA is of limited value in CKD. The conflicting data on DXA-derived measures of BMD in CKD are consistent with these limitations: DXA results have been variable, with mean BMD values that are higher than, the same as, or lower than control subjects [83–90]. Given the limitations of DXA in children with CKD, the National Kidney Foundation clinical practice guidelines do not recommend DXA scans for children with CKD [53].

QCT

QCT provides a cross-sectional image unobscured by overlying structures [91]. In contrast to DXA, this technique describes authentic volumetric BMD (in grams per cubic centimeter), accurately measures bone dimensions, and distinguishes between cortical and trabecular bone. In order to minimize radiation exposure, special high-resolution scanners have been developed for the peripheral skeleton (pQCT). Spine QCT data in CKD confirmed biopsy histomorphometric data: trabecular BMD was increased in high-turnover disease (+1.6 standard deviations) and decreased in low-turnover disease (−1.2 standard deviations), relative to age-matched controls [92].

The impact of CKD on BMD during childhood was examined using pQCT in 21 children on peritoneal dialysis [93]. Trabecular BMD was significantly higher ($P < 0.0001$) and cortical BMD was significantly lower ($P < 0.001$) in children with CKD compared with controls. In patients with adynamic bone, trabecular BMD was less than in those with high-turnover lesions ($P < 0.001$). Similarly, cortical BMD was lower in patients with high-turnover lesions than in those with low-turnover lesions ($P < 0.05$).

A recent study by Jamal *et al.* underscored the advantages of QCT versus DXA in CKD [94]. She reported that DXA in the hip and spine failed to discriminate between patients with and without fractures; in contrast, QCT measures of cortical BMD and thickness discriminated between fractures and nonfractures very well.

Summary

The management of renal osteodystrophy in children should be tailored to optimize rates of bone turnover, bone acquisition, and growth, while avoiding metabolic abnormalities associated with vascular calcifications. The evidence ratings for phosphate binders and vitamin D therapy are summarized in Table 60.4. The paucity of randomized controlled trials and the poor subject retention in some trials reflect the difficulties in conducting these multicenter studies in children with CKD. As detailed in the National Kidney Foundation K/DOQI clinical practice guidelines for bone metabolism and disease in children with chronic kidney disease

future studies [53], studies are needed to address the impact of existing therapies and new vitamin D analogs on bone health, growth, and vascular calcification in children.

61 Anemia

Susan Furth[1] & Sandra Amaral[2]

Introduction: causes of anemia in chronic kidney disease

Anemia is a common problem in children and adolescents with chronic and end-stage kidney disease. A recent cross-sectional study of 366 children and adolescents with chronic kidney disease (CKD) stages 1–5 revealed anemia, defined as any medical treatment for anemia or hemoglobin (Hb) of <12 mg/dL, in 36.6%, which varied from 31% at stage 1 to 93.3% at stages 4 and 5 CKD [1]. Similarly, in a report by the North American Pediatric Renal Transplant Cooperative Study of children with an estimated glomerular filtration rate (GFR) of <75 mL/min/1.73 m^2, 30% (of 1725) had anemia, as defined by a hematocrit of <30% [2]. Compared to adults on chronic dialysis in the USA, pediatric patients more often have mean annual Hb levels of <11 g/dL, with 54% versus 39.8% in pediatric versus adult hemodialysis (HD) patients and 69.5% versus 55.1% pediatric versus adult peritoneal dialysis patients [3]. Anemia remains a problem even after kidney transplantation. The prevalence of anemia posttransplant in one single-center study of 231 pediatric patients was 25.5% at 1 year posttransplantation [4].

A number of factors contribute to the development of anemia in children and adults with kidney disease. As kidney function declines, affected individuals experience a decrease in circulating red blood cell mass, indicated by low blood Hb concentration. The kidney plays a central role in regulating red blood cell mass through the production of erythropoietin and the regulation of plasma volume through excretion of salt and water. It has been proposed that the kidney functions as a "critmeter" by sensing oxygen tension and extracellular volume and translating a measure of plasma volume as tissue oxygen pressure in order to regulate erythropoietin production [5]. Effective circulating red blood cell mass is controlled by specialized interstitial cells in the kidney cortex that are exquisitely sensitive to small changes in tissue oxygenation. If tissue oxygenation decreases because of anemia or other causes, these specialized interstitial cells in the kidney cortex sense hypoxia and produce erythropoietin. Surface receptors on erythroid colony-forming units, the progenitors of red blood cells, bind erythropoietin, thus preventing apoptosis. If erythropoietin production is impaired in kidney disease, there is no inhibition of apoptosis and erythrocyte progenitor cells experience cell death. Also, nutritional problems during CKD and end-stage renal disease (ESRD) can lead to folate and vitamin B$_{12}$ deficiency, leading to disordered DNA synthesis, maturation arrest, and ineffective erythropoiesis. Iron deficiency can also slow synthesis of heme and globin and further impair erythropoiesis. Inflammation, another common problem in CKD, impairs both erythropoiesis and the utilization of iron in red blood cell production. Inflammatory cytokines inhibit erythropoietin production, impair the growth of red blood cell progenitors, and stimulate hepatic release of hepciden, which blocks iron absorption in the gut [5].

Definitions and guidelines

Recently in the USA, the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) published clinical practice guidelines for anemia in CKD based on an evidence-based review. In the production of the guidelines, a systematic literature review was performed of Hb thresholds for initiating therapy, Hb level therapeutic goals, iron status goals, and efficacy of adjuvants in achieving Hb goals. When the quality of evidence was considered high or moderately high, clinical practice guidelines were presented based on the evidence. When the quality of the evidence was low, very low, or missing, the workgroups presented clinical practice recommendations. For the pediatric population, clinical practice recommendations were presented. As stated by the committee, "the only evidence of sufficient strength to support evidence based guidelines are available from studies of the adult population" [6]. The K/DOQI pediatric workgroup defined anemia in a child as a reduction in Hb level to less than the fifth percentile for their age and sex, with the caveat that adjustment in normal levels should be done for children living at higher altitudes. The normative values

Table 61.1 Definitions of anemia in children with CKD.

Age group (yrs)	5th percentile Hb level (g/dL)	
	Boys	Girls
1–2	10.7	10.8
3–5	11.2	11.1
6–8	11.5	11.5
9–11	12.0	11.9
12–14	12.4	11.7
15–19	13.5	11.5

Source: Adapted from the K/DOQI recommendations [6].

for children older than 1 year of age published in the K/DOQI guidelines were adapted from data from the National Health and Nutrition Evaluation Survey III reference data [6] (Table 61.1), whereas the values for children from birth to 1 year of age were derived from the textbook *Hematology of Infancy and Childhood* [7]. The workgroup included clinical practice recommendations on evaluation of anemia in CKD (Table 61.2), target Hb range (>11 g/dL), use of erythropoiesis-stimulating agents (ESAs) and iron agents, as well as adjuvants, transfusion indications, and evaluation of persistent failure to reach or maintain intended Hb level. The conclusions of the K/DOQI pediatric workgroup on each of these topics are presented throughout this chapter.

Other national guidelines groups, including the Caring for Australians with Renal Impairment (CARI) group [8], have reviewed the issue of anemia in CKD in pediatrics. With regard to anemia and growth in children, the CARI group systematically reviewed the evidence and determined that no evidence-based recommendations were possible based on level I or II evidence in 2005. In suggestions for clinical care, they stated that there was no evidence to support that treatment of anemia improves growth in pediatric CKD cases; however, correction of anemia is indicated to improve quality of life (QoL) and cardiac performance (Table 61.3). In 2003, the European Pediatric Peritoneal Dialysis Working Group published guidelines on the management of anemia in pediatric peritoneal dialysis patients. These guidelines stated that after a thorough diagnostic workup, anemia treatment should aim for a target Hb concentration of at least 11 g/dL through administration of erythropoietin and iron preparations.

Iron should preferably be prescribed as an oral preparation, and there is no place for carnitine supplementation in the treatment of anemia in pediatric peritoneal dialysis patients (Table 61.4) [9].

Sequelae of anemia in CKD

Risk of death

Studies in adults with ESRD have consistently demonstrated reduced risk of death and hospitalization when Hb levels are ≥11 g/dL, but the upper limit of target Hb is more controversial [10–12]. In 2004, the Cochrane Renal Group performed a meta-analysis of randomized clinical trials (RCTs) to evaluate the harms and benefits of different Hb targets in adult patients with CKD; they found lower risk of all-cause mortality with Hb of <12 versus >13 g/dL (relative risk [RR], 0.84; 95% confidence interval [CI], 0.71–1.00) [13]. This Cochrane review was updated in August 2006, included 22 RCTs, and had similar results [14]. The authors indicated the need for more adequately powered and better-designed trials. In November 2006, two additional RCTs investigating optimal target Hb were published [15,16]. Drueke *et al.* randomly assigned 603 patients with estimated GFRs of 15–35 mL/min/1.73 m^2 and Hb of 11–12.5 g/dL to a target Hb of 13–15 g/dL versus Hb of 10.5–11.5 g/dL. Over 3 years, they found that early complete correction of anemia did not reduce risk of cardiovascular events in patients with CKD.

Singh *et al.* conducted an open-label trial of 1432 patients with CKD assigned to receive epoetin alfa to either a target Hb of 13.5 g/dL or Hb of 11.3 g/dL [16]. In this study, the use of target Hb of 13.5 g/dL versus 11.3 g/dL was associated with an increased risk of death, myocardial infarction, hospitalization for congestive heart failure, and stroke. In children, there is less systematic evidence concerning the risks of anemia in CKD. The NKF K/DOQI practice guidelines for anemia management were primarily based on adult studies. In the pediatric population, Warady and Ho demonstrated an association between baseline hematocrit of <33% at 30 days post-initiation of dialysis and increased risk of

Table 61.4 Anemia treatment clinical practice recommendations from K/DOQI.

Parameter	ESAs	Iron agents
Frequency of monitoring	Hb monitored monthly: target, >11 g/dL	Iron status tests every month with initial ESA treatment, then every 3 months Goals: serum ferritin >100 ng/mL, TSAT >20%; if ferritin >500 ng/mL, assess clinical status
Dosing	Determined by Hb level, target level, and observed rate of increase	Related to iron preparation chosen
Contraindications	Hypertension, vascular access occlusion, inadequate dialysis, history of seizures, or compromised nutritional status *are not* contraindications	Risk of acute adverse events: hypotension, anaphylactoid reactions
Route of administration	Determined by clinical conditions; convenience favors s.c. in non-HD and i.v. administration in HD CKD	Prefer i.v. in patient with HD CKD, i.v. or oral in for nondialysis CKD or PD CKD
Frequency	Determined by treatment stage, setting, efficacy considerations, and class of ESA; convenience favors less frequent administration, particularly in non-HD CKD	Related to selected iron preparation

Abbreviations: s.c., subcutaneous; TSAT, transferrin saturation.

prolonged hospitalization and death in incident ESRD patients less than 18 years of age from the NAPRTCS registry [17]. Using data from the US Centers for Medicare and Medicaid Services' ESRD Clinical Performance Measures Project (Oct–Dec 1999 and 2000) linked with the US Renal Data System hospitalization and mortality records, Amaral *et al.* assessed whether achieving target Hb levels of >11 g/dL in 677 adolescents on HD was associated with decreased risk of death. In this retrospective cohort study, 11.7% with Hb of <11 g/dL at study entry died compared to 5% of those with initial Hb of ≥11 g/dL ($P < 0.0001$) [18]. In a multivariate analysis, Hb of ≥11 g/dL was associated with decreased risk of death (hazard ratio [HR], 0.38; 95% CI, 0.20–0.72). When Hb was recategorized into Hb levels of <10, ≥10 to <11, ≥11 to ≤12, and >12 g/dL, risk of mortality declined as Hb level increased. At Hb levels of 11 to ≤12 g/dL versus <10 g/dL, mortality risk decreased by 70% (HR, 0.30; 95% CI, 0.19–0.74). Risk of mortality was similar for Hb levels of 11–12 g/dL and >12 g/dL. Hb of >12 g/dL remained strongly associated with decreased risk of mortality (HR, 0.20; 95% CI, 0.07–0.56) [18]. This observational study's findings are consistent with literature on adults, showing decreased mortality in ESRD patients who meet Hb targets of >11 g/dL for adolescents on HD.

There are currently no pediatric data to support an Hb target above the current target of 11 g/dL; furthermore, no pediatric study to date has weighed the cost of increased use of ESAs with the benefits of achieving a normalized Hb. Future studies in the form of RCTs are needed to assess optimal Hb levels for all adolescents with CKD and ESRD. To this end, the pediatric workgroup of the K/DOQI committee recommended the lower limit of Hb as 11 g/dL or greater, but in the opinion of the workgroup, there was insufficient evidence to recommend an upper limit of Hb. These guidelines were formulated prior to the two recent RCTs in adults, which were consistent with higher mortality with higher Hb levels,

and the FDA Black Box warning (issued in February 2007), which advised about the increased risk of death with higher Hb targets. An upper limit of 12 g/dL is reasonable in this context.

Risk of CKD progression

A number of studies have suggested that anemia may accelerate decline in kidney function through decreased oxygen delivery to tissues, accelerating ischemic changes and increasing endothelial injury. It has been proposed that hypoxia of renal tubule cells may stimulate extracellular matrix production and release of profibrotic cytokines, thereby accelerating kidney disease progression. Several clinical trials in adults have suggested that erythropoietin treatment and correction of anemia may ameliorate the progression of CKD [19]. In children, a recent prospective cohort study by Furth *et al.* demonstrated an association between anemia and accelerated progression of CKD in children, independent of GFR [20]. However, at the time of this writing, there is insufficient evidence to suggest that treatment of anemia slows progression of CKD in the pediatric population.

Anemia, QoL, and cognitive function

Anemia associated with CKD has long been associated with a negative impact on QoL. Several studies have revealed that the treatment of anemia in CKD improves QoL in adults with CKD and ESRD [21–24]. One single, blind, placebo-controlled crossover study in 11 children with ESRD showed improvement in exercise tolerance, physical performance, and health and better school attendance with correction of anemia [25]. Decreasing anemia using recombinant human erythropoietin in a multicenter pediatric study of 44 children with chronic kidney failure undergoing HD also showed marked improvement in QoL, particularly in activity levels [26]. Another cross-sectional study, by Gerson *et al.*, examined the link between QoL and anemia in a

cross-section of 116 adolescents with renal insufficiency on dialysis and post-kidney transplantation. The authors found that anemia was associated with poorer QoL [27]. By caregiver assessment, adolescents with kidney disease and anemia (defined as hematocrit of <36%) were less satisfied with their health, participated less in activities at school and with friends, and were less physically active. These findings mirrored findings of studies examining the correlation between anemia and QoL in adults with CKD.

Regarding cognitive function, one multicenter trial of subcutaneous erythropoietin showed increased Wechsler intelligence scores in 11 children with chronic kidney failure who were treated for anemia over a 12-month period [28]. In the literature on adults, several studies have demonstrated significant improvement in electrophysiological markers of cognitive function with improvement of anemia in patients with chronic and end-stage renal disease [29–34]. Further study in the pediatric population is needed.

Cardiac function

In adults, observational evidence in CKD has shown an association between anemia and left ventricular hypertrophy (LVH) [35,36]. Optimal Hb levels to prevent LVH and cardiovascular events are not clear, based on the current body of evidence [37,38]; some studies have suggested increased risk at higher Hb levels. In 1998, Besarab *et al.* halted an RCT in adults with cardiac disease on HD who were receiving Epoetin to achieve a hematocrit of 42% versus 30%. The group with a higher hematocrit experienced decreased event-free survival [39]. More recently, Volkova and Arab performed an evidence-based literature review of the relationship between Hb and/or hematocrit and mortality in dialysis patients. They included five trials and 13 observational studies. They showed either no effect or a benefit of Hb level target higher than 11 g/dL in a general dialysis population and increased mortality associated with greater Hb concentration in cardiac patients [40]. They concluded that "most observational studies supported the increased mortality associated with Hb levels less than the reference range of Hb 11–12 g/dL (110–120 g/L)"... and that "evidence of risks or benefits of Hb levels greater than 11–12 g/dL (110–120 g/L) is variable" [40].

Evidence supporting cardiac benefits associated with the treatment of anemia in children with CKD is more limited, although cardiac-related events and LV remodeling have been reported in pediatric CKD and ESRD populations, including children post-kidney transplantation [41–43]. According to the K/DOQI reviews, a single blinded crossover trial of 11 children aged 2–12 years on dialysis demonstrated an improvement in cardiac index by 6 months and significant reduction in LV mass by 12 months in those treated with ESAs [44]. Two additional observational studies of patients with severe LVH demonstrated that children with lower Hb levels had more severe LVH and lower LV compliance [45,46].

Treatment

Anemia therapy in patients with CKD requires the effective use of ESAs and iron agents to achieve and maintain target Hb levels. In

1989, recombinant human erythropoietin was first introduced to stimulate bone marrow production of red blood cells. Since then, other forms of ESAs have been developed. The term ESA refers to any agent used to enhance erythropoiesis by acting directly or indirectly on the erythropoietin receptor. Currently available ESAs include the Epoetins (Epoetin alpha and beta) and darbopoetin, the hyperglycosolated EPO analog [47]. Epoetins are short-acting and are generally dosed 1–3 times per week. Darbopoetin is long-acting and can be dosed once every 2 weeks. A summary of the clinical practice recommendations of the pediatric workgroup of the K/DOQI treatment guidelines is included in Table 61.4. There is little available evidence in the form of RCTs to assess differential efficacy between ESAs in children or adults with CKD (Tables 61.5 and 61.6). Warady *et al.* randomized 124 children on stable recombinant human erythropoietin to either continue on recombinant human erythropoietin or convert to darbopoetin. The authors detected no statistically significant difference in mean change in Hb between the two groups [48]. Thus, because there are some data in pediatrics supporting the adult findings and no data supporting differing recommendations, the current practice recommendations have been adapted from the evidence-based recommendations in adults. In general, it is recommended that Hb be monitored monthly, with closer monitoring at 1- to 2-week intervals when initiating and/or making significant changes to the ESA dose. Initial doses and dose adjustments vary widely in pediatrics. All pediatric providers are advised to carefully evaluate the individual patient's response and to adjust dosing regimens and frequency of monitoring accordingly. For short-acting ESAs administered in the dialysis population, reports suggest that peritoneal dialysis patients require approximately 225 U/kg/week compared to 300 U/kg/week for HD patients. Younger patients <1 year old require an average of 350 U/kg/week. For the nondialysis population, fewer reports are available, but doses of 150–450 U/kg/week have been used. Fewer data are available on dose requirements for long-acting ESAs (darbopoetin alfa) in either dialysis or nondialysis populations. There is a wide range of recommended dosing, 0.25–0.75 μg/kg/week, and most frequently 0.45 μg/kg/week is recommended [6]. Reports on acceptable rates of increases of Hb levels in pediatric CKD vary widely. The European Pediatric Peritoneal Dialysis workgroup recommended an increase of approximately 0.66 g/dL/month as a minimally acceptable level [9].

In children with CKD, as in adults with CKD, the most common reason for poor response to ESA therapy is iron deficiency. Iron repletion in CKD requires either intravenous (i.v.) or oral iron therapy. Current i.v. forms of iron supplementation include iron dextran, sodium ferric gluconate, and iron sucrose. There are currently no adequately powered trials comparing i.v. agents for adults or children [49]. Several studies comparing i.v. versus oral iron in adult HD and CKD patients demonstrated superior efficacy of i.v. forms of iron in repleting iron stores and minimizing ESA dosing [50–52]. RCT evidence comparing i.v. versus oral iron in adult CKD, including nondialysis, HD, and peritoneal dialysis patients, is presented in Table 61.6. In 2005, Gillespie and Wolf published a meta-analysis that combined clinical data on i.v. iron use in

Table 61.5 Pediatric studies examining efficacy of erythropoiesis stimulating agents (ESAs) in anemia of CKD and ESRD for pediatric patients.

Reference*	Type	Population	Intervention	Sample Size	Follow-up	Outcome
Sinai-Trieman et al, 1989	Prospective cohort	Transfusion-dependent PD pts	Subcutaneous (SC) recombinant human erythropoietin (rHuEpo): initial dose 150 units/kg thrice weekly	5 children, 12-18 yrs old	8 mos	All pts had increase in Hemoglobin (Hb) and reticulocyte count and none required further transfusions.
Offner et al, 1990	Prospective cohort	CAPD and CCPD	300 units/kg IV rHuEpo once weekly	14 children, 6–22 yrs old	One year	Mean Hematocrit (HCT) and retic. count increased within one month. Dosage was decreased after 3 mos to keep HCT >30%.
Campos and Garin, 1992	Prospective cohort	HD	IV rHuEpo: thrice weekly	11 children, 6 mos-20 yrs old	9 mos	HCT rose after 8 wks from 20.3% (mean) to 31.7%.
Reddingius et al, 1992	Prospective cohort	CAPD	Intraperitoneal (IP) rHuEpo: initial dose 300 units/kg/week	16 children	8 mos	Mean Hb increased. No pts required blood transfusions after initiation of therapy.
Montini et al, 1993	Prospective cohort	PD	SC rHuEPO: initial dose 25 IU/kg twice weekly	24 children	24 wks	6 pts censored, 18 remaining pts all had increased Hb.
Brandt et al, 1999	Prospective randomized study	CKD, PD and HD pts	IV or SC rHuEPO: low-dose (150 units/kg/week) vs. high-dose (450 units/kg/week) divided thrice weekly	44 children <21 yrs old: 25 pre-dialysis, 10 PD, 9 HD	12 wks or until "target" Hb was attained	82% pts reached "target" Hb by 8 wks; 95% pts in high-dose group reached target vs. 66% in low-dose group. HD pts required higher doses.
De Palo et al, 2004	Prospective cohort	HD pts previously on epoietin alfa	Darbepoetin 1.59 ± 1.19 mcg/kg/week	7 children	6 mos	Increase of >1g/dL Hb in first month. By 2nd month, dose reduced. Mean Hb at 3 mos 11.8 ± 1.4 g/dL and mean darbepoietin dose 0.51 ± 0.51 mcg/kg/week.
Geary et al, 2005	Prospective cohort	CKD with GFR <30 cc/min/1.73 m^2, HD and PD pts	Darbepoetin alfa 0.45 mcg/kg/week	23 children	28 wks	73% of pts were receiving darbepoetin less than once weekly by 12 wks and 87% by 28 wks to maintain Hb 10–12.5 g/dL.
Durkan et al, 2006	Prospective cohort	Infants with CKD <8 kg	Darbepoetin 0.5 mcg/kg/week	6 infants	20 wks	For 3 pts, mean darbepoietin dose was decreased and dosing interval increased to 3–4 wks. 3 pts required increase in weekly dose.
Warady et al, 2006	Randomized open-label, non-inferiority study	CKD with GFR <30 cc/min/1.73m^2, HD and PD pts who were receiving stable rHuEpo treatment	Subjects randomized (1:2) to either continue rHuEpo or convert to darbepoetin alfa	124 children, aged 1–18 yrs, receiving stable rHuEpo	28 wks	Adjusted mean change in Hb between baseline and evaluation period for rHuEpo vs. darbepoetin groups was not statistically different. Darbopoetin was found to be non-inferior to rHuEpo.

*References listed in reference section.[57–62]

children on HD [53]. They included nine studies that included eight cohort studies and one prospective trial with historical controls, and they showed increased Hb, ferritin, and transferrin saturation levels and reduced use of ESAs with i.v. iron use. In 2006, Warady *et al*. performed an RCT to examine the preferential route of iron administration for children. The authors prospectively randomized 35 iron-replete children <20 years old with ESRD on HD to receive either i.v. iron dextran with each dialysis session ($n = 18$) or oral iron daily ($n = 17$) for up to 16 weeks. In both groups the Hb was stable, but the i.v. iron group experienced a

Table 61.6 Erythropoiesis stimulating agents. Evidence-based recommendations.

Intervention	Systematic review	Evidence rating[a]	Comment on rating	Recommendation[b]	Comment on recommendation
rHuEpo once weekly vs. twice weekly in dialysis pts	Cochrane Review, 2005[63]: 11 RCT of 719 pts	Moderate	The duration and frequency of the studies differed and there were small nos. of participants.	There is insufficient evidence to recommend one regimen of frequency of rHuEpo dosing.	There was no significant difference between once weekly vs. twice weekly dosing. Large RCTs with longer duration and greater nos. of subjects are needed.
ESA vs. placebo in HD and PD pts	12 RCT, including one pediatric*	Moderate	The duration, dosing frequency and outcomes of the studies differed.	The current body of evidence is insufficient to recommend one ESA agent or dosing pattern and potential benefits and risk must be weighed for each patient.	ESAs are effective for reducing the requirement for blood transfusions in ESRD pts. ESRD pts on ESA therapy may have improved quality of life. Use of ESAs may be associated with increased blood pressure and lower Kt/V. It is difficult to assess the separate impact of ESAs from improved Hb and HCT.
rHuEpo in pre-dialysis pts vs. no treatment or placebo	Cochrane Review, 2005[64]: 15 trials, including 461 pts	High for reduction in anemia. Moderate for improved quality of life and exercise capacity. Low for impact on progression of CKD.	rHuEpo was shown to correct anemia and reduce need for blood transfusion. Quality of life and exercise capacity also improved in the treatment group.	rHuEpo may be used to reduce anemia for people with chronic kidney disease who do not yet require dialysis.	Further study is needed to assess whether rHuEpo use can slow the progression of CKD.
Epoetin vs. Darbopoetin (short-acting vs. long-acting ESAs)	1 RCT[65] of 522 HD and PD pts, 1 cross-over study[66] of 524 pts with CKD	Low	There is only one RCT currently published which compares darbopoetin and Epoetin in the form of RCT. This study shows no statistically significant difference between the two types of ESA. For the cross-over study, there was no control group.	There is insufficient evidence to recommend one ESA agent's use over another's.	Darbopoetin alfa was found to maintain Hb as effectively as rHuEpo but with a reduced dose frequency for up to 52 weeks in both studies.

*Data adapted from "Clinical Practice Recommendations for Adults 2.1:Hb Range" Am J Kidney Dis 2006; 47:S33-S53

Table 61.7 Iron supplements. Evidence-based recommendations for CKD, including Nondialysis, Hemodialysis and Peritoneal Dialysis[a]. *Data adapted from "Clinical Practice Recommendations for Adults 3.2: Using Iron Agents" Am J Kidney Dis 2006; 47:S58-S70.

Intervention: IV vs. PO iron	Systematic review	Evidence rating[b]	Comment on rating	Recommendation[c]	Comment on recommendation
IV iron dextran vs. oral iron[d]	3 RCTs: 2 HD pts, 1 ND pts (2 RCT included placebo arm, 1 RCT included PD)	Moderately high to high for HD pts. Moderately high for ND and PD pts.	Some inconsistencies for studies which examined ND-CKD pts. Studies in HD pts were reasonably consistent. No RCTs with PD pts only.	The preferred route of iron administration is IV in pts with HD-CKD. The route of iron administration may be either IV or PO for ND-CKD and PD-CKD pts.	Final mean Hb ranged higher 0.9-4.5 g/dL (90-450 g/dL) in IV arms vs. PO for HD pts. Mean final ESA dose was lower in IV arms in studies with HD pts. No significant difference in ESA dosing was found in nondialysis pts on IV vs PO iron.
IV iron sucrose vs. oral iron[d]	3 RCTs: ND pts				
IV iron sodium gluconate vs. oral iron[d]	1 RCT: HD pts				

[a] Nondialysis (ND), Hemodialysis (HD), Peritoneal Dialysis (PD).

[b] Evidence rating based on study design, study quality, consistency and directness of results.

[c] Recommendation based on assessment of risks and benefits, quality of evidence, translation of evidence into practice.

[d] oral iron = ferrous sulfate or iron polysaccharide.

significant increase in serum ferritin and the oral iron group did not. There was no statistically significant difference in ESA dosing detected between the two groups [54]. Thus, further study is needed to compare various methods of iron administration for children. For iron agents and iron dosing, the K/DOQI pediatric group stated goals of avoiding storage iron depletion, preventing iron-deficient erythropoiesis, and achieving and maintaining target Hb levels, as outlined in Table 61.4. Hyporesponse to ESAs and iron therapy is defined as "a significant increase in the erythropoiesis stimulating agent dose requirement to maintain a certain Hb level or a significant decrease in Hb levels at a constant erythropoiesis stimulating agent dose, or a failure to increase the Hb level to greater than 11 g/dL (110 g/L) despite an erythropoiesis stimulating agent dose equivalent to epoeitin greater than 500 IU/kg/week."

In addition to iron deficiency, there are a few readily reversible factors that contribute to ESA hyporesponsiveness. Some evidence suggests that younger children, those with hyperparathyroidism, and those with more evidence of inflammation are at increased risk of hyporesponsiveness. Although several pharmacological and nonpharmacological agents have been studied as potential adjuvants to ESA and iron treatment for CKD in children, in the opinion of the K/DOQI workgroup there is insufficient evidence to recommend the use of either L-carnitine or vitamin C in the management of anemia in children with CKD. Additionally, as in adults, androgens should not be used as an adjuvant to ESA treatment in anemic patients with CKD. Red blood cell transfusion should be used cautiously in patients with CKD because of the potential for development of sensitivity that would adversely affect future kidney transplantation. There is no evidence to suggest that a single Hb concentration justifies or requires transfusion.

In summary, anemia is a prevalent and serious problem among children with CKD. At all stages of CKD, low Hb has been associated with increased risk of hospitalization and death, more rapid decline in GFR, lower cognitive function, increased LVH, and decreased LV compliance. Guidelines for clinical management of anemia in children with CKD are primarily based on adult data. Although the majority of existing pediatric studies do support the current adult guidelines, more pediatric-based research in the form of multicentered RCTs is needed to establish valid pediatric-specific treatment goals. At this time, for children with CKD, the treatment goal for anemia management should be a target Hb of ≥ 11 g/dL and < 12 g/dL, using ESAs and iron as necessary adjuncts to achieve this target.

Management of Renal Failure/Transplants

62 Renal Transplantation

Pierre Cochat & Justine Bacchetta

Centre de Référence des Maladies Rénales Rares, & Inserm UMRS-820, Hôpital Femme mère enfant, Bron, France, Hospices Civils de Lyon & Université de Lyon, Lyon, France

Successful kidney transplantation has been shown to be associated with less disability and greater well-being compared with either in-center hemodialysis or continuous ambulatory peritoneal dialysis in adults [1]e. Despite major advances in pediatric dialysis strategies, kidney transplantation remains the treatment of choice for children with end-stage renal disease (ESRD) [2,3]e. Indications for pediatric renal transplantation include the following: 1) symptoms of uremia not responsive to conservative therapy; 2) failure to thrive due to limitations in total caloric intake; 3) delayed psychomotor development; 4) uncontrolled hypervolemia; 5) uncontrolled hyperkalemia; and 6) metabolic bone disease due to renal osteodystrophy. Preemptive transplantation should be performed whenever it is available, using either living or deceased donors. Transplantation care of pediatric patients must be provided by a multidisciplinary team of pediatric health care professionals.

In order to improve standards and results of pediatric kidney transplantation, several issues should be specifically addressed, such as patient selection, choice of study end points, standardized definitions and classification of histopathology, qualification and quantification of acute and chronic graft dysfunction, strategies for limiting the number of patients, investigation of surrogate markers, and new approaches to statistical analysis and decision making [4]. The CONSORT (Consolidated Standards of Reporting Trials) and QUOROM (Quality of Reporting of Meta-analyses) criteria should be integrated in the process of any design and analysis of further clinical trials, but randomized controlled clinical trials in pediatrics are scarce. To date, most information about kidney transplantation in children comes from experience in adults, but a substantial number of problems are specific to the pediatric age group [5]e.

Note: Throughout this chapter, reference numbers corresponding to systematic reviews and meta-analyses for adult populations are followed by a superscript "a," pediatric study references are followed by "p," combined adult and pediatric study references are followed by "c," reference numbers corresponding to randomized controlled trials (RCTs) are followed by "r," and reference numbers for literature reviews and expert opinions are followed by "e."

Epidemiology and outcomes for patient and graft

Trends in pediatric renal transplantation have been changing during the last decade [6], with remarkable improvement in the rates of acute rejection, rejection reversal, short- and long-term survival, and quality of life. In addition, 1-year graft survival has become comparable between recipients of deceased donor and living donor transplants, as well as in infants compared to other age groups. However, some problems remain, such as nonadherence in adolescents, chronic rejection, and the adverse effects of immunosuppression.

Patient and graft survival

North American and French reports from 2004 on pediatric transplant activity are summarized in Table 62.1 [7,8]. The North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) is a voluntary registry, and the French registry includes all children with ESRD. Causes of graft failure are listed in Table 62.2, and causes of death are listed in Table 62.3 [8]. Patient survival in North America is shown on Table 62.4 [8].

Short- and middle-term outcomes

From most recent series in children, 1-, 3-, and 5-year graft survival rates are 91–95%, 83–87%, and 80–85% for living donor recipients and 83–92%, 71–75%, and 65–74% for deceased donor recipients, respectively [8,9]. Current transplantation strategies have brought the short-term graft survival of deceased donor transplantation very close to that of living donor transplantation. Even in two series of 68 and 45 high-risk infant recipients 15 kg or smaller, graft survival was excellent, with 92% at 1 year and 85% at 5 and

Table 62.1 Summary of the North American (2005) and French (2004) reports.

Patient characteristic	% of patients with indicated characteristic	
	France (90 patients)[a]	North America (8435 patients)[b]
Primary diagnosis		
Glomerulonephritis	25.6	24.8
Malformation	25.6	34.1
Inherited renal disease	16.7	13.5
Chronic tubulo-interstitial nephritis	18.8	7.0
Vascular disease	2.2	4.4
Other/unknown	11.1	16.2
Recipient age (years)		
0–2	6.2	5.3
2–10	43.2	35.6
11–15	46.9	31.3
>16	3.7	23.7
Recipient gender		
Male	51.9	59.4
Female	48.1	40.6
No. of transplant		
Primary transplant	95.1	82.3
Repeat transplant	4.9	17.7
Preemptive transplantation	22.0	24.6
Type of donor		
Living	19.8	52.0
Deceased	80.2	48.0
Donor (cadaver) age (years)		
0–2	0	1.6
2–10	19.8	20.0
11–15	37.0	15.6
16–29	22.2	30.0
>30	21.0	32.8
Graft survival (years)		
1	92.8 (LD + DD)	94.8 (LD), 91.7 (DD)
5	82.9 (LD + DD)	85.0 (LD), 74.2 (DD)

Abbreviations: LD, living donor; DD, deceased donor.
[a]: annual report
[b]: cumulative report

10 years in one series [10] and 100% at 2 years and 89.6% at 8 years in the other series [11].

Long-term data

The current overall half-life of kidney transplants is 19–20 years [12], but there have been few long-term studies in children. Offner *et al.* reported a 25-year actuarial survival of 81% for patients and 31% for the first graft, with best results with a living donor, preemptive transplant, and with immunosuppression using cyclosporine A [13].

Table 62.2 Causes of graft failure among pediatric kidney transplant recipients in North America[a].

Cause of graft failure	% of all graft failures
Chronic rejection	33.6
Acute rejection	13.1
Vascular thrombosis	10.6
Death with functioning graft	9.2
Recurrence of primary disease	6.9
Patient discontinued medication	4.4
Primary non function	2.2
Bacterial or viral infection	1.8
Accelerated acute rejection	1.7
Other technical	1.3
Malignancy	1.2
Hyperacute rejection	0.7
Renal artery stenosis	0.6
Cyclosporine toxicity	0.4
de novo kidney disease	0.4
Other/unknown	11.9

[a] In the NAPRTCS 2005 report [8], a total of 2414 graft failures among 9243 transplants (26.1%) were reported.

Table 62.3 Causes of death among pediatric kidney transplant recipients in North America.

Cause of death	% of all deaths
Cardiopulmonary	15.4
Bacterial infection	12.9
Cancer or malignancy	11.1
Viral infection	8.5
Other infection	7.9
Hemorrhage	6.7
Dialysis-related complication	2.8
Disease recurrence	1.6
Other	24.4
Unknown	8.7

[a] In the NAPRTCS 2005 report [8], a total of 495 deaths among 8420 patients have been reported.

Table 62.4 Three-year kidney transplant patient survival in North America.

Recipient age (years)	% Survival at 3 years (mean ± SE)	
	Living donor (n = 4801)	Cadaver donor (n = 4427)
0–1	91.90 ± 1.54	81.30 ± 4.00
2–5	96.90 ± 0.70	91.70 ± 1.27
6–12	97.60 ± 0.42	96.10 ± 0.56
>12	97.10 ± 0.43	97.50 ± 0.55
All ages	96.80 ± 0.26	95.90 ± 0.39

Estimation of graft function

As well as patient and graft survival, pediatric renal transplant outcomes can be evaluated using surrogate markers, such as glomerular filtration rate (GFR) and kidney biopsy. GFR closely correlates with disease progression and interstitial fibrosis, but the ideal test for GFR assessment remains to be determined. In transplant patients, GFR is most commonly estimated using inulin clearance, [125I]iothalamate, EDTA-51Cr, and cystatin-C [14]. In addition, both surveillance and clinically indicated kidney biopsies provide relevant information for the care of children with transplants and can be performed with minimal risk. In the NAPRTCS experience of 212 biopsies from 21 centers, 9 (4.2%) biopsy-related adverse events were reported (gross hematuria in 6, perinephric hematoma in 1, and intraperitoneal graft bleeding requiring transfusions and surgical exploration in 2) [15].

Other outcomes of pediatric renal transplant

Organ transplantation has been shown to produce improvements in physical functioning, mental health and cognitive status, social functioning, and overall quality of life perceptions [16]c. Compared to other renal replacement therapies in adults, successful renal transplantation results in less disability and greater well-being [1]. In addition, a randomized trial showed that exercise training after kidney transplantation resulted in higher levels of measured physical functioning (with measurement of peak oxygen uptake and isokinetic muscle testing for muscle strength) and self-reported physical functioning (via the SF-36 Health Status Questionnaire); however, exercise alone did not affect body composition as assessed by dual-energy X-ray absorptiometry [17]r.

Growth is a major issue in children posttransplant. Several studies have evaluated the safety and efficacy of recombinant human growth hormone (rhGH) after pediatric renal transplantation, with a small number of placebo-controlled randomized trials published. One showed a significant improvement in height velocity without any acceleration in bone maturation, increase in acute rejection rate, or change in GFR [18]r. In an open-label randomized crossover multicenter trial (rhGH vs. no rhGH), growth velocity was significantly increased (7.7 cm versus 4.6 cm during the first year of treatment), although an increased risk of rejection was reported in patients with a previous history of more than one acute rejection episode [19]r. In contrast, another study with comparable design found no significant change in the incidence of acute rejection [20]r. Most of these trials were small and gave conflicting results, particularly for final height. The largest multicenter experience is from the NAPRTCS (randomized controlled study of 68 children), which concluded that rhGH is safe and effective in relation to growth velocity without an associated increase in adverse events, including rejection episodes [21]r. Regardless of their treatment status (chronic renal insufficiency, maintenance dialysis, or posttransplant), the use of rhGH is recommended at a dose of 1.4 mg/m^2 per day (0.05 mg/kg/day), which provides a significant increase in growth velocity at least for the first 2 years of treatment [20,22]. Regarding bone structure, rhGH has been shown to maintain bone mass but is unable to increase bone for-

mation rate [23]. The use of oral alfacalcidol (0.25 μg/day) in children with low bone mineral density (BMD) as measured by dual-energy X-ray absorptiometry seemed to be safe and efficient, as BMD increased from –2.1 to –0.6 g/cm^2 ($P < 0.001$) in a RCT of 30 children [24]r.

These favorable results for growth and nutrition in pediatric kidney transplant patients were in part independent of rhGH and due to other interventions, such as volunteer bias, steroid-sparing regiment, optimization of protein and energy intake, and correction of metabolic acidosis.

Donor and recipient factors affecting outcome

Donor factors

Living kidney donation is an important source of organs for children with ESRD, and there has been a major trend to laparoscopic donor nephrectomy during the last decade. There is limited RCT evidence supporting this practice, but it is likely to become the standard method for donor nephrectomy due to greater donor satisfaction, less morbidity, and equivalent graft outcome [25,26].

Due to organ shortage, kidneys from non-heart-beating donors have been used increasingly in selected centers during the last decade. From a case series in adults (72 non-heart-beating donors vs. 192 heart-beating donors), the 5-year survival was 73% and 65%, respectively (not statistically significant), suggesting that kidneys from non-heart-beating donors are a useful source of organs for transplantation [27]. The current experience with non-heart-beating donors in pediatric recipients is very limited, but such donors may be considered in the near future for pediatric recipients.

Recipient factors

The use of kidney-protecting agents to prevent acute tubular necrosis has been investigated in adults and was summarized in a large literature review [28]e that concluded that despite the large number of potentially beneficial drugs (frusemide, dopamine, theophylline, mannitol, β2-adrenergic receptor agonists, cardiac glycosides, natriuretic peptides, prostaglandins, and nitric oxide), volume loading and maintenance of renal perfusion pressure with pressor agents (catecholamines) appear to be the only reliable protectors of kidney function in critically ill patients with ischemic injury to the tubule. High-dose calcium antagonists may have a benefit following kidney transplantation in adults [29,30].

Evidence for efficacy of primary immunosuppression regimens for both induction and maintenance

Induction therapy

Induction therapy is used for prophylaxis against acute rejection in kidney transplant recipients. A systematic review of RCTs found that interleukin-2 receptor antagonists were as effective as other antibody therapies but provided significant fewer side effects; there

was no apparent difference between basiliximab and daclizumab [31].

In a multicenter randomized trial in children, OKT3 was compared to intravenous cyclosporine A. Maintenance immunosuppression included oral cyclosporine A (an oil-based preparation and a microemulsion were randomized, 1:1), methylprednisolone–prednisone, and either azathioprine or mycophenolate mofetil [32][r]. Graft failure after 4 years appeared to be more frequent with OKT3, but results were not significant (27% vs. 19%; $P = 0.15$), and the incidence of acute rejection was not improved by OKT3 induction therapy compared with intravenous cyclosporine A induction.

Trials of induction therapy are associated with different concomitant medications, so that recommendations for pediatric use may be questionable. Generally, the use of OKT3 is now limited to patients with steroid-resistant acute rejection. Induction therapy with basiliximab or daclizumab is still under investigation in the pediatric population and may help in steroid and calcineurin inhibitor sparing. Available data about induction therapies in pediatric renal transplantation are summarized in Table 62.7, [32–41].

Maintenance immunosuppression

Most standard protocols in current use include three drugs from different pharmacological groups, each directed to a site in the T-cell activation and proliferation cascade: a calcineurin inhibitor (cyclosporine A or tacrolimus), an antiproliferative agent (mycophenolate mofetil or azathioprine), and steroids (prednisolone or prednisone). It is still unclear whether new regimens are more specific or simply provide more adequate immunosuppression.

When used as primary immunosuppression in adults, tacrolimus is superior to cyclosporine A microemulsion for both graft function and graft survival, as shown in an RCT with a 2-year follow-up that aimed at blood level targets of 10–20 and 5–15 ng/mL for tacrolimus and 100–400 and 100–200 ng/mL for cyclosporine A during months 0–3 and 4–6, respectively [42]. Such conclusions have been confirmed by systematic reviews, but the rates of posttransplant diabetes and neurological and gastrointestinal side effects are increased with tacrolimus [43]. From the same review, there was insufficient information to assess the cost and quality of life of tacrolimus versus cyclosporine A. A randomized multicenter trial in children that compared tacrolimus and cyclosporine A microemulsion found a lower incidence of acute rejection (36.9 vs. 59.1%, respectively; $P = 0.003$) and a lower incidence of steroid-resistant acute rejection episodes (7.8 vs. 25.8%, respectively; $P = 0.001$) with tacrolimus. At 1 year, patient survival was similar (96.1% vs. 96.6%), and the mean GFR (estimated using the Schwartz formula) was significantly higher in the tacrolimus group (62 ± 20 vs. 56 ± 21 mL/min/1.73 m^2) [44][r]. At 4 years, patient survival was similar but graft survival and renal function were significantly better in the tacrolimus group [45][r]. There was no difference in the incidence of serious adverse events (posttransplant lymphoproliferative disease [PTLD], life-threatening infections, etc.).

The use of tacrolimus in children may be associated with some specific problems (gastrointestinal disturbances, food allergy, incidence of PTLD, diabetes, or incidence of BK virus nephropathy), and these have not been investigated sufficiently in this age group. The use of calcineurin inhibitors could therefore be based on cyclosporine A initially with a later switch to tacrolimus using lower trough blood concentrations (5–10 ng/mL instead of 10–20 ng/mL). Transplant recipients could be switched from cyclosporine A to tacrolimus in those at higher risk for chronic renal allograft failure. In a RCT of 186 adult patients, conversion resulted in improved renal function and lipid profiles and significantly fewer cardiovascular events, with no differences in the incidence of acute rejection or new-onset hyperglycemia [46]. In children, there have been no RCTs evaluating treatment conversion from cyclosporine A to tacrolimus.

The experience with sirolimus is still limited in children, and most information has come from trials in adult recipients [47][a]. In a long-term RCT of tacrolimus–sirolimus (group A) versus tacrolimus–mycophenolate mofetil (group B) versus cyclosporine A–sirolimus (group C), the 3-year interim analysis showed the following: 1) patient and graft survival were not significantly different; 2) group B had a lower rate of biopsy-proven acute rejection episodes (10, vs. 26% in group A and 20% in group C); 3) there was a trend for better GFR in groups A (72.8 ± 4.3 mL/min) and B (721.1 ± 4.1 mL/min) vs. group C (61.8 ± 3.8 mL/min); and 4) there was less *de novo* development of posttransplant diabetes mellitus and lipid disorders in group B compared to group A and group C. A combination of tacrolimus and mycophenolate mofetil seemed, therefore, superior to other combinations, including sirolimus [48][r]. Everolimus was also compared to mycophenolate mofetil in a 3-year randomized, multicenter study, with comparable efficacy but more adverse events with everolimus [49][r].

Because maintenance therapy with calcineurin inhibitors is responsible for some graft nephrotoxicity, various calcineurin inhibitor-sparing schedules have been proposed. The use of sirolimus maintenance therapy instead of cyclosporine A may be an option [50][r], but withdrawal of cyclosporine A from a mycophenolate mofetil-containing regimen results in an increased risk of acute rejection and graft loss despite better 1- and 5-year posttransplant GFR [51][r].

The question of steroid withdrawal is very relevant to children because of the growth, bone, and cosmetic complications of long-term steroid use. A meta-analysis of six trials (four with cyclosporine A and two with tacrolimus, all with initiation of steroid withdrawal at 3–6 months posttransplantation) in both adult and pediatric patients on triple therapy with a calcineurin inhibitor and mycophenolate mofetil showed a low but significant risk of acute rejection after steroid withdrawal (relative risk [RR], 2.28; 95% confidence interval [CI], 1.65–3.16). However, the risk of subsequent early graft failure was not increased (RR, 0.73; CI, 0.42–1.25) in either the short- or medium-term follow-up [52][a,c]. Further reports have been published, including a randomized trial comparing a combination of daclizumab, tacrolimus, and mycophenolate

mofetil (group A, $n = 260$) versus tacrolimus, mycophenolate mofetil, and steroids (group B, $n = 278$) at 6 months posttransplant [53][a]; 88.8% of patients in group A remained free from steroids, the incidences of biopsy-proven acute rejection (16.5% in both groups) and renal function (median serum creatinine of 125 µmol/L [1.39 mg/dL] in group A vs. 131 [1.46 mg/dL] in group B) were comparable, and the overall safety profile was similar in both groups. In group A, the incidence of new-onset insulin-dependent diabetes mellitus was significantly reduced (5.4% vs. 0.4%), and the mean total cholesterol concentration was lower. A comparable study aimed at avoiding steroids has been designed recently for the pediatric population and is currently under way. In a randomized study of 27 prepubertal patients, deflazacort was shown to be superior to methylprednisolone for the outcomes of height loss, bone loss, fat accumulation, and lipoprotein profile [54][r]. However, deflazacort is not widely available, and confirmatory studies are needed before deflazacort can be recommended as the steroid of choice in children.

Available data about maintenance therapy in pediatric renal transplantation are summarized in Table 62.7, [44,45,55–80] .

Evidence for efficacy of treatment of acute rejection

The evidence base for the treatment of acute rejection in children is very limited, so that it is not discussed further in this chapter.

Epidemiology, outcomes, and management of chronic rejection and allograft nephropathy

Chronic rejection is responsible for one-third of all graft failure in North America [8] (Table 62.2). There has been no pediatric study on the effects of fish oil supplementation on kidney transplantation, but there have been several RCTs in adults. It has been concluded that there is no significant change in either 1-year rejection rate (RR, 0.91; CI, 0.74–1.10) or overall graft survival (RR, 1.00; CI, 0.96–1.05); there was only a slight benefit on triglyceride levels [81][a].

Epidemiology, outcomes, and management of infectious diseases

Cytomegalovirus

Cytomegalovirus (CMV) infection is associated with substantial morbidity and mortality in solid organ transplant recipients, mainly during the first 6 months after transplantation. Antiviral drugs against CMV include acyclovir, ganciclovir, valacyclovir, and valganciclovir. Compared to placebo or no therapy, both universal prophylaxis (odds ratio [OR], 0.20; CI, 0.13–0.31) and preemptive strategies (OR, 0.28; CI, 0.11–0.69) reduce CMV organ disease

in solid organ transplant recipients [82][a]. In kidney transplant recipients, prophylactic treatment using acyclovir and/or ganciclovir in 100 patients would avoid 18 patients developing CMV disease and 19 developing CMV infection [83,84][c]. Oral versus intravenous preemptive treatment showed no significant difference for the outcomes of CMV disease or all-cause mortality [84][c]. The risk of acute rejection is reduced by both preemptive and prophylactic treatment [82][a,c], and there is no significant difference in the relative effects of either treatment [84][a,c]. All-cause mortality is comparable between preemptive treatment and prophylaxis, but confidence intervals are wide, and head-to-head trials are required to determine the relative benefits and harms of preemptive and prophylaxis therapy [84][a,c]. The benefit of prophylactic strategies has been reported in high-risk organ transplant recipients (i.e. donors with positive CMV serostatus and recipients with negative CMV serostatus with or without antibody induction) in reducing CMV organ disease [82][a]. However, two Cochrane reviews did not find any difference in benefit between high-risk patients (i.e. CMV-positive recipients and CMV-negative recipients of CMV-positive organ donors) and other patients [83,84][a,c]. In the Cochrane meta-analysis, ganciclovir was more effective than acyclovir in preventing CMV disease (RR, 0.37; 95% CI, 0.23–0.60); valganciclovir and intravenous ganciclovir were as effective as oral ganciclovir [83][a]. Overall, there is a much stronger evidence base for routine use than preemptive use of antiviral medications. There are considerably more and larger trials, and some important outcomes have been demonstrated for routine use—reduction in graft loss and all-cause mortality—which have not been shown in preemptive trials. Also, benefit has been shown in all donor groups, except in the uncommon scenario of a CMV-negative recipient of CMV-negative donor, in which the risk is very low.

Many meta-analyses and RCTs have included transplantations of all organs and all recipient ages, which limits conclusions for pediatric renal transplantation, and the specific profile of serological status in children is rarely considered separately. In addition, several studies did not provide information to discriminate between CMV organ disease and CMV syndrome or data about the timing of CMV organ disease.

Other viruses

Most PTLD cases are associated with Epstein–Barr virus (EBV) infection. EBV infection is a major issue in pediatric solid organ transplantation, because many recipients are EBV negative and many donors are EBV positive, resulting in a high risk of primary infection (and a relatively low risk of reactivation compared with adults). The risk of incidence of PTLD is significantly higher in pediatric kidney recipients, 1.2–10.1%, compared to 1.0–2.3% in adults [85][e]. PTLD is related to the total burden of immunosuppression. Its treatment includes a reduction in immunosuppression, anti-B-cell antibodies (rituximab), and sometimes chemotherapy. There is no evidence-based information on the most appropriate management, including prophylactic, preemptive, versus curative treatments for children or adults [85][e].

BK virus represents a growing cause of chronic graft dysfunction and graft loss. In the general healthy adult population, seroprevalence is 65–90%. In adults after transplantation, 30–60% of patients develop viruria, 10–20% viremia, and 5–10% BK-associated nephropathy [86][r]. Up to 50% of patients with BK-associated nephropathy have premature graft loss. A retrospective study in 100 children found a 70% seroprevalence for BK virus before transplantation, a 26% prevalence for viruria, 5% for viremia, and 3% for BK virus-associated nephropathy [87]. Recipient seronegativity is a risk factor for BK virus-associated nephropathy. When BK virus-associated nephropathy occurs, viremia and viruria findings are positive [88]. There is no consensus for treatment of BK virus infection; a decrease in immunosuppression, particularly calcineurin inhibitors, is often proposed. Small series have evaluated cidofovir, leflunomide, intravenous immunoglobulins, and fluoroquinolones; however, further evaluation with prospective controlled studies is warranted [89][e].

Despite their frequency in transplant patients, there is no available evidence on the treatment of warts. A systematic review of studies in nonimmunocompromised patients (only 2 trials are classified as high-quality among 50 trials) has shown that topical treatments containing salicylic acid have a therapeutic effect and there is some evidence for the efficacy of dinitrochlorobenzene; less evidence was found for the efficacy of other treatments, including cryotherapy [90][a,c].

Fungal infections

Invasive fungal infections may cause morbidity and mortality in solid organ transplant recipients. However, unlike liver transplant recipients, neither fluconazole nor clotrimazole significantly reduce invasive fungal infection in renal transplant recipients [91][c].

Available data about CMV, EBV, and antifungal therapy in pediatric renal transplantation are summarized in Table 62.7, [92–99].

Epidemiology, outcomes, and management of disease recurrence

The posttransplant recurrence rates of primary diseases are listed in Table 62.5. Recurrence of the primary disease is responsible for about 7% of all graft failures in North America [8] (Table 62.2). This proportion has increased during the last decade, relative to other causes of graft failure, because of improvements in treatment for acute rejection during the first months posttransplantation. Because recurrence of individual diseases is relatively infrequent, management is mainly based on information obtained from nonrandomized and uncontrolled case series.

Steroid-resistant nephrotic syndrome

Steroid-resistant nephrotic syndrome is the cause of 10–12% of ESRD in children and is one of the most challenging recurrent diseases to treat posttransplantation. It recurs in about

Table 62.5 Recurrence rates of primary diseases in children and adults after renal transplantation.

Primary disease	Recurrence rate (%)
Steroid-resistant nephrotic syndrome (FSGS)	20–65
FSGS in case of retransplantation	80–100
IgA nephropathy (Berger disease and HSP)	50–60
MPGN type 1	20–80
MPGN type 2	80–100
Atypical HUS	30–80
Systemic lupus erythematosus	30–40
Primary hyperoxaluria type 1	90–100

Abbreviation: HSP, Henoch-Schönlein purpura.
FSGS: Focal segmental glomerulosclerosis
MPGN: membrano-proliferative glomerulonephritis

one-third of recipients with primary focal segmental glomerulosclerosis (FSGS), and graft loss occurs in about one-third. The overall graft survival is 50–55% 6 years after transplantation (Table 62.5) [100,101][e]. The presence of a circulating factor(s) and also T-cell activation have been implicated, so that recurrence usually occurs immediately after transplantation. Risk factors for recurrence have been reported [100,101][e] and include the following: aggressive clinical course of primary FSGS with a time interval from diagnosis to ESRD of less than 3 years, age at onset of nephrotic syndrome between 6 and 15 years, histopathology of the native kidney consistent with diffuse mesangial proliferation, Caucasian background, and first graft failure after recurrence. The influence of genetic factors (e.g. podocin mutation) is still under investigation [100,101][e]. There is no association between duration of dialysis prior to transplantation, HLA-DR matching, type of donor, or pretransplant nephrectomy and risk of recurrence [100,101][e]. Several case series reported the efficacy of either high-dose cyclosporine A (oral dose to maintain a trough level of 200–300 ng/mL) and plasmapheresis–protein adsorption (5–30 sessions) with or without cyclophosphamide instead of azathioprine or mycophenolate mofetil [100,101].[e] There is no clear benefit of protein adsorption over plasmapheresis, and cyclosporine A seems to be more effective than tacrolimus. There is no evidence on the optimal duration of these two therapeutic options, and no randomized trial has been published. Nevertheless, on the basis of the current available literature, the use of early plasmapheresis (1–3 days following the onset of posttransplant nephrotic syndrome) may be recommended for renal transplant patients with recurrent steroid-resistant nephrotic syndrome [101–103][e]. The use of preemptive plasmapheresis in high-risk patients (rapid progression to renal failure or previous recurrence posttransplantation) was evaluated in a prospective nonrandomized study. Ten adult patients underwent a course of eight plasmaphereses in the perioperative period. Seven patients were free of recurrence (238–1258 days of follow-up) [104]. A retrospective pediatric study found similar results [105]. However, larger randomized and controlled studies are warranted for the evaluation of preemptive plasmapheresis. The

use of living donors is debated, because there has been no graft survival benefit demonstrated in large series from collaborative studies [106], whereas it may benefit individual patients, provided that it is associated with pretransplantation cyclosporine A therapy [101]e.

Other recurrent diseases

The risk of histopathologic recurrence of immunoglobulin A (IgA) nephropathy (Berger disease and Henoch-Schönlein purpura) is 50–60% and seems to be increased for living donor transplantation (Table 62.5), but graft loss from recurrence is below 5% and no specific treatment has been investigated [101]e.

The risk of histopathologic recurrence of membrano-proliferative glomerulonephritis (MPGN) type 1 is 20–80% in a first graft (Table 62.6), often leading to progressive graft failure and recurrence in further grafts. Graft survival after recurrence of proteinuria averages 40 months, and no immunological intervention, including plasmapheresis, has been successful [101]e. MPGN type 2 has a very high risk of histopathologic recurrence (Table 62.5) but a relatively low rate of graft loss due to recurrence; no treatment can reasonably be recommended.

Atypical hemolytic uremic syndrome (HUS) is associated with variable risk of recurrence according to its pathophysiology, but time to recurrence is usually less than 1 month (Table 62.5). There is a 40–80% risk of recurrence and subsequent graft failure in patients with abnormal complement alternative pathway proteins (factor H deficiency, presence of anti-factor H autoantibodies, factor I deficiency, or abnormal MCP/CD46 ratio) [101]e; the management of such a recurrence is rather challenging, and combined liver (factor H source) and kidney (target organ) transplantation has been attempted with variable outcomes. In the absence of available protein substitution (with factor H-enriched plasma fraction, recombinant factor H, end-pathway complement inhibitors, liver transplantation, or gene therapy), retransplantation of such patients should be avoided. In contrast, the management of ESRD patients with HUS due to von Willebrand factor deficiency (ADAMTS 13) is easier in case of recurrence, because fresh frozen plasma (10 mL/kg every 2–4 weeks) is able to provide enough replacement enzyme protein, and recombinant ADAMTS 13 will be available in the future. The use of cyclosporine A has no effect on outcome or HUS recurrence, but some immunological events, such as CMV infec-tion, allograft rejection, and bacterial infection, may trigger HUS recurrence [101]e.

Available data about disease recurrence in pediatric renal transplantation are summarized in Table 62.7 [101,105,107–113].

Epidemiology, outcomes, and management of malignancy

Due to ongoing evolution of immunosuppression strategies, both long-term graft survival and risk of malignancy have increased, without any improvements in overall patient survival [8]. Changes in risks of malignancies are shown in Table 62.6.

Evidence for effects of treatment adherence on graft outcome

Adherence to medical regimens after kidney transplantation is a major issue regarding the functional status of the transplanted organ [114]. Nonadherence with medication, medical procedures, and/or diet is one of the main causes of chronic allograft nephropathy, graft loss, and mortality. The risk of nonadherence is increased by distance to the treatment center, economic difficulties, degree of social support, psychological distress, family functioning, and physiological side effects of drugs. The transition from childhood to adulthood may be challenging for patients with kidney transplants because of low self-esteem, social adjustment difficulties, depression, and behavioral disturbances. However, independent of the immunological rationale and favorable results associated with treatment adherence, there is no available evidence to correlate adherence and graft and patient outcomes.

Conclusions

Pediatric kidney transplantation is characterized by specific primary diseases (urinary tract malformations, renal dysplasia or hypoplasia, focal segmental glomerular diseases, inherited renal diseases, etc.) associated with specific problems posttransplantation. In addition, kidney transplantation requires special surgical and postoperative care in small children and special education for adolescents due to adherence issues. Moreover, due to specific serological and pharmacokinetic profiles, there are many differences between adult and pediatric kidney transplantation. Table 62.8 summarizes the evidence rating and recommendations for interventions in pediatric renal transplant recipients. High evidence data in pediatric renal transplantation are missing (e.g. use of mTor inhibitors or corticoid withdrawal, management of acute rejection, CMV prophylaxis and recurrence, etc.). We are still far from evidence-based recommendations for all aspects of managing the pediatric kidney transplant recipient, and so many further trials are required.

Table 62.6 Posttransplant malignancy rates in North America.

Time period (no. of transplants during period)	% Malignancy rate (mean ± SE) at:	
	1 year	3 years
1987–1991 (2689)	0.62 ± 0.16	0.96 ± 0.21
1992–1995 (2530)	1.30 ± 0.24	2.00 ± 0.30
1996–2004 (4024)	2.00 ± 0.25	3.14 ± 0.34

a In the NAPRTCS 2005 report [8], a total of 232 malignancies (179 lymphoproliferative diseases and 43 nonlymphoproliferative neoplasias) were reported.

Table 62.7 Summary of pediatric studies in renal transplantation[a].

Therapy group and intervention	Reference(s)	Design and results, including adverse effects	Conclusions and comments
Induction therapy			
Antibody therapy: OKT-3	Benfield 2005 [32]	Multicenter RCT, open label, parallel groups 287 patients, 147 OKT3, 140 iv cyclosporine	The incidence of acute rejection and graft failure in pediatric patients is not improved by OKT3 induction therapy relative to cyclosporine induction.
		OKT3: 2.5 mg/kg (for <30 kg body weight) or 5 mg/kg (>30 kg). First perioperative dose, then daily i.v. infusion; 10 doses	
		Cyclosporine: 165 mg/m^2 (<6 yrs) or 4.5 mg/kg (>6 yrs), intraoperatively, as continuous infusion over 24-h period; i.v. administration for first 3 days after transplantation.	OKT3 graft survival is inferior in children under 6 yrs ($P = 0.05$, unadjusted for multiple comparisons).
		Maintenance therapy: second randomization to receive either oral cyclosporine (Sandimmune or Neoral), 500 mg/m^2 (<6 yrs) or 15 mg/kg (>6 yrs). Full dose on day 3 in the i.v. cyclosporine group and low dose (250 mg/m^2) from day 3–10 then full dose in OKT3 group. Other immunosuppressive drugs: CS and azathioprine (2 mg/kg/day) or MMF (600 mg/m^2 twice daily).	The use of OKT3 as induction therapy should be abandoned.
		Results: 1 yr same graft survival and renal function; 4 yr, no significant difference for graft loss (27% in OKT3 group vs 19%; $P = 0.154$), incidence of rejections and incidence of steroid-resistant rejections.	
		In multivariate analysis, OKT3 seems to have a numerically inferior graft survival, but confidence intervals are wide (RR 1.4, CI 0.8–2.2; $P = 0.22$).	
		No differences for PTLD, infections, or patient survival.	
Antibody therapy: ATG-ALG	Acott 2001 [33]	Retrospective study with historic group control, comparing induction ATG/ALG and basiliximab.	No RCTs about ATG-ALG are available in pediatric renal transplant recipients.
		50 patients (27 ATG/ALG and 23 basiliximab)	
		Results: 3 yr similar graft survival (94%)	
		Side effects: unexplained fever (52% ATG-ALG vs 0% basiliximab group), lymphopenia in both groups. Pulmonary edema, fluid retention, and thrombocytopenia with ATG-ALG. EBV and CMV infections more frequent in ATG-ALG group.	
		Basiliximab seems to be superior to ATG-ALG for induction therapy for pediatric renal transplantation.	
	Khositseth 2005 [34]	Historical cohort study to compare efficacy and safety of ATGAM vs thymoglobulin, as polyclonal antibody induction. 198 patients.	
		Results: Significantly lower incidence of acute rejection with thymoglobulin. Significantly higher incidence of EBV infection with thymoglobulin. No differences for patient and graft survival, CAN, PTLD, and other infections.	
	Dharnidharka 2005 [35]	Retrospective study to estimate risk for PTLD after polyclonal antibody induction.	
		87 cases of PTLD among 5238 kidney transplant recipients. In an analysis restricted to pediatric recipients, equine ATG was associated with a higher adjusted relative risk for PTLD compared with rATG and ALG.	
	Kamel 2005 and 2006 [36,37]	1) Prospective open controlled trial in parallel groups, evaluating rATG as induction therapy for pediatric deceased donor kidney transplantation.	
		120 consecutive kidney transplants in 95 patients.	
		Results: actuarial graft survival in group receiving rATG significantly better than control group. Significant difference in incidence of graft loss secondary to acute rejection. No difference in infectious complications. No PTLD.	
		2) Retrospective study to evaluate efficacy of rATG in preventing graft thrombosis. 95 patients receiving 120 kidney transplants.	
		rATG use reduced the risk of graft thrombosis in multivariate analysis; classic risks of graft thrombosis were similar in both groups.	
	Shapiro 2006 [38]	Prospective open noncontrolled trial, evaluating antilymphocyte antibody induction and tacrolimus monotherapy.	
		17 patients; two groups: ATG ($n = 8$) and alemtuzumab ($n = 9$). Results: acute rejection seems to be more frequent with ATG induction, but difference in efficacy is small.	
		Side effects: no systemic infectious complications, no PTLD, two diabetes mellitus cases. Data were not recorded for BK virus.	

	Study	Description	Conclusion
	Ault 2002 [39]	Retrospective study, evaluating short-term outcome of rATG induction; 17 patients. Results: 1-yr patient and graft survival 100 and 93%, respectively. No symptomatic CMV or EBV infections. No PTLD.	
	Hastings 2006 [40]	Retrospective study, evaluating long-term outcome of rATG induction. First results described by Ault (2002); 33 patients. Results: 3-yr graft survival 73%; no PTLD, no malignancy. One case symptomatic CMV disease. None of the patients experienced an infusion reaction.	
IL-2 receptor blockers	Grenda 2006 [41]	Multicenter RCT, open label, parallel groups. 192 patients; 93 tacrolimus + azathioprine + CS, 99 patients tacrolimus + azathioprine + CS + 2 doses of basiliximab (10 mg for body weight <40 kg, and 20 mg for >40 kg; day 0 and day 4) Target serum levels of tacrolimus: 10–20 ng/mL from day 0–21 and 5–15 ng/mL after day 21. Initial dose of tacrolimus 0.3 mg/kg per day, in two equal oral doses. Results at 6 months: no difference in incidence of acute rejection or steroid-resistant acute rejection, graft survival, patient survival, and renal function. Two side effects significantly more frequent in basiliximab group: toxic nephropathy (increase of serum creatinine >10% above baseline posttransplant with undesired increase in tacrolimus whole-blood trough levels and resolving after tacrolimus dose reduction) and abdominal pain. No differences for diabetes mellitus, antihypertensive use, cholesterol levels, infections, and malignancies.	Adding basiliximab to a tacrolimus-based regimen is safe in pediatric patients; however, it does not improve clinical efficacy at 6 months.

Maintenance therapy

	Study	Description	Conclusion
Antiproliferative agents	Bunchman 2001, 2005 [55,56]	Prospective, multicenter, open-label, single-arm study. Evaluation of MMF as primary immunosuppression. 100 patients. Results, 1yrs: patient and graft survival 98 and 93%, respectively. 49% of patients experienced side effects resulting in MMF reduction or cessation. Trend toward more frequent diarrhea, leukopenia, sepsis, and anemia in children under 6 yrs. Results, 3 yrs: side effects accounted for 12% of premature withdrawals of MMF. At least one rejection episode occurred in 30% of patients. Creatinine clearance remained stable during the 3-yr follow-up period for patients who did not lose their graft. Side effects: 25% hematological disturbances (leukopenia) and 16% diarrhea; more often in youngest age group (<6 yrs). 57 recipients experienced at least one opportunistic infection: 22 CMV viremia, 1 CMV infection, 4 CMV tissue invasions, 1 Aspergillus, 1 PTLD.	No RCT with MMF are available. Since some MMF-related side effects occur more frequently with high MMF exposure and since rejection episodes are conversely more frequent with low MMF exposure, therapeutic drug monitoring of MMF may be useful to enhance the efficacy and safety of MMF therapy in the pediatric renal transplantation population. This hypothesis is currently being tested in an ongoing RCT, in both adult and pediatric kidney transplant recipients.
	Virji 2001 [57]	Retrospective single-center study. Evaluation of MMF as primary immunosuppression or rescue. 24 patients. Side effects: diarrhea, abdominal pain, leukopenia, thrombocytopenia, symptomatic CMV infection. No malignancy.	
	Jungraithmayr 2003 [58]	Evaluation of MMF as primary immunosuppression. 86 patients. Historic group control (n = 54). At 3 yrs, patient and graft survivals favorable to MMF compared to azathioprine. Infection rates similar to those reported in adults.	
	Ojogho 2003, Ojogho 2002 [59,60]	Retrospective study. Controlled to historic cohort to examine use of MMF in immunosuppressive strategy avoiding antibody induction. 43 patients, 30 historic control patients. Results, 1 yr: no differences for renal function, graft and patient survival, urinary tract infections, and PTLD. MMF seemed to result in fewer CMV infections, but results not statistically significant.	

Table 62.7 (*continued*).

Therapy group and intervention	Reference(s)	Design and results, including adverse effects	Conclusions and comments
	Ojogho 2005 [61]	Retrospective single-center study to evaluate use of MMF in immunosuppressive strategy avoiding antibody induction vs induction with basiliximab. 41 patients (25 no induction, 16 induction with basiliximab)	
		Results, 6 months: no differences for incidence of acute rejection, graft and patient survival, urinary infections, and CMV infection.	
		Results, 1 yr: no difference for graft and patient survival	
	Cransberg 2005 [62]	Evaluation of MMF as primary immunosuppression. 96 patients. Historic group control (n = 207).	
		Graft loss, incidence of acute rejection, and CMV infections significantly decreased with MMF. No differences for malignancies.	
		Bronchiectasis described as a new complication of MMF treatment.	
	Ferraris 2005 [63]	Evaluation of MMF as primary immunosuppression. 29 patients. Historic group control.	
		Significant improvement of linear growth (reduction in dose of steroids) and renal function at 5 yrs in MMF group. Significant decrease in incidence of acute rejection.	
	Otukesh 2005 [64]	Retrospective controlled single-center evaluation of MMF as primary immunosuppression or as rescue treatment in CAN. 216 patients, 100 MMF and 116 azathioprine.	
		Results: significantly fewer graft failures in MMF group. Patients who received MMF as primary immunosuppression experienced significantly fewer graft loss and acute rejection episodes in first 3 months. Patients who received MMF at the time of diagnosis of CAN had significant better graft survival than those receiving azathioprine.	
	Henne 2003 [65]	Evaluation of MMF in CAN. Noncontrolled open trial. 36 patients.	
		Promising results at 1 yr.	
	Benz 2006 [66]	Retrospective evaluation of MMF in addition with cyclosporine A in CAN. 17 patients.	
		Results: after introduction of MMF, stabilization of GFR; after cyclosporine A reduction, improvement of GFR.	
		1 acute rejection episode.	
Steroid withdrawal	Chakrabarti 2000 [67]	Withdrawal of CS, retrospective study, 80 patients receiving tacrolimus-based immunosuppression.	In 1994, a systematic review of published pediatric studies showed that under maintenance with cyclosporine A monotherapy or dual therapy with cyclosporine A and azathioprine, steroid withdrawal was associated with a significant risk of acute transplant rejection [115].
		1-, 3-, and 5-year actuarial patient survival rates in withdrawal group were 100, 98, and 96% and the actuarial graft survival rates were 100, 95, and 82%. 22.5% of patients restarted on CS.	CS withdrawal or avoidance in children on newer immunosuppressive therapies: evidence rating of these studies does not allow clinicians to determine whether CS can be withdrawn safely. An RCT is under way in pediatric patients.
	Höcker 2004 [68]	Withdrawal of CS, retrospective case control study. 40 patients.	
		CS withdrawal was not systematic (n = 20). After CS withdrawal, graft function remained stable, and prepubertal and pubertal patients exhibited significant catch-up growth; mean arterial blood pressure and use of antihypertensive drugs decreased.	
		In conclusion, late steroid withdrawal seems to be safe and successful in stable patients under immunosuppressive maintenance therapy with cyclosporine A and MMF.	

	Oberholzer 2005 [69]	Early withdrawal of CS, retrospective case–control study with age-matched historic controls. 13 patients and 13 historic controls. No difference for graft and patient survival. Significantly higher creatinine clearance at 6 and 12 months, lower delta BMI, higher delta height Z-score, less hyperlipidemia and need for antihypertensive drugs in withdrawal group.	
	Birkeland 1998 [70]	Avoidance of CS: retrospective study. 14 patients receiving initial course of ALG, cyclosporine A w/ or w/o MMF. Same levels of long-term graft survival and renal function as data reported in registries of pediatric renal transplant recipients.	
	Sarwal 2003 [71]	Avoidance of CS; pilot steroid-free protocol, controlled to matched cohort. 57 patients. Daclizumab induction, tacrolimus and MMF. Results, 1 yr: steroid-free recipients showed significant improvement for acute rejection, graft function, hypertension, and growth. No increased infectious complications.	The incidence of BK virus-associated nephropathy and food allergy has not been studied. These problems have not been investigated enough in the pediatric population. The beneficial effect on lipid profiles of tacrolimus may be of particular importance for cardiovascular disease prevention.
Calcineurin inhibitors	Trompeter 2002, 2005 [44,45]	Multicenter RCT, open label, parallel groups. 196 patients (103 tacrolimus, 93 cyclosporine A). Tacrolimus: 0.15 mg/kg b.i.d; target serum levels 10–20 ng/mL from day 0–30 and 5–10 ng/mL after day 30. Cyclosporine: 150 mg/m^2 b.i.d; target serum levels 150–250 ng/mL during the first 6 weeks, 100–200 ng/mL after the sixth week posttransplant. Results, 1 yr: significantly lower incidence acute rejections and steroid-resistant acute rejections, better renal function (Schwartz) in tacrolimus group. Hypomagnesemia and diarrhea significantly more frequent with tacrolimus, whereas hypertrichosis and flu syndrome more frequent with cyclosporine. No differences for hypertension, urinary tract infections, diabetes mellitus, and PTLD. Results, 4 yrs: significantly better graft survival (86 vs 69%; $P = 0.025$) and renal function (71.5 ± 22.9 vs 53 ± 21.6 mL/min/1.73 m^2; $P = 0.0001$) in tacrolimus group. No differences for patient survival (90–95%), PTLD, use of antihypertensives, or diabetes mellitus. Significantly higher cholesterol level in cyclosporine group.	
Sirolimus and everolimus	Vester 2002 [72]	Open, prospective, multicenter, nonrandomized trial to study efficacy, tolerability, and safety of everolimus as primary treatment in combination with CS and Neoral in 10 patients. Results, 3 months: no acute rejection, no graft failure, no death. Severe side effects observed in 4 patients: lymphocele, urinary tract infections, dyslipidemia, lymphocele abscess, fever, and unexplained increased creatinine. Neither CMV disease nor pneumocystosis (systematic cotrimoxazole prophylaxis).	No RCT available. Heavy proteinuria has been described in pediatric renal transplant patients receiving sirolimus [116]; two hypotheses are discussed (toxic effect of sirolimus and/or lower CNI exposure). Early detection of proteinuria may be helpful. Another side effect of sirolimus has been described: gastrointestinal leukocytoclastic vasculitis, which disappeared after sirolimus discontinuation [117]. Overall, side effects appear to be important with mTor inhibitors. Further larger studies are necessary to assess the impact of side events in pediatric transplant population receiving sirolimus and to evaluate the full potential of sirolimus as initial immunosuppression and/or as a rescue drug in CAN.

(continued)

Table 62.7 (continued).

Therapy group and intervention	Reference(s)	Design and results, including adverse effects	Conclusions and comments
	Vilalta 2003 [73]	Open, prospective, nonrandomized, noncontrolled trial to study efficacy and safety of sirolimus (1.15 mg/m²/day) as primary treatment. 6 patients.	
		Results, 1 yr: all patients show normal creatinine levels and lead normal lives. No adverse effects or opportunistic infections observed. After cyclosporine withdrawal, sirolimus doses were increased by mean 40%.	
	Filler 2005 [74]	Retrospective single-center study to evaluate retrospectively sirolimus efficacy as rescue agent in patients with CAN and receiving tacrolimus-based immunosuppression. 8 patients.	
		Results: when adding sirolimus, a significant decrease in tacrolimus dose observed; tacrolimus blood levels should be monitored frequently in this situation.	
	Hymes 2005 [75]	Monocenter, open, prospective, nonrandomized, noncontrolled trial to evaluate sirolimus efficacy and safety as a primary treatment. 66 patients.	
		Results, 6 months: patient and graft survival 100 and 98%, acute rejection 11%, acute steroid-resistant rejection 0%, mean serum creatinine 0.9 ± 0.4 mg/dL.	
		Side effects described: EBV, PTLD, CMV, surgical wound dehiscence, noninfectious pneumonitis, nephrotic syndrome, diabetes mellitus, perinephric abscess, and serum cholesterol levels higher than 200 mg/dL.	
	Ibanez 2005 [76]	Retrospective study of 18 patients to evaluate retrospectively sirolimus efficacy and safety as a rescue agent.	
		Results, 3 months: significant improvement in renal function. Steroid-sensitive acute rejection episode occurred early after conversion. No differences for proteinuria, serum cholesterol, triglycerides, and platelet counts.	
		Three serious side effects: central nervous system relapse of EBV-related B-cell lymphoma, sepsis in course of acute pyelonephritis, and asymptomatic pancreatic pseudocyst. Other side effects: HSV infections (oral acyclovir, no need to change immunosuppression), leg lymphedema. No need to discontinue sirolimus.	
	Höcker 2006 [77]	Single-center case–control study, 10 patients sirolimus, MMF, CS, CNI withdrawal vs 9 patients CNI minimization, MMF, CS. Patients with chronic CNI toxicity.	
		Results, 1yr: no acute rejection, significant improvement in renal function in both groups. Absolute and relative gains of GFR in the two groups not significantly different.	
		Side effects: no differences between the two groups for hypertension, infectious episodes, or white blood cell count. Hypercholesterolemia in 70% of patients receiving sirolimus.	
	Garcia 2006 [78]	Retrospective study, 16 patients, to evaluate retrospectively sirolimus efficacy and safety as a rescue agent. Different immunosuppressive regimens.	
		Side effects: nephrotic proteinuria, anemia (25% of patients needed erythropoietin therapy), hypercholesterolemia requiring statins in 5 children, and mucosal ulceration. Heterogenous patients; a favorable evolution was observed in 11 patients.	
	Falger 2006 [118]	Monocenter, open, prospective, nonrandomized, noncontrolled trial to evaluate effects of conversion protocol (from CNI to sirolimus) in CAN. 8 patients.	
		Results, 1 yr: significant stabilization of GFR, no graft loss, no discontinuation of sirolimus.	
		Side effects: initial increase of triglycerides and serum cholesterol that both decreased towards initial values at 1 yr. Acne, bacterial pneumonia, CMV-pneumonitis, HSV labialis, diarrhea.	
	Harmon 2006 [80]	Pilot trial of CNI avoidance after living donor kidney transplantation. 34 patients.	
		Results: two graft losses (1 CAN, 1 PTLD). Patient survival 100%. Acute rejection at 6 and 12 months, 21.8 and 31.5%, respectively. Side effects: 2 PTLD	

Anti-infective therapy

CMV therapy	Flynn 1997 [92]	CMV prophylaxis treatment. Prospective open study, evaluating efficacy of i.v. immunoglobulins as prophylaxis to CMV-negative children who received CMV-positive allografts. Historic controls.	Few trials are available in children.
		Results: prophylactic treatment significantly decreased incidence of CMV disease posttransplantation. CMV diseases also occured significantly later than in untreated children. Infections seem to be less severe with prophylaxis.	No RCTs available.
	Bock 1997 [93]	CMV prophylaxis treatment. NAPRTCS registry, patients hospitalized for CMV infections during the first post-renal transplant year (n = 142). Retrospective case–control study.	
		Results: prophylaxis with anti-CMV IgG significantly reduced risk of CMV hospitalization. Prophylactic use of antiviral agents was associated with significantly decreased risk of major organ involvement during CMV infection. Among patients with CMV, the 3-yr graft survival was significantly better for those who received any form of prophylaxis than for those who received none.	
	Filler 1998 [94]	CMV prophylaxis treatment. Prospective pharmacokinetic study of oral ganciclovir. 14 patients, CMV seronegative who received a graft from a CMV-seropositive donor.	
		Results: no CMV disease developed in any of the patients during oral ganciclovir. One patient presented with positive CMV viremia 5 weeks after discontinuation of ganciclovir.	
		No particular side effects	
	Rubik 2006 [95]	CMV prophylaxis treatment. Prospective open noncontrolled evaluation of pharmacokinetics of valganciclovir oral suspension. 10 patients.	
		Results: no episode of drug toxicity or withdrawal. Data about efficacy not reported.	
	Melgosa-Hijosa 2004 [96]	CMV preemptive treatment. Open, noncontrolled prospective study. 42 patients all receiving i.v. ganciclovir prophylaxis for CMV posttransplant. CMV viremia in 22 children, 5 were symptomatic. Asymptomatic patients received oral ganciclovir. Symptomatic patients received i.v. ganciclovir.	
		Results: no CMV disease, ganciclovir resistance, acute renal rejection, or renal dysfunction. GFR at 1 yr similar to that of uninfected children.	
EBV therapy	Srivastava 1999 [97]	Retrospective monocenter study. 84 renal transplant recipients, 6 PTLD. All positive EBV serology and PCR at time of diagnosis of PTLD. Treatment consisted of reduced immunosuppression and ganciclovir/acyclovir in all patients.	Treatments of both EBV infection and PTLD remain controversial in adults.
		Results: PTLD resolved in all patients and all patients are alive 2–54 months after PTLD diagnosis.	Very few trials are available in children. No RCTs are available.
			Surveillance of EBV viremia may be useful to promptly reduce immunosuppression [119].
			Data about the benefit of antiviral agents in positive EBV viremia without PTLD remain uncertain; however, many centers seem to use prophylactic antiviral agents during the first 3/6 months after transplantation [119].
			Many treatments have been proposed for established PTLD: immunosuppressive drug reduction is used in over 90% of cases. Rituximab, interferon alpha, chemotherapy, radiotherapy, and surgery have been proposed [85].

(continued)

Table 62.7 *(continued).*

Therapy group and intervention	Reference(s)	Design and results, including adverse effects	Conclusions and comments
	Shroff 2002 [98]	Prospective EBV surveillance post-transplant. 43 patients. Aim of study was to detect EBV viremia as early as possible and thereby attempt to avoid PTLD by reduction of immunosuppression. Results: higher incidence of EBV disease in children receiving quadruple therapy and tacrolimus compared with those given cyclosporine-based immunosuppression. After positive EBV viremia, immunosuppression was reduced and all patients remained asymptomatic.	No RCTs are available in children.
Fungal	Playford 2004 [99]	No specific data for pediatric patients.	Cochrane systematic review: in renal transplant recipients, neither ketoconazole nor clotrimazole significantly reduced invasive infections.
Disease recurrence			
FSGS	Seikaly 2004, Newstead 2003, Dall'Amico 1999, Salomon 2003, Ohta 2001, Dantal 1994 [101,105,107–110]	Different therapeutic options have been reported. Plasmapheresis (PP): Ohta found prophylactic PP may be valuable. retrospective analysis of 21 allografts, receiving either prophylactic PP (n = 15) or curative PP (n = 6) revealed 5 recurrences in the prophylactic group vs 4 recurrences in nonprophylactic group. D'All Amico found PP after recurrence seemed to provide remission. In open noncontrolled trial, proteinuria decreased in 9 of 11 patients treated with PP and cyclophosphamide after recurrence of FSGS; in 7 persistent remission was obtained. Cyclophosphamide (see above) Cyclosporine: uncontrolled clinical studies are not conclusive. i.v. cyclosporine (3 mg/kg/day with target blood level 250–350 ng/mL) induced remission of recurrence of FSGS in 14 of 17 patients. Persistent remission observed in 11 children. Plasma protein absorption: efficacy of this modality therapy is not encouraging. ACEi, indomethacin: reported to partially reduce proteinuria without affecting graft survival	No RCTs are available; management of recurrence of FSGS posttransplant is still controversial. There are only nonblinded, noncontrolled case series. Multicenter international RCTs are lacking.
HUS	Seikaly 2004, Quan 2001, Loirat 2003 [101,111,112]	NAPRTCS report: of 68 renal allografts, HUS recurred in 6 allografts. Poor outcome (83% graft loss) despite treatment with fresh-frozen plasma or PP. Cyclosporine had no effect on outcome or HUS recurrence. French report: risk of recurrence different, according to D+HUS (0.8%) or D-HUS (21%). Cyclosporine and tacrolimus may cause thrombotic microangiopathy; however, avoidance of CNI does not seem to prevent recurrence of HUS in children D-HUS.	No RCT available. Apart from the exceptional situation of deficiency of Von Willebrand factor-cleaving protease, there is currently no effective treatment of HUS after transplantation.
MPGN	Seikaly 2004 [101]	Anecdotal responses to PP have been reported in adults. Treatment of recurrent MPGN type 2 with PP induced remission in a single pediatric patient.	Very few data are available; there are no RCTs. Clinical recurrence is often characterized as asymptomatic proteinuria and low complement 3 levels.
IgA/HSP	Seikaly 2004 and Ponticelli 2004 [101,113]	Symptoms are often minor and could include hematuria and proteinuria. No pediatric data. Probable interest in ACEi in adults in decreasing proteinuria.	After recurrence of nephropathy, incidence of graft loss seems to be different in IgA nephropathy (3%) and in Henoch-Schönlein purpura (22%). Moreover, recurrence is more frequent with living, related donor than cadaveric donor in both diseases.

Abbreviations: CAD/LD: cadaveric donor/living donor; CNI, calcineurin inhibitors; CAN, chronic allograft nephropathy; ALG, antilymphocyte globulin; rATG, rabbit polyclonal antithymocyte globulin; CS, corticosteroids; MMF, mycophenolate mofetil; PP, plasmapheresis; HSV, herpes simplex virus; D+HUS/D-HUS, HUS with/without diarrhea; IgA/HSP, IgA nephropathy and Henoch-Schönlein purpura; WBC, white blood cell count. ACE: ansiotensiu converting enzyme inhibitors

[a] When RCTs were available, other studies have not been included. Only pediatric trials or reports about renal transplantation have been taken into account.

Table 62.8 Evidence ratings and recommendations for interventions in renal transplant recipients[a].

Intervention [reference(s)]	SR[b]	Evidence rating[c]				Recommendation[d]			
		High	Moderate	Low	Comment	I	II	III	Comment
Induction with IL-2 receptor blockers (Il2-Ra) [41,120]	C− A+	• A	• C		Systematic review in adults (Cochrane), 4893 patients 1 RCT, 192 children Consistent results	•			In adults, compared with placebo, no differences for graft loss at 1 and 3 yrs (RR 0.88, 95% CI 0.64–1.22). Incidence of acute rejections decreased at 1 yr (RR 0.67, 95% CI 0.6–0.75). No differences for malignancies and CMV infections at 1 yr. Compared with other antibody induction, no significant difference for efficacy, but adverse effects favored Il2Ra. High evidence. In children, adding basiliximab to a tacrolimus-based regimen is safe; however, it does not improve clinical efficacy at 6 months. Moderate evidence. Need more data on long-term efficacy.
OKT3 vs. i.v. cyclosporine [32]	C−		•		1 RCT, 287 children Consistent results	•			Use of OKT3 induction therapy should be avoided. Moderate evidence.
Polyclonal and monoclonal antibodies for treating acute rejection [31]	C− A+	•			Systematic review in adults (Cochrane), 1387 patients			•	In reversing first rejection any antibody is better than steroids (RR 0.57, 95% CI 0.38–0.87) and also prevents graft loss (RR 0.74, 95% CI 0.58–0.95). In reversing steroid-resistant rejection, effects of different antibodies not significantly different. Moderate to high evidence. Need more pediatric data.
Tacrolimus vs cyclosporine [43,45]	C− A+	• A	• C		Systematic review in adults (Cochrane), 4102 patients 1 RCT, 196 children Consistent results		•		In adults, tacrolimus is superior to cyclosporine in improving graft survival (at 6 months, RR 0.56, 9% CI 0.36–0.86) and preventing acute rejection (at 1 yr, RR 0.69, 95% CI 0.6–0.79), but more diabetes mellitus (RR 1.86, 95% CI 1.11–3.09) and gastrointestinal side effects are described. No differences in infections or malignancies. High evidence. In children, tacrolimus seems more effective than cyclosporine. Moderate evidence. Need more data on harms.
Sirolimus [47,121]	C− A+	• A		• C	Systematic review in adults (Cochrane) for primary immunosuppression (7114 patients) Systematic review in adults (Mulay) for conversion from CNI to sirolimus in CAN (1040 patients) At least 9 case series in children (176 patients)			•	Need more data for primary immunosuppression and rescue treatment, for both efficacy and safety. Moderate to low evidence for children. Side effects. Need more data on benefits and harms in children.
Mycophenolate vs azathioprine [122]	C− A+	• A		• C	Systematic review in adults, 8457 patients for efficacy and 6387 for safety At least 3 case series in children (429 patients) 1 ongoing RCT in children			•	MMF more efficient than azathioprine in reducing incidence of acute rejections but associated with an increase in gastrointestinal, hematological, and infectious (CMV infections) side effects. No confidence intervals available. Moderate evidence. Need more data on benefits and harms in children.

(continued)

Table 62.8 (*continued*).

Intervention [reference(s)]	SR[b]	Evidence rating[c] High	Moderate	Low	Comment	Recommendation[d] I	II	III	Comment
Steroid withdrawal [52,123]	C− A+	•A		•C	Systematic reviews in adults, 1519 patients and 1681 patients. At least 5 case series in children (204 patients) 1 ongoing RCT in children			•	Pascual: Renal allograft recipients on triple therapy with calcineurin inhibitor, MMF, and steroids are at low but significant risk of acute rejection after steroid withdrawal (RR 2.28, 95% CI 1.65–3.16) but do not present an increased risk of early graft failure (RR 0.73, 95% CI 0.42–1.28). Tan: Similar results for acute rejection. Steroid withdrawal reduces incidence of opportunistic and urinary tract infections (RR 0.8, 95% CI 0.64–1 and RR 0.74, 95% CI 0.6–0.92, respectively) High evidence in adults. Need more data on benefits and harms in children.
Anti-CMV therapy [83,84]	C− A+	•A		•C	Systematic review in adults (Cochrane). At least 5 case series in children (208 patients)		•		Prophylaxis with antiviral therapy reduces risk of CMV disease (RR 0.42, 95% CI 0.34–0.52), CMV infection (RR 0.61, 95% CI 0.48–0.77) and all-cause mortality (RR 0.63, 95% CI 0.43–0.92) in solid organ transplant recipients. No conclusion for preemptive therapy vs prophylaxis. Moderate to high evidence. Need more pediatric data.
Treatment for FSGS recurrence	C− A			•A, C	Only case series in adults and children.			•	Low evidence. Need more data.
Treatment for HUS recurrence	C− A			•A, C	Only case series in adults and children.			•	Low evidence. Need more data.
Treatment with GH [22]	C+			•C	Systematic review in children (629 patients with CKD)	•			1 yr of 28 IU/m²/wk rhGH in children with CKD resulted in 3.8 cm/yr increase in height velocity above that of untreated patients (95% CI 3.2–4.39). Trials too short to determine if continuing treatment resulted in increase in final adult height. High evidence. Moderate benefit. Harms of daily injections. High cost.

Abbreviations: CNI, calcineurin inhibitor; MMF, mycophenolate mofetil; CAN, chronic allograft nephropathy; CKD, chronic kidney disease.

[a] RCTs in children have been taken into account. There are no systematic reviews in for pediatric renal transplantation, except for GH therapy. Where no pediatric data were available, systematic reviews in adults are listed.

[b] Systematic review of RCTs. C, children; A, adults; −, no systematic review; +, systematic review of RCT.

[c] Evidence rating based on study design, study quality, consistency, and directness of results. No intervention was rated with a high evidence rating.

[d] Recommendations based on trade-offs between benefits and harms, quality of evidence, and translation of evidence into practice in a specific setting, including availability of medication and any uncertainty about baseline risk of disease in the population. I, recommend to give or not to give; II, suggest to give or not to give; III, no recommendation possible.

63 Peritoneal Dialysis in Children

Jaap W. Groothoff & Maruschka P. Merkus

Department of Pediatric Nephrology, Emma Children's Hospital, Academic Medical Center,
1105AZ Amsterdam, The Netherlands.

Introduction

Soon after the introduction of continuous ambulatory peritoneal dialysis (CAPD) in 1978 [1], PD became the most popular mode of chronic dialysis for children in most countries. In comparison with hemodialysis (HD), PD has the social advantage of being a home treatment with relatively low cost [2]. Especially in small children, PD is technically more feasible and offers easier metabolic control, a more liberal diet, and less fluid restriction. Yet, no evidence exists on the advantage of PD over HD in children with respect to mortality or end-stage renal disease (ESRD)-related comorbidity, such as cardiovascular disease and metabolic bone disease. The apparent advantages of PD in the care of children have led to a preference for PD over HD for children in most countries, leaving HD for the more complicated patients. This has made unbiased comparison of the relative effects of PD and HD very difficult. Combined with a general policy to keep time on dialysis while waiting for transplantation to a minimum, this has meant a lack of studies on the outcome of chronic dialysis treatment in the pediatric population.

Searching for evidence

We searched the Renal Health Library 2005, produced by The Cochrane Renal Group for Systematic Reviews, randomized controlled trials (RCTs) on management of PD and, additionally, the Cochrane Central Register of Controlled Trials, DARE, MEDLINE, and EMbase for RCTs published more recently. In light of the available trial evidence, we critically reviewed the most recent guidelines on management of PD in children. In the absence of any RCT, important observational studies were reviewed. Data on mortality

and comorbidity were obtained from registries and cohort studies published after 1996. Studies published before 1990 were excluded, as they are not applicable to current practice. We also excluded studies on additive medication (phosphate binding, erythropoietin [EPO], etc.) in PD, as this is covered in other chapters.

Patient survival and causes of death

Most data were obtained from registry analyses and a few cohort studies [3–14], and they are summarized in Table 63.1. All studies suffer from lack of information on ESRD patients who were not accepted for chronic renal replacement therapy (RRT). Moreover, most reports concern chronic RRT and not chronic PD, because transplantation is the preferred RRT in children and, therefore, time on dialysis is usually kept to a minimum. Two comprehensive nationwide cohort studies both reported a 30-fold-increased overall mortality risk in children with ESRD [9,11]. Survival rates had increased over time, especially in very young children, until the mid 1980s, after which survival has not improved [9,11].

Determinants
Young age at onset of RRT and a prolonged dialysis period (beyond 2 years) are reported by all studies as the most important risk factors for death [9]. Over time, a trend towards improved survival is found predominantly among children under the age of 10 years, especially among the very young, but not in older children [9,11]. Yet, all these studies suffer from the lack of registration of those children with ESRD who were never accepted for therapy. Because there has been an increased acceptance of relatively sick children for RRT over time, these data probably underestimate the progress that has been made.

PD versus HD
Comparison between outcomes of PD and HD suffers from selection bias. Some studies found a higher mortality rate with PD than with HD (Italian Registry, patients ages 0–19 years, onset of RRT, 1989–2000: 17/295 deaths among PD group versus 2/163 in HD

Table 63.1 Studies on mortality in children on chronic dialysis.

Study and design [reference]	Patients	Outcome	Risk factor(s) for adverse outcome	Comments on study quality	Clinical implications
Italian Registry, 23 centers, PD & HD [3]	295 CPD 163 HD (1989–2000)	Overall 5-yr survival: HD 96.9%, PD 90.5% 17 PD pts died, 10 cardiovascular deaths	Young age (<5 yrs)	+ large study − incomplete data, registry study − no registration of untreated pts	Advocates more attention for prevention of cardiovascular disease
NAPRTCS, 150 centers [4]	584 HD (1992) & PD (1992–1998)	MR/100 pt-yrs: 0–2 mos, 15.7; 2–12 mos, 11.5; 1–2 yrs, 8.2; 2–5 yrs, 6.1; 6–12 yrs, 3.5; >12 yrs, 2.2	Young age	+ large study − incomplete data, registry study −no registration untreated pts	No conclusion for clinical practice
USRDS, 1991–1996 [5]	1454 ESRD, 0–19 yrs old	MR/100 pt-yrs: 3.84	Young age	+ large group − retrospective − incomplete data − no registration untreated pts	Advocates more attention for prevention of cardiovascular disease
USRDS, all patients, 1990–1996 [6]	1380 ESRD, 0–19 yrs old, deaths	23% cardiovascular deaths	Predictors of cardiac death: Black race (OR 1.56), dialysis status (Tx vs. dialysis, OR 0.22)	+ large group − no data on total cohort − incomplete data − no information on methodology registration cause of death	Advocates early transplantation
NAPRTCS Registry [7]	2971 PD, 1572 HD (1992–2001) 0–15 yrs old	Overall 3-yr survival : 85.7 ± 1.4%; 3-yr survival for 0–1 yr, 68.2 ± 3.9%; infection 24.3%, cardiovascular 21.5%	Young age	+ large study − incomplete data, registry study − no registration untreated pts − large group cause of death unknown'' (11.7%)	Advocates more attention for prevention of infections and cardiovascular disease
Turkish Registry, 12 centers, PD [8]	514 PD (1989–2002) CAPD	5-yr PD 70% survival, overall MR/100 pt-yrs 8.3	Young age RR vs >15 yrs old: <2 yrs old, 7.3 (CI 2.8–19.2) ; <1 yr, 9.7 (CI 3.5–26.5)	+ large study of children commencing RRT with PD -no completeness check	No conclusion for clinical practice
ANZDATA Registry [9]	1634 ESRD, 0–19 yrs old (1962–2002)	MR/100 pt-yrs: HD 4.8 (4.2–5.6), PD 5.9 (4.9–7.2); Tx 1.1 (0.9–1.3); SMR 30, cardiovascular cause of death 45% all pts, 43% PD pts	Young age, no transplantation, RRT onset before 1983; for PD vs. HD, delay to Tx <2 yrs not significant	+ large study + complete and comprehensive + methodology + long-term follow-up − retrospective − no registration untreated pts − no quality check death causes	Advocates transplantation within 2 yrs after onset RRT and attention for prevention of cardiovascular disease
Japanese Registry, 1981–1997 [10]	807 PD	87 deaths (10.8%) patient 3 y. survival 91%; 5 y.. 86% cardiovascular death 39.4% infection 36.6%	Young age	+ large study − registry study − incomplete data	Change from lethal infections to relatively more cardiovascular casualties over time advocates attention for prevention of cardiovascular disease
National Cohort study [11]	249 Dutch patients, <15 yrs, onset RRT 1972–1992, born before 1979	Overall survival, 87% 5-yr, 82% 10-yr, 78% 20-yr survival Overall SMR, 31 (1972–1999), 21 (1992–1999) Causes of death RRT: cardiovascular (41%), infection (21%), cessation of therapy (11%), malignancies (10%), complication of treatment (8%)	Predictors: young age (<6 yrs old), RRT onset <1982, hypertension, HD vs. PD, long duration dialysis	+ complete data of all Dutch pts <15 yrs old, no missing data + quality check cause of death + long follow-up − no registration for untreated pts − period/inclusion bias PD vs. HD − adolescents >14 yrs old not included	Advocates more attention for prevention of cardiovascular disease and treatment, hypertension, and early transplantation

(Continued)

Table 63.1 *(Continued)*

Study and design [reference]	Patients	Outcome	Risk factor(s) for adverse outcome	Comments on study quality	Clinical implications
EDTA registry [12]	3184, 0–19 yrs old (1980–2000)	Adjusted mortality HR (95% CI): Onset dialysis in 1995–2000 vs. 1980–1984, overall 0.64 (0.41–1.00), age 0–4 yrs 0.21 (0.09–0.51) Causes of death, PD pts: infection (23%), cardiovascular (10%)	Infection most important cause of death in PD, large "unknown" group	+ large population – registry study – incomplete data from several countries – unreliable data on cause of death	Advocates more attention for prevention of infections
1 centre [13]	98 (80 PD, 18 HD), 0–16 yrs old; (1984–2006)	17/98 deceased (7 PD, 3 HD, 7 Tx); survival at 1 yr 92%, 5 yrs 88%, 10 yrs 84%; cardiovascular deaths in 7/17	Young age Comorbid condition present in 76%	+ no missing patients + long-term follow-up –only retrospective chart data –small cohort	PD probably not superior to HD with respect to cardiovascular comorbidity
1 centre [14]	20 PD, age 32 wks (gest.)–1 yr, RRT 1986–1998	Duration PD 17.3 mos (1–59); 4 deceased, 11 successful transplant, 4 to HD followed by Tx, 1 continued PD, 14/16 survivors normal development milestones	Not determined	+ complete cohort + comprehensive + data on primary refusal RRT – small study	CPD feasible in (premature) infants
Japanese registry [21]	582 ESRD <20 yrs old, 1998	41.5% PD, 17.3% HD, 41.1% Tx Causes of death all patients: cardiovascular (56.9%), infection (42.9%)	Young age MR/100 pt-yrs, 0–4 yrs old, 2.22; 5–9 yrs, 3.39; 10–14 yrs, 1.48; 15–19 yrs, 0.10	+ large cohort + large PD population – registry study – very incomplete response (61.7%) –short-term follow-up	Cardiovascular disease most prominent

group) [15], but others have found no difference [9] or conflicting results (Dutch cohort, hazard ratio [HR] for HD versus PD, 2.1; 95% confidence interval [CI], 1.0–4.4) [11]. However, in the Italian study the PD patients were on average much younger than the HD patients (7.7 ± 4.8 versus 11.4 ± 3.1 years), and nearly all patients under the age of 5 years were on PD. Sixteen of the 17 deaths in PD patients occurred in those with onset of ESRD while they were children less than 5 years old, with six occurring in infancy [15]. No difference in survival was found between PD and HD patients in the age group 5–15 years. The Dutch analysis suffers from period and selection bias. During the period with the highest mortality (1972–1982), very few patients were treated with PD, and after 1982 most Dutch centers chose PD, leaving the more complicated patients to receive HD [11].

Adult studies have shown that preservation of residual kidney function is the most important determinant for survival in PD patients [16]. As in adults, PD is associated with better preservation of residual kidney function compared with HD [17], but there are no data that show a survival benefit in children with PD compared with HD.

Causes of death

Establishment of the exact cause of death in kidney disease patients can be troublesome. Apart from the Dutch study, no study defined the methodology used for cause of death assessment [11]. Cardiovascular disease is the most important cause of death in children on RRT in all studies, followed by infection [5,9–11,18–20]. Data on PD-associated causes of death are difficult to interpret, because most studies do not mention explicitly if patients had been treated only with PD during their RRT history. According to most studies, cardiovascular disease is also the most important cause of death in PD-treated children. Most comprehensive and reliable studies indicate a high burden of cardiovascular deaths in PD-treated children. In the Italian Registry study, 10 of 17 cardiovascular deaths occurred on PD. In the Japanese Registry study, cardiovascular disease was the cause of 56.9% of all deaths, 80% of which occurred

on PD. In the Australian cohort study 43% of cardiovascular deaths occurred on PD, but there was no mention of the other causes of death in PD patients [9,15,21]. Two other registry studies with incomplete data have reported infection as the most important cause of death in PD patients [7,12].

Technique survival

Large European studies on PD in children reported catheter survival rates of 82–80% and 57–58% after 1 and 4 years, respectively [22,23]. The North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) has reported a 20% transition (194 of 994 incident patients) from PD to HD [4]. The most common reasons were infection (43%), patient choice (7%), access failure (7%), and ultrafiltration failure (7%) [4,24].

Technique failure occurs more commonly with PD than HD (Italian Registry: 14.9% modality failure for PD, 7.4% for HD patients; patients aged 5–15 years; PD vs. HD technique failure rates of 40% vs. 5%; $P = 0.002$). Infection (peritonitis and/or exit site infection) accounted for 65.9% of all modality switches to HD [15]. Data on the association between age and technique failure are conflicting and often biased by unequally divided early cessations of PD in various age groups [15,24].

Comorbidity

Growth retardation, cardiovascular disease, metabolic bone disease causing pathological fractures, pain, impairment of movement, and cognitive impairment are the most important comorbidities in children and young adults with ESRD [5,18,25–30]. A prolonged period of dialysis is the most important risk factor for most of these complications, but the exact roles of PD versus HD remain to be elucidated. There is evidence that hypertension is an important determinant for cardiovascular disease, as in adults [11,31]. Observational studies in young adults with pediatric ESRD suggest that, among other factors, a high parathyroid hormone and high calcium–phosphate product might be responsible for early life-threatening vascular calcification [32]. After follow-up of 6–30 years, a 10-fold-increased incidence in malignancies was found among children with ESRD [19].

Hospitalization

In a multicenter Italian study, the hospitalization rates of a cohort of 149 PD and 111 HD patients in the period 1989–1994 were compared. Patients more than 5 years old on PD had a significantly higher hospitalization rate than age-matched HD children (days per dialysis month, 1.87 vs. 0.92; $P < 0.01$) [33].

Clinical implications with respect to choice of RRT

Early transplantation remains the ultimate goal in the treatment of children with ESRD. Currently there is no evidence in favor of PD over conventional HD treatment three times per week with respect to mortality or comorbidity. A recent small study by Fischbach *et al.* showed promising results of extended 5–6 times per week HD for the prevention of cardiovascular and metabolic bone disease, as well as improved a general well feeling [34]. This is in line with our own experience, but these data have to be confirmed in larger prospective studies.

Use and placement of PD catheter

Guidelines
An Ad Hoc Committee for elective chronic PD in pediatric patients that includes representatives of 12 European countries has formulated guidelines regarding the initiation of PD in children on behalf of the European Pediatric Peritoneal Dialysis Working Group. These guidelines are largely based on expert opinion [35]. The most important recommendations regarding the use and placement of the PD catheter are given in Table 63.2.

Available evidence
Most guidelines aim to prevent mechanical and, in particular, infectious complications. The recommendations for partial omentectomy and intraperitoneal heparin at PD catheter insertion to avoid catheter obstruction are not supported by evidence from pediatric RCTs. There are only data from retrospective observational studies to support the recommendation for partial omentectomy (no omentectomy versus omentectomy, 7/27 obstructions vs. 4/62 obstructions [Macchini], and 4/10 obstructions vs. 0/11 obstructions [Pumford]) [22,36]. Several studies in adults show evidence for anti-inflammatory, membrane-protective, and improved ultrafiltration properties of intraperitoneal heparin [37,38]. Yet, the protective effects of heparin against catheter obstruction by fibrin clot formation are based solely on clinical experience and have not been shown in studies.

In a nonrandomized prospective study in 42 children age 0.1–19 years, Daschner *et al.* found less leakage and similar rates of obstruction after laparoscopic implantation compared to conventional implantation of Tenckhoff catheters, despite the fact that patients with preexistent intra-abdominal adhesions were preferentially allocated to the laparoscopic procedure [39]. A retrospective study showed a favorable effect of delayed (>14 days) compared to early (<14 days) catheter use after placement on incidence of dialysate leakage but no effect on malfunction or infection rates [40]. In a single-center, open-label RCT of 45 CPD children with 52 catheter placements, application of fibrin glue to the peritoneal cuff suture resulted in a significantly lower incidence of leakage during the first 60 days after implantation compared to no sealant. No effect was seen on incidence of infection [41] (Table 63.3).

Table 63.2 Guidelines on inititation of PD and management of peritonitis.

Guideline

Implantation catheter
- Double-cuff, swan neck designed, curled Tenckhoff catheter
- Exit site downward; partial omentectomy
- Luer lock connections
- A disconnect "flush-before-fill" system
- Irrigation of catheter in-theater until dialysate is clear
- Heparin at 500 IU/L i.p. until clear effluent
- Immobilization of catheter and no application of keyhole dressing
- If possible, leave catheter for 2 weeks until patient returns for training, otherwise only use low volumes (10 mL/kg/cycle)
- Cephalosporin prophylactic antibiotic at time of catheter insertion.

Diagnosis of infection
- Peritonitis: cloudy effluent and effluent white blood cell count of >100/mm^3, >50% polymorphnuclear leukocytes
- Catheter exit site infection: purulent discharge from sinus tract or marked pericatheter swelling, redness, and/or tenderness, with or without pathogenic organism cultured from exit site

Treatment of peritonitis
- Empirical start with antibiotics as soon as peritonitis is suspected
- Fever and/or severe abdominal pain, recent methicillin-resistant *S. aureus* infection, recent or current exit site or tunnel infection or nasal exit site colonization with *S. aureus*, patients <2 years: glycopeptide (vancomycin or teicoplanin) and ceftazidime i.p.
- All other patients: cephalosporin and ceftazidime
- Modification according antibiogram (see Figure 63.1)
- 2 week treatment for all organisms, unless *S. aureus, Pseudomonas* or *Stenotrophomonas* species, multiple organisms, and/or anaerobes, then treatment for 3 weeks
- For fungal peritonitis, amphotericin B i.v. or a combination of imidazole–triazole and flucytosine; early catheter removal recommended; always if improvement does not occur with 3 days of treatment initiation; treatment duration following catheter removal for all patients should be at least 2 weeks

Indications for catheter removal and replacement
- Relapse of treated *S. aureus* or *Pseudomonas* peritonitis with an *S. aureus/Pseudomonas* catheter-related infection, fungal peritonitis, refractory (at 72–96 h) peritonitis, refractory (at 72–96 h) anaerobic peritonitis, refractory catheter exit site, tunnel infection.

Prophylactic antibiotic therapy
- *S. aureus* nasal carriage (single dose of antibiotics at time of catheter implantation), accidental intraluminal contamination, prior to dental procedures, and prior to procedures involving the gastrointestinal or urinary tract

Treatment of catheter exit site infection
- Treatment after culture results have been obtained, unless signs of severe infection
- Treatment duration 2–4 weeks

Sources: ISPD guidelines [35,47; www.peritonitis.org].

Clinical implications

There is weak evidence that omentectomy at implantation may reduce the risk for obstruction. Intraperitoneal heparin does no harm, but its benefit has not been proven. Laparoscopic catheter implantation might be advantageous over conventional implantation. Fibrin glue application on the peritoneal cuff at implantation may reduce the risk for leakage.

PD-associated infections

Epidemiology

Peritonitis and catheter-related infections are the major causes of morbidity and treatment failure of peritoneal dialysis in children. The control of infectious complications is particularly relevant to pediatric patients, because peritoneal adhesions and fibrosis caused by severe or recurrent peritonitis may prevent further use of the peritoneal membrane [42]. Exit site and tunnel infections occur in approximately one-third of pediatric PD patients after 1 year on PD and are the main reason for catheter removal [43]. Reported rates of peritonitis worldwide vary, with one episode every 13–70 patient PD months [7,15,24,43–45].

The incidence of peritonitis in pediatric patients is higher than that seen in adults and is highest in infants and younger children [7,43,44]. Data from NAPRTCS show an increasing frequency of exit site and tunnel infections and peritonitis with time on PD [43]. Exit site and tunnel infections increase the risk of peritonitis and access revision twofold and of hospitalization for access complications almost threefold [43]. Nasal carriage of *Staphylococcus aureus* in patients and caregivers is a risk factor for catheter-related

Table 63.3 Evidence ratings and recommendations for interventions to treat and prevent exit site and tunnel infections and peritonitis in pediatric PD patients.

Intervention	SR	Evidence rating[a]		Comment [reference(s)]	Recommendation[c]			Comment
		Moderate	Low		I	II	III	
Antibiotic treatment of peritonitis								
Intermittent vs continuous glycopeptide (vancomycin or teicoplanin)/ceftazidime, i.p.	—	•		1 RCT, relatively large sample size (152 pts, 168 episodes); suboptimal methodological quality [47]	•			Gram-positive peritonitis: Success rate (overall 95%) not different between intermittent and continuous or between vancomycin and teicoplanin treatment; 3 pts with vancomycin oversensitivity, 1 pt with ototoxicity vs. 0 pts teicoplanin side effects
								Gram-negative peritonitis: Intermittent treatment less effective than continuous according to clinical judgment (success rate, 3/11), but not according to DSS (10/14); no ceftazidime side effects
								More evidence needed for gram-negative peritonitis; teicoplanin has some advantages over vancomycin regarding side effects and reliability of blood levels after intermittent administration
Ceftazidime, cefazolin combination, i.p.	—		•	1 case series (27 pts, 50 episodes) [53]			•	Effective in 90% of episodes, no mention of adverse effects
								Advantage of this combination is that harms of aminoglucosides are avoided; disadvantage is that methicillin-resistant staphylococci are resistant to this combination
								Further evidence required.
Fluconazole and catheter removal for treatment of fungal peritonitis; adjunct amphotericin B in case of clinical sepsis	—		•	2 case series (6 and 12 pts) [54,55]			•	Success rate 4/6 and 9/12, respectively
								More data needed
Technique-related treatment of peritonitis								
Endoluminal brushing	—		•	1 case serie (3 pts) [56]			•	Peritonitis resolved in 2 of 3 cases; no adverse effects
								More data needed
Antimicrobial prophylactic interventions								
Mupirocin vs. placebo, intranasal in patients and caregivers with *S. aureus* carriage	—	•		1 RCT (92 families of CPD pts), double blind, placebo controlled; results not yet published [46]	•			Significant protective effect of mupirocin prophylaxis on ESI rate; *S. aureus* strains are shared among family members and transmission from parental noses to exit sites is common (Schaefer, pers. commun. 2006)
								Risk of resistance; trial not yet published; low likelihood that trial will show harm; evidence from adult studies shows benefit
Mupirocin intranasal in patients with *S. aureus* carriage	—		•	1 single-arm trial (47 pts) with historical controls (77 pts), 1 case series (13 pts); inconsistent results [65,66]			•	Both no benefit and benefit reported
								More data needed
								Prophylactic treatment of both patient and caregivers with *S. aureus* carriage suggested (see above)
Oral rifampin and topical bacitracin vs. no treatment in patients with *S. aureus* carriage	—		•	1 small RCT (15 pts), suboptimal quality [57]			•	Infection rate in treated vs no treatment group, 0/7 vs. 4/8; rate diff −50% (95% CI, −79 to −0.05)
								More data needed

(*Continued*)

Table 63.3 *(Continued)*

Intervention	SR	Moderate	Low	Comment [reference(s)]	I	II	III	Comment
Perioperative antibiotics at surgical catheter placement vs. no treatment	—		•	1 retrospective cohort study (73 pts, 29 CPD pts) [58]	•			Postoperative peritonitis rate 6/61 in antibiotic group vs. 7/16 in no-treatment group Low likelihood that trials will show harm; evidence from SR of adult RCTs shows benefit for perioperative antibiotics
Povidone iodine (PI) vs. chlorhexidine (CH) exit site care	—		•	2 retrospective cohort studies (130 and 33 pts), inconsistent results [45,63]			•	Increases and no increases in ESI rates reported for PI vs. CH; no difference in peritonitis rates; adverse effects for PI reported; CH occasionally causes skin irritation Inconsistent evidence; more data needed
3% amuchina vs. 50% amuchina exit site care	—		•	1 single-arm trial (27 pts) (case series) with historical controls (18 pts) [64]			•	Similar ESI rates in both groups; no side effects More data needed
Technique-related prophylactic interventions								
Flush-before-fill APD	—	•		1 RCT (121 pts), suboptimal methodological quality [59]			•	Uncertain benefit; only benefit shown in women was peritonitis rate, flush vs no-flush group 1/44.7 vs. 1/12.4 pt-mos; no expected harm in men Further data needed
Fibrin glue vs. no sealant	—		•	1 RCT (45 pts, 52 catheters), small sample size, suboptimal methodological quality, one case series (8 pts) [41,60]		•		RCT: ESI (3/26) and peritonitis rates (1/26) similar; leakage with fibrin glue vs. no sealant, 3/26 vs. 14/26, rate diff −42% (95% CI, −61 to −17%); no side effects Use to prevent leakages suggested, more evidence needed regarding prevention of infections
Double vs. single cuff	—		•	NAPRTCS Registry (2971 pts), 1 retrospective cohort study (78 pts), 1 pseudo-controlled trial (two consecutive groups) (40 pts); inconsistent results [7,22,61]			•	Both increased and decreased infection rates of single vs. double cuff have been reported Inconsistent evidence, more data needed. No benefit of single or double cuff shown in SR of adults RCTs
Two disconnect vs. spike	—		•	One retrospective cohort study (53 pts)[67]		•		Peritonitis rate two-disconnect vs. spike, 1/58 vs. 1/10 Superiority of two disconnect shown in SR of adult RCTs; low likelihood that trials will show harm
Exit sites pointing downward vs. upward or lateral	—		•	NAPRTCS Registry (2971 pts), one retrospective cohort study (130 pts). Inconsistent evidence[7,45]			•	Both decreased and similar infection rates of downward vs. upward and lateral reported Low and inconsistent evidence base, more data needed
Delayed vs. early catheter use postplacement	—		•	2 retrospective observational studies (90, 53 pts)[40,62]			•	No difference in infection rates (ESI, TI, peritonitis) between both groups; different definitions of early and delayed use (14 vs. 7 days) More data needed

Abbreviation: ESI, TI,

a Evidence rating based on study design, study quality, consistency, and directness of results. No intervention was rated with a high evidence rating.

b Recommendations based on trade-offs between benefits and harms, quality of evidence, translation into clinical pratice, uncertainty about the baseline risk of the disease in the population. I, recomend; II, suggest; III, no recommendation possible.
Figure 63.1 Proposed therapeutic strategy of peritonitis in gram-positive and gram-negative organisms on culture. From the ISPD Guidelines (www.ispd.org) published by Warady [48].

infections [46]. *S. aureus* peritonitis is responsible for the most serious episodes of infection [47].

Guidelines

The International Society for Peritoneal Dialysis (ISPD) guidelines, which are largely expert opinion-based, for the management of peritonitis in pediatric PD patients are currently the most specific, clinically useful guide to the appropriate treatment of these patients [48]. Recently, an International Pediatric Peritonitis Registry has been established among pediatric PD centers worldwide to evaluate the impact of these guidelines (www.peritonitis.org) [49]. The most important issues are summarized in Table 63.2 and Figure 63.1.

Available evidence

Our search identified three Cochrane systematic reviews of RCTs on antimicrobial and technique-related strategies to prevent PD-related infections that included both adult and pediatric patients [50–52]. However, pediatric data could not be separated from most individual trial data. Moreover, numbers were far too small to allow subgroup analyses. Only a few pediatric RCTs have been conducted, with most of them including a small number of patients and of suboptimal methodological quality to allow evidence-based treatment recommendations. Most pediatric studies are retrospective observational studies or case series. Table 63.3 summarizes the evidence on interventions to treat and prevent PD-associated infections [7,22,40,41,45,46,47,53–67]. We have focused on only the most important studies.

Treatment of peritonitis and catheter-related infections

The best pediatric evidence has been provided by a multicenter RCT in a relatively large pediatric sample of 152 children with CPD-associated peritonitis that compared continuous versus intermittent intraperitoneal glycopeptide–ceftazidime treatment on treatment response [47]. This RCT showed that a combination of a glycopeptide with ceftazidime as first-line treatment is efficacious and safe. Intermittent and continuous treatment, either with vancomycin or teicoplanin, are equally efficacious and safe when measured by objective clinical criteria (DSS score). In gram-negative peritonitis, intermittent treatment was less successful than continuous treatment according to clinical judgment (27% vs. 73%) but not according to DSS (73% vs. 86%). Hence, more evidence is needed for this subgroup. These findings are in line with results in adults [68] and support the ISPD guidelines. Pediatric RCTs evaluating the efficacy of interventions to treat exit site and tunnel infections are lacking.

Preventive antibiotic interventions

S. aureus is the most frequent microorganism involved in catheter-related infections [69]. We identified two RCTs [46,57] on antibiotic preventive strategies in pediatric PD patients. In line with evidence from adult studies [52], a recently completed

placebo-controlled RCT showed that the use of intranasal mupirocin in nasal *S. aureus* carrier families, that is, patients and caregivers, had a significant protective effect on|exit site|infection rate in the first treatment year (F. Schaefer, personal communication, 2006). It also showed that *S. aureus* strains are shared among family members and that transmission from parental noses|to exit sites is common. Up to 50% of patients and/or caregivers were colonized with *S. aureus* within 6 months [46]. These findings support ISPD recommendations to use prophylactic antibiotic therapy for *S. aureus* carriers. Widespread use of mupirocin carries the risk of emergence of mupirocin-resistant *S. aureus* strains (MuRSA). The emergence of high-level MuRSA was reported in 4 of 149 adult CPD patients of one dialysis unit after 4 years of prophylactic use of mupirocin at the exit site. Therefore, large PD centers using mupirocin in CPD patients should have periodic surveillance, at least yearly, to detect the emergence of MuRSA [70].

The recommendation by the Ad Hoc Committee [35] of prophylactic antibiotic treatment prior to PD catheter insertion is only supported by one retrospective analysis in pediatric CPD patients. This study showed a peritonitis rate, within 14 postoperative days, of 44% in untreated patients versus 10% in prophylactically treated patients [58]. A meta-analysis of RCTs in adult PD patients showed a significantly reduced risk of early peritonitis in patients who received perioperative antibiotics compared to no treatment. No effect was seen on exit site infections and peritonitis at 1 month after catheter insertion (RR, 0.15; 95% CI, 0.15–0.80) [52].

Technique-related preventive strategies

RCTs in pediatric PD patients to evaluate the effect of technique-related preventive strategies are scarce. We identified one RCT of 121 children on APD that evaluated the impact of the flush-before-fill technique on peritonitis frequency [59]. Overall, no difference in peritonitis rate was seen between patients in the flush and no-flush groups. Gender-stratified analysis showed a significant improvement in peritonitis rate in the flush compared to no-flush group in female patients but no difference in male patients. Because this subgroup analysis was not based on an *a priori* hypothesis and there is no biological plausibility for this finding, confirmation of this result is needed. Use of fibrin glue, compared with no sealant, prevented catheter leakage in an RCT of 45 CPD children. No effect was seen on incidence of catheter infections or peritonitis [41]. Studies evaluating the effect of catheter type (double- vs. single-cuffed catheters; downward- vs. upward- or lateral-pointing exit sites) in children have shown conflicting results [7,22,45,61]. Evidence from two systematic reviews of adult RCTs on technique-related preventive interventions showed that the only technique-related measure that reduced infection rate was the use of disconnect rather than conventional spike systems. Because many studies have been small and follow-up is often short, the possibility of a type 2 statistical error cannot be excluded [50,51].

Recommendations regarding proper training were supported by an ISPD survey [71]. This survey found that the peritonitis rate was significantly lower in programs with longer training time dedicated to theory and practical, technical skills [71]. Also, the low peritonitis rates reported by Japanese centers with long and rigorous training programs support these recommendations [45]. Observational studies in children report improvement of catheter survival over time, suggesting that routine and local skills with respect to the technical procedure might be of more importance than the specific type of catheter used [15,24].

Clinical implications

There is a lack of good-quality evidence from studies on the prevention and treatment of PD-related infections in children on which to base definitive treatment recommendations. There is a need for better-designed RCTs in this area.

The skills of the surgeons who place the catheters, and also the nurses and caregivers in achieving aseptic technique, may be of more importance in the prevention of PD-associated infections than the type of catheter or the several proposed prophylactic antibiotic strategies. There is no evidence supporting the superiority of any specific catheter design. Intravenous antibiotics at implantation may reduce the incidence of early peritonitis and can be recommended. The use of mupirocin may reduce the incidence of *S. aureus* infections, but possibly at the cost of an increase in resistance. A strategy to start mupirocin prophylactically after the first *S. aureus* infection is reasonable. Vancomycin or teicoplanin can be safely administered intermittently in case of peritonitis.

Adequacy of Dialysis

It is difficult to define outcomes of adequate dialysis in children, because most children remain on dialysis for a relatively short period and, although the death rate for children on RRT is high in relation to children without RRT, in absolute terms it is low. Only two observational studies have assessed the association between adequacy of PD treatment and clinical outcome. Höltta *et al.* compared the outcome of 10 PD patients less than 5 years old, who were treated between 1995 and 1999, with 27 age-matched patients who had been treated between 1989 and 1995 [72,73]. Peritoneal equilibration tests (PET), urea Kt/V, and creatinine clearance assessments were added to the program, and the optimal dialysis regimen was calculated using the PD ADEQUEST program (Baxter Healthcare). Targets for total weekly urea Kt/V and normalized creatinine clearance were >1.7 and >40 L/week, respectively, between 1995 and 1997 and >2.0 and >60 L/week, respectively, after 1997. Other treatment guidelines and the care team were unchanged. They found a 37% reduction in hospitalization, a 30% reduction in peritonitis rate, and a reduction from 41% to 0% of pulmonary edema in the 1995–1999 group compared to the 1989–1995 cohort. Metabolic control was significantly better in the 1995–1999 group with respect to serum mean phosphate levels (1.51 ± 0.48 vs. 2.01 ± 0.42; $P = 0.004$) with a lower calcium supplementation (836 ± 558 vs. 3641 ± 1717 mg/day; $P < 0.0001$). Schaefer *et al.* prospectively evaluated growth velocity, nutritional status, dialysis adequacy, and peritoneal membrane characteristics in a cohort of 51 CPD patients, ages 0.1–15.7 years, during an 18-month

period [74]. A high transporter state appeared associated with poor growth velocity and a high creatinine clearance. Moreover, high transporters appeared to be at risk for obesity.

In 2002, the Ad Hoc committee published guidelines, based largely on clinical experience, on adequacy of PD prescription in children [75]. The committee identified 15 clinical studies that evaluated the effects of strategies aimed at increasing adequacy. Only surrogate outcomes were studied, such as metabolic control, ultrafiltration, Kt/V, and creatinine clearance [73,76–89]. Details of these studies are summarized in Table 63.4 and will briefly be discussed below in the context of the European Workgroup guidelines.

Bicarbonate-buffered versus lactate-buffered dialysate

Three trials comparing the effects of bicarbonate-buffered versus lactate-buffered dialysate in children on PD and that used surrogate outcomes have been carried out [76–78]. Two of these studies were of moderate quality [76,77]. Results of a randomized crossover trial in 28 children on APD showed that neutral pH bicarbonate-buffered PD provided more effective correction of metabolic acidosis than conventional lactate dialysate after 12 weeks of treatment. Younger age appeared to be associated with increasing pH towards alkalosis on bicarbonate dialysis. Additionally, a twofold increase in carcinogen antigen-125 appearance rate in the effluent during bicarbonate dialysis was seen, suggesting a higher mesothelial regeneration rate during bicarbonate-buffered sessions (Table 63.4). A crossover RCT compared peritoneal transport in one PET using bicarbonate dialysate versus one PET using lactate PD in 25 children on APD [77]. Creatinine and phosphate clearances were 10% lower with bicarbonate dialysate compared to lactate dialysate. No other differences in peritoneal transport kinetics were found [76–78].

A small crossover trial in six children on APD showed less intraperitoneal pressure at a given intraperitoneal volume with combined bicarbonate–lactate–buffered dialysis compared to pure lactate-buffered dialysis [78], but these findings were not confirmed by others [80]. None of the studies reported differences in adverse effects between the two fluids. To clarify the clinical significance of the buffer choice in biocompatible PD fluids, a multicenter European RCT in 60 CPD children (EPPS) comparing 10 months of use of bicarbonate- versus lactate-buffered dialysate on the preservation of the peritoneal membrane, metabolic control, and peritonitis rate, is ongoing [79]. No intervention studies are reported on the combination of bicarbonate dialysis and daytime icodextrin. One observational retrospective analysis reported a rise in mean blood bicarbonate from 23 ± 2 mmol/L up to 27 ± 2 mmol/L ($P < 0.05$) in 12 children 14 days after conversion from lactate-based dialysis to partly bicarbonate-buffered and partly lactate-buffered dialysate (Physioneal; Baxter) in combination with a daytime dwell with icodextrin [20].

Icodextrin

Five crossover trials have been performed in order to investigate the use of icodextrin dialysate on adequacy and safety aspects in children [80–82,84]. Although these studies were of insufficient methodological quality (small sample sizes, not randomized, short observation period), they support results of adult studies with respect to ultrafiltration and solute clearances [90], at least in children older than 2 years of age.

In a crossover study in eight children, 2–12 years old, undergoing nocturnal intermittent PD (NIPD), the addition of a daytime dwell with icodextrin increased weekly Kt/V from 1.99 to 2.54, phosphate clearance by 23%, and ultrafiltration by 44%. At the same time, a significant increase in peritoneal loss of essential amino acids was observed [83]. Although lower serum levels of amino acids were not found, the follow-up period was only 2 weeks, so studies with longer follow-up are necessary. Ultrafiltration was found to be much higher with daytime icodextrin than with a daytime 1.36% dextrose dwell and were comparable with a daytime 3.86% dextrose dwell in a crossover trial in 11 children ages 2.8–15.5 years [84].

Amino acid dialysate

Only three trials have been performed on the use of amino acid dialysis in children. In a randomized crossover study in seven children treated with CCPD for 3 months, amino acid dialysis appeared comparable to dextrose dialysis regarding peritoneal transport and metabolic control, except for higher urea levels. Improved appetite was the only benefit observed [86]. The amino acid dialysis was well-tolerated. No differences were found in growth velocity or nutritional status, although the follow-up was only 3 months. The same research group found similar results in a study of similar design in eight children on CAPD [85] treated with pure dextrose dialysate for 6 months and subsequently for 6–12 months with 1% amino acid dialysate substitution for one dwell per day. Correction of low blood levels of some essential amino acids (histidine, leucine, phenylalanine, valine, and isoleucine) was seen, but no change in anthropometric measures was found [87].

Fill volume, Kt/V, and creatinine clearance

In the previously discussed study by Schaefer *et al.* on adequacy in 52 CPD children, they found low fill volumes to be associated with low creatinine clearance and impaired growth and a hyperpermeable state to be associated with impaired growth [74]. RCTs are needed to confirm this association.

The area of the peritoneal membrane is twofold larger in infants than in adults if expressed per kg body weight (533 vs. 284 cm^2/kg) but independent of age if expressed per square meter of body surface. This implies that fill volumes should be prescribed per body surface and not by body weight. De Boer *et al.* compared the effect of dwell volume prescription by body weight (40 mL/kg) with prescription by body surface area (1,200 mL/m^2) on peritoneal transport within the same patients. An association was observed between age and net ultrafiltration when patients were treated with a dwell volume of 40 mL/kg body weight ($r = 0.68$; $P < 0.01$) but not when they were treated with a dwell volume of 1200 mL/m^2 body surface area [88]. The Ad Hoc Committee advises a maximal target of 1400 mL/m^2 fill volume in supine

Table 63.4 Evidence ratings and recommendations for interventions to enhance the adequacy of treatment in paediatric PD patients.

Intervention	SR	Moderate	Low	Comments [reference(s)]	I	II	III	Comments
Bicarbonate 34 m M vs. lactate 35 mM dialysate	—	•		3 multicenter RCTs (28, 25, and 60 pts); relatively large pt numbers, suboptimal methodological quality; consistent results; 1 trial ongoing [76,77,79]		•		***Favors bicarbonate dialysate*** *Better treatment acidosis *Less mesothelial damage *Small children alkalosis (?) *Equal transport, lower phosphate clearance not of clinical relevance *Well-tolerated *Less acidotic dialysate No clinical outcomes; insufficient follow-up time; more data needed
Bicarbonate/lactate vs. lactate dialysate (Physioneal vs. Dianeal, [Baxter])	—		•	1 single-center RCT, crossover (6 pts); small study, suboptimal methodological quality [78]		•		***Favors bicarbonate dialysate*** *Less inflow pain *Less intraperitoneal pressure, enhanced fill volume tolerance *Less capillary recruitment, better preservation membrane No clinical outcome, except dialysis comfort; more data needed
Icodextrin 7.5% vs. dextrose 3.86%	—		•	3 small open trials (9, 9, and 11 pts); suboptimal methodological quality; consistent results [80,82,84]		•		***Icodextrin can replace dextrose 3.86 and is safe*** Icodextrin: long dwells needed for adequate UF Short follow-up; no small children; clinical implications maltose/icodextrin in serum not known; more data needed
Icodextrin 7.5% vs. dextrose 1.36%	—		•	2 open trials (5, 9 pts); very small studies, wide age range, insufficient methodological quality; consistent results [81,82]		•		***Icodextrin better UF and phosphate & clearance clear but caution because of protein loss*** No small children; very short observation period; more data needed
Icodextrin 7.5% vs. no last bag	—		•	1 crossover trial (8 pts); small sample size; insufficient methodological quality; no information on serum AA levels at midterm (intervention stopped after 2 wks of increasing AA loss) [83]		•		***Increased loss of amino acids by icodextrin daytime dwell vs. no daytime dwell*** More data needed; monitoring serum levels of essential amino acids, indicated especially in young children
Amino acid (AA) daytime dwell vs. dextrose daydwell in CCPD (1) & CAPD (2,3)	—		•	3 open trials (7, 7, and 8 pts); small studies; insufficient methodological quality; consistent results [85–87]		•		***Amino acid is probably safe and could enhance appetite in children on PD*** No hard clinical outcome or apparent advantage; more data needed
Dwell volume 1200 m/m² vs. 40 mL/kg	—		•	1 open trial (4/4 pts.); small study; no mention of age of study group; insufficient methodological quality [88]		•		Dwell volumes scaled by kg body wt may lead to underdialysis with respect to UF in small children More data needed
Tidal vs. CCPD: 50% TD vs. CCPD, both overnight 1000 mL/m² fill volume & daytime dwell, 500 mL/m²	—	•		1 crossover trial (17 pts); suboptimal methodological quality [73]		•		Tidal higher dialysate flow rate and lower glucose concentration dialysate; both groups same Kt/V urea Tidal dialysis indicated in patients with high transport and reduced UF More data needed
Supine vs. upside posture	—		•	1 trial (6 pts); small study; insufficient methodological quality [89]		•		NIPD might be advantageous over CAPD as result of lower IPP and consequently superior solute transport. More data needed

a Evidence rating based on study design, study quality, consistency, and directness of results. No intervention was rated with a high evidence rating.

b Recommendations based on trade-offs between benefits and harms, quality of evidence, translation into clinical pratice, and uncertainty about the baseline risk of the disease in the population. I, recommend; II, suggest, III, no recommendation possible.

position and 1000–1200 mL/m² in the upright position [75]. This was suggested by the mass transfer area coefficient and ultrafiltration outcomes under various fill volumes in an observational study by Fischbach *et al.* in which fill volumes over 1400 mL/m² were associated with decreased phosphate clearance and clinical intolerance [91]. Apart from the prospective cohort study of Schaefer *et al.* [74], there are no pediatric data that support the adult recommendations of a weekly Kt/V of >2.0–2.2 or a weekly creatiine clearance of >60–66 L/1.73 m².

CCPD/NIPD CAPD tidal PD

Automatic PD is mostly prescribed for its obvious social advantages over CAPD in children. No studies exist that have compared the outcomes of CAPD and continuous cycling PD (CCPD) in children. Fischbach *et al.* studied the effects of supine versus upright position on peritoneal transport in six children. The use of the same dialysis prescription in the supine position compared to the upright position resulted in an approximately 17% higher equilibration of creatinine and phosphate as well as urea, lower loss of protein, a higher glucose absorption rate, and a lower intraperitoneal pressure. The net ultrafiltration was equal in both positions [89]. In theory, these outcomes favor the supine position, that is, NIPD over CAPD. However, the clinical significance of these outcomes is unclear, and the quality of the study is insufficient for clinical decision making. Höltta *et al.* compared tidal peritoneal dialysis and CCPD in a randomized, crossover trial in 17 children and found better clearances and lower glucose exposure in patients on tidal PD, especially in "high transporters" [73].

Clinical implications of the evidence on adequacy of PD in children

There is sufficient evidence that dialysate buffered with bicarbonate or combined bicarbonate–lactate is well-tolerated in children, at least in older children. In young children, at least in combination with an icodextrin daytime dwell, overt alkalosis may occur, which could lead to low ionized calcium levels. Phosphate clearances may be somewhat lower than with lactate-buffered dialysate, but not to an extent that has clinical implications. There is indirect evidence that, compared to lactate, pure bicarbonate-buffered or partly bicarbonate-buffered dialysate causes less mesothelial damage. Whether this will also lead to a more prolonged preservation of the peritoneal membrane still must be proven in long-term studies. There is sufficient evidence that icodextrin is as effective as 3.86% dextrose with respect to ultrafiltration and solute clearance. Because of the avoidance of high glucose exposure to the peritoneal membrane, icodextrin can be recommended in children over 2 years of age. Little data exist on its use in children less than 2 years of age.

Further studies are warranted to explore the possible harm of extensive loss of essential and nonessential amino acids, as well as the impact of high blood pH, that might occur in small children on icodextrin in combination with bicarbonate-buffered NIPD. A daytime dwell with amino acid dialysate might correct low blood levels of amino acids and enhance the appetite and caloric intake in undernourished children on PD, but more data are warranted to prove its real benefit in the long term. There is only very weak evidence that increasing creatinine clearance due to PD is associated with better clinical outcome in children; there is even more uncertainty with urea Kt/V. Optimal fill volumes are associated with optimal ultrafiltration and offer the possibility for use of dextrose concentrations as low as possible, which may enhance peritoneal membrane preservation. There is moderate evidence that tidal PD is advantageous over NIPD in high transporters. There is no evidence that NIPD is superior to CAPD.

64 Pediatric Hemodialysis

Stuart L. Goldstein

Renal Dialysis Unit and Pheresis Service, Baylor College of Medicine, Houston, USA

Introduction

Provision of evidence-based pediatric hemodialysis recommendations is hampered by a number of epidemiological issues. Kidney transplantation remains predominant and the preferred renal replacement therapy modality for children, peritoneal dialysis is a viable modality option for many pediatric patients [1], and children with end-stage renal disease (ESRD) exhibit significantly better survival rates compared to adult patients [2]. Thus, no long-term pediatric outcome study comparable to the HEMO study [3] or the National Cooperative Dialysis Study [4] would be adequately powered to detect an effect of delivered hemodialysis dose on pediatric patient outcome.

Technological advances and professional expertise specific for pediatric patients with kidney failure have developed relatively slowly. In the past 10 years, however, the hemodialysis procedure has become increasingly sophisticated, and many of the theoretical and technological advances studied previously in adult patients have been applied to children receiving hemodialysis. In fact, the most recent US Renal Data System report revealed that more children receive hemodialysis than peritoneal dialysis for their maintenance dialysis modality [1].

Data to support the recommendations cited in this chapter, therefore, are generally limited to reports from large, multicenter registries or government-sponsored databases and single-center reports. Specifically, pediatric data related to small-solute clearance measurement, vascular access placement and surveillance, ultrafiltration management, and nutrition provision will be reviewed. Recommendations and consensus guidelines from various working groups will be presented in each section, but they are collated together in a single table (Table 64.1).

Physiology of hemodialysis: pediatric issues

The factors that govern the physiology of hemodialysis, namely, diffusion and convection, are the same for pediatric and adult patients. Currently, most pediatric patients receive maintenance hemodialysis on a thrice-weekly in-center schedule, but recent data suggest that home nocturnal hemodialysis or more frequent hemodialysis may lead to improved blood pressure control and growth, a decreased need for dietary and fluid restrictions, and improved health-related quality of life [5,6]. Most pediatric-specific issues arise in hemodialysis provision to infants and small children, for whom the size of the extracorporeal circuit and blood pump flow rates can affect hemodynamic stability.

The hemodialysis circuit is comprised of the patient's blood compartment access in the form of an arteriovenous fistula (AVF) or graft (AVG) or a venous catheter, polyethylene tubing through which the patient's blood travels to and from the dialyzer, and the dialyzer itself. Blood tubing is produced in a variety of sizes and should be matched to allow for optimal blood flow while minimizing the volume of the extracorporeal circuit, which is the sum of the blood tubing volume and hollow fiber dialyzer volume. To prevent excessive repeated blood loss in the circuit and hemodynamic instability, the extracorporeal circuit should not exceed 10% of the patient's calculated blood volume [7]. Neonatal lines with a volume of 40 mL are available for use in children weighing less than 15 kg.

In order to prevent hypovolemia during initiation of dialysis treatment, the circuit should be primed with either saline or colloid. In some infants, for whom even the smallest blood tubing and dialyzer volumes would exceed 10% of patient blood volume, the circuit should be primed with colloid (5% albumin or packed red blood cells diluted with albumin to a measured hematocrit of 35%) instead of crystalloid. Weekly serum hematocrit values should be obtained to monitor for anemia resulting from excessive blood loss in the hemodialysis circuit for infants less than 10 kg maintained on chronic hemodialysis. The blood pump flow rate (Qb) should be prescribed to provide optimal clearance of solute safely. Use of

Table 64.1 Current guidelines and clinical practice recommendations for pediatric patients receiving maintenance hemodialysis.

Guideline	Country or Region	Year	Recommendations
Hemodialysis Adequacy			
K/DOQI	USA	2006	sp*Kt*/*V*, calculated either by formal UKM or by the second-generation natural logarithm formula should be used for month-to-month assessment of delivered hemodialysis dose.
			Pediatric patients should receive at least the delivered dialysis dose recommended for the adult population.
			For younger pediatric patients, prescription of higher dialysis doses and higher protein intake at 150% of the RNI for age may be important.
			Dialysis dose prescription should not only be a urea dialysis dose. Removal of the other uremic toxins should be considered, not only middle molecules but overall phosphate.
European Pediatric Dialysis Working Group	Europe	2005	Urea kinetic assessment enables not only urea dialysis dose calculation, i.e.*Kt*/*V*, but also estimation of protein intake by use of nPCR. Fasting to enable a short-duration three times/week dialysis schedule is inadequate care management.
Ultrafiltration Management			
K/DOQI	USA	2006	Accurate assessment of patient intravascular volume during hemodialysis treatment should be provided to optimize ultrafiltration.
Vascular Access Management			
K/DOQI	USA	2006	Permanent access in the form of an AVF or AVG is the preferred form of pediatric vascular access.
			Circumstances under which a central venous catheter may be acceptable for chronic access include lack of local surgical expertise to place permanent vascular access in small children, patient size too small to support a permanent vascular access, bridging hemodialysis for peritoneal training or peritoneal catheter removal and expectation of expeditious kidney transplantation.
			If surgical expertise to place permanent access does not exist in the patient's pediatric setting, efforts should be made to consult vascular access expertise among local adult-oriented surgeons to either supervise or place permanent vascular access in children.
			Serious consideration should be given to placing permanent vascular access in children >20 kg who are expected to wait more than 1 year for kidney transplant.

a maximum Qb of less than 400 mL/min/1.73 m^2 of patient body surface area minimizes the risk of cardiovascular compromise.

Hemodialysis adequacy

Definition and background
The term hemodialysis adequacy is derived from the National Co-operative Dialysis Study, which aimed to control dialysis treatment dosing in adult patients and correlate a particular dose with patient outcome [4]. Formal urea kinetic modeling (UKM) solves two unique, but interrelated, differential equations for two variables: patient total body water (V, in milliliters) and urea generation rate (G, in milligrams per minute). Values for V and G are then used to calculate normalized urea clearance during a dialysis treatment and the patient protein catabolic rate (PCR). The PCR is then divided by the postdialysis patient weight (in kilograms) to yield a normalized protein catabolic rate (nPCR). The fractional urea mass removed during hemodialysis is affected by the following factors: dialyzer urea clearance coefficient (K, in milliliters per minute), pre- and posttreatment blood urea nitrogen (BUN), treatment duration (t, in minutes), patient total body water (V, in milliliters), the amount of plasma water removed during dialysis

(ultrafiltrate), and the intradialytic G. Pre- and postdialysis measured BUN levels, the dialyzer K for urea at the delivered blood pump flow rate, time of treatment, and pre- and postdialysis patient weight are provided to the UKM algorithm. The difference between the pre- and postdialysis weights yields the ultrafiltration volume obtained during the treatment.

Pediatric-specific issues
Subsequent studies, such as the HEMO trial [3], which assessed the effect of small-solute clearance and increased convective clearance on mortality in adult maintenance hemodialysis patients, have not been performed in pediatric patients because relatively few children receive hemodialysis. Nevertheless, some recent pediatric data exist to describe the most accurate methods for quantifying urea removal, correlate delivered dose of dialysis with inflammation, and looking at other components of the dialysis prescription, including ultrafiltration and nutrition provision. These data can serve as a basis for clinical practice recommendations in caring for children receiving hemodialysis [8]. Although no current data exist to recommend a minimally acceptable hemodialysis dose for children, measurement of *Kt*/*V* is important in order to control for hemodialysis dose in outcome studies. For instance, Tom and colleagues demonstrated that improved growth could be achieved

Table 64.2 Pediatric hemodialysis adequacy studies.

Study ID	Assessment	No. of measurements
spKt/V		
Goldstein 1999	Comparison of Daugirdas II to UKM	21 patients, 103 measurements
Goldstein 2001	Comparison of Daugirdas II to UKM	39 patients, 367 measurements
eqKt/V		
Smye 1994	Mid-dialysis BUN sample to estimate eqBUN	14 patients, 14 measurements
Goldstein 1999	Logarithmic extrapolation of a 15-min post-BUN sample to estimate eqBUN	6 patients, 6 measurements
Sharma 2000	Use of a variable volume two-pool UKM to estimate eqKt/V	17 patients, 17 measurements
Goldstein 2000	Logarithmic extrapolation of a 15-min post-BUN sample to estimate eqBUN	21 patients, 21 measurements
Marsenic 2004	Linear regression equation	15 patients, 38 measurements
Goldstein[a] 2006	Comparison of eqKt/V and spKt/V to determine if 0.20 expected difference would lead to prescription changes	1513 measurements

[a] Conducted as part of the Center for Medicare and Medicaid Services Clinical Performance Measures (CMS CPM) project.

in patients with intensive hemodialysis (Kt/V of 2) and nutrition [9]. Goldstein showed that the proinflammatory cytokine concentrations were inversely proportional to Kt/V[10].

Current recommendations from the Kidney Disease Outcomes Quality Initiative (K/DOQI) suggest that children undergoing thrice-weekly maintenance hemodialysis receive at least the same minimum amount of urea clearance recommended for adults, namely, a single-pool Kt/V (spKt/V) of 1.2 [11]. No other guideline committee has offered pediatric-specific hemodialysis dose recommendations to date.

The K/DOQI recommendations are based on a number of single-center studies, which mostly focus upon urea clearance measurement methods. Substantial investigation has been performed to develop and validate Kt/V measurement methods more simple than UKM. Of these, only the natural logarithm formula of Daugirdas [12] garnered acceptance for spKt/V approximation in adults and children. The Daugirdas natural logarithm formula (Daugirdas II) is as follows: $Kt/V = -\ln(C_1/C_0 - 0.008 \times t) + [4 - 3.5 \times C_1/C_0)] \times$ UF$/W$, where C_0 is the predialysis BUN, C_1 is the postdialysis BUN, t is the session duration (in hours), UF is the ultrafiltration volume (in milliliters), and W is the postdialysis weight (in kg). The accuracy of the Daugirdas II equation resides in the accounting for dialysis treatment duration and urea removed by ultrafiltration.

Goldstein demonstrated Daugirdas II to be a reliable and practical alternative to formal UKM for estimation of Kt/V in a large group of pediatric patients receiving hemodialysis [13,14]. A total of 367 dual Kt/V analyses comparing UKM Kt/V to Daugirdas II Kt/V demonstrated less than a 6% difference in every treatment, and the difference did not vary with patient size. K/DOQI guidelines recommend a prescription for Kt/V of 1.3 to ensure Kt/V delivery of 1.2 and allow for the use of Daugirdas II to calculate spKt/V [15].

The Kt/V calculation is based upon sampling the pre- and post-treatment BUN levels. In adults and children, the posthemodial-ysis BUN concentration rises in a logarithmic fashion until equilibration occurs 30 to 60 min after a hemodialysis treatment, a phenomenon termed urea rebound. As the BUN rises with equilibration posthemodialysis, the resultant calculation of Kt/V yields a lower value. Calculation of Kt/V by single-pool kinetics using the immediate, 30-s postdialysis BUN (BUN$_{30s}$) sample does not take urea rebound into account and leads to overestimation of the true urea mass removed during dialysis. Calculation of Kt/V by double-pool kinetics (eqKt/V) is based on a postdialysis BUN level actually drawn or estimated after the completion of urea rebound. Numerous studies in both children and adults have demonstrated that urea rebound ranges from 7.6% to 24% and accounts for a 12.3–16.8% difference between spKt/V and eqKt/V values [16–21]. It is impractical to wait 1 h after a treatment to obtain an equilibrated BUN (eqBUN) level for calculation of eqKt/V. Many formulas have been devised to estimate eqKt/V by applying a cofactor to spKt/V and relying solely on a pretreatment and 30-s posttreatment BUN levels. Smye and colleagues used a mid-dialysis BUN sample 80 min after treatment initiation and used the following approximation formula to estimate eqBUN: Ceq $= C_0 \times e^{-\lambda T}$, where $\lambda = (1/T - S) \ln(C_s/C_t)$ and C_0 is the pre-hemodialysis urea concentration, T is the duration of the dialysis session, S is the time into the hemodialysis session that the urea sample C_s was drawn, C_s is the BUN concentration at time S, and C_t is the BUN concentration at the end of hemodialysis [17]. In 14 patients, an average error in the calculation of Kt/V of 35% (range, 19–75%) by the single-pool UKM was reduced to 13% (range, 1–55%, but eight measurements were <7%) using the approximate technique. Marsenic has derived linear regression equations to describe a relationship between spKt/V and eqKt/V in children, demonstrating a mean difference of 0.26 + 0.18 and an excellent correlation ($R^2 = 0.76$; $P < 0.0001$) [22]. However, this regression equation has not been validated in a different patient group.

Sharma developed a pediatric-specific variable volume double pool kinetic model with measurements from a cohort of

15 patients and then applied that model to predict measured eq*Kt/V* in 17 different measurements [16]. Results from this study demonstrated a very low difference in measured versus estimated eq*Kt/V* (0.06 + 0.07) and performed better than the Smye method, variable-volume, and fixed-volume single-pool methods. Because urea rebound is primarily characterized by a first-order logarithmic, concentration-dependent intercellular fluid (ICF)-to-extracellular fluid (ECF) urea movement, Goldstein evaluated a more recent method for estimating eqBUN by extrapolating the rise in BUN from 30 s to 15 min posttreatment (ΔBUN) [19]. Since urea rebound is 69% complete at 15 min postdialysis [21], eqBUN can be estimated (estBUN) using the following formula: estBUN = $[(BUN_{15min} - BUN_{30s})/0.69] + BUN_{30s}$.

The difference between eq*Kt/V* based on a measured eqBUN and estimated eq*Kt/V* based on estBUN by logarithmic extrapolation was less than that of other published eq*Kt/V* estimation methods used in adult and pediatric patients.

A recent pediatric study evaluated potential differences in hemodialysis treatment prescription using the Center for Medicare and Medicaid Services Clinical Performance Measures data sets [23]. An expected difference in *Kt/V* ($\Delta Kt/V$ = sp*Kt/V* − eq*Kt/V*) of 0.20 was set based on results of the HEMO study [3]. Adequacy discordance was defined as a $\Delta Kt/V$ of >0.20, because such a discordance could lead to an adequate sp*Kt/V* but an inadequate eq*Kt/V*, thereby resulting in different clinical actions. A total of 1513 paired sp*Kt/V* and estimated eq*Kt/V* results were available for comparison. Examination of the different sp*Kt/V* and estimated eq*Kt/V* pairings revealed a greater adequacy discordance rate between a 0.20 difference in sp*Kt/V* and estimated eq*Kt/V* at higher *Kt/V* values, but *Kt/V* discordance rates only varied from 0.3 to 5.5%, depending on the paired *Kt/V* values used. The authors suggested that these low discordance rates supported the use of sp*Kt/V* as acceptable for patient management.

The K/DOQI hemodialysis guidelines do not recommend eq*Kt/V* as essential in the measurement of month-to-month patient hemodialysis adequacy, stating that sp*Kt/V* assessment of urea clearance is sufficient for patient management. However, the guidelines recommend use of eq*Kt/V* to control for hemodialysis dose in outcome studies [11].

Target dry weight assessment and ultrafiltration management

Accurate determination of patient target weight is a challenging task when treating hemodialysis patients. Symptoms of hypovolemia may be difficult to assess, as the behavior of small children receiving dialysis is often difficult to interpret. Furthermore, children are growing and have variable appetites, so that real weight loss and weight gain may occur more frequently than in adults.

Accurate determination of pediatric target weight is critical, because an underestimation of dry weight can lead to hypovolemia with acute symptoms, whereas chronic overestimation of target weight can lead to chronic volume overload with resultant hypertension, pulmonary edema, congestive heart failure, and left ventricular hypertrophy. Ultrafiltration-associated symptoms may occur with an appropriately determined dry weight, especially in patients with large interdialytic weight gains. Approaches to minimize ultrafiltration-associated symptoms include sequential ultrafiltration and dialysis (or isolated ultrafiltration at the start of a treatment), sodium modeling, and noninvasive monitoring (NIVM) of hematocrit.

Sodium modeling

Sodium modeling is a machine-programmed algorithm that varies the dialysate sodium concentration during the treatment. Most modeling programs utilize hyperosmolar dialysate sodium concentrations at the beginning of treatment, which are designed to offset the decrease in serum osmolarity resulting from urea removal during dialysis. Sadowski demonstrated sodium modeling to be effective in decreasing both intra- and interdialytic symptoms in a prospective study of 16 adolescent and young adult patients [24].

NIVM of hematocrit

Because red blood cell volume remains constant during dialysis, changes in hematocrit will be inversely proportional to changes in intravascular volume. Continuous optical methods of NIVM for hematocrit take advantage of this relationship to demonstrate a real-time association between fluctuating hematocrit and intravascular volume during the hemodialysis treatment.

NIVM has been studied recently in pediatric patients receiving hemodialysis. Jain conducted a retrospective single-center review of ultrafiltration-associated event rates (hypotension, headache, or cramping that required a nursing intervention) in 200 matched treatments with and without NIVM. Event rates were lower, especially for patients less than 35 kg, when NIVM was performed, without a sacrifice in target weight achievement [25]. When NIVM was performed, symptom events in the first 90 min of a treatment occurred only with a blood volume change of greater than 8%/h. Seventy-one per cent of events occurring after 60 min of treatment initiation were associated with a blood volume change greater than 4%/h. Michael employed these treatment time and event observations to prospectively model ultrafiltration rates to lessen the need for antihypertensive medications and minimize intra- and interdialytic patient symptoms [26]. That model prescribes half of the total treatment ultrafiltration volume to be removed in the first 60 min of treatment with a maximum of a total 12% blood volume change as depicted on the NIVM. The remainder of the ultrafiltration volume is then removed during the final 2–3 h of treatment. Goldstein conducted a retrospective review before and after institution of this NIVM-guided UF algorithm and found a significant reduction in patient hospitalizations and additional treatments for fluid overload and hypertension [27]. The current K/DOQI guidelines now recommend NIVM for ultrafiltration modeling in children receiving maintenance hemodialysis [11].

Table 64.3 Semipermanent hemodialysis catheter and patient size guidelines.

Patient size (kg)	Catheter option(s)
<10	Made on case-by-case basis
10–20	8-French dual lumen
20–25	7 French twin Tesio®
25–40	10 French dual lumen
	10 French Ash Split®
	10 French twin Tesio®
>40	10 French twin Tesio®
	11.5 or 12.5 French dual lumen

Nutrition management

The important relationship between nutrition status and outcome for patients with ESRD prompted the K/DOQI to create guidelines to assess and treat malnutrition in both children and adults with ESRD [28]. The pediatric K/DOQI guidelines recommend measurement of serum albumin, height or length, dry weight, midarm circumference, skinfold thickness, fronto-occipital circumference, and height Z-score to monitor nutrition status and intensive enteral nutrition administration to treat protein energy malnutrition (PEM). There are also data on prealbumin being a more sensitive measure of current nutritional status than anthropomorphic indices. Although these measures may be important to monitor for and treat PEM, they may not be sufficient in all cases. Investigation into the validity of nPCR has been performed since the early 1980s and has demonstrated a positive correlation between dietary protein intake and nPCR [29]. These studies suggested that positive

nitrogen balance, which is essential for growth, can be achieved with moderate protein intake and without an increase in dialysis requirements. A recent investigation has shown nPCR to be more sensitive and specific than serum albumin as a marker for nutrition status in malnourished pediatric hemodialysis patients [30,31].

Provision of adequate nutrition is essential to delivering optimal dialysis. Tom performed a prospective study of 12 patients and showed that increased protein administration (150% of the recommended daily allowance for protein) and urea clearance (Kt/V, 2.0) led to improved growth in children receiving hemodialysis who did not receive growth hormone [9]. Krause [32], Goldstein [30], and Orellena [31] have used intradialytic parenteral nutrition to treat severe PEM in a total of 13 children receiving hemodialysis.

Vascular access

Adequate provision of hemodialysis depends upon a properly functioning vascular access. Current maintenance hemodialysis access options are divided into two categories: permanent access in the form of an AVF or AVG and semipermanent access in the form of catheters with a subcutaneous cuff.

Permanent vascular access in the form of an AVF or AVG can function for many years and is preferred over indwelling catheters for most children. The majority of children receiving maintenance hemodialysis in the USA are dialyzed via a catheter [33,34]. Reasons for high catheter use include small patient size, lack of local surgical experience of permanent access creation in smaller patients, anticipation of a short dialysis course prior to transplantation, or a dialysis unit philosophy to decrease painful procedures (i.e. repeated needle sticks for children with AVF or AVG). The 2006 K/DOQI Vascular Access update featured pediatric-specific

Table 64.4 Evidence ratings and recommendations for hemodialysis prescription to improve outcomes in pediatric patients.

Intervention	SR[a]	Evidence rating[a,b] Moderate	Low	Comment	Recommendation[c] I	II	III	Comment
eqKt/V and spKt/V vs UKM	—	•		8 studies (767 patients); generally consistent results	•			Simple, convenient, consistent measurements
Increased Kt/V (>1.2)	—		•	2 studies (12 patients for growth, 13 for inflammation)			•	Increased growth; reduced risk of inflammation, no separation of dialysis dose vs duration
Sodium modeling	—		•	1 study (16 patients)			•	Reduced intra- and interdialytic symptoms
NIVM	—		•	3 studies (74 patients); generally consistent results		•		Reduced hospitalization, hypertension, and intradialytic event rates
Ultrasound dilution to predict access stenosis	—		•	2 studies (22 patients); generally consistent results			•	Reduced flow predicts thrombosis

[a] Systematic review of randomized controlled trials.

[b] Evidence rating based on number of studies, study design, study quality, and consistency of results. No intervention was rated with a high evidence rating.

[c] Recommendations based on efficacy, trade-offs between benefits and harms, quality of evidence, and availability of intervention. I, recommend; II, suggest; III, no recommendation possible.

recommendations for the first time [11]. While the K/DOQI guidelines advocate permanent access placement in children >20 kg in size, Bourquelot has demonstrated successful AVF placement in children <10 kg in size by using microsurgical techniques [35,36]. The main drawback for AVF creation in such small children is an extended maturation time of up to 6 months.

Thrombosis of permanent access is a significant cause of morbidity for the hemodialysis patient population [37]. In many instances, thrombosis results from decreased access flow caused by a stenosis of the access venous outflow tract [38,39]. Many methods for assessing outflow stenosis in adult patients have significant drawbacks that preclude routine use. Ultrasound dilution is a practical, noninvasive, and reliable indicator of vascular access flow (QA, in milliliters per minute) and has been used effectively to identify venous stenosis in adult patients receiving hemodialysis [40–42]. The hemodialysis lines are temporarily reversed (to create recirculation), and a 20-mL bolus of saline is injected quickly into the venous line proximal to a sensor. The sensors are attached to a computer that interprets the changes in Doppler velocity within each line as the hematocrit changes in relation to dialyzer blood flow to report QA.

Goldstein has shown that a QA corrected for patient size (QA_{corr}) of <650 mL/min/1.73 m^2 is extremely sensitive and specific for predicting AVG and AVF stenosis in pediatric patients receiving hemodialysis [43]. Furthermore, when patients with a QA_{corr} of <650 mL/min/1.73 m^2 were referred for venography and balloon dilatation angioplasty within 48 h of ultrasound dilution measurement, a 90% reduction in the vascular access thrombosis rate was realized, compared to an aggressive surveillance venography protocol [44]. The reduction in thrombosis rate was associated with decreased patient hospitalization and a 40% reduction in unit cost per patient for vascular access management [27].

Chand assessed the ability of increased dynamic venous pressure to detect AVG venous stenosis and decrease thrombosis rates. She found increased venous pressures to be poorly predictive of stenosis and did not correlate with thrombotic events [45].

Sheth evaluated long-term AVG and AVF survival in pediatric patients [48]. One, 3-, and 5-year pediatric AVF survival was 90, 60, and 40%, respectively. One-, 3-, and 5-year pediatric AVG survival was 90, 50, and 40%, respectively [46]. These data demonstrated that although 5-year AVG and AVF survival rates are not significantly different, AVG rates do exhibit higher thrombosis and surgical intervention rates. However, this cohort was studied prior to institution of the ultrasound dilution venous stenosis surveillance protocol, so current AVG survival potential may be extended in the future.

Although catheters are not preferred for hemodialysis vascular access, a patient size of <20 kg and expectation of kidney transplantation in less than 1 year are acceptable reasons for provision of hemodialysis to children with catheters [11]. Table 64.3 lists some of the available cuffed hemodialysis catheter options and provides a guideline for matching catheter size and type with patient size [11].

A few pediatric cross-sectional descriptive studies have assessed the survival rates and complications for pediatric hemodialysis catheters [47–49]. The most common complications observed include infection (either tunnel infection or line sepsis), kinking of the catheter, and thrombosis. Gram-positive organisms, especially *Staphylococcus* species, are the most common causative organisms in hemodialysis catheter infections.

Pediatric studies have demonstrate a dual-lumen hemodialysis catheter median survival of 204–280 days. Sheth conducted a single-center comparison of Tesio catheters versus dual-lumen catheters and found Tesio catheters exhibited significantly longer survival and provided adequate hemodialysis more reliably than dual-lumen catheters of similar size [49].

Evidence table

An evidence table summarizing the research base for various aspects of hemodialysis prescription in children is provided at the end of the chapter (Table 64.4). The most extensive research has occurred in hemodialysis dose measurement and vascular access management. No randomized controlled trials have been conducted in the pediatric hemodialysis population, but moderate evidence exists to support the routine measurement of hemodialysis dose in terms of Kt/V, and more specifically as eqKt/V, to control for hemodialysis dose in interventional trials. Further study is warranted to determine if more frequent, shorter-duration hemodialysis would lead to improved outcomes in pediatric patients.

Introduction

Urinary tract infection (UTI), vesicoureteric reflux (VUR), and incontinence are the most commonly encountered problems in pediatric nephrology. The treatment of these conditions is important yet often controversial.

Urinary tract infection

Clinical presentation

UTIs can be grouped into asymptomatic bacteruria, cystitis, and acute pyelonephritis. Cystitis is most commonly seen in girls over 2 years of age and is an infection limited to the urethra and bladder. Patients usually present with localizing symptoms, which may include pain on urination (dysuria), frequency, urgency, cloudy urine, and lower abdominal discomfort.

A positive urine culture can be found in children without symptoms of illness (asymptomatic or covert bacteriuria), and antibiotics are not required because long-term outcomes appear similar in treated compared with untreated patients [1,2].

Pyelonephritis is the most severe form of UTI in children and is associated with systemic features such as high fever, vomiting, malaise, abdominal pain or tenderness, poor feeding, irritability in infants. Diagnosis may be assisted by imaging of the kidneys with a technetium 99^m-labeled dimercaptosuccinic acid (DMSA) scan and assessment of inflammatory markers in the blood, for example, erythrocyte sedimentation rate and C-reactive protein.

Diagnosis

The diagnosis of UTI is based on the culture of a pure growth of bacteria in an uncontaminated sample of urine in the presence of

symptoms of illness. Microbiological criteria for diagnosis of UTI are provided in Table 65.1.

Urine collection methods in children are important for the diagnosis, because of the problems with contamination and false-positive tests. The method least likely to involve contamination, the suprapubic bladder tap, may be impractical in some settings. Transurethral catheterization, the collection method second to a bladder tap for false positivity, also presents technical challenges, and both of these tests are invasive. Voided samples are more feasible but can be problematic. Some clinicians use a urine bag, but contamination rates are too high for this method to be recommended [3]. The clean catch method is reasonable but requires patience and cooperation from parents. Across health care settings, collection methods vary widely because time, skill, attitudes, and facilities, as well as contamination rates, are all influential.

The preferred method for urine collection in children who cannot void upon request is catheterization, after weighing criteria of contamination, technical feasibility, and invasiveness. For children above 2 years of age who are toilet trained, a midstream urine sample is recommended.

Urine culture requires a minimum of 18 h before a result is known, and this may be longer in some situations. Clinicians often use rapid tests to guide initial diagnosis and management decisions. Urinalysis, or dipsticks, and urine microscopy for white cells or visible bacteria are widely used. Dipsticks are quick, easy, and inexpensive and can be used in any setting. Microscopic examination usually requires specialized technical personnel. A systematic review of the literature [4] demonstrated that a dipstick result showing positive findings for both leukocyte esterase and nitrite is reasonably good for identifying UTI (LR+, 28.2). A dipstick negative for both generally rules out UTI (LR−, 0.20). The more common finding of a single positive result is considerably less helpful for guiding decisions (leukocyte esterase LR+, 5.5; nitrite LR+, 15.9). When available, combined positive microscopy findings perform well at ruling in the diagnosis (LR+, 37.0), and two negative microscopy results also perform reasonably well at excluding UTI (LR, −0.21). A single positive microscopy result is less helpful in guiding management (pyuria LR+, 5.9; bacteriuria

Table 65.1 Microbiological criteria for diagnosis of UTI in children.

Collection method	Definite UTI[a]		Probable UTI[b]	
	No. of organisms (species)	CFU/L	No. of organisms (species)	CFU/L
Suprapubic bladder tap	1	Any	2	Any
Transurethral catheter	1	$\geq 10^7$	1	$\geq 10^6$
			2	$\geq 10^7$
Voided samples (clean catch, midstream, bag)	1	$\geq 10^8$	1	$\geq 10^7$
			2	$\geq 10^8$

CFU, colony-forming unit(s).

[b] Based on consensus opinion of three senior staff specialists in infectious disease, general medicine and nephrology (Children's Hospital at Westmead).

LR+, 14.7). Urine culture is always needed to confirm the diagnosis.

Epidemiology

Precise estimates of rates of UTI are difficult to ascertain; however, a large population-based study, with a verified outcome of UTI, showed that 8% of girls and 2% of boys had at least one UTI by 7 years of age [5]. Rates of disease in subgroups of the population have been studied more readily, with one systematic review of 12 studies of febrile children showing that approximately 5% of febrile infants (0–2 months) had had a UTI [6]. A similar rate was found in studies that included older children (0–5 years) with fever [7,8].

Pathogenesis

UTIs are more common in girls after the first year of life, whereas boys are 5–10 times more susceptible to UTIs in the neonatal period. The increased rate in infant boys is highest in uncircumcised males [9,10].

Infection of the urinary tract is likely to be related to host and bacterial factors. Bacterial virulence factors that have been well-studied in UTI include adherence, growth factors, and features that allow the bacteria to avoid destruction by the human immune response [11]. Characteristics of bacteria only partly explain the differential colonization of the urinary tract, because healthy volunteers inoculated with virulent *Escherichia coli* rapidly eradicate the bacterium [12]. Characteristics of the human immune system are likely to contribute to disease risk. With so many components involved, any of which can vary with genetic and environmental factors, identifying attributable risk for each is difficult. Studies looking at some of these components have found inconsistent results [13–16]. Study design limitations are likely to explain the variability.

Children with lesions of the spinal cord and neurologic abnormalities have increased risk of UTI, but the management issues are different and thus are not discussed here.

Recurrence

Ten to 30% of children with UTI will have at least one more infection [17,18]. The majority occur within the first 12 months after the primary infection, and risks for recurrence include age less than 6 months at first UTI (odds ration [OR], 2.9; 95% confidence interval [CI], 1.4–6.2), presence of dilating VUR (OR, 3.6; CI, 1.5–8.3), and renal damage detected at primary UTI [18], which may be congenital in origin.

Acute treatment

Evidence on which to base specific treatment choices is limited in very young children, because they are often excluded from randomized controlled trials. However, clinical experience suggests infants aged 1 month or less with UTI require intravenous antibiotics, because there is an approximately 10% risk of concomitant bacteremia [19,20] and a significant chance of finding uropathology [21], such as posterior urethral valves or obstructed duplex systems. *E. coli* and *Enterococcus faecalis* are the most likely pathogens in this age group [22], indicating empirical treatment with a β-lactam antibiotic and an aminoglycoside. Intravenous treatment is usually continued until systemic signs have resolved (2–3 days), after which time an oral antibiotic is given for 7–10 days.

Evidence supporting treatment for children over the age of 1 month with pyelonephritis includes 18 randomized controlled trials and was summarized in a Cochrane review [23]. Two well-designed trials of 693 children compared oral antibiotics (cefixime, amoxicillin-clavulinic acid) with intravenous (IV) antibiotics for 3 days, or until defervescence, followed by oral antibiotics. No differences in time to fever resolution (weighted mean difference, 1.54 days; 95% CI, 1.67–4.76), recurrence of UTI (relative risk [RR], 0.67; 95% CI, 0.27–1.67), or frequency of renal parenchymal defect at 6–12 months (RR, 1.45; 95% CI, 0.63–3.03) were demonstrated (Figure 65.1). Four trials involving 480 children compared oral with IV administration of antibiotic after 3–4 days of IV treatment for both groups. Although antibiotic type varied, there was no difference in recurrence of UTI (Figure 65.1) or renal parenchymal defects between the long-duration IV antibiotics and the short-duration IV plus oral antibiotic groups. These findings provide good evidence that oral antibiotics are an effective treatment choice for children with a diagnosis of acute pyelonephritis (Table 65.2). Intravenous treatment can be reserved for children who present seriously ill or have persistent vomiting. Optimal

Oral vs IV for initial treatment of acute pyelonephritis

Figure 65.1 Acute antibiotic treatment options for UTI in children.

Table 65.2 Evidence ratings and recommendations for acute treatment and prophylaxis of UTI in children.

Intervention	Treatment type	Evidence rating[a]	Comment	Recommendation[b] I	II	III	Comments
Oral vs IV initial treatment	Acute	High	2 trials, 693 children, good design	• oral			Oral cefixime as effective as IV
Short (3–4 days) vs long (10–18 days) initial IV treatment	Acute	Moderate	4 trials, 480 children, reasonable design		• Short		3–4 days initial IV
Duration of antibiotic therapy for cystitis (lower tract UTI) 2–4 days vs 7–14 days Single dose vs 7–14 days	Acute	Moderate	3 systematic reviews 11 trials, 652 children 9 trials, 383 children, inconsistent quality		•	•	2–4 days sufficient; single dose less effective
Duration of antibiotic therapy for pyelonephritis	Acute	Low	1 trial 10 vs 42 days 2 trials 1dose vs 7–10 days			•	Suggest standard therapy 7–14 days
Renal tract imaging For localization of infection For detection of VUR For detection of renal scarring	Acute	Low	Included studies poorly reported; primarily cross-sectional design, no long-term follow-up			•	Suggest ultrasound after first UTI (inexpensive, noninvasive, readily available, will detect gross abnormalities); consider DMSA if recurrence
Prophylactic antibiotics vs no prophylaxis (<50% participants with VUR)	Prophylactic	Low	2 trials had outcome of symptomatic UTI, inconsistent results 4 trials had outcome of repeat positive urine culture, antibiotics were beneficial			•	Possible benefit, may elect to try after second infection
Prophylactic interventions for children with VUR Antibiotics vs no treatment Antibiotics vs surgery + antibiotics	Prophylactic	Moderate	2 trials, showed no difference in effect 7 trials, showed little difference in effect			•	Possible benefit, may elect to try antibiotics after second infection
Cranberries for prevention of recurrent UTI	Prophylactic	Moderate, but uncertain applicability	Most trials were adults, 2 trials in children with neuropathic bladder		•		Harmless intervention, possible benefit in children, uncertainty about dose
Circumcision for prevention of UTI	Prophylactic	Low	1 trial, 4 cohort studies, ORs concordant		• (restricted application)		Suggested for boys with recurrent UTI or high-grade (≥3) VUR

[a] Rating of systematic reviews: "high,'' included trials are good quality and applicable; "moderate,'' included trials are of moderate quality and applicability; "low,'' included trials are of low quality and are not directly applicable.

[b] I, recommend; II, suggest; III, evidence does not support a recommendation.

duration of antibiotic treatment for children with acute pyelonephritis is poorly supported by evidence because the existing trials have not compared short-course with standard therapy [23].

A large evidence base (22 trials and three systematic reviews) [24–26] (Table 65.2; Figure 65.1) supports the treatment options for children presenting with symptoms suggestive of cystitis. Findings show that short-duration therapy (2–4 days) is as effective as standard treatment (7–14 days) in eradicating urinary bacteria at 0–10 days posttreatment and 1–15 months posttreatment [25]. Further trials have demonstrated than single-dose therapy may be insufficient to successfully treat cystitis in children [26].

Prevention of recurrence

Good evidence exists to show that children who have had one UTI are at considerable risk (10–30%) for recurrence [17]. Without proper understanding of causality, it is not possible to reliably prescribe methods to prevent recurrence of UTI. However, many people recommend avoidance of constipation, complete bladder emptying, good intake of fluids, and avoidance of possible irritation from underclothing or bubble baths. These measures are supported by a weak evidence base.

A systematic review [27] of five trials, including one with a crossover design, that have compared prophylactic antibiotics with placebo or no treatment in a group of children where the majority did not have VUR is summarized in Table 65.2. One trial,

Figure 65.2 Antibiotic prophylaxis to prevent recurrent UTI in children, of whom the majority do not have VUR.

involving 61 children, in which repeat symptomatic UTI was the primary outcome, found that twice as many repeat infections occurred in the antibiotic arm compared to the placebo group [28] (Figure 65.2). In the crossover trial, 14 of 18 children had recurrent symptomatic infections, and all occurred during the placebo phase [29]. This rate of recurrence (78%) is large, very different from the findings of other studies, and suggests considerable selection bias in trial participants. The other four trials, which utilized repeat positive urine culture as the primary outcome, demonstrated a reduced risk of 0.44 (95% CI, 0.19–1.0) of repeat positive culture in the antibiotic prophylaxis group [28,30–32] (Figure 65.2). Three trials, including one with a crossover design, compared different antibiotic types [33–35]. Findings were variable, and without clear evidence that antibiotics are effective in preventing recurrent UTI,

it is potentially misleading to recommend one antibiotic over another. The evidence to support the use of prophylactic antibiotics to prevent recurrent UTI in children without reflux is weak and probably not generalizable to children experiencing their first UTI.

Other interventions for prevention that have been studied in randomized controlled trials include cranberry products [36], immuno-active agents (e.g. Uro-vaxom) [37], and probiotics [38]. Most trials demonstrating benefit have not focused on children, and thus the applicability of their results is questionable. Despite the absence of appropriate studies in children, cranberry products are harmless, readily available, beneficial in adults, and may prevent recurrent UTI in children (except in those with spina bifida).

Circumcision as a treatment for prevention of recurrent UTI has been evaluated in studies of various designs. A meta-analysis

of randomized trials and observational studies [39] identified one randomized controlled trial, four cohort studies, and seven case–control studies that addressed this issue. Circumcision significantly reduced the risk of UTI (OR, 0.13; 95% CI, 0.08–0.20), but importantly, 111 circumcisions would need to be done to prevent 1 UTI. In boys with a considerably greater risk of recurrent UTI (high-grade VUR, recurrent UTIs), the number of circumcisions needed to prevent 1 UTI drops to less than 11 circumcisions. In summary, there is a net benefit of the intervention only in boys at greater risk than those presenting with first UTI.

Renal tract evaluation and imaging

Available guidelines [40,41] recommend renal tract imaging for very young children with UTI. However, a systematic review has shown that the evidence for improved outcomes for children is weak [42]. Renal ultrasound reveals anatomical information about the kidneys and urinary tract. It is noninvasive, inexpensive, and readily available, but results rarely change management. Micturating or voiding cystourethrogram (VCUG) is performed to detect VUR. VCUG is a traumatic imaging technique, and in the absence of good evidence for improved outcomes through better management of children with VUR, it is not justifiable in children presenting with a first UTI. A DMSA scan demonstrates renal focal abnormalities and determines differential renal function. Identification of renal focal abnormalities in many cases does not alter management.

Imaging by ultrasound can be justified where there is easy access to qualified sonographers, as it is a noninvasive procedure and it has a high sensitivity for renal tract obstruction. Strong observational evidence demonstrates that surgical treatment of children with obstructive uropathy improves outcome. Accordingly, almost all pediatricians report they recommend ultrasonography for all children with UTI [43]. Considerable variability in the use of DMSA and VCUG reflects the uncertainty about whether these tests do more good than harm in children with UTI.

Vesicoureteric reflux

Definition and diagnosis

VUR is the retrograde flow of urine from the bladder into the ureter and towards the kidney. Severity is graded using the five-grade International Reflux Study system, which includes domains such as height of retrograde flow and dilatation and tortuosity of the ureters [44]. The reference standard test for diagnosis of VUR is a VCUG.

Epidemiology

VUR is common in children with UTI. There have been numerous case series of children with UTI, and they have consistently shown that 25–30% of children with UTI have VUR [45–48]. Incidence in the wider population is less clear, although most review articles suggest a rate of less than 1% in "well" children [49–51].

Clinical spectrum

VUR may be an isolated finding, primary VUR, or it may be associated with other urological abnormalities, such as posterior urethral valves or a neurogenic bladder, in which case it is referred to as secondary VUR [52–55]. VUR may also occur as part of multiorgan malformation syndromes [56–59]. The appearance of VUR with other abnormalities of kidney and ureteric development within families has led to the collective classification of these as CAKUT (congenital abnormalities of the kidney and ureteric tract) [60–62]. Although most well-designed, prospective studies are small, follow-up of children with primary VUR suggests that the majority have resolution of the VUR without further morbidity. In follow-up studies VUR is a poor predictor of kidney damage and longer-term hypertension [63–66].

VUR as an inherited trait

Many groups have studied reflux in the context of an inherited disorder, because sibling recurrence, parent–child transmission, and twin concordance rates support this theory [67–73]. The majority of reported pedigrees have shown dominant inheritance patterns [73–77], but cases of recessive [75] and X-linked inheritance [78,79] have also been reported. Clinical characteristics of VUR cases can differ within families [80,81]; therefore, the same genetic change can result in different disease expression. This suggests other factors also influence expression of the VUR phenotype, and these may include other genes, environmental exposures, and the interaction of genes with environmental factors.

Screening

An antenatal ultrasound finding of renal dilatation of ≥4 mm is commonly suggested as an indication of VUR. It is, however, a non-specific screening tool for VUR, as fewer than 10% of VUR cases are diagnosed by subsequent VCUG [82–84]. Some clinicians advocate testing asymptomatic siblings of children with VUR, because VUR can be familial [85]. However, given the insufficiency of evidence for the benefits of early treatment for VUR, early detection cannot be justified.

Prognosis

From a comparison of the frequency of VUR overall and end-stage kidney disease attributed to VUR [86], it is evident that the outcome for the vast majority of children with VUR is excellent. Assuming that about 3% of children (or 30,000 per million children) have reflux, only about 1 in 6,000 (or 5 per million) will ultimately develop end-stage kidney disease. VUR is a relatively common condition, and end-stage kidney failure due to reflux nephropathy is a very rare problem. For around 5–7% of people entering end-stage kidney failure programs, reflux nephropathy is nominated as the primary cause [86–90].

Management

Management of a child with VUR is controversial. The use of low-dose prophylactic antibiotics to prevent recurrent UTI and kidney damage has been the standard of care for many children

Favours combined   Favours antibiotics

Figure 65.3 Interventions to prevent recurrent UTI in children with VUR.

with VUR. A recent systematic review highlighted the very weak basis for this practice [91]. Two trials, of 247 children, found no significant difference in risk of UTI or of renal parenchymal abnormality between the antibiotic group and the surveillance group [92,93] (Figure 65.3). Six trials compared ureteric reimplantation by open surgery plus antibiotic prophylaxis with antibiotic prophylaxis alone, and two trials compared subureteric injection plus antibiotics with antibiotics alone. Combining these studies demonstrates that the risks of UTI at 1–2 and 5 years (Figure 65.3) and of new or progressive renal parenchymal abnormality at 5 years are not significantly different between the surgery plus antibiotic groups compared to the antibiotics-alone group (RR of new renal parenchymal damage at 5 years, 1.09; 95% CI, 0.79–1.49; RR of progression of renal parenchymal damage at 5 years, 0.99; 95% CI, 0.69–1.42). The only difference was a lower risk (RR, 0.43; 95% CI, 0.27–0.70) of febrile UTI over 5 years in the surgery plus antibiotic group. This means that nine children would undergo surgery and take prophylactic antibiotics to prevent one febrile UTI over 5 years. In 2006, 10-year follow-up data on 252 of an original group of 306 trial participants were published [94]. These data showed that renal growth, UTI recurrence, somatic growth, and renal function did not differ between the antibiotic and the surgery plus antibiotic groups.

Two trials compared different subureteric injection substances, and numerous case series of this intervention have been published [91,95]. Common to most of these studies is the absence of the clinically relevant outcome, symptomatic UTI. Case series suggest subureteric injection frequently resolves the physical abnormality, VUR, but the effect on recurrence of UTI is not known. In summary, the trial data that support the use of prophylactic antibiotics, reimplantation surgery, and subureteric injection to prevent recurrent UTI in children with VUR is weak and inconclusive. Given that the risk of harm for no treatment is small, interventions to prevent recurrence of infection after first UTI are unjustifiable.

Urinary incontinence

Definition, clinical presentation, and diagnostic tests
Urinary incontinence may present as nocturnal enuresis, daytime incontinence, or both.

Nocturnal enuresis
Nocturnal enuresis is the involuntary loss of urine at night in the absence of organic disease by the developmental age of 5 years [96]. Nocturnal enuresis is classified as primary (no consistent night dryness) or secondary (bedwetting after a previous dry period of at least 6 months). It is also classified as monosymptomatic (with no daytime urinary symptoms) or non-monosymptomatic.

Epidemiology
Nocturnal enuresis occurs in up to 20% of school-aged children, with 2.4% wetting at least nightly [97]. The prevalence is approximately 20% in 5-year-olds, 10% in 10-year-olds, and 3%

in 15-year-olds [98]. Younger children tend to outgrow nocturnal enuresis, with a spontaneous remission rate of approximately 14% annually, while 3% remain enuretic as adults [98]. Nocturnal enuresis is more common in boys.

Risk factors
The etiology of nocturnal enuresis is a complex interaction of genetic and environmental factors. Secondary nocturnal enuresis is likely to be associated with recognizable psychological or organic causes. Non-monosymptomatic nocturnal enuresis (with daytime urinary symptoms) suggests an underlying bladder dysfunction [99,100].

Reported risk factors for primary nocturnal enuresis include nocturnal polyuria and a deranged circadian rhythm of antidiuretic hormone (ADH) [101], defects in sleep arousal [102], nocturnal detrusor overactivity with reduced functional bladder capacity [103], upper airway obstruction [104], and sleep apnea [105]. Nocturnal enuresis has also been linked to chromosomes 8, 12, 13, and 22 with an autosomal dominant inheritance [98]. Risk factors for secondary nocturnal enuresis include UTIs (which may cause temporary detrusor and/or urethral instability), diabetes mellitus and insipidus, stress, sexual abuse, and other psychopathology. Risk factors for both primary and secondary nocturnal enuresis include constipation [106], attention deficit hyperactivity disorder [107], and developmental delay and other neurological dysfunction [108]. Reported risk factors for non-monosymptomatic nocturnal enuresis are the same as those for daytime incontinence.

Assessment and investigation
Thorough history taking (from child and parents) and physical examination are essential for differentiating the type of nocturnal enuresis and directing management. Few investigations are required for children with monosymptomatic nocturnal enuresis. A urine culture to exclude UTI is recommended [109].

Management
Timing of when to seek treatment for bedwetting should be determined by the age of the child (at least 7 years), the severity of symptoms, and the child's level of concern. There are a number of Cochrane systematic reviews on the management of nocturnal enuresis (Table 65.3). First-line treatment for monosymptomatic nocturnal enuresis is the enuresis alarm, which is activated by micturition. Common alarm types include the bell and pad alarm (where a large mat is placed on the bed) and a personal alarm (which is clipped onto the child's underpants). There is insufficient evidence to draw conclusions on the relative effectiveness of the different types of alarms, but children generally prefer a personal alarm to a bell and pad alarm, and alarms using electric shock are unacceptable to children (Figure 65.4). Alarms are commonly used until 14 consecutive dry nights are achieved, with treatment beyond 16 weeks being unlikely to produce a cure [110]. Two-thirds of children become dry during alarm training (RR for failure, 0.38; 95% CI, 0.33–0.45), and one-half maintain dryness

Intervention	Existing systematic reviews	Overall evidence rating		Comment	Recommendation[a]	Comments
		Moderate	Low			
Enuresis alarm vs no treatment	•	•			I	Alarms more effective than no treatment; insufficient evidence to compare different types of alarms (e.g. bed or personal alarms); alarms using electric shock not acceptable
Enuresis alarm vs desmopressin	•	•			I	Alarms and desmopressin equally effective; desmopressin more immediate effect than alarm, but alarm more prolonged effect compared with desmopressin
Overlearning with alarm training	•		•	Few studies, poor quality	II	Lower relapse rates after alarm training with overlearning
Desmopressin vs no treatment	•	•			II	Desmopressin more effective than no treatment
Tricyclics	•		•		Not recommended	Risk of significant side effects in children; treatment no longer recommended
Other drugs	•	•			III	Although some other drugs more effective than no treatment, there is insufficient evidence to recommend use of other drugs
Behavioral interventions	•		•	Few studies	II	Some simple methods such as rewards, lifting, and waking worked better than no treatment, but not as effective as alarm training; penalties reduced likelihood of success
Complementary therapies	•		•	Poor quality	III	Weak evidence to support hypnosis, psychotherapy, acupuncture, and chiropractic adjustment
Combination therapy	•		•	Few studies	II	Uncertainty whether combination therapy may be more effective than alarm alone

[a] I, recommend; II, suggest; III, evidence does not support a recommendation.

after completion of treatment compared with almost none after no treatment (RR of failure or relapse, 0.56; 95% CI, 0.46–0.68) [111]. Relapse can be halved, from about 50% to about 25%, with "overlearning" with extra bedtime fluids while continuing alarm training after initial success (RR, 1.92; 95% CI, 1.27–2.92) [112,113].

Desmopressin (an ADH analog) is a second-line therapy and is effective in 60% of children with monosymptomatic nocturnal enuresis. Desmopressin has a more immediate effect (RR, 0.71; 95% CI, 0.50–0.99) (Figure 65.5) and can be used for short-term overnight sleep-overs, but it has limited sustained effect compared with alarm training (RR, 0.27; 95% CI, 0.11–0.69) (Figure 65.6).

Although tricyclics and related drugs are effective in about 20% of cases, they are no longer recommended for the treatment of nocturnal enuresis because of their potentially serious cardiotoxic adverse effects [114,115]. In children with upper airway obstruction, treatment of the obstruction may improve nocturnal enuresis [116].

Although other therapies are often more effective than no treatment, studies comparing alarms to other therapies, including other pharmacological interventions [117], behavior interventions (such as reward systems, bladder training, lifting, and scheduled wakening) [118, 119], fluid deprivation, and complementary therapies such as hypnosis, psychotherapy, acupuncture, and chiropractic [111], were either inconclusive or showed alarm therapy to be superior. However, supplementing alarm therapy with other behavior interventions, such as dry bed training, reduced the relapse rate from 63% to 27% (RR, 2.0; 95% CI, 1.25–3.20), whereas penalties after wetting appear to reduce success [111].

For nonresponders to monotherapy with alarm or desmopressin, combination therapy with alarm and desmopressin can be tried [99]. Although combination therapy decreased the initial number of wet nights, success rates while on treatment or after treatment were not significantly different from alarm alone [111]. Antimuscarinics (oxybutynin) can be added to desmopressin in those who do not respond to monotherapy [120], although there is insufficient evidence to assess the effectiveness of this treatment.

Children with non-monosymptomatic enuresis should be treated for their daytime incontinence before addressing their nocturnal enuresis, as treatment failure rates for nocturnal enuresis

are higher in the presence of daytime symptoms and nocturnal enuresis sometimes resolves with treatment of daytime symptoms alone [109].

Daytime urinary incontinence
Epidemiology
Daytime urinary incontinence is defined as any uncontrollable leakage of urine during the daytime [99]. Becoming continent usually occurs between 2 and 3 years of age, with most children achieving full bladder control by the age of 4.

Prevalence
Daytime urinary incontinence is more common in girls than in boys [121–124]: 6% of girls compared to 4% of boys have at least one episode of wetting in the previous 3 months, and 2% of 7-year-old boys and 3% of 7-year-old girls wet every week [125].

Figure 65.6 Alarm versus desmopressin for nocturnal enuresis in children.

Daytime urinary incontinence has been reported in 7% of boys and 17% of girls in the 11- to 12-years age group, a difference that is statistically significant [123]. The majority of these children wet occasionally.

Risk factors

In most children the cause(s) for their daytime urinary continence is unknown. Daytime urinary incontinence is commonly associated with other symptoms of bladder dysfunction (urgency, frequency, squatting to prevent incontinence, or incomplete bladder emptying), with constipation, fecal soiling, attention deficit hyperactivity disorder, and with UTI. From cross-sectional data, likely risk factors for daytime incontinence are family history of daytime incontinence, especially in the male lineage [126], low birth weight [127], developmental delay [127], a frightening or emotional stressful event [126], and psychiatric disorders [128]. One such study found that family history and emotional stressors accounted for up to 60% of the attributable risk for daytime incontinence in multivariate analysis [126]. None of these studies had a longitudinal component, so determining causality is difficult.

Natural history

Little is known about the natural history of daytime incontinence, and more prospective longitudinal studies are necessary. One study reported that daytime urinary incontinence decreased with age when children from 5 to 9 years of age were followed [129]. A study

of 1176 healthy adolescent school children assessed the prevalence of daytime urinary incontinence at two ages, 11–12 years and 15–16 years [130]. This study reported prevalence rates of daytime urinary incontinence of 12% at 11–12 years and 3% at 15–16 years. A Swedish cohort study reported that the point prevalence of daytime urinary incontinence decreased in girls from 6% at age 7 to 4% at age 17 [131].

Assessment

According to the recommendations of the International Children's Continence Society [99], initial assessment of daytime incontinence should include history taking, physical examination, and urinalysis to detect anatomical or neurological abnormalities, UTI, and diabetes mellitus. Noninvasive diagnostic investigations involve a frequency volume chart, which gives a detailed recording of fluid intake and urine output over a 24-h period, a 12-h pad test, which evaluates the quantity of urine lost, plain X-ray of the abdomen to quantify the grade of constipation, assessment of urinary flow patterns, and ultrasound of the upper and lower urinary tracts. Ultrasound of the urinary tract is an important noninvasive test to identify children who have renal tract abnormalities, residual urine, or thickening of the bladder wall. Based on the results of these tests, other invasive procedures, such as VCUG, urodynamics, renal scans, or intravenous urography or cystourethroscopy, may be required. Urodynamic investigations are invasive and usually performed on children who do not respond to conservative treatments, such as bladder training, education about how and

Table 65.4 Evidence rating and recommendations for treatment of daytime urinary incontinence.

Intervention	Existing systematic reviews	Overall evidence rating		Comment	Recommendation[a]	Comments
		Moderate	Low			
Bladder training	None	●		No available RCT	I	Noninvasive technique that offers effective first-line treatment and is less costly
Oxybutynin vs biofeedback	1	●		1 RCT	II	Adequately powered trial required to reveal effectiveness of intervention
Oxybutynin vs placebo	1	●		1 RCT	II	Adequately powered trial required to reveal effectiveness of intervention
Imipramine vs placebo	1	●		1 RCT	Not recommended	Historical interest only due to its side effects
Terodiline vs placebo	1	●		2 RCTs	Not recommended	Withdrawn due to serious cardiac side effects, hence historical interest only
Tolterodine vs placebo	None	●		2 large RCTs; limited evidence in children; reduction in wetting episodes and fewer side effects noted compared to oxybutynin	II	2 large RCTs did not show a difference in efficacy between the two treatment arms
Biofeedback vs standard therapy	1	●		1 RCT	II	Adequately powered trial required to reveal effectiveness of intervention
Electrical stimulation	None	●		Insufficient data available	II	Controlled trials needed to test efficacy of this treatment
Alarm treatment	1	●		1 RCT comparing contingent and with a noncontingent alarm	II	Adequately powered trial required; with current evidence does not appear useful for daytime incontinence

[a] I, recommend; II, suggest, III, evidence does not support a recommendation.

when to void, treatment of constipation, and management of UTI.

Management of daytime urinary incontinence

Bladder training is the first-line therapy for the management of daytime urinary incontinence, but the evidence about the efficacy of this treatment is variable [99]. Bladder training is a behavior therapy in which rehabilitation of the bladder and pelvic floor muscles is applied using different modalities, such as explanation and instructions for timed toileting [99]. When conservative treatment is not successful, more active treatments, including pharmacotherapy, pelvic floor muscle relaxation techniques, biofeedback, and electrical stimulation, are introduced.

Pharmacotherapy involves the use of antimuscarinics, which reduce detrusor overactivity. Oxybutynin has been shown to reduce daytime incontinence in uncontrolled studies. The randomized controlled study that compared oxybutynin with biofeedback and placebo did not show any decrease in the proportion of children with no improvement in the frequency of daytime incontinence after either biofeedback or oxybutynin treatment [132]. Side effects (headache, blurred vision, constipation, dry mouth, flushed

cheeks, and incomplete bladder emptying) limit adherence. Other commonly used antimuscarinics include propantheline bromide and tolterodine. Recent studies, including two large randomized controlled studies, have shown that tolterodine is safe in children and has fewer side effects than oxybutynin [133,134]. Other drug therapies include imipramine and terodiline. The results of the imipramine trial showed that there was no significant increase in maximum functional bladder capacity [135]. Although the two terodiline trials [136,137] showed a small decrease (0.5–0.8) in the frequency of daily incontinent episodes compared with placebo, it is no longer used due to serious cardiac side effects. Table 65.4 summarizes the evidence for management of daytime urinary incontinence.

Several other interventions have been inadequately evaluated to allow recommendation. One randomized clinical trial evaluated the use of a contingent alarm (sounded when the children wet) versus a noncontingent alarm (sounded at intermittent intervals) and showed no difference in the proportion of children with persistent daytime wetting in the two alarm groups (RR, 0.67; 95% CI, 0.29–1.56) [138]. Many uncontrolled studies suggest that biofeedback using electromyograms may be a useful treatment for

daytime urinary incontinence [139,140]. Similarly, oxybutynin with biofeedback may also be a useful intervention [141]. Neuro-muscular electrical stimulation is an invasive, experimental treatment modality and can be used to stimulate the pelvic floor or the detrusor muscle [142,143].

Conclusions

UTI, VUR, nocturnal enuresis, and daytime incontinence are common problems in pediatric patients. Diagnosis and management can be controversial and difficult. Evidence supporting clinical practice is frequently suboptimal in quality or absent, and clinicians increasingly require critical appraisal skills to determine what evidence should be utilized and which should be ignored.

Epidemiology and General Management of Childhood Idiopathic Nephrotic Syndrome

Nicholas J. A. Webb

Department of Nephrology, Royal Manchester Children's Hospital, Manchester M27 4HA, UK

Introduction

Nephrotic syndrome develops when an abnormality of glomerular permeability results in the development of heavy proteinuria, hypoalbuminemia, and generalized edema. The nephrotic syndrome can occur in the course of many different glomerular diseases. Nephrotic syndrome not associated with systemic disease is termed primary or idiopathic nephrotic syndrome, and where it occurs as part of a systemic disease or is related to a drug or other toxin it is termed secondary nephrotic syndrome. The list of causes of childhood nephrotic syndrome is extensive (Table 66.1), although the large majority of children have primary disease. Within this group, two histological subgroups predominate: minimal change disease (MCD) and focal segmental glomerulosclerosis (FSGS). There has been debate whether these should be considered distinct entities or whether they represent different ends of a single spectrum of disease, as there have been reports of transformation from MCD to FSGS histology [1]. In their typical presentation, they behave differently in their response to steroid therapy and the likelihood of progression to end-stage renal disease (ESRD). Furthermore, recent advances in genetics have revealed that a substantial proportion of children with FSGS have an underlying genetic basis for their disease.

Biopsy studies in the 1970s reported MCD to be the predominant cause of nephrotic syndrome, occurring in around 80% of cases [2,3]. This is in contrast to adult series, where MCD accounts for only around 25% of cases [4]. FSGS and mesangiocapillary glomerulonephritis (MCGN) were responsible for the majority of the remaining cases, along with a small number of cases of membranous nephropathy (MN) and a variety of other histological diagnoses [2,3]. Overall, 80% of children achieved remission with a standard 8-week course of corticosteroid (prednisone or prednisolone) therapy. Response varied according to histology, with

over 90% of children with MCD responding compared with only 17–30% of those with FSGS [3,5]. Of steroid-sensitive children, 91.8% had MCD and 8.2% had other histological diagnoses [5]. Consequently, the majority of children now receive an empiric course of steroid therapy, with biopsy being reserved for those with atypical presenting features (suggestive of non-MCD histology) or where the child is steroid unresponsive. As such, most children with nephrotic syndrome do not have a histological diagnosis but are classified according to their steroid responsiveness: so-called steroid-sensitive nephrotic syndrome (SSNS) and steroid-resistant nephrotic syndrome (SRNS).

Epidemiology

Incidence

The incidence of childhood idiopathic NS is reported to be around 2 cases/100,000 child population/year [6–10]. A recent study in Yorkshire, UK, reported an incidence of 2.3 cases/100,000 patient-years in children below 15 years of age [11]. Of these, 2.0 cases/100,000 had SSNS and 0.3 cases/100,000 had SRNS. Although the overall incidence of childhood nephrotic syndrome has been relatively stable, the incidence of FSGS appears to be increasing in children and adults [12–14], particularly in the African American and Hispanic populations in the USA.

Gender

Nephrotic syndrome is more common in boys, with a male/female ratio of 1.6:1 (1.7:1 for SSNS and 1.2:1 for SRNS) [11].

Age

The incidence of nephrotic syndrome and SSNS peaks in the 1- to 4-year-old age group (Table 66.2) [11]. In the International Study of Kidney Diseases in Children (ISKDC), the median ages at presentation with MCD, FSGS, and MCGN were 3, 6, and 10 years, respectively [2]. The age of the child at presentation is therefore a strong predictor of the likely underlying cause of the nephrotic syndrome. Children aged below 1 year generally have Finnish-type

congenital nephrotic syndrome, or variants thereof, congenital infections, and a variety of genetic disorders (Table 66.1). This group of disorders is outside the scope of this chapter.

Ethnic variation

The incidence of nephrotic syndrome and the underlying histological causes vary among ethnic groups. The incidence of SSNS in the UK South Asian population (Indian, Pakistani, and Bangladeshi) is four to six times higher than in the UK white population [9,11,15] (7.4 versus 1.6 per 100,000 children, respectively; $P < 0.01$). The

incidences in the Hungarian gypsy population, who migrated to Europe from the Indian subcontinent, and in the Arab population are also higher than in the white population [16,17]. The patterns of histological disease and steroid sensitivity in Indian children are similar to that seen in the ISKDC, and UK studies, and in white South Africans [18–20]. In black Africans, fewer cases of nephrotic syndrome are due to MCN [21–24]. Instead, the predominant causes are quartan malaria and MCGN in West Africa and MN (predominantly hepatitis B-associated) in South Africa. In the USA, African American and Hispanic children are more likely to have steroid-resistant FSGS than white children [25], with rates of FSGS as high as 69% in one series from Texas [13]. In this series the incidence of FSGS had risen in African Americans, Hispanics, and whites from 23% before 1990 to 47% after 1990. The differences in histological diagnoses between the different age and ethnic groups were further exemplified in a biopsy study in a predominantly African American group of adolescents, of whom only 20–30% had MCD histology [26].

Genetics

SSNS is more common in first-degree relatives of affected individuals. Of 1877 children with nephrotic syndrome (excluding congenital nephrotic syndrome), 63 (3.3%) had a positive family history [27]. Idiopathic nephrotic syndrome has been reported in identical twins [28]. Recent genetic family studies have identified a possible locus for the so-called SSNS1 gene at 2p12-p13.2 [29]. The congenital nephrotic syndromes are associated with mutations in the NPHS1 (nephrin), NPHS2 (podocin), and WT-1 genes. Familial and sporadic SRNS may be associated with NPHS2 mutations. Studies investigating children with SSNS have all failed to detect evidence of homozygous or compound heterozygous NPHS2 mutations [30,31].

SSNS

Definitions

Commonly used definitions in idiopathic nephrotic syndrome are shown in Table 66.3. These definitions are largely based upon those used in the ISKDC studies.

Indications for renal biopsy in childhood idiopathic nephrotic syndrome
Presenting episode
Because most children presenting with nephrotic syndrome will be steroid responsive, a therapeutic trial of steroids without prior biopsy is justified. Biopsy is generally restricted to those presenting with atypical clinical and laboratory features, who are more likely to have alternative histological diagnoses, such as MCGN or MN. Atypical presenting features include age of <12 months (congenital and infantile nephrotic syndrome), age of >16 years (adult pattern of disease), family history of nephrotic syndrome, impaired renal function unresponsive to volume correction, persistent hypertension, macroscopic hematuria, low C3, and evidence

Table 66.2 Nephrotic syndrome in Yorkshire, UK, 1987–1998.

Age group	SSNS		SRNS		All primary nephrotic syndromes	
	Incidence[a]	95% CI	Incidence	95% CI	Incidence	95% CI
0–<1	0.5	0.0–1.1	0.2	0.0–0.5	0.5	0.0–1.1
1–4	4.1	3.3–5.0	0.5	0.2–0.8	4.6	3.7–5.5
5–9	1.7	1.2–2.3	0.2	0.0–0.4	1.9	1.4–2.5
10–15	0.9	0.6–1.2	0.2	0.1–0.4	1.1	0.7–1.5

[a] Incidence per 100,000 person.

of systemic disease (rash, arthropathy, etc). Isolated microscopic hematuria may be present in one-fourth of children with MCD histology [2] and is not an indication for biopsy. Steroid resistance is widely accepted as an absolute indication for renal biopsy before commencing alternative noncorticosteroid therapy, but there is no consistent definition of steroid resistance. Some define resistance as failure to respond to 4 weeks of daily steroid therapy, and others use the term after failure to respond to 4 weeks of daily and 4 weeks of alternate-day steroids. Although lacking in any evidence base,

Table 66.3 Definitions used in idiopathic nephrotic syndrome [2,5].

Classification	Definition
Nephrotic syndrome	Edema, proteinuria >40 mg/m^2/h or protein/creatinine ratio >0.2 g/mmol; hypoalbuminaemia <25 g/L
Remission	Urinary protein excretion ≤4 mg/m^2/h or 0-trace of protein on urine dipstick or protein/creatinine ratio <0.02 g/mmol for 3 consecutive days
Initial responder	Attainment of complete remission within initial 8 weeks of steroid therapy
Initial nonresponder/steroid resistance	Failure to achieve remission during initial 8 weeks of steroid therapy[a]
Relapse	Urinary protein >40 mg/m^2/h or protein/creatinine ratio >0.2 g/mmol or 2+ protein on urine dipstick for 3 consecutive days, having previously been in remission
Frequent relapse	Two or more relapses within 6 months of initial response or four or more relapses within any 12-month period
Steroid dependence	Two consecutive relapses during steroid therapy or within 14 days of ceasing therapy
Late nonresponder	Proteinuria for >8 weeks following one or more remissions

[a]There is a lack of a consistent definition of steroid resistance both in the literature and in clinical practice, with some using this term after failure to respond to 4 weeks of daily steroid therapy, but others using the term after failure to respond to 4 weeks of daily and 4 weeks of alternate-day steroids.

children in the UK resistant to 4 weeks of daily steroids are commonly given 3 days of intravenous methylprednisolone [32]. Those who respond appear to follow a typical course for steroid-sensitive patients. Biopsy is only performed in those who remain unresponsive to this additional therapy. There is evidence that prolonging oral steroid therapy beyond 8 weeks results in an additional 3.3% of children with MCD entering remission [33].

Frequently relapsing and steroid-dependent nephrotic syndrome

Biopsy of children with frequently relapsing and steroid-dependent disease was recommended previously, prior to giving an alkylating agent, because some studies suggested that the post-biopsy clinical course was strongly dependent upon histology. Permanent remission and long periods of remission occurred more frequently in those with MCD, compared with those with FSGS or a mesangioproliferative lesion [34–37]. Most children with SSNS have a favorable response to an alkylating agent irrespective of their histology [38–43]. Furthermore, response to therapy appears to correlate well with the prior pattern of relapses, as shorter post-alkylating agent remission periods occur in those with steroid dependency compared to those with non-steroid-dependent frequent relapses [44]. Among 75 children with steroid-dependent nephrotic syndrome treated with alkylating agents, the response to therapy did not differ between those who had or who had not undergone renal biopsy [45]. In Australia, the UK, and many other European countries, biopsy of the child with SSNS is no longer routine before alkylating agent therapy. Surveys of US and Spanish pediatric nephrologists indicate that about 60% would biopsy children with SSNS prior to alkylating agents [46–47]. It is the author's opinion that, given the good response to alkylating agents seen in the large majority of children with frequently relapsing or steroid-dependent disease, the inconvenience and risks of biopsy are not justified given the small amount of useful additional information that will be obtained by making a histological diagnosis.

Secondary steroid resistance

When steroid resistance occurs following relapse in a previously steroid-sensitive child, so-called secondary steroid resistance, biopsy is indicated. While most such cases will respond

to further immunosuppressive therapy [42,48], a small number of children will remain steroid resistant, in association with the presence of FSGS on biopsy, and the rate of progression to ESRD is high.

Calcineurin inhibitor therapy

Chronic ciclosporin nephrotoxicity, characterized by arteriolar lesions (ciclosporin-associated arteriolopathy) and tubulointerstitial lesions, has been reported in some series in up to 50% of patients after 2 years of therapy [49,50]. Biopsy is therefore frequently recommended for children receiving calcineurin inhibitors for steroid-dependent nephrotic syndrome after 2 years of therapy. When the biopsy is normal, then treatment can be safely continued, although the biopsy should be repeated after a further 1–2 years.

Relapses of SSNS

At least 70% of children with SSNS will relapse following treatment of their first episode. The early ISKDC studies reported that after 8 weeks of corticosteroids, 45% of children were relapse-free at 6 months and 28% at 2 years [51]. Longer-term follow-up studies have shown the overall rate of relapse to be closer to 85% [52,53]. Of those children who experience relapses, approximately 50% will develop frequently relapsing or steroid-dependent disease [54].

Factors at presentation predicting subsequent pattern of relapse

The ISKDC reported that, among 218 steroid-responsive children, no correlation was found between the frequency of relapse following presentation and the different histological subtypes of MCD, baseline clinical and laboratory characteristics, time of initial response to corticosteroids, or the time to first relapse [51]. Similarly, no correlations were found with the presence of microscopic hematuria [52]. Young age at disease presentation was predictive for a higher number of relapses and longer disease duration [55–57]. Frequent relapses during the first 6 months after initial steroid therapy were predictive for frequent relapses over the subsequent 18 months [51,52]. In one study, time to remission of 9 or more days with steroid therapy was associated with an increased risk of steroid dependency [58]. There is emerging evidence that the rate of subsequent relapse can be reduced by the use of a longer initial corticosteroid regimen [59].

Triggers of relapses

Upper respiratory tract infections precede 71% of relapses; respiratory syncytial virus is the most commonly encountered pathogen [60]. In this same study, four children were exposed to varicella-zoster virus, all of whom developed relapses. Paradoxically, exposure to measles virus is known to induce permanent disease remission [61].

When to treat relapses

The ISKDC definition (Table 66.2) of relapse is 3 days of significant proteinuria. Exacerbation of proteinuria may be transient, with spontaneous remission occurring in 23% of frequently relapsing and 10% of steroid-dependent patients. Proteinuria resolves within 4–14 days in 79% of such cases [62]. It is generally accepted practice to defer commencement of corticosteroid therapy until after 5 days or so of proteinuria, although it is important to avoid the development of generalized edema. Although no definitive data exist on this subject, it is the author's observation that some individuals are more likely to consistently undergo spontaneous remission and others rapidly develop generalized edema and hypovolemia. With knowledge of the natural history of previous relapses, it is possible to individualize the timing of the commencement of relapse therapy.

Long-term outcome of SSNS

Early follow-up studies suggested that the long-term prognosis for children with SSNS was excellent, with all retaining normal renal function and over 90% achieving long-term remission at the end of puberty [53,57]. However, more recent follow-up studies have reported substantially higher rates of disease relapse occurring during adult life and have provided data on morbidity in adults treated for SSNS during childhood. In four studies from Finland [63], the UK [55], Switzerland [64], and France [65], the rate of relapse during adult life was reported to be 14%, 19%, 33%, and 42%, respectively. Of the 43 patients with disease continuing into adult life in the French series, 28 were receiving steroids, 3 were receiving cytotoxic agents, and 3 were receiving ciclosporin. These reports might imply that a change is occurring in the natural history of the disease, but it is more likely that these findings have arisen because of more complete follow-up [55,63] and tertiary center follow-up of a select group of patients with a more severe disease course [64,65].

Consistent risk factors for relapses continuing into adult life include very frequent relapses during childhood and adolescence and the use of either cytotoxic agents or ciclosporin. One study reported an increased risk with young age at presentation [65], although two other studies did not [55,64]. In patients in whom permanent remission was achieved during childhood, this appeared to occur in the majority at 13–16 years of age [65]. Renal function was preserved in almost all. Of the 309 patients followed in these four studies, only 2, who relapsed in adult life, developed abnormal renal function, 1 with ESRD [65] and the other with a creatinine clearance of 63 mL/min [63]. Other series have reported the incidence of renal failure in children with initial SSNS to be less than 1% and limited to those who develop secondary steroid resistance unresponsive to cytotoxic and other therapies in association with the presence of FSGS on biopsy [48,52].

The existing data on long-term follow-up of children with SSNS are insufficient to conclude that their outcome is universally good into adult life. Although sophisticated modern imaging modalities, such as electron beam computer tomography scanning, have not been used to identify early vascular changes, there is no evidence yet that this population has an increased rate of premature cardiovascular disease [64,66]. Similarly, the rate of malignancy in adult life does not appear to be increased [64,67].

A Finnish study reported an increased rate of diabetes mellitus, asthma, and ulcerative colitis compared with an age-matched population [63]. Hegarty *et al.* reported a decrease in forearm trabecular volumetric bone mineral density as measured by peripheral quantitative computed tomography in adult survivors at a median age of 35.5 years [68], although Leonard *et al.*, who used dual X-ray absorptiometry of the whole body and spine in 60 children with relapsing disease at a mean age of 9.0 years, did not detect any significant abnormalities during childhood [69]. Long-term side effects of corticosteroid therapy were present in 19 of 36 patients with proteinuria persisting into adulthood in the French series [65].

General management of nephrotic syndrome

Introduction and epidemiology

Children with nephrotic syndrome are at increased risk of bacterial infection because of edema, urinary losses of immunoglobulins and complement alternative pathway components factors B and D, impaired neutrophil function, immunosuppressive therapy, and other factors. Large follow-up series have reported an overall mortality rate for childhood SSNS of 1–7%, with deaths being largely due to sepsis and thrombosis [53,55,57]. Many of these deaths occurred in patients treated in the 1960s and 1970s, and current mortality rates are thought to be substantially lower, although there are no definitive data to support this view.

Peritonitis, bacteremia, and cellulitis remain the most common infections, and they are caused by bacteria with a polysaccharide capsule, particularly *Streptococcus pneumoniae* and gram-negative organisms, including *Escherichia coli*. There is a relatively high rate of bacteremia associated with peritonitis in children with nephrotic syndrome, in contrast to those on peritoneal dialysis [70]. Series from India have reported urinary tract infections and tuberculosis to be common [71,72]. Varicella is a highly contagious disease that is usually benign but may have serious and potentially fatal consequences in children with nephrotic syndrome receiving immunosuppressive agents.

Available evidence

No randomized controlled trials (RCTs) have investigated the use of prophylactic antibiotics or vaccination against pneumococcus or varicella-zoster virus. Five RCTs from China have investigated intravenous immunoglobulin (IVIG), thymosin, and Chinese herbs (Tiaojining).

Pneumococcal vaccination for prevention of infection

Two types of pneumococcal vaccine currently exist. The older 23-valent pneumococcal polysaccharide vaccine (23PS; Pneumovax), which was introduced in the early 1980s, is known to induce a good antibody response to *S. pneumoniae* serotypes 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19F, 19A, 20, 22F, 23F, and 33F in healthy adults and older children, but the

geometric mean antibody response is lower and of shorter duration in children with immunological impairment, including those with nephrotic syndrome [73–77]. The vaccine is not licensed for use in children less than 2 years of age, in whom the burden of the disease is highest, because it does not stimulate effective long-lasting immunity in this age group [78,79]. The newer heptavalent pneumococcal conjugate vaccine PCV7 (Prevnar in the US and Prevanar in the UK) contains polysaccharide from seven common capsular types (4, 6B, 9V, 14, 18C, 19F, and 23F) and is estimated to provide coverage against 82% of invasive infections in UK children under 5 years of age [80]. In the US, universal vaccination with PCV7 has been recommended in all children under 2 years of age at 2, 4, 6, and 12–15 months of age. The US guidelines for children at risk of invasive pneumococcal infection, including those with nephrotic syndrome, are shown in Table 66.4 [81,82]. The 23PS vaccine is administered after 2 years of age to boost the antibody concentrations of serotypes present in both PCV7 and 23PS vaccines and to broaden the serotype coverage. No efficacy data and limited safety and immunogenicity data are available regarding the use of PCV7 in children 5 years of age and older, and UK guidelines state that a single dose of 23PS should be administered. No RCTs of either vaccine have been performed specifically for this disease population to support these recommendations. In children with sickle cell disease, nine RCTs involving 547 children have compared a polysaccharide or conjugate pneumococcal vaccine regimen with a different regimen or no vaccination [83]. The risk of pneumococcal disease (reported in only one trial) was not significantly reduced by the polysaccharide pneumococcal vaccine PPV14 in children younger than 3 years [84]. Antibody responses were increased compared to control groups, including those in infants, in three trials of conjugate vaccines, but clinical outcomes were not measured.

Table 66.4 American Academy of Pediatrics recommendations for pneumococcal vaccination in children 24–59 months old with nephrotic syndrome [81].

Previous vaccination	Further vaccination
4 doses of PCV7	1 dose of 23PS at 24 months of age, at least 6–8 weeks after last dose of PCV7
1–3 doses of PCV7 before 24 months	1 dose of PCV7 at least 6–8 weeks after last dose of PCV7, then a dose of 23PS 6–8 weeks later; an additional dose of 23PS should be given no earlier than 3–5 years after the initial dose of 23PS
1 dose of 23PS	2 doses of PCV7 to be given at an interval of 6–8 weeks, commencing no earlier than 6–8 weeks after the last dose of 23PS; further dose of 23PS 3–5 years after first PS dose
No previous dose	2 doses of PCV7 at interval of 6–8 weeks, followed by single dose of 23PS no less than 6–8 weeks after the last dose of PCV7; an additional dose of 23PS is recommended 3–5 years after the last dose

Prophylactic antibiotics for prevention of infection

Many nephrologists routinely use prophylactic phenoxymethyl-penicillin when a child is edematous or has heavy proteinuria. No RCTs have been performed to evaluate the efficacy and safety of this therapy for this condition. Penicillin has been shown to reduce the risk of infection in children with sickle cell disease (three RCTs, 857 children; odds ratio, 0.37; 95% confidence interval [CI], 0.16–0.86) [85]. Adverse effects of therapy were rare and minor in nature. It has been estimated that 110 children with nephrotic syndrome would need to be treated with penicillin for 1 year to prevent one episode of pneumococcal infection [86].

IVIG for prevention of infection

Three RCTs (208 children) compared IVIG with no specific therapy in children with nephrotic syndrome [87–89]. The dosage and duration of IVIG varied considerably, and the quality of the studies was generally poor. There was a consistent positive effect of IVIG on preventing nosocomial infection or unspecified infection in children with nephrotic syndrome (relative risk [RR], 0.39; 95% CI, 0.18–0.82; $P = 0.01$) [90].

Thymosin for prevention of infection

Thymosin is an immunomodulating agent that can influence T-cell maturation and antigen recognition, the stimulation of interferon and cytokine production, and the activity of NK cell-mediated cytotoxicity [91]. Thymosin reduced the risk of infection compared to no specific therapy in children with nephrotic syndrome (one RCT, 40 patients; RR, 0.50; 95% CI, 0.26–0.97; $P = 0.04$) [92]. There was no significant difference in the types of infection observed in the treatment and control groups.

Chinese herbal preparations for prevention of infection

A single RCT showed a significant effect of Chinese herbs (Tiaojining) on preventing infections in children with nephrotic syndrome compared with no specific therapy (60 children; RR, 0.59; 95% CI, 0.43–0.81; $P = 0.001$) [93]. There was no significant difference in the range of infections between the two groups.

Strategies for the prevention of varicella-zoster infection

The current standard of care in the UK and Australia is that immunocompromised children should receive varicella-zoster immunoglobulin (VZIG) following exposure to varicella-zoster virus. VZIG significantly reduces morbidity and mortality, although breakthrough infection is well-recognized [94]. VZIG is no longer available in the USA. Postexposure acyclovir prophylaxis reduces the transmission rate of varicella in immunocompetent children [95]. In a RCT of eight patients (10 exposures) given acyclovir prophylaxis (10 mg/kg 6 hourly) and VZIG (12.5 U/kg of body weight; minimum of 125 U and maximum of 625 U), none developed varicella compared with one case in four controls given VZIG alone [96]. In two recent studies of varicella vaccines in children with SSNS, protective antibody levels developed in 85–100%. Three children developed mild varicella during the follow-up period. Thirteen children received alternate-day

steroids; none developed skin lesions secondary to replication of the vaccine strain. Studies were not powered to determine whether vaccination resulted in an increased risk of disease relapse [97,98]. Where vaccination is contraindicated because of the administration of high-dose steroids or other immunosuppressive agents, vaccination of household contacts is recommended.

Influenza vaccination for prevention of infection

UK guidelines recommend an annual influenza vaccination in children with nephrotic syndrome. This has been shown to be immunogenic [99,100], although no large-scale trials investigating efficacy and safety have been performed in this population. A single case report exists that describes an adult who developed MCD following the use of this vaccine [101].

Adverse effects of routine childhood vaccination

A single study has reported an association between the administration of the meningococcal C conjugate vaccine and relapse [102]. In the 12 months prior to the introduction of the vaccine in the UK, 63 relapses occurred in a population of 106 children with nephrotic syndrome compared with 96 relapses in the equivalent time period following the introduction of vaccination ($P = 0.009$). These findings have not been replicated elsewhere.

Thrombosis

Introduction and epidemiology

The reported incidence of symptomatic thromboembolic complications is as high as 50% in adults [103] and 2–4% in children [104–106]. The risk of thrombosis appears to be greater in children with SRNS who have persistent proteinuria, compared with children with SSNS who have intermittent proteinuria; 9 of 17 cases of thrombosis in two published series had SRNS [104,105]. Subclinical episodes of thrombosis are common. Of 26 children with nephrotic syndrome in remission who were examined via a ventilation perfusion scan, 7 had abnormal scans and 10 were found to have abnormal or suspicious changes [107].

Thromboembolic complications have been found to be more frequent in the venous rather than arterial system in some but not all series [104,105]. The deep leg veins are most frequently affected, except in congenital nephrotic syndrome, where renal vein thrombosis and thrombosis of the inferior vena cava predominate. Other reported sites of vascular thrombosis include the superior vena cava, the mesenteric artery, hepatic veins, the saggital sinus, and middle cerebral arteries. No single laboratory test can reliably predict thrombotic risk, although fibrinogen concentration has been proposed as a surrogate marker [108].

Prevention of thromboembolic complications

A number of general measures can be undertaken to reduce the risk of thromboembolic events. Bed rest should be avoided, sepsis prevented or adequately treated, and factors which cause

Table 66.5 Evidence ratings and recommendations for interventions to prevent infection and thromboembolic complications in childhood nephrotic syndrome.

Intervention	SR[a]	Evidence rating[a,b]		Studies peformed	Recommendation[c]			Comment
		Moderate	Low		I	II	III	
Prevention of bacterial infections								
Pneumococcal vaccination	—		●	No RCTs in NS patients; 9 RCTs (547 patients) in children with sickle cell disease	●			Benefit in well children; in children with sickle cell disease the conjugate vaccine has been shown to be immunogenic, although clinical outcomes were not measured; no significant harms.
Prophylactic antibiotics	—		●	No RCTs in NS patients; 3 RCTs (857 patients) in children with sickle cell disease		●		Odds of infection reduced (OR 0.37) with penicillin prophylaxis in children with sickle cell disease; adverse effects few and minor
IVIG	+	●		3 RCTs (208 patients); consistent results			●	Expensive medication; requires IV administration; dose unclear
Thymosin	+		●	1 RCT (40 patients)			●	Need more information on harms; not generally available
Chinese herbs	+		●	1 RCT (60 patients)			●	Need more information on harms; not generally available
Prevention of viral infections								
Varicella vaccination	—		●	No RCTs; 5 case series (238 patients) in NS patients	●			100% seroconverted with two-dose schedule; no significant harms; uncertain impact on disease relapses
VZIG + acyclovir	—		●	1 RCT (12 patients)			●	Uncertain benefit; no significant harms
Prevention of thromboembolic complications								
Anticoagulants	—		●	No RCTs			●	Risk of anticoagulant treatment likely to exceed benefit
Antiplatelet agents	—		●	No RCTs			●	Little value to prevent venous thrombosis

[a]Systematic reviews of RCTs;
[b]Evidence rating based on number of studies, study design, study quality, and consistency of results. No intervention was rated with a high evidence rating.
[c]Recommendations based on efficacy, trade-offs between benefits and harms, quality of evidence, and availability of medication. I, recommend; II, suggest; III, no recommendation possible.

hemoconcentration, such as dehydration from acute gastroenteritis and injudicious use of diuretic therapy, should also be avoided. Central venous catheters should not be used unless essential. Studies in adults have suggested that prophylactic oral anticoagulation may be of benefit in MN [109], but no RCTs or other studies have investigated the prophylactic use of any anticoagulant or antiplatelet agent to prevent thomboembolic complications in children with nephrotic syndrome. Possible approaches include the use of warfarin or subcutaneous low-molecular-weight heparin, although the latter is only likely to be effective where antithrombin III levels are adequate. Platelet function is consistently increased, and platelet aggregation inhibitors, such as low-dose aspirin and/or dipyridamole, are logical choices, although no data from controlled studies are available.

It is unclear how long prophylactic therapy should be continued following an episode of thrombosis: the use of prophylactic warfarin has been recommended for at least 6 months and perhaps during future relapses by some [110], but others have suggested that treatment with warfarin should continue for as long as nephrotic-range proteinuria is present [111].

Established thromboembolic complications

The treatment of thromboembolic complications in children with nephrotic syndrome has never been subjected to a RCT or other form of prospective clinical trial. Studies in adult patients have shown treatment with heparin and warfarin for renal vein thrombosis to be effective and safe, but this has not been assessed in RCTs [112]. In patients in whom thrombosis has been more extensive, involving both renal veins, the inferior vena cava, or where the vascular supply of other key organs is compromised, case reports describe successful therapy with anticoagulation and thrombolytic therapy with streptokinase [113] and tissue plasminogen activator

[114] therapy. This therapy is reserved for cases where critical organ function is compromised because of the risk of bleeding.

Edema

For some children, a modest fluid restriction alone may suffice, but in others oral diuretic therapy is necessary to induce diuresis. A combination of a loop diuretic such as furosemide, given two to three times daily, in combination with a potassium-sparing agent (spironolactone), is frequently used, particularly where there is significant ascites. The child should be regularly assessed for signs of intravascular volume depletion. The use of diuretic therapy in children with SSNS is controversial because of the risk of unrecognized hypovolemia once urine output increases.

Resistance to loop diuretics may occur because of a combination of hypoalbuminemia, which results in decreased delivery of protein-bound loop diuretic to the proximal tubules, increased volume of distribution, and intraluminal binding of secreted loop diuretics [115]. Increasing the dose of the diuretic may increase tubular delivery but may also increase the risk of toxicity. Where edema is unresponsive to diuretic therapy and there is risk of skin breakdown (the scrotum is a particularly vulnerable area), intravenous albumin given in conjunction with intravenous furosemide may be indicated. This intervention may cause acute pulmonary edema [116]. No studies have been performed to investigate the optimum dose and duration of intravenous 20% albumin, and some worldwide variation in practice exists. In the UK, a dose of 1 g/kg (5 mL/kg of 20% albumin) is generally given over 4 h, with furosemide given midway through the infusion. Elsewhere, others are more cautious, giving the same dose over 8 h, and others may use doses as large as 2 g/kg.

Evidence-based recommendations

On the basis of the available evidence, it is difficult to make strong evidence-based recommendations regarding the use of drug therapy, antibody therapy, or vaccination for the prevention of infection in children with nephrotic syndrome (Table 66.5). The routine use of IVIG for this indication is very infrequent in Western nations, and both thymosin and Chinese herbal preparations are unlicensed, making widespread adoption of their use unlikely. The evidence of efficacy of both pneumococcal and varicella vaccination based upon uncontrolled case series and RCTs in other disease groups suggests that their use should be recommended, although further studies are necessary to determine the optimal vaccine schedule. Following a similar rationale, the use of prophylactic phenoxymethylpenicillin for prevention of pneumococcal infection is suggested.

It is not possible to make any evidence-based recommendations for the use of anticoagulants or antiplatelet agents for the prevention or treatment of thrombosis.

Introduction

The majority of children with idiopathic nephrotic syndrome have minimal change nephrotic syndrome, but 10% have mesangio-proliferative glomerulonephritis or focal and segmental glomerulonephritis [1]. The response to corticosteroids is highly predictive of histology, with 93% of children with minimal change nephrotic syndrome achieving remission following an 8-week course of prednisone [2]. Between 25 and 50% of children with mesangio-proliferative glomerulonephritis or focal and segmental glomerulonephritis on biopsy also responded to prednisone [2,3]. Children with idiopathic nephrotic syndrome are now classified according to their initial response to corticosteroids as having either steroid-sensitive nephrotic syndrome (SSNS) or steroid-resistant nephrotic syndrome, as the majority are steroid sensitive and do not undergo renal biopsy at diagnosis.

Of children with SSNS, 75–90% will have one or more relapses, and about half will relapse frequently or become steroid dependent [4,5]. The majority will continue to respond to corticosteroids throughout their subsequent disease course [4–6], and the long-term prognosis for complete resolution with normal renal function is good. In the International Study of Kidney Disease in Children (ISKDC), the proportion of children without relapse reached 80% by 8 years of follow-up [5]. About 10% of patients overall [7,8] and 30–40% of patients with steroid-dependent or frequently relapsing SSNS will continue to relapse as adults [6,9].

In children with SSNS, the aim of corticosteroid therapy is to induce and then maintain remission while minimizing adverse effects. Corticosteroid-sparing agents are used to achieve prolonged remissions in children with frequently relapsing or steroid-dependent disease who have significant adverse effects from prednisone therapy. In this chapter the current evidence base for corticosteroid therapy and corticosteroid-sparing agents in children with SSNS will be reviewed.

Treatment of the first episode of nephrotic syndrome with corticosteroids

Because of the clear benefits of corticosteroids compared with no treatment, no randomized controlled trials (RCTs) comparing prednisone with placebo have been performed in children with nephrotic syndrome. The ISKDC agreed on a standard corticosteroid regimen for the first episode of SSNS [10], and subsequently researchers have used this regimen or similar regimens as the standard comparator when testing other regimens. In the ISKDC regimen children received prednisone at 60 mg/m^2/day (maximum dose, 80 mg) in divided doses for 4 weeks followed by 40 mg/m^2/day (maximum, 60 mg/day) in divided doses on three consecutive days out of 7 days for 4 weeks. During the second month of therapy alternate-day prednisone is now preferred [11].

Table 67.1 lists the characteristics of study populations and interventions in relevant RCTs of prednisone in an initial episode of SSNS [12]. A single trial demonstrated that prednisone given for 8 weeks was more effective than a shorter duration of treatment (one trial, 60 patients; relative risk [RR], 1.46, 95% confidence interval [CI], 1.01–2.12) [13]. To investigate if longer courses of prednisone could reduce the 70% risk of relapse at 12–24 months seen in the control group after 2 months of therapy, six RCTs [14–19] compared 2 months of prednisone with periods of 3–7 months. A meta-analysis [12] of these trials demonstrated that the risk of relapse was reduced by 30% at 12–24 months (Figure 67.1a). In addition, there were significant reductions in the number of children who relapsed frequently (six trials; RR, 0.63; 95% CI, 0.46–0.84) and in the mean number of relapses per year (four trials; weighted mean difference [WMD], −0.65; 95% CI, −1.29 to 0.00). There was no significant difference in the cumulative prednisone dose (three trials; WMD, 0.71; 95% CI, −0.67 to 2.09), but significant heterogeneity between studies was found. In four trials [17,20–22], prednisone therapy for 6 months was

Table 67.1 Characteristics of populations and interventions in randomized trials of prednisone in the initial episode of SSNS.

*Trials with three arms; only two of the three arms are included in each comparison.
Abbreviations: MP, methylprednisolone; IV, intravenous.

compared with 3 months of treatment. A meta-analysis [12] of these trials demonstrated that 6 months of therapy significantly reduced the risk for relapse compared with 3 months (Figure 67.1b). In addition, there were significant reductions in the number of children with frequent relapses (four trials; RR, 0.55; 95% CI, 0.39–0.80) and in the relapse rate per year (three trials; WMD, −0.44; 95% CI, −0.82 to −0.07). No additional benefit was demonstrated in one trial of treatment for 12 months compared with 5 months

[23]. In the six trials comparing 2 months of treatment with 3–7 months, the risk of individual prednisone-related adverse effects did not differ significantly between experimental and control groups of the RCTs [12], although there was heterogeneity between trials (Figure 67.2).

Increased duration of corticosteroid therapy results in an increased total dose of corticosteroid, making the effects of duration and dose difficult to separate. Compared with the standard

Figure 67.1 Meta-analyses of RR (95% CI) for relapse of nephrotic syndrome by 12–24 months after the initial episode of SSNS in (a) six trials comparing prolonged prednisone therapy (3–7 months) versus 2 months and in (b) four trials comparing 6 months versus 3 months of prednisone therapy in children. Results are shown ordered by trial weights. The test statistic Z indicates that an increased duration of prednisone was significantly more effective than 2 or 3 months of prednisone. (Reproduced from Hodson *et al.* [12] with permission from John Wiley and Sons.)

induction dose of prednisone of 2240 mg/m^2, administered doses of 2922–5235 mg/m^2 significantly reduced the risk for relapse at 12–24 months (seven trials [14–19,24], 481 children; RR, 0.69; 95% CI, 0.59–0.81). Plotting the RR for relapse against the dose/duration ratio suggested that duration was more important than dose [12]. Two trials [21,24] have now examined different total doses of prednisone administered for the same duration (3 or 6 months). A meta-analysis of these studies showed that the risk of relapse was reduced by 40% with higher doses of corticosteroids (two trials; RR, 0.59; 95% CI, 0.42–0.84), suggesting that both an increased dose and prolonged duration of corticosteroids are important determinants of the risk of relapse [12].

There is an inverse linear relationship between the risk for relapse and duration of induction therapy, suggesting an increase in benefit with treatment for up to 7 months (RR = 1.26 − 0.112 duration; r^2 = 0.56; P = 0.03) [12,25]. With each increase of 1 month of therapy beyond 2 months, the RR for relapse falls by 11%. With a relapse rate of 70% with treatment for 2 months, the calculated number of children relapsing by 12–24 months will fall by 8% for every increase by 1 month in the duration of therapy, so that treatment for 6 months would reduce the risk of relapse

by 32% (4 × 8%), to 38%. In populations with lower relapse rates following 2 months of therapy, the benefit of longer courses of prednisone will be smaller.

These data suggest that to reduce the risk of relapse following the first episode of SSNS, prednisone therapy should be given for 3 months or more, with increased benefit with up to 6 months of therapy. Despite the available data from RCTs, a survey of pediatric nephrologists in North America demonstrated considerable variation among respondents in their approach to the first episode of idiopathic nephrotic syndrome, although about 70% used durations of therapy exceeding the ISKDC's 8-week regimen [26]. Pediatric nephrologists may have been reluctant to increase the duration of prednisone therapy because data on benefits and harms have come from relatively small trials of varied methodological quality. Nevertheless, these trials have provided consistent results, demonstrating that increased duration and dose of corticosteroids reduces the risk for relapse without an increase in harm. The results of a well-designed adequately powered and placebo-controlled RCT comparing 2 months versus 4 months of prednisone therapy with an emphasis on adverse effects, which has recently commenced in the United Kingdom, are expected to help clarify this issue [27].

Figure 67.2 Meta-analyses of Risk Difference (RD) (95% CI) for adverse effects of corticosteroids from six trials comparing prolonged prednisone therapy (3–7 months) versus 2 months. Results are shown ordered by trial weights. The test statistic *Z* indicates that there were no significant differences in the risks of adverse effects with prolonged prednisone therapy (3–7 months) compared with 2 months. (Reproduced from Hodson *et al.* [12] with permission from John Wiley and Sons.)

Treatment of the first episode of nephrotic syndrome with corticosteroids and cyclosporine

Based on the hypothesis that increased immunosuppression reduces the risk for relapse further, but with physicians unwilling to use longer courses of corticosteroids because of the adverse effects, the Arbeitsgemeinschaft für Pädiatrische Nephrologie (APN) compared 12 weeks of prednisone alone with 12 weeks of prednisone plus 8 weeks of cyclosporine [28]. The risk of relapse was significantly lower in the cyclosporine group at 6 months (104 children; RR, 0.33; 95% CI, 0.13–0.83) but not at 12 or 24 months. The mean relapse rate per patient was significantly lower in the cyclosporine group at 6 and 12 months but not at 24 months. Blood pressure and renal function did not differ between groups. Psychological disturbances, hirsutism, and gum hypertrophy were more common during cyclosporine treatment but resolved when cyclosporine was ceased. The authors concluded that because of the attenuation of benefit after 1 year, the side effects of cyclosporine, and the need for monitoring of blood levels, this experimental protocol could not be recommended as a replacement for protocols using prednisone alone in the first episode of SSNS.

Treatment of relapsing SSNS with corticosteroids

There are few data from RCTs on corticosteroid regimens for children with relapsing SSNS, with individual trials addressing different questions. The trial populations and interventions are listed in Table 67.2. Alternate-day prednisone was more effective in maintaining remission than prednisone given on three consecutive days out of 7 days (48 children; RR, 0.60; 95% CI, 0.36–1.02) [11]. There were no significant differences in the time to remission (94 children; WMD, −0.30; 95% CI, −1.64 to −1.04) or risk for relapse (RR, 1.07; 95% CI, 0.77–1.50) between single daily doses and divided daily doses of prednisone. Prednisone can be administered as a single daily dose during daily therapy, which should improve adherence [29]. Deflazacort given for 12 months was significantly more effective than equivalent doses of prednisone in reducing the risk for relapse (40 children; RR, 0.44; 95% CI, 0.25–0.78) in children with steroid-dependent SSNS without differences in adverse effects [30], but deflazacort is not widely available. Prednisone given for 7 months reduced the risk of relapse by 1 year compared with 2 months of therapy (76 children; RR, 0.43; 95% CI, 0.29–0.65) [31]. No significant reduction in the risk of relapse at 1 year could be demonstrated with high-dose intravenous methylprednisolone followed by oral prednisone for 6 months compared with oral prednisone alone (64 children; RR, 1.06; 95% CI, 0.75–1.52) [32]. The total dose of oral prednisone administered was higher in the control group than in the group receiving intravenous prednisone. Children with steroid-dependent SSNS averaged three fewer relapses during 2 years of follow-up if they received daily rather than alternate-day therapy during intercurrent upper respiratory tract infections (38 children; WMD, −3.30; 95% CI, −4.03 to −2.57) [33].

Table 67.2 Characteristics of populations and interventions in randomized trials of corticosteroids in relapsing SSNS.

Trial ID [reference]	No. of patients	Experimental intervention	Control intervention	Follow-up (months)
Alternate-day prednisone versus intermittent therapy in frequently relapsing patients

APN 1982 [41]	50	CPA 2 mg/kg/day for 8 weeks, prednisone for 4 weeks	CHL 0.15 mg/kg/day for 8 weeks, prednisone for 4 weeks	24

Abbreviations: CPA, cyclophosphamide; CHL, chlorambucil; IV, intravenous.

Corticosteroid-sparing agents in frequently relapsing and steroid-dependent SSNS

Alkylating agents, cyclosporine, and levamisole have been demonstrated in RCTs to be effective in reducing the risk for relapse in frequently relapsing and steroid-dependent SSNS. There are no data demonstrating any differences in efficacy between alkylating agents, levamisole, and cyclosporine, so their use depends on availability and patient and physician preferences.

Alkylating agents

The characteristics of clinical trials with alkylating agents are shown in Table 67.3. A meta-analysis of five trials [34–38] demonstrated that cyclophosphamide or chlorambucil reduced the risk for relapse at 6–12 months by 70% in children with frequently relapsing SSNS compared with prednisone alone (Figure 67.3a) [39,40]. There was no significant difference in efficacy between cyclophosphamide and chlorambucil (50 children; RR, 1.15; 95% CI, 0.69–1.94) [41]. Cyclophosphamide therapy for 8 weeks was significantly more effective than administration for just 2 weeks in reducing the risk of relapse at 12 months (22 children; RR, 0.25; 95% CI, 0.07–0.92) [42]. There was no significant difference in the risk of relapse at 12 months between therapy lasting for 8 versus 12 weeks (73 children; RR, 1.04; 95% CI, 0.75–1.44) [43], although an APN study using historical controls had suggested that 12 weeks was superior [44]. Monthly intravenous cyclophosphamide given for 6 months reduced the risk of relapse at the end of therapy compared with oral cyclophosphamide given for 12 weeks (47 children; RR, 0.56; 95% CI, 0.33–0.92), but there was

no difference after 2 years [45]. To determine long-term outcomes, 26 studies of cyclophosphamide and chlorambucil usage in SSNS were analyzed [46]. Overall relapse-free survival after 5 years was below 40%. For frequently relapsing SSNS, relapse-free survivals were 72% and 36% after 2 and 5 years, respectively. For steroid-dependent children, relapse-free survival was 40% and 24% after 2 and 5 years, respectively.

Adverse effects with alkylating agents are frequent and may be severe. Latta and coworkers identified adverse effects from 38 reports on frequently relapsing SSNS that involved 866 children who received 906 courses of cyclophosphamide and 638 children who received 671 courses of chlorambucil [46]. With cyclophosphamide, 0.8% of children died, 1.5% suffered serious infections, 32% developed leukopenia, 2.2% had hemorrhagic cystitis, and 18% had hair loss. With chlorambucil therapy 1% of children died, 6.3% suffered serious infections, 33% developed leukopenia, and 5.9% had thrombocytopenia. Alkylating agents may cause gonadal dysfunction in men, but most reports observed little or no toxicity in women treated for SSNS [46]. With cyclophosphamide treatment in SSNS, there is a dose-dependent relationship between the number of men with sperm counts below 10^6/ml and the cumulative dose of cyclophosphamide. Some individuals have developed oligospermia at cumulative cyclophosphamide doses of 200 mg/kg, suggesting that single courses of cyclophosphamide at a dose of 2 mg/kg/day should not exceed 12 weeks (cumulative dose, 168 mg/kg) and that second courses should be avoided. There are few data on gonadal toxicity with chlorambucil in SSNS. However, in male patients treated for lymphoma, azoospermia occurred with cumulative doses of 10–17 mg/kg, which are equivalent to doses used in SSNS treatment [47].
Figure 67.3 Meta-analyses of the RR (95% CI) for relapse of nephrotic syndrome at 6–12 months in children with frequently relapsing SSNS following (a) alkylating agents (cyclophosphamide [CPA] or chlorambucil [CHL]) compared with prednisone or placebo and (b) cyclosporin compared with alkylating agents. Results are shown ordered by trial weights. The test statistic Z indicates that alkylating agents are more effective than prednisone alone and that the efficacy of cyclosporine and alkylating agents is not significantly different. (Reproduced from Durkan *et al.* [40] with permission from John Wiley and Sons.)

Cyclosporine

Single trials [48,49] (Table 67.4) have demonstrated no significant difference in efficacy during treatment between cyclosporine (6 mg/kg/day in divided doses) and cyclophosphamide or chlorambucil (Figure 67.3b) [40]. The majority of children treated with cyclosporine relapse when therapy is ceased. Adverse effects are significant, with 4% of children developing hypertension, 9% reduced renal function, 28% gum hypertrophy, and 34% hirsutism [40]. In long-term studies remissions of 1 and 2 years are achieved in 60% and 40% of children, respectively. However, 40% of children require low-dose long-term alternate-day prednisone to maintain remission despite adequate blood levels of cyclosporine [50]. Cyclosporine is usually commenced at 5 mg/kg/day in two divided doses with subsequent dosing altered to achieve predose blood levels of 50–100 ng/mL (measured by fluorescence polarization immunoassay). The dose of cyclosporine required to maintain trough levels can be reduced by one-third by administering ketoconazole as a cyclosporine-sparing agent [51]. Glomerular filtration rate was significantly better in the group receiving ketoconazole. Recently, using a 2-h postdose level of 300–400 ng/mL to guide dosage, lower doses of cyclosporine could be used without changes in relapse rate [52].

Cyclosporine-induced tubulo-interstitial lesions on renal biopsy are reported in 30–40% of children who have received cyclosporine for 12 months or more [53, 54], with 80% having interstitial fibrosis when treated for 4 or more years. Cyclosporine-associated arteriopathy is uncommon. Risk factors for fibrosis are more than 3 years of cyclosporine therapy, age below 5 years at the start of therapy, and having heavy proteinuria for more than 30 days during therapy [53,55]. Arteriopathy, but not interstitial fibrosis, improves after cyclosporine has been ceased for 12 months or more [56]. Because of these histological changes, it is recommended that children with SSNS receive cyclosporine for periods of only 2–3 years [53,55] or undergo annual renal biopsies if cyclosporine is continued [53], particularly as interstitial changes may occur in the absence of renal impairment [57].

Levamisole

The efficacy of levamisole in SSNS has been demonstrated in many studies [58] and evaluated in four RCTs [59–62] (Table 67.4). Currently, levamisole is not available because its manufacturer ceased production [58]. Levamisole reduced the risk of relapse by 40% in comparison with prednisone alone in three trials (137 patients; RR, 0.60; 95% CI, 0.45–0.79) [40,59–61]. It was ineffective in a fourth trial [62] in which children with frequently relapsing

*British Association for Paediatric Nephrology

and/or steroid-dependent SSNS received a total levamisole dose of 20 mg/kg/month, compared with the 35-mg/kg/month dose used in the other two trials [59,61] that enrolled children with frequently relapsing and/or steroid-dependent SSNS. In addition, levamisole was administered on two consecutive days of seven in the Weiss trial compared with alternate-day dosing in the other two trials. These data suggest that lack of efficacy in the Weiss trial [62] could have resulted from inadequate total dose and/or inappropriate dosing intervals. In an RCT comparing levamisole with intravenous cyclophosphamide, there was no significant difference in the risk of relapse at 12 months after the end of therapy (40 children; RR, 0.89; 95% CI, 0.68–1.16) [63]. Similarly, in a retrospective analysis of children with steroid-dependent SSNS treated with levamisole for 6 months or oral cyclophosphamide for 8–12 weeks, the proportion of children who were relapse-free after 1 year did not differ between treatment groups [64]. Adverse effects of levamisole are uncommon but include leukopenia, gastrointestinal effects, and occasionally vasculitis [65,66].

Other corticosteroid-sparing agents

In RCTs (Table 67.4), no significant reduction in the risk of relapse has been demonstrated with azathioprine compared with prednisone alone (two trials, 60 children; RR, 0.90; 95% CI, 0.59–1.38) [67,68]. There was no significant difference in relapse rates in an RCT comparing mizoribine with placebo (Table 67.4). The hazard ratio of cumulative remission rate was 0.79 (95% CI, 0.57–1.08) [69]. Sixteen percent of treated patients developed hyperuricemia.

Mycophenolate mofetil (MMF) is now widely used in children with SSNS as a corticosteroid-sparing agent, but to date no data on its efficacy are available from RCTs, although a crossover trial comparing MMF and cyclosporine is in progress through the APN [70]. Three prospective studies involving 76 children who were

treated with MMF for 6–12 months reported reductions in relapse rates of 50–75% during treatment [71–73]. Prednisone dose could be reduced in many patients, but most children relapsed when MMF was ceased. Studies have used 900–1200 mg/m^2/day in two divided doses. Trough levels of mycophenolic acid, measured by enzymatic immunoassay, below 2.5 μg/mL were associated with a slightly but not significantly greater risk of relapse, suggesting that dose regimens should be guided by therapeutic drug monitoring [73]. Kidney function improved on transfer from cyclosporine to MMF [73]. The main adverse effects of MMF in kidney transplant patients are abdominal pain, diarrhea, anemia, leukopenia, and thrombocytopenia, although to date MMF has been well-tolerated in children with SSNS, with only mild abdominal pain reported [71,73]. In children who relapse on MMF alone, a combination of cyclosporine and MMF may maintain remission with the potential for using lower cyclosporine doses [73].

There are few data on the use of tacrolimus, another calcineurin inhibitor, in children with steroid-dependent SSNS. A retrospective study reported data on 10 children who were transferred to tacrolimus because of a poor response to or adverse effects of cyclosporine, and it compared the therapy periods on cyclosporine versus tacrolimus therapy in these children [74]. There was no difference between the therapy periods in the rate of relapse per year, corticosteroid dose, glomerular filtration rate, need for antihypertensive agents, or calcineurin inhibitor toxicity on renal biopsy. One child on tacrolimus developed insulin-dependent diabetes mellitus. A second study of five children with steroid-dependent SSNS reported that only one patient improved substantially with tacrolimus and two children developed insulin-dependent diabetes mellitus [75]. Thus, to date there are no data suggesting that tacrolimus offers any additional benefits over cyclosporine in children with SSNS.

Table 67.5 Evidence rating and recommendations for corticosteroid therapy in steroid sensitive nephrotic syndrome.

	Evidence rating[a,b]			Recommendations[c]			
Intervention	Moderate	Low	Comment	I[d]	II[e]	III[f]	Comment
Corticosteroids in the initial episode of steroid sensitive nephrotic syndrome							
Prednisone 3–7 mths vs 2 mths	•		6 RCTs (422 patients), 3 trials of poor quality, consistent results	•			RD[g] −0.23 (95% CI −0.33 to −0.13). NNT[h] 4. Moderate evidence base, no excess harms documented.
Prednisone 6 mths vs 3 mths	•		4 RCTs (382 patients), 2 trials of poor quality, consistent results	•			RD −0.31 (95% CI −0.41 to −0.22). NNT 3. Moderate evidence base, no excess harms documented.
Prednisone high vs low dose		•	2 RCTs (91 patients), one trial of poor quality, consistent results			•	RD −0.32 (95% CI −0.51 to −0.13). Low evidence base. Need more data on harms.
Corticosteroids in relapsing steroid sensitive nephrotic syndrome							
Prednisone alt day vs 3/7 days	•		1 RCT (64 patients); wide 95% CI	•			RD −0.29 (95% CI −0.55 to −0.02). NNT 3.5. Moderate evidence base, no excess harms documented.
Prednisone daily vs divided dose	•		1 RCT (106 patients); wide 95% CI	•			No differences in efficacy or harms. Moderate evidence base. Could improve compliance.
Prednisone 7 mths vs 2 mths	•		1 RCT (90 patients); 20% lost to follow up		•		RD −0.50 (95% CI −0.68 to −0.32). NNT 2. Moderate evidence base. Further RCTs required.
Daily prednisone dose for URTI		•	1 small RCT (36 patients); poor quality			•	3 relapses fewer/yr. Low evidence base. Further RCTs required.
Deflazacort vs prednisone	•		1 small RCT (40 patients)			•	RD −0.50 (95% CI −0.75 to −0.25). NNT 2. Moderate evidence base. Further RCTs required. Deflazacort not generally available.

[a] Evidence rating based on study design, study quality, consistency and directness of results. All data from systematic reviews of randomized controlled trials.

[b] No intervention was rated with a high evidence rating.

[c] Recommendations based on trade-off between benefits and harms, quality of evidence, translation of evidence into practice in a specific setting including availability of medication and any uncertainty about the baseline risk of the disease in the population.

[d] Recommend, [e] Suggest, [f] No recommendation possible.

[g] Risk difference (95% confidence intervals).

[h] Number needed to treat.

Conclusions

The evidence ratings (based on numbers of trials, study design, study quality, and consistency of results) and recommendations (based on the trade-offs between benefits and harms, the quality of the evidence, and the ability to translate into clinical practice) for use of corticosteroids and corticosteroid-sparing agents in children with SSNS are listed in Tables 67.5 and 67.6.

For an initial episode of SSNS, the overall evidence rating is classified as moderate for the recommendation to use prednisone therapy for durations of 3–7 months compared with 2 months and for durations of 6 months compared with 3 months. Although the trials evaluating prolonged duration of prednisone are small

and of variable quality, the benefits are consistent across trials: the effect size is large (RR, 0.70; 95% CI, 0.58–0.84), and no significant differences in harm has been documented, although there is some heterogeneity among trials. The number needed to treat (NNT) is four, indicating that only four children need to be treated with prednisone for 3–7 months compared with 2 months to prevent one child from relapsing and avoiding the morbidity associated with relapse. The evidence rating for high total dose compared with lower total dose is low, so that no recommendation can be given for this medication schedule at present.

In relapsing SSNS, the evidence rating is classified as moderate for the recommendations to use single daily doses rather than divided doses to induce remission and to use alternate-day prednisone rather than three consecutive days out of seven to maintain

Table 67.6 Evidence ratings and recommendations for corticosteroid sparing agents in frequently relapsing steroid sensitive nephrotic syndrome

| Intervention | Evidence rating[a,b] | | Comment | Recommendations[c] | | | Comment |
	Moderate	Low		I[d]	II[e]	III[f]	
Alkylating agents							
Alkylating agents for 8 wks vs prednisone	•		5 RCTs (134 patients), some of poor quality. Consistent results.	•			RD[g] −0.61 (95% CI −1.00 to −0.23). NNT[h] 2. Moderate evidence base for efficacy and safety.
Cyclophosphamide vs chlorambucil	•		1 RCT (50 patients).	•			No differences in efficacy or harms. Moderate evidence base.
Intravenous vs oral cyclophosphamide	•		1 RCT (47 patients).			•	No obvious difference in efficacy/harms by 2 yrs. Moderate evidence base.
Cyclosporin							
Cyclosporin vs alkylating agents	•		2 RCTs (95 patients). Consistent results.	•			No difference in efficacy between agents during treatment. Moderate evidence base.
Levamisole							
Levamisole for 4–12 mths vs prednisone	•		3 RCTs (137 patients) show benefit. Consistent results. 1 RCT (48 patients) using lower dose no effect.			•	RD −0.31 (95% CI −0.46 to −0.16) (3 RCTs). NNT 3. Moderate evidence base. No excess harms documented. Levamisole not currently available.
Levamisole vs cyclophosphamide		•	1 RCT (40 patients); poor quality			•	Sparse data; no obvious difference in efficacy. Levamisole not currently available.
Mycophenolate mofetil							
Mycophenolate mofetil		•	3 prospective studies (76 patients); consistent results			•	Poor evidence base. No RCTs. Apparent benefit in 50–75% patients.
Tacrolimus							
Tacrolimus		•	2 studies (15 patients); consistent results			•	Sparse data; no demonstrable benefit over cycloporin.

[a] Evidence rating based on study design, study quality, consistency and directness of results. All data from systematic reviews of randomized controlled trials.
[b] No intervention was rated with a high evidence rating.
[c] Recommendations based on trade-off between benefits and harms, quality of evidence, translation of evidence into practice in a specific setting including availability of medication and any uncertainty about the baseline risk of the disease in the population.
[d] Recommend, [e] Suggest, [f] No recommendation possible.
[g] Risk difference (95% confidence intervals). [h] Number needed to treat.

remission. There is no biological reason why these regimens should not be equally effective in the initial episode of SSNS, although this has not been evaluated in RCTs. It is suggested that prolonged duration of prednisone treatment can also be used for relapsing SSNS, but further RCTs are required to document the adverse effects of corticosteroids in children, who require multiple courses of prednisone. No recommendation can be made for deflazacort or for daily prednisone during upper respiratory infections without further RCTs to examine the benefits and harms.

In children with frequently relapsing or steroid-dependent SSNS, the evidence rating is classified as moderate for use of alkylating agents compared with prednisone or no treatment, with no difference demonstrated in efficacy between cyclophosphamide and chlorambucil. Alkylating agents can be recommended for children with frequently relapsing or steroid-dependent SSNS who

have serious adverse effects from corticosteroids. Significant harm is associated with alkylating agents, with about a 3% risk of serious infections and 1% risk of death. Alkylating agents reduce the risk of relapse by 70% (NNT, 2), so one can estimate that 3 serious infections and 1 death due to treatment will occur per 100 patients avoiding a relapse. The evidence rating for using intravenous compared with oral cyclophosphamide is moderate, but no recommendation for its routine use can be made because of the additional potential harm related to intravenous access and treatment costs, which were not considered in the study. The evidence rating for using cyclosporine is classified as moderate, and this agent can be recommended as an alternative to alkylating agents as no difference in efficacy between cyclosporine and these agents has been demonstrated. The evidence rating is classified as moderate for the efficacy of levamisole compared with prednisone

or placebo, but no recommendation can be made for its use, as this medication is no longer manufactured. The evidence rating for MMF and tacrolimus is classified as low, and no recommendations can be made for their use.

Although the evidence base from randomized trials in the treatment of SSNS is relatively large, many of the trials performed have been small and/or of inadequate quality. Further information, particularly on potential harms, is required to determine the optimal duration and total dose of prednisone in the initial episode of SSNS, with clarification of the relative contributions of dose and duration. In frequently relapsing and steroid-dependent SSNS, more information is required on the relative efficacies of alkylating agents, cyclosporine, MMF, and levamisole (assuming that production of levamisole is resumed). In addition, information is needed on the relative efficacies of corticosteroid-sparing agents in children with steroid-dependent or frequently relapsing SSNS. These important questions can be answered with well-designed and adequately powered international multicenter trials.

68 Steroid-Resistant Nephrotic Syndrome

Annabelle Chua[1] & Peter Yorgin[2]

[1]Section of Pediatric Nephrology, Texas Children's Hospital, Baylor College of Medicine, Houston, USA
[2]Section of Pediatric Nephrology, Loma Linda University, Loma Linda, CA, USA

Introduction

Steroid-resistant nephrotic syndrome (SRNS) is a heterogeneous disease characterized by the persistence of proteinuria after 4–8 weeks of corticosteroid therapy [1,2]. The incidence of new-onset childhood SRNS is about 0.3 cases/100,000 patient years [3]. Approximately 15% of children treated for new-onset nephrotic syndrome are steroid resistant [4–6]; some patients are corticosteroid resistant after the first corticosteroid course, whereas others become corticosteroid resistant after receiving two or more treatment courses. Steroid resistance is more common in South Asians [3], African Americans [4], older children [4], and those children who relapse more rapidly [4].

Most pediatric nephrologists perform a renal biopsy to determine the glomerular histology prior to initiating a noncorticosteroid-based therapy in SRNS [7]. The International Study of Kidney Diseases in Children (ISKDC) reported that focal segmental glomerulosclerosis (FSGS) was responsible for 7% of new-onset nephrotic syndrome cases [1]. A recent study suggested that the number of children with FSGS may be increasing to 0.5 cases/100,000 children/year [8]. A retrospective study of 42 children with SRNS at Stanford University reported 24% with minimal change disease (MCD), 17% with mesangial proliferative glomerulonephritis (MesPGN), 24% with FSGS, and 36% with FSGS and mesangial proliferation [9].

The treatment of SRNS can be directed toward abrogating the causes of the proteinuria through the use of additional corticosteroids, alkylating agents, and calcineurin inhibitors or by inhibiting the damaging effects of the proteinuria and nephrotic syndrome through the use of statins and angiotensin converting inhibitors. The stakes are high, as patients who respond to therapy regain a sense of well-being and are less likely to progress to end-stage renal disease (ESRD) [10,11]. Treatment failure, even after achieving an initial remission, correlates with poor long-term

outcome. Overall, children with MCD-associated SRNS tend to respond best to therapy, whereas those with FSGS comprise the majority of those who progress to ESRD [9,12]. Despite one case report of successful treatment of familial FSGS [13], patients with familial (genetic) forms of SRNS generally do not respond to therapy, and so this form of the disease will not be considered further in this chapter.

Treatment of SRNS: methods

A MEDLINE search was conducted to develop evidence-based treatment guidelines for children with SRNS. Pediatric studies were preferentially selected. However, if pediatric data could be extracted from a study population that also included adults, the information was added to the analysis. For consistency, the results reported reflect initial, not final or long-term, responses to therapy. Patients respond to therapy either completely, where urinary protein/creatinine (U_{Prot}/U_{Creat}) ratios return to normal (<0.20 mg/mg; <0.02 g/mmol), partially with at least a halving of the proteinuria (U_{Prot}/U_{Creat}, <2 mg/mg, or <0.2 g/mmol), or not at all (treatment failure).

There is controversy regarding the nomenclature of MesPGN, as some pathologists consider MesPGN to be an early form of FSGS. Because a significant number of the pediatric studies have characterized their patients as having MesPGN, the term MesPGN is used in the tables found in this chapter.

Calcineurin inhibitor therapy

Cyclosporine

There is more literature supporting calcineurin inhibitor therapy in SRNS than any other medication [14,15] (Table 68.1). Although both cyclosporine (CsA) and tacrolimus have been used to treat SRNS in children, there are substantially more data regarding the outcomes of patients treated with CsA. Twenty-four retrospective and prospective uncontrolled studies, with a total of 531 patients

Table 68.1 Evidence ratings and recommendations for interventions to achieve remission in SRNS.

| Intervention | SR[a] | Evidence rating[b] | | Studies conducted | Recommendation[c] | | | Benefit–risk trade-offs |
		Moderate	Low		I	II	III	
Calcineurin inhibitors (vs standard care)	+	•		3 small RCTs (46 patients); 21 case series (507 patients); generally consistent results	•			Benefits exceed harms; RR −0.26 (95% CI −0.49 to −0.04); NNT 4
Oral steroids (vs oral alkylating agents)	+	•		2 RCTs (88 patients) with consistent results; 11 case series (104 patients) with inconsistent results		•		No evidence of benefit in FSGS in RCTs; significant harms
ACEi (vs standard care)	+	•		3 RCTs (87 patients) with consistent results; 6 case series (46 patients) with inconsistent results	•			Benefits exceed harms; proteinuria reduced by 0.95 g/day (95% CI −1.21 to −1.05) in 1 RCT; few harms reported
Pulse intravenous steroids	−		•	3 case series (94 patients), generally consistent results			•	Remission in 30–60%; need more data on harms
Intravenous alkylating agents	−		•	5 case series (71 patients), generally consistent results			•	Remission in 30–100%; need more data on harms
Combined therapy (PMT + CPA)	−		•	8 case series (204 patients), generally consistent results			•	Remission in 50–80%; need more data on harms

[a]SR, systematic review(s) available on RCT(s).

[b]Evidence rating based on study design, study quality, consistency, and directness of results. No intervention received a high evidence rating.

[c]Recommendation based on trade-off between benefits and harms, quality of evidence, and translation of evidence into practice in a specific setting, including availability of medication and any uncertainty about the baseline risk of the disease in the population. I, recommend to give or not to give; II, suggest to give or not to give; III, no recommendation possible; NNT, number needed to treat.

(497 treated with a calcineurin inhibitor) have been conducted to evaluate the effectiveness of CsA in the treatment of SRNS (Table 68.2) [13,16–33]. The response to CsA is variable, with complete remission rates that range from 7 to 100%. The recent Cochrane review of randomized controlled trials (RCTs) concluded that CsA, compared with placebo or no treatment, significantly increased the number of children who achieved complete remission (three RCTs, 49 children; relative risk [RR] for persistent nephrotic syndrome, 0.64; 95% confidence interval [CI], 0.47–0.88) [34].

The dosing regimen of CsA varies widely and has changed over time. Although lower-dose CsA therapy (100 mg/m^2/day) has been advocated [25], most current treatment regimens empirically start with a dose of 5–7 mg/kg/day [22,24,31,32]. Inguilli *et al.* suggested that the CsA dose and trough level should be titrated upwards when patients have higher cholesterol levels [24]. Most regimens report twice-daily dosing; however, single-daily dosing of CsA has also been effective [16,21]. When starting with a higher dose, tapering of the CsA to 3–4 mg/kg is frequently undertaken after treatment response [31,35]. CsA trough levels effective in inducing remission have ranged from 50 to 300 ng/mL [22,24,28,32,36,37].

CsA-induced side effects include hirsutism [30,32], gingival hyperplasia [16,30,32,36], hypertension [16,22,32,33,36,38–40], and nephrotoxicity characterized by tubular atrophy and progressive interstitial fibrosis [16,22,25,28,29,36,41,42]. Investigators have reported that CsA reduces the glomerular filtration rate (GFR)

and causes significant nephrotoxicity [36,43]. Some children have reversible arteriopathy [42], with recovery of GFR when CsA is ceased [43], but about 15% have irreversible changes [22,28].

Relapses of nephrotic syndrome after withdrawal of CsA therapy are common, affecting approximately 50% of patients [16,18,23,25,28,29,32,36,44]. It is unclear how relapses impact long-term kidney function, how long patients can reasonably continue to receive therapy, whether resistance to treatment develops over time [45], and how frequently renal biopsies should be performed to monitor CsA nephrotoxicity.

Tacrolimus

Two pediatric case series have demonstrated that tacrolimus has an antiproteinuric effect similar to CsA and may be effective in achieving remission in CsA-resistant SRNS children [39,46]. Tacrolimus therapy does not induce hirsutism or gingival hyperplasia, which are common with CsA, but it dose cause insulin resistance and diabetes (in 2–3% of pediatric kidney transplant recipients) [47,48]. The lack of an RCT means that tacrolimus therapy cannot be recommended until further data are available.

Corticosteroid therapy

Oral corticosteroid therapy

Oral corticosteroid therapy remains a therapeutic "cornerstone" in the management of SRNS. Given that children with SRNS are,

by definition, resistant to steroid therapy, resuming or continuing oral corticosteroid therapy may seem counterintuitive. Yet, there is evidence that some patients with SRNS can respond to oral corticosteroids.

There have been two prospective RCTs in children with SRNS in which oral corticosteroid therapy was selected as the control treatment arm [49,50]. Children with MCD-induced SRNS may have higher remission rates [49] than those with FSGS [50]. Studies of children with FSGS have reported complete remission rates of 0–28% [49–51]. Yet, oral corticosteroid therapy alone may be insufficient to maintain remission, as 25% subsequently relapsed and progressed to ESRD [50,51].

Despite their well-known adverse effect profile, 3–6 months of oral corticosteroids has been recommended in the therapy of SRNS when combined or used in sequence with other therapies [52]. The current NIH-funded SRNS FSGS study is using alternate-day oral corticosteroid therapy at a dose of 0.5 mg/kg/day for 6 months.

Short course of high-dose (pulse) intravenous corticosteroid therapy

Early reports of successful treatment of glomerular diseases with pulse methylprednisolone therapy (PMT) [53,54] led to PMT studies in children with SRNS. Whereas some investigators used three consecutive doses or alternate-day doses [55–57], others used six doses of intravenous PMT (1 g/1.73 m^2 or 30 mg/kg with a maximum dose of 1 g) or dexamethasone (5 mg/kg) [54,58–60].

Ninety-four children were treated with intravenous corticosteroids in three prospective, nonrandomized studies [54,58,60] (Table 68.3). When intravenous PMT or dexamethasone therapy was used alone, 33–63% of patients achieved complete remission. Equivalent remission rates have been achieved using intravenous dexamethasone or methylprednisolone [59,60] ($P = 1.00$; RR, 0.958; 95% CI, 0.335–2.461). Although patients may go into remission, most require another agent to maintain remission [54,58,60].

The adverse effects of pulse intravenous methylprednisolone or dexamethasone therapy can include dysrhythmias [61], hyperglycemia (3%) [60], hypokalemia (48%) [60], nausea and vomiting (9%) [62], mood swings (18%) [62], and posterior lenticular cataracts (9%) [62]. Hypertension has been reported to occur in about 50% of children [60].

An RCT examining the efficacy of pulse intravenous corticosteroid therapy in the treatment of SRNS is needed.

Purine synthesis inhibitors

Azathioprine

Abramowicz et al. conducted an RCT comparing azathioprine (60 mg/m^2/day) plus intermittent prednisone (40 mg/m^2/day for three consecutive days per week) versus intermittent prednisone alone [2]. There was no difference in outcomes (12.5% achieved remission) between the azathioprine and prednisone alone groups ($P = 1.00$). White et al. reported the use of high-dose azathioprine therapy (4–14 mg/kg/day for 4–60 weeks) in combination

with steroid therapy to treat children with SRNS [63]. Although 38% of those treated with high-dose azathioprine improved, two patients died. The remission rate for azathioprine treatment is so low that it cannot be recommended in the treatment of SRNS.

Mycophenolate mofetil

No RCTs have evaluated the effect of mycophenolate mofetil (MMF) in childhood SRNS. A retrospective analysis of five pediatric patients with SRNS who were treated with MMF, with or without subsequent weaning of CsA, reported fewer relapses per year on treatment (1.4 ± 1.1) compared to the 12 months prior to MMF (2.8 ± 1.3) [64]. Only two patients were weaned off CsA, and two had the same number of relapses pre- and posttreatment with MMF. A cohort study of five patients with cyclophosphamide (CPA)-resistant and CsA-resistant SRNS reported only one MMF-induced remission [65]. A study conducted by Ulinski et al. evaluated treatment conversion from CsA to MMF in children with steroid-dependent nephrotic syndrome and SRNS [43]. Overall, the calculated GFR increased while the amount of corticosteroid therapy needed to retain the remission decreased.

The current NIH-sponsored FSGS study is comparing MMF (25–36 mg/kg/day) and dexamethasone in one group and CsA treatment in the other group [41]. An RCT of MMF is needed to determine its efficacy for this indication.

Mizoribine

The mechanism of action for mizoribine is similar to that of MMF. Although studies conducted in Japan reported that mizoribine was effective in the treatment of a limited number of children with SRNS [66,67], there have been no RCTs. In a study of patients with SRNS due to FSGS, 7 of the 15 (47%) children achieved remission [67]. Doses of 3–10 mg/kg have been used without significant adverse effects [66,68,69].

Alkylating agents

Oral CPA

Two RCTs concluded that children with SRNS respond poorly to alkylating agents, with only 17–25% of patients achieving remission [50,70]. The RCT performed by Tarshish et al. reported that there was no significant difference between the outcomes in children with FSGS treated with cyclophosphanide (CPA) ($P = 1.00$; RR, 1.050; 95% CI, 0.750–1.470) compared to oral prednisone alone. In addition, those study authors reported that 9/25 subjects receiving prednisone and 20/35 on CPA had kidney dysfunction ($P = 0.13$; RR, 1.59; 95% CI, 0.87–2.88). The ISKDC study, which included children with MCD or FSGS, reported a somewhat higher complete remission rate with CPA and intermittent prednisone (56%) than with intermittent prednisone alone (40%), but there was no significant difference in outcomes between the treatments ($P = 0.718$; RR, 0.714; 95% CI, 0.158–3.231) [49]. When the two RCTs are combined in a meta-analysis for the outcome of failure to achieve remission, results are no different ($P = 1.00$; RR, 1.01; 95% CI, 0.74–1.36). A large observational study by Martinelli et al.

[d]NR, not reported.

[51] reported comparable outcomes for children treated with CPA compared to those treated with prednisone, but CPA-induced remission rates were still low (27%).

There may be a differential response to alkylating agents that depends on the underlying renal pathology in children with SRNS (Table 68.4). Oral CPA appears to be more effective in children with MCD-associated SRNS, with short-term remission rates of 50–100% [71–75].

Both chlorambucil and CPA have been successfully used to treat children with SRNS. Elzouki and Jaiswal [76] reported chlorambucil responsiveness despite CPA resistance in five SRNS patients. Because 4–8% of patients treated with chlorambucil develop seizures [77,78] and reported outcomes are similar, there appears to be no advantage to using chlorambucil compared with CPA.

Dosing for CPA in children has been based on studies performed by Barrett and Soothill. Patients who received 3 mg/kg/day for 8 weeks had longer remissions and fewer relapses [79]. Most of the current studies report using 2–3 mg/kg for 8–12 weeks [8,51,77,80,81]. Some investigators reported using a second, or even third, course of alkylating agent when the first course was not effective [75]. The study by Drummond *et al.* reported excellent results with longer-term therapy (up to 1 year) with CPA [82].

All patients receiving oral alkylating therapy should be advised of the risks of infertility [83–85], alopecia [86], leucopenia [77,87], and hemorrhagic cystitis [49]. Alkylating agent-induced infertility is particularly concerning. In the meta-analysis by Latta *et al.*, there was no safe threshold CPA cumulative dose for men; greater cumulative doses correlated with a greater risk of infertility [77]. Conversely, women rarely develop oral alkylating agent-induced infertility [77]. A recent study by Ruth *et al.* reported that only 8 of 42 adults who had received CPA therapy for nephrotic syndrome as children had borne children, although it was uncertain whether CPA-induced fertility was the cause [84]. Etledorf *et al.* reported that four men who received CPA at 2–4 mg/kg/day for 49–60 days had normal semen, whereas four other men who received 2–5 mg/kg for 89–489 days were azoospermic [88]. Trompeter *et al.* found lower ejaculate volumes and sperm densities with a higher percentage of immotile and abnormal forms in 19 men who received CPA at 3 mg/kg for 8 weeks [83], but the abnormalities were not severe enough to suggest infertility. Sperm banking may be offered to older adolescent men as a hedge against the possibility of sterility.

Intravenous CPA

Reports of excellent outcomes in patients with lupus nephritis treated with intravenous CPA have encouraged some investigators to attempt intravenous pulse CPA therapy in children with SRNS. Intravenous CPA has been used by clinicians in settings where frequent visits for therapy are not feasible. There have been six studies (involving a total of 71 patients) in which children received monthly pulse CPA (in doses ranging from 500 to 750 mg/m² per dose) for 6 months with concurrent oral corticosteroid therapy (Table 68.5) [86,89–92]. One RCT was performed that compared intravenous versus oral CPA [91]. All of the subjects ($n = 7$) who

received intravenous CPA achieved remission, whereas only one (25%) of the subjects ($n = 4$) who received oral CPA responded to therapy. However, small numbers led to imprecision of results, so that the difference was not significant (RR, 0.09; 95% CI, 0.01–1.39), and further RCTs are required.

Intravenous pulse CPA therapy has been described as well-tolerated, safe, and effective, but with some increase in the risks of infection [90], alopecia [86,89,90], and transient vomiting [86,89]. Although not reported in any intravenous CPA SRNS studies, patients treated with intravenous CPA may develop hemorrhagic cystitis [93], which may recur with reintroduction of intravenous CPA [94]. The use of 2-mercaptoethane sodium sulfonate (Mesna) has been shown to reduce the risk of hemorrhagic cystitis due to intravenous CPA [94–98].

The long-term effects on fertility of intravenous pulse CPA are concerning. Women with systemic lupus erythematosus treated with intravenous pulse CPA are at risk of ovarian toxicity. In a study by Park *et al.*, logistic regression analysis showed that older age, high damage index at initiation of therapy, and high cumulative dose were the independent risk factors of ovarian failure [85].

Because of small patient numbers, diverse histology, and extreme variability of treatment responses, it is not possible to make a recommendation regarding intravenous CPA.

Other antineoplastic and immunosuppressant medications

Nitrogen mustard therapy (mechlorethamine) and vincristine

There have been no RCTs of mechlorethamine. Mechlorethamine therapy with corticosteroids or adrenocorticotropic hormone was advocated as an effective treatment for SRNS from the 1950s to the 1980s. All patients achieved partial or complete remission in the study conducted by Fine *et al.* [99], in which mechlorethamine was infused intravenously for four consecutive days. A subsequent study by Armugan *et al.* [100] did not report encouraging results. None of the seven patients achieved a complete remission. Vomiting was a common adverse effect of mechlorethamine therapy [99,101].

Although primarily used as an antineoplastic drug in the treatment of malignancies, there have been two small cohort studies of vincristine treatment in children with SRNS [102,103]. Response rates to therapy, defined as combined complete and partial remissions, were 38% [102] and 43% [103]. Both studies concluded that vincristine was relatively ineffective in inducing remission. However, patient selection for both studies appeared to be biased towards unresponsiveness to any therapy. There is insufficient evidence to make a recommendation regarding vincristine therapy.

Combination therapy

The use of combination therapy, consisting of two or three different medications, has been advocated by many investigators

[a] Details on six of six studies are shown.
[b] Complete remission only.

[38,59,92,104–108] (Table 68.6). There have been at least 10 studies with a total of 204 patients treated with combination therapy, but no RCT has been conducted. The mean complete remission rate for all combination therapies is 58%. Nearly all patients with MCD respond to combination therapy, whereas only 47% of FSGS patients achieve a complete remission.

Triple therapy: PMT + alternate-day oral corticosteroids + CPA

One of the most common combinations, a triple therapy with a combination of intravenous PMT, oral CPA, and alternate-day prednisone therapy, was first described by Griswold *et al.* [104]. Large doses, 30 mg/kg methylprednisolone up to a maximum of 1 g, were infused intravenously three times per week for 2 weeks (six doses) and then weekly for at least 4–6 weeks. Decreasing the frequency of the PMT dose to every other week and monthly occurred when U_{Prot}/U_{Creat} levels decreased to near normal levels. For patients who did not respond to pulse intravenous corticosteroid therapy (PICT) alone, oral CPA at 2 mg/kg/day was prescribed for 75–90 days. Alternate-day oral corticosteroid dosing was decreased relative to the patient's response.

In the six triple therapy studies (150 patients), 50–75% of patients achieved a complete or partial remission [57,59]. African American patients may be less responsive to triple therapy than other ethnic groups [109], and outcomes in patients who have failed treatment with calcineurin inhibitors have been disappointing [57]. A long-term analysis of FSGS patients by Tune *et al.* reported that 9% of patients progressed to ESRD [107].

Adverse effects, including transient hypertension, vomiting, steroid-induced cataracts, and headaches, are reported to be self-limited [38,59,104–108]. RCTs are needed to determine the effectiveness and safety of this therapy.

Other combination therapies

Waldo *et al.* conducted a prospective cohort study in which PMT and CsA therapy was combined in 10 children with FSGS, 80% of whom achieved remission [38]. Four of the patients were African American, and all four responded to therapy. Yorgin *et al.* also reported the use of combined PMT, angiotensin converting enzyme inhibitor (ACEi), and CsA therapy in a subset of study subjects [13]. CsA therapy was used to maintain remission after it had been achieved by PMT.

Kano *et al.* reported the successful use of combination therapy with PMT, intravenous immunoglobulin and a statin [110], with 77% achieving a complete or partial remission.

The study by Mori *et al.* prospectively evaluated the use of heparin therapy and PMT administered for three consecutive days [57]. The combination therapy was given 14 times over 2 years. The patient group consisted of children who were expected to have a poor prognosis due to their resistance to CPA or CsA, and 60% achieved a partial or complete remission.

El-Reshaid *et al.* reported a 100% remission rate in 21 children with SRNS in a sequential protocol consisting of a calcineurin in-hibitor followed by the addition of MMF and then by monthly intravenous CPA for three consecutive months [92]. All patients required antihypertensive therapy after starting calcineurin inhibitor therapy.

Nonimmunosuppressant therapy

ACEi therapy

A recent Cochrane review [34] concluded that ACEi significantly reduced proteinuria in children with SRNS (two RCT trials [111,112] with 70 children in total). The RCTs and a small number of prospective and retrospective uncontrolled studies [113–117] reported a 40–80% reduction of proteinuria (Table 68.7). In the RCT by Yi *et al.*, children with SRNS were randomized to receive fosinopril and prednisone treatment for 12 weeks or to receive prednisone alone for the same duration [111]. Fosinopril-treated subjects consistently had lower 24-h urinary protein excretion. After 12 weeks of treatment, fosinopril reduced proteinuria by 0.95 g/24 h (95% CI, −1.21 to −0.69).

ACEi therapy appears to have a dose-dependent effect. In a randomized crossover trial evaluating low-dose versus high-dose enalapril [112], patients who received enalapril at a dose of 0.6 mg/kg/day had an almost twofold greater reduction in the $U_{albumin}/U_{creat}$ ratio compared with patients who received 0.2 mg/kg/day. Investigators had initiated enalapril at a low dose of 0.2 mg/kg/day and then gradually increased the dose to 0.5–0.6 mg/kg/day. Careful monitoring of GFR and serum potassium values is necessary when using ACEi therapy.

Statin therapy

Patients with nephrotic syndrome typically have apoB overproduction, with high levels of very-low-density lipoproteins and low-density lipoproteins (LDL) in plasma. HMG-CoA reductase inhibitors (statins) have been evaluated in both animal and adult studies to ameliorate hypercholesterolemia associated with nephrotic syndrome [118,119]. Two small uncontrolled trials evaluated the efficacy of statin therapy in children with SRNS. Coleman *et al.* evaluated the efficacy of simvastatin in seven pediatric patients with SRNS and reported that study participants who received a median simvastatin dose of 10 mg/day had 41% and 44% reductions in cholesterol and triglycerides, respectively [120]. One patient who was concurrently treated with prednisolone experienced complete remission.

Sanjad *et al.* reported that statin therapy significantly reduced plasma levels of total cholesterol, LDL cholesterol, and triglycerides [121]. Statin therapy did not result in a significant reduction in the level of proteinuria or increase serum albumin levels. The rate of progression to ESRD was not affected by statin therapy.

RCTs of statin therapy in a larger population of patients with SRNS are necessary to evaluate if statins have renoprotective and/or cardioprotective roles.

Pheresis-based therapies

The efficacy of plasma exchange (TPE) in children is thought to be due to the removal of the focal segmental permeability factor described by Savin *et al.* [122–124] and other nephrotic syndrome-inducing permeability factors. The successful use of TPE in treatment-resistant FSGS in nontransplanted children has been reported in a limited number of patients [125–129]. The largest series conducted is the multicenter prospective study by Franke *et al.*, who treated seven children with FSGS using 2.5 volume TPE, PMT, CsA, and replacement intravenous immunoglobulin. Four of the seven patients (57%) achieved a remission. One patient developed *Streptococcus pneumonia* sepsis after two TPE sessions.

Hattori *et al.* were the first to report decreased proteinuria and improved renal function in FSGS with LDL apheresis (LDL-A) [130]. Lipoprotein pheresis systems use a dextran sulfate cellulose column, which binds LDL cholesterol. Brunton used LDL-A to treat 20 patients with nephrotic syndrome. Two patients experienced a remission while receiving the therapy, and LDL-A was effective in reducing LDL cholesterol and was deemed safe [131]. In a multicenter trial, 17 patients with SRNS due to FSGS were treated with corticosteroid therapy and LDL-A twice a week for 3 weeks and then weekly for 6 weeks [132]. In addition to a rapid improvement in hyperlipidemia, 71% achieved remission or partial remission. In a retrospective study, where LDL-A was compared to corticosteroid treatment alone in patients with FSGS, the LDL-A treatment group experienced a decrease in phospholipid, cholesterol, and proteinuria [133]. Hattori *et al.* conducted a prospective study of LDL-A in which 7 of 11 nephrotic children with steroid- and CsA-resistant primary FSGS achieved remission [134]. In a retrospective study by Muso *et al.*, patients in one group ($n = 17$) received LDL-A twice a week for 3 weeks and then weekly for 6 weeks, whereas the other group ($n = 10$) was only treated with corticosteroids. The length of time required to achieve a U_{Prot}/U_{Creat} ratio was shorter in the LDL-A group. Seven patients in the LDL-A group (41%) experienced remission of nephrotic syndrome.

Antibody therapy

Rituximab (anti-CD20)

There are two case reports of remission in response to rituximab therapy. Benz *et al.* reported a 16-year-old boy with SRNS due to FSGS who responded to CPA and CsA therapy but had relapses whenever therapy was withdrawn. After an episode of idiopathic thrombocytopenic purpura treated with rituximab, the patient no longer experienced relapses while on CsA therapy [135]. Nozu *et al.* reported the case of a 12-year-old kidney transplant recipient with recurrent FSGS who developed posttransplant lymphoproliferative disorder [136]. After treatment of the posttransplant lymphoproliferative disorder with rituximab, the patient's nephrotic syndrome completely resolved. Insufficient data exist to recommend this treatment.

Bone marrow transplantation

Shueng-Wai Chan *et al.* reported a case of a 13-year-old with membranous glomerulopathy, which on rebiopsy showed FSGS; the patient achieved remission after bone marrow transplantation [137].

Conclusions

Children with SRNS have access to reasonably effective empiric therapy. Calciuneurin inhibitor therapy and ACEi therapy are recommended therapies for the treatment of SRNS (Table 68.1). Oral CPA may be helpful in the treatment of SRNS due to MCD. Other therapies, including combination therapy, intravenous alkylating agents, MMF, statins, and a brief course of pulse methylprednisolone, may hold promise but due to their low evidence base cannot be recommended. Children with SRNS who experience a sustained remission have better outcomes.

A "one size fits all" approach to immunosuppressive medications has yielded a less-than-optimal record of treatment success. Children with primary steroid resistance due to FSGS are a challenging population, as treatment outcomes are generally inferior to those with MCD [138]. When treating a child who does not respond to a first-line and then second-line of therapy, consideration should be given to performing podocin gene (NPHS2) and the focal segmental permeability factor laboratory studies.

The pediatric nephrology community will need to cooperate to a far greater extent than in the past to effectively assess treatment strategies. Most articles reviewed for this chapter concluded with a statement that, "prospective randomized studies are needed." No single center or regional cooperative group has sufficient numbers to conduct a meaningful RCT. The current slow enrollment for the FSGS NIH study is concerning and indicates that either there are far fewer patients to be studied than originally thought or there is insufficient nephrologist "buy-in" to the multicenter investigative process or the specific treatment regimen offered. The pediatric nephrology community must work cooperatively to answer the pressing challenges of SRNS treatment.

Other Pediatric Renal Diseases

69 Henoch-Schonlein Nephritis and Membranoprolifertive Glomerulonephritis

Sharon Phillips Andreoli

Department of Pediatrics, James Whitcomb Riley Hospital for Children,
Indiana University Medical Center, Indianapolis, USA

Introduction

The clinical manifestations of Henoch-Schonlein purpura (HSP), including the typical rash, arthralgias, arthritis, gastrointestinal involvement, and renal involvement, have been well-described. Less common manifestations include testicular inflammation and pulmonary and central nervous system, as well as other organ, involvement [1–5]. The occurrence of kidney disease has been estimated to be as low as 20% in some studies and up to 50% in other studies [1–4]. The renal disease in HSP is quite variable, with the majority of patients demonstrating spontaneous resolution of the nephritis. Treatment strategies are based on the risk of progressive disease [2–5]. HSP is a very common disorder in pediatric patients and is less common in adults, but the development of HSP nephritis is more common and more severe in adolescent and adult patients [6–12]. Treatment strategies for HSP are based on very few randomized controlled trials (RCTs) with prednisone to prevent the development of renal disease in HSP, and there have been virtually no RCTs for therapy of severe HSP nephritis. Although there are no controlled trials of therapy for HSP nephritis, there are multiple case series and anecdotal reports of successful immunosuppressive therapy for HSP nephritis.

Membranoproliferative glomerulonephritis (MPGN) types I, II (also known as dense deposit disease), and III are also common forms of glomerulonephritis in pediatric and adult patients [5,13–15]. In contrast to HSP nephritis, the natural history of all types of MPGN is progression to chronic kidney disease in the majority of patients [5,13–15]. However, the natural history and rate of progression within and between types I, II, and III are quite variable. Treatment strategies in MPGN are also based on reports of series of patients treated with immunosuppressive therapy and very few controlled trials of therapy. This chapter reviews the etiology, epidemiology, natural history, and treatment strategies for HSP nephritis and idiopathic MPGN.

Etiology, epidemiology, and natural history of HSP nephritis

Etiology

Although the clinical manifestations of HSP are well-known, the specific pathogen(s) that triggers the clinical features of HSP is unknown. Associations with group A beta-hemolytic streptococcal infections, infections with viruses including hepatitis B, herpes simplex, human parovovirus B, and influenza viruses, other infections, and other agents have been reported by many investigators [16]. However, the large majority of the reports associating specific infectious agents, drugs, or immunizations with HSP are anecdotal reports, and despite extensive investigation, there is no clear pathogen that is accepted as a trigger for the clinical manifestations of HSP. Given the lack of a single etiological agent identified for HSP, it is likely that the disease is caused by multiple agents and that the immune responses to different agents are similar in individuals who develop HSP. Recent studies suggest genetic susceptibility to the development of HSP, and it is also likely that genetic and environmental factors play a role in the development of HSP and HSP nephritis.

HSP is a leukocytoclastic vasculitis that affects small vessels. The pathology demonstrates white blood cell infiltration, small vessel inflammation, and deposition of immunoglobulin A (IgA) in vessels obtained from skin biopsies and in kidney biopsies. Since infections, particularly respiratory infections, are associated with HSP, it has been suggested that abnormal mucosal IgA production following infection may precipitate the vasculitis. Reported findings of IgA-containing immune complexes in the kidney and extrarenal sites, of IgA rheumatoid factor in some patients, and of IgA fibronectin complexes and mesangial cell autoantigens support immune dysregulation as a cause of the vasculitis [17]. Abnormalities in the O-linked glycosylation of IgA1 may contribute to the abnormal IgA in HSP and in IgA nephropathy [16].

Epidemiology of HSP nephritis

Whereas HSP and HSP nephritis have been described in all age ranges, HSP is most common in children, with a peak incidence at ages 4–6 years. Age has a major influence on the development of HSP nephritis; multiple studies have demonstrated that the incidence of renal disease in HSP and the severity of the renal disease increase with age. The large majority of children with HSP in the first decade of life do not develop serious renal involvement, but significant renal disease occurs commonly in adolescents and adults with HSP [7–12].

The incidence of HSP has been reported in several population studies. In Taiwan, the annual incidence of HSP was 12.9/100,000 children less than 17 years of age [18]. In a study of 78 children in Spain, the incidence of HSP was also noted to be the highest in the fall and winter months. The median age at the onset of symptoms was 5.5 years, and the annual incidence was 10.45/100,000 children aged 14 and younger [19]. In a study of 150 Italian children, the male/female ratio was 1.8:1, the mean age was 6.1 years, and renal involvement occurred in 54%, with 7% of the children demonstrating severe nephritis and 2% with acute renal failure [20].

Several interesting studies have demonstrated that genetic polymorphisms may predispose individuals to the development of HSP and/or to the pathogenic evolution to HSP nephritis. In a study of 57 patients with HSP, no significant differences in the allele or genotype frequencies for two vascular endothelial cell growth factor polymorphisms between patients with HSP and control patients were found, but the high vascular endothelial growth factor producer allele was increased in patients with HSP nephritis compared to healthy controls [21]. Polymorphisms of the interleukin-1β gene were not different in patients with HSP compared to controls, but each of the 5 patients who developed severe nephropathy carried the rare T allele, compared with 16 of the remaining 44 patients [22]. Other interesting studies have demonstrated that the TT genotype of the C-509T polymorphism of the transforming growth factor β gene was significantly more common in children with HSP than in control children, and the TT genotype was more common in children with severe HSP [23]. Polymorphisms of the renin–angiotensin system have also been associated with the development of HSP and possibly the development of renal disease [24]. Patients with familial Mediterranean fever have a higher incidence of HSP, with approximately 5% of patients with familial Mediterranean fever developing HSP [25]. Other studies have demonstrated no association with uteroglobin gene polymorphism in childhood HSP [26]. Similarly, polymorphisms in thrombophilia genes, including methylenetetrahydrofolate reductase, prothrombin, and factor V genes, did not differ in patients with HSP and controls [27]. Although more studies need to be performed, these early studies suggest that there may be a genetically determined susceptibility to risk and increased severity of HSP nephritis.

Natural history of HSP nephritis

The majority of children with HSP have mild to no renal disease, and when renal disease occurs it usually resolves spontaneously without need for therapy [1–5]. Older children, adolescents, and adults with HSP have a higher incidence of renal disease, and when renal disease occurs it is more severe than in younger children [6–12]. Children with HSP nephritis who were followed for several years were found to have a high incidence of renal disease in adulthood compared to those that did not have initial renal disease, and there was a high incidence of complications during pregnancy even in the absence of active kidney disease [4,28].

The majority of patients with HSP who are destined to develop nephritis will demonstrate renal disease within a few months of the onset of HSP, but unusual cases of the late occurrence of HSP nephritis also have been described [29]. A systematic review of 12 studies of 1,133 patients found that 34.2% developed renal involvement, of whom 85% developed renal disease within 4 weeks, 91% within 6 weeks, and 97% within 6 months [30]. The most common manifestation is hematuria alone, which generally resolves spontaneously and does not require therapy. Some patients also develop proteinuria in addition to hematuria, and in the majority of such patients the nephritis will also resolve spontaneously. Proteinuria that is increasing in quantity and/or has evolved into nephrotic syndrome, and/or evidence of rapidly progressive glomerulonephritis, is highly suggestive of more severe pathology and a worse long-term prognosis. Although there are many notable exceptions, in general the severity of the clinical presentation, including laboratory values, correlates with the severity of the pathologic findings [5,31–34]. Among 1,133 children, persistent renal impairment did not occur in any child with a normal urinalysis. Persistent renal impairment developed in 1.6% of children with minor urine abnormalities, and 19.5% of children with nephritic and/or nephrotic syndrome developed renal impairment [30].

Evidence for the efficacy of therapies in HSP nephritis

In this section we review two aspects of therapy for HSP nephritis. First, we review evidence that therapy can alter the development of nephritis in patients with HSP; second, we review the evidence that therapy can alter established HSP nephritis.

Evidence that therapy can alter the development of HSP nephritis

Steroid therapy has been used to treat the abdominal symptoms and joint pain of HSP, and it has been suggested that steroid therapy may prevent the development of nephritis. Four trials and other retrospective studies have been performed to address this issue [35–39] (Table 69.1). Two well-designed randomized, double-blind, placebo-controlled trials did not demonstrate any benefit of prednisone over placebo in preventing renal disease at 6–12 months after diagnosis. In one RCT 40 children with HSP seen in an emergency room were randomized to receive placebo or oral prednisone at 2 mg/kg/day for 1 week with weaning of the prednisone over the next week. At 1 year, there was no difference in the incidence of renal involvement between the two groups [35]. In a larger RCT, 84 children were treated with 1 mg/kg/day prednisone for 2 weeks with a tapering dose of prednisone over the next 2 weeks, while 87 children received placebo [36]. The investigators

Table 69.1 Evidence for therapy to prevent the the development of HSP Nephritis.

Study	Therapy	Number of patients and patient characteristics	Outcome
Mollica, 1992 randomised controlled study	1mg/kg/day prednisone for two weeks	84 patients treated with prednisone 84 patients not treated with prednisone (age not reported)	No treated patient developed nephritis 10 (11.9%) control patients developed nephritis
Saulsbury, 1993 retrospective study	any prednisone therapy	50 children without nephritis	20% of patients who received predisone and 20% who did not receive prednisone developed nephritis
Islek, 1999 randomized controled trial	1 mg/kg/day for 10 days and weaning dose for one week	70 patients treated with prednisone and 50 not treated with prednisone aged 9.2 +/− 2.7 yrs	21% (15/70) of treated patients and 36% (18/50) control patients developed nephritis
Huber, 2004 randomized placebo controlled, double blind trial	2 mg/kg/day prednisone for one week and weaning dose for one week	21 treated patients and 19 placebo patients treated aged 2-15 years	No difference in rate of renal involvement; 3/21 treated and 2/19 placebo developed nephritis
Ronkainen, 2006 randomized placebo controled double blind trial	1 mg/kg/day prednisone for two weeks and weaning dose for two more weeks	84 treated patients and 87 placebo children ages 1.7 to 15.6 years	No difference in rate of renal symptoms 38/84 treated and 36/87 control patients had renal symptoms

concluded that prednisone did not prevent the development of renal symptoms, although prednisone may be effective in treating HSP nephritis. A retrospective study of 50 children with HSP without renal disease at the time of diagnosis demonstrated that prednisone therapy did not prevent the development of nephritis [38]. In contrast, two poorly designed controlled studies of early administration of prednisone in children with HSP and no signs of renal involvement demonstrated that, in the two studies, respectively, 0% and 21% of children treated with prednisone compared with 12% and 36% not treated developed nephropathy within 2–6 weeks after the acute episode of HSP [37,38].

Evidence for whether therapy can alter established HSP nephritis

There are very few trials of therapy for established HSP nephritis (Table 69.2). In the study described above, to determine if prednisone therapy prevented the development of HSP nephritis, the investigators found that in those who developed nephritis and were treated with prednisone, renal symptoms resolved significantly more rapidly in the patients in the prednisone group compared to the placebo group [36]. However, this finding was the result of a post hoc analysis, and further trials are needed to determine if steroids are beneficial for HSP nephritis.

In a randomized trial of cyclophosphamide and supportive therapy or supportive therapy alone, 28 children received supportive therapy and 28 received supportive therapy plus cyclophosphamide at 90 mg/m²/day for 42 days [40]. The clinical status at last follow-up (mean, 6.93 years) demonstrated that there was no difference in outcome between the two groups. In a study (published as a meeting abstract) of 19 patients with severe HSP, 10 of 10 (100%) cyclosporine A-treated patients achieved remission compared with 5 of 9 (56%) patients who received pulse solumedrol [41].

Although there is a dearth of high-quality studies to provide evidence-based recommendations for therapy in HSP nephritis, there are numerous retrospective case studies of therapy for HSP nephritis (Table 69.2) [34,42–52]. A case series of prednisone treatment, with or without methylprednisolone, found improvement in the majority of the children [44]. Similar studies of prednisone and other immunosuppressive agents, including cyclophosphamide and azathioprine, have also described improvement in most children [34,42,43,45,46]. Finally, at least two retrospective case studies have demonstrated that therapy with cyclosporine in severe HSP nephritis is beneficial [47,48]. Additional therapies, including intravenous immunoglobulin therapy, plasmapheresis, and tonsillectomy, have been reported to improve a patient's response to immunosuppressive therapy [49–52].

Recommendations for therapy of HSP and HSP nephritis

Two randomized double-blind controlled trials and one retrospective study of therapy with prednisone in patients with HSP did not demonstrate a benefit of therapy in preventing the development of HSP nephritis, whereas two RCTs with poor methodological quality demonstrated a benefit of prednisone therapy in preventing HSP nephritis. Although these studies are not conclusive, the body of evidence suggests that prednisone therapy should not be used to prevent the development of HSP nephritis in patients with HSP (Table 69.3).

The study described above that was conducted to determine if prednisone therapy was beneficial for the prevention of HSP nephritis found, as a secondary outcome, that prednisone was beneficial for HSP nephritis, but this was determined from a post hoc analysis and so further studies are needed [36]. A controlled trial of cyclophosphamide therapy did not demonstrate a benefit of therapy, but these patients did not receive pulse solumedrol or prednisone therapy [40]. Other than a very small trial with short

Table 69.2 Evidence that therapy can alter established HSP nephritis.

Study	Therapy	Number of patients and patient characteristics	Outcome
Oner, 1995 case reports	pulse SM, cyclophosmaide, dipyridamole, oral prednisone	12 patients, 6-14 years of age	7 patients complete remission 4 patients partial remission 1 patient persistent nephrotic syndrome
Faedda, 1996 case reports	pulse SM, oral cyclophosmide, oral prednisone	8 patients, ages 13-61 years of age	7 patients complete remission
Niaudet, 1998 prospective uncontrolled study	pulse SM followed by oral prednisone	38 children ages 3 to 14 years of age with severe HSP nephritis	27 children recovered normally 7 children had residial abnormalities 4 children had ESRDl
Bergstein, 1998 retrospective study	pulse SM followed by oral prednisone and azathihoprine	21 children ages 1 to 16 years with severe HSP nephritis	19 children improved 2 progressed to ESRD
Iijima, 1998 retrospective study	prednisone, cyclophosphamide, heparin/warfarin, and dipyridamole	14 children ages 5 to 17 years with severe HSP	9 children were normal 3 had minor abnormalites, 1 heavy proteinuria no child had ESRD
Foster, 2000 retrospective study	prednisone 1-2 mg/kg/day and azathioprine 1-2 mg/kg//day	17 children ages 4 to 19 years with severe HSP	15 of 17 (88%) had a favorable outcome
Tanaka, 2003 retrospective study	prednisone 1.5 mg/kg/day and cyclophosphosmide 2mg/kg/day	9 children ages 6 to 16 years with severe HSP	At last folowup (78 months) 7 were normal and two had protieniura, no ESRD
Ronkainen, 2003 retrospective study	cyclosporin A	7 children ages 7 to 15 with severe HSP	4 in remission off cyclosporin, 3 in remission on cyclospirin and are dependent
Tarshish, 2004 prospective randomized trial	supportive therapy with or with out 90mg/m2/day cyclophosmide	56 children; 28 treated 28 control	No difference in renal outcome
Shin, 2005 retrospective study	cyclopsorin A	7 children ages 3.9 to 13.8 years with severe HSP	all patients improved with reduction in proteinuria
Shin, 2005 retrospective study	comparision of prednisone alone or prednisone and azathioprine	10 children in each group	children treated with prednisone and azathioprine did better than children treated with prednisone alone
Ronkainen, 2006 randomized placebo controled double	1 mg/kg/day prednisone for two weeks and weaning dose for two more weeks	84 treated patients and 87 placebo children ages 1.7 to 15.6 years	61% of prednisone treated renal symptoms resolved 34% of placebo treated renal symptoms resolved

follow-up that compared cyclosporine with methylprednisolone treatment, there are no other trials to guide evidence-based treatment recommendations. Although there are no other clinical trials on which to make treatment recommendations, there are several retrospective case series reports that have described a benefit of immunosuppressive therapy in established HSP nephritis. Given the well-described poor outcome of severe HSP nephritis, RCTs of therapy versus placebo are unlikely to be conducted, but trials to compare specific therapies are needed. Until such studies have been performed, evidence-based treatment recommendations cannot be formulated, but steroids (pulse solumedrol followed by oral prednisone or oral prednisone alone, depending upon the severity of the nephritis) with or without other immunosuppressive agents are reasonable therapies for severe disease. Since HSP nephritis is a variable disease, individual risk factors for progressive renal disease need to be taken into consideration when formulating therapy for patients with HSP.

Etiology, epidemiology, and natural history of MPGN

MPGN can be secondary to infections, such as hepatitis B or C virus or human immunodeficiency virus infection, or it may be secondary to collagen vascular diseases [53,54]. Idiopathic MPGN occurs in the absence of infections or other known causes of secondary MPGN. When MPGN is secondary to another infection or disease, therapy needs to be directed at the underlying cause of MPGN, such as interferon therapy for hepatitis or immunosuppressive therapy for collagen vascular diseases.

Etiology

The precise etiologies of the various types of MPGN are unknown. MPGN also has been called mesangiocapillary glomerulonephritis

Table 69.3 Evidence rating and recommendations for therapy in Henoch-Schonlein Purpura

Intervention	Evidence rating[a,b]			Recommendations[c]			Comment
	Moderate	**Low**	**Comment**	**I[d]**	**II[e]**	**III[f]**	
Corticosteroids in the prevention of nephritis							
Prednisone compared with placebo/no treatment	•		4 RCTs (499 patients), 2 trials of poor quality, inconsistent results			•	No significant benefit for preventing nephritis in 2 trials; 2 trials of poor quality suggested benefit
Corticosteroids in the treatment of nephritis							
Corticosteroids compared with placebo	•		1 RCT (171 children); Post hoc analysis		•		Among children with nephritis, reduction in symptoms more rapid with prednisone
Solumedrol and oral prednisone			1 Case series (38 children)				Normal recovery in the majority of children
Cyclophosphamide in the treatment of nephritis							
Cyclophosphamide compared with supportive treatment	•		1 RCT (56 patients); wide 95% CI			•	No significant benefit in reducing risk of any renal involvement or ESRD in RCT
Cyclophosphamide and prednisone with or without dipyridamole			4 Case series (43 children)				Majority of children improved and majority returned to normal in case series
Cyclosporin in the treatment of nephritis							
Cyclosporin compared with methylprednisolone	•		1 RCT (19 patients); small numbers			•	More patients on cyclosporine achieved remission in RCT.
Cyclosporin			2 Case series (14 patients)				Majority of children improved in case series
Prednisone and azathioprine in the treatment of nephritis							
Prednisone and azathioprine compared to prednisone alone	•		1 Retrospective study (20 children)			•	Combined therapy was better than prednisone alone
Prednisone and azathiopine	•		2 Case series (38 children)				Treated patients improved more than historic controls

or peripheral lobular glomerulonephritis. Type II MPGN is also called dense deposit disease, due to the characteristic deposits seen on electron microscopy. Although there are three types of MPGN, types I and III share similar clinical and pathologic features; in contrast, type II MPGN (dense deposit disease) has distinct clinical and pathological features. The pathologic features of MPGN include an inflammatory infiltrate with increased mesangial cellularity and increased mesangial matrix leading to an accentuated lobular appearance of the glomerular tuft, hence, the name peripheral lobular glomerulonephritis. Immunofluorescence studies in type I and type III MPGN are usually positive for several complement components and immunoglobulins, whereas immunofluorescence findings in type II MPGN are remarkable for the absence of immunoglobulin deposition but with intense complement deposition [13–15,54]. The electron microscopic findings are distinct for each type of MPGN, and these findings provide the basis for the division of MPGN into three subtypes. Type I MPGN is characterized by prominent subendothelial deposits, whereas type III MPGN has subendothelial and subepithelial deposits. Electron microscopy findings in type II MPGN include characteristic dense deposits within the lamina densa and the basement membranes [13–15,54].

In MPGN types I and III complement C3 and C4 levels are usually depressed, suggesting that the classical pathway is preferentially activated, whereas in type II MPGN the C3 level is depressed and the C4 level is normal, suggesting activation of the

Table 69.4 Evidence that therapy can alter MPGN - randomized controled trials.

Study	Therapy	Number of patients	Outcome
Mota-Hernandez, 1985 double blind controlled trial	Prednisone vs lactose	18 children, biopsies performed at diagnosis, 3 and 5 years	At 6.5 years, 4 patients in control group and none in treatment group developed ESRD; two in control and one in treated in remission; decreased activity and increased chronic changes on biopies in all patients.
Tarshish, 1992 randomized, double blind controlled trial RTC	Prednisone 40mg/m2 every other day vs lactose (47 treatment, 33 controls)	80 children ages 5.2 to 16.9 years 42 type I, 14 type II, 17 type III mean duration of therapy was 41 months	Treatment failure 55% in controls, 40% in treated group; of types I and III, treatment failure 58% in controls and 33% in treated group. eatd
Zimmerman, 1983 prospective trial	warfarin and dipyridamole	18 completed a control or treatment year 13 completed both a control and treatment year	Renal function stable during year of therapy, renal function declined with no therapy, proteinuria decreased during therapy
Donadio, 1984 RCT	Dipyridamole 225 mgs and aspirin 975 mg for 1 year	40 adult patients, 21 treated, 19 control	GFR better in treated group, rate of decline in treated 1.3 ml/min per 1.73m2 compared to 19.6 ml/min/1.73m2 in control, fewer treated pateints progressed to ESRD
Cattran, 1985 RCT	cyclophosphamide, coumadin and dipyradimole vs control	59 patients (27 treated, 32 control) with greater than 2gm/day proteinuria	At 6, 12, and 18 months no difference in renal function, serum creatinine, slop of creatinine clearance, or proteinuria
Zauner, 1994 randomized trial RCT	aspirin and dipyridamole vs supportive therapy	18 adults (15 type I, 3 type II) with nephrotic syndrome followed for 36 months	No change in renal function both groups, proteinujria decrease more in the treated group (8.3 ± 1.4 to 1.6 ± 0.7 treated vs 7.1 ± 1.6 to 4.3 ± 1.1 gm/day controls)
Giri, 2002 RCT	All patients received diuretics & beta-blockers, 1/3 treated with ACEI, 1/3 treated with CCB, 1/3 no additional therapy (control)	30 adults, 28 completed nine months of therapy	Serum creatinine and proteinuria significantly increased in controls, ACEI group had decrease in serum creatinine proteinuria, CCB group had decrease in serum creatinine and increase in proteinuria

alternative pathway. C3 nephritic factor is present in all types but is more common in type II MPGN [14]. Because a low serum level of C3 is the laboratory hallmark of MPGN, abnormal regulation of the complement system in particular is thought to be central to the pathogenesis of MPGN [13–15,54,55]. Aberrant complement regulation is due to the presence of C3 nephritic factor, an autoantibody directed against the C3 convertase of the alternative pathway [55]. The binding of this antibody protects C3bBb from enzymatic inactivation so that there is continued C3 breakdown [56,57]. Genetic mutations of the factor H genotype have been implicated in the pathogenesis of type II MPGN [58,59]. Factor H is a soluble complement regulatory protein that has a primary role in regulating the activity of alternative complement pathway MPGN [59]. Factor H gene mutations result in a lack of plasma factor H or in a functional defect in factor H proteins. Loss of factor H function can also be caused by inactivating factor H autoantibodies, C3 mutations preventing interaction between C3 and factor H, or autoantibodies against C3 [59].

Epidemiology

MPGN occurs more commonly in children and young adults than in adults. All types of MPGN can occur in pediatric patients and are usually idiopathic and rarely associated with hepatitis B or C

virus infections. In adults, types I and III of MPGN are more common, and MPGN is frequently associated with hepatitis infections and mixed cryoglobulinemia [53,54,60]. Type II MPGN can occur in patients with partial lipodystrophy and may be associated with retinal changes [61,62]. Types I and III reoccur in renal transplant patients in approximately 20–30% of renal transplant recipients [63]. Graft loss due to recurrent disease is approximately 30–40% [64]. Type II MPGN reoccurs in renal transplant patients in up to 100% of cases, but graft loss due to recurrent disease is quite variable, with reports ranging from 10 to 50% [64,65]. In a large retrospective study, 5-year graft survival for patients with type II MPGN was significantly worse than for those transplanted for other causes (50.0% ± 7.5% versus 74.3% ± 0.6%, respectively) [66].

Natural history of MPGN

Since MPGN was first described in 1965, it has been recognized to be a progressive glomerulonephritis, and the natural history is progression to end-stage renal disease in the majority of cases [13–15,54,67]. In a series of 105 children with MPGN, 67% presented with nephrotic syndrome, 88% had hematuria, 33% had renal insufficiency, and 25% had hypertension [68]. After 5.75 years of follow-up, 34 patients had kidney failure or were dead, 8 had chronic kidney failure, 7 had hypertension with normal renal

Table 69.5 Evidence that therapy can alter MPGN - uncontrolled trials and case series.

Study	Therapy	Number of patients and patient characteristics	Outcome
McEnery PT, 1990 uncontrolled trail	Alternate day prednisone in 50 children additional agents in 21 children	71 children treated for a mean of 7.7 years and followed for a mean of 10.6 years	Cummulative renal survival 75% at 10 years and 59% at 20 years
Ford, 1992 uncontrolled trial	oral predinisone in all, pulse methylprednisolone in those more severe	19 children with type I MPGN followqed up for a mean of 6.5 years	Biopsy at two years showed decreased activity in 88% of children, Eight children have normal urinalysis
Bergstein, 1995 uncontroled trial	Pulse methylprednisolone followed by alternate day prednisone	16 children ages 5 to 14 years mean follow up 52 months	Improvement in serum albumin and creatinine clearance, decrease in proteinuria and hematuria; repeat kidney biopsies decreased active disease increased chronic changes
Iitaka, 1995	Low dose alternate prednisone, low dose followed by high dose alternate day prednisone, or high dose alternate day prednisone	41 children ages 3 to 15 years identified by school screening	Remission of urinary abnormalities was highest in those treated with high dose alternate day prednisone
Arslan, 1997 uncontrolled trail	All received oral steroids; those who did not respond received pulse MP and/ or cyclophosphamide	96 children, ages 2 to 17 years	Renal survival was 81.9% and 61% at 5 and 10 years respectively
Braun, 1999 retrospective comparison studies	Comparison of alternate day prednisone therapy in type I and type III MPGN	21 children with type I and 25 children with type III MPGN	At last follow-up, type I patients had improved GFR, type III had decreased GRF; type I had hematuria in 38%, type III had hematuria in 72%, type I had proteinuria 0% type III had proteinuria 28%.
Yanagihara, 2005 Case series	Prednisone 2mg/kg/day after pulse solumedrol (n = 16) or cyclophosamide (n = 3)	19 children ages 7 to 16 followed for more than 10 years, mean 14.6 $\pm$ 4.6 years	At last observation, 15 had normal UA, normal renal function, normal C3 levels; 4 had residual proteinuria, no ESRD
Ronkainen, 2006 RCT	cyclosporine or pulse solumedrol	19 children ages , 10 treated with cyclosporine and 9 treated with pulse solumedrol followed for three months	10 od 10 (100%) cyclosporine treated patients achieved remission compared with 5 of 9 (56%) pulse solumedrol treated patients
Orlowski, 1988 uncontrolled trial	prednisone, azathioprine, chlorambucil and/or cyclophosphamide	40 adults mean age at diagnosis 23.5 $\pm$ 1.6 years followed for an average of 10.6 years	Triple therapy was more effective in reducing proteinuria.
Jones, 2004 retrospective study	Comparison of oral prednisolone and mycophenolate with no therapy	5 adults received therapy and 6 received no therapy	Significant protein reduction in the treated group from 5.09 to 2.59 at 18 months while there was no reduction in the untreated group; serum creatinine increased in controls and did not in treated patients

function, 50 had residual proteinuria, and 6 were protein free [68]. Thus, 95% of children had evidence of disease and only 5% were normal. In another large series of 104 adults and children with MPGN, follow-up of 2–21 years with a mean of 8 years demonstrated that only 7 (6.5%) of the patients were in clinical remission whereas 38% of the patients with type I and 49% of type II patients required dialysis or had died [14].

In a study of 53 children with MPGN, the mean age of presentation was 8.8 years, and these children were followed for a median of 3.5 years; 31 children had type I disease, 14 had type II disease, and 2 had type III disease (the others could not be classified) [13]. Those with nephrotic syndrome at presentation had a mean renal survival of 8.9 years compared to 13.6 years in those with-

out nephrotic syndrome [13]. A review of 273 patients in Norway with a mean age of 40 ± 17 years with a diagnosis of MPGN (some of whom had IgA deposits possibly representing IgA nephropathy) showed that 3 years after diagnosis, 7% had developed kidney failure and 8% had died [69]. Similar to other studies, clinical and laboratory variables associated with progressive disease were increased serum creatinine, high-grade proteinuria, hypertension, depressed serum albumin, focal sclerosis on biopsy, and interstitial fibrosis [69].

Evidence for efficacy of therapies in MPGN

Because the natural history of idiopathic MPGN is usually progression to chronic kidney failure, several therapies have been proposed

Table 69.6 Evidence rating and recommendations for therapy in MPGN

Intervention	Evidence rating[a,b]		Comment	Recommendations[c]			Comment
	Moderate	Low		I[d]	II[e]	III[f]	
Corticosteroids in the treatment of MPGN							
Alternate day prednisone compared with placebo/no treatment	•		2 RCT (98 children) Uncontrolled trials, retrospective studies and case series (309 children)	•			Each RCT showed benefit of therapy, uncontrolled trials, retrospective studies and case series support therapy, perhaps benefit is best in MPGN type I
Pulse methylprednisolone followed by alternate day prednisone therapy		•	4 uncontrolled trials, retrospective studies or case series. Indications for pulse methylprednisolone variable			•	Children with more severe MPGN treated with pulse methylprednisolone
Corticosteroids with other immunosuppressive agents in the treatment of MPGN							
Prednisone, azathioprine, chlorambucil or cyclophosphamide		•	1 Uncontrolled trial (40 adults)			•	Triple therapy reduced proteinuria
Prednisone and mycophenolate		•	1 Retrospective study (5 adults), small numbers			•	Proteinuria decreased and creatinine remained stable
Antiplatelet therapy in the treatment of MPGN							
Warfarin and dipyridamole		•	1 RCT (31 adults) small numbers, poor quality study			•	Beneficial effect of therapy
Dipyridamole and aspirin		•	2 RCTs (58 adults),small numbers, inconsistent results			•	One trial supports therapy, one does not
Cyclophosphamide, coumadin and dipyridamole		•	1 RCT (adults) *All performed prior to the association of hepatitis C with MPGN			•	No benefit of therapy

[e] Suggest

[f] No recommendation possible

to alter the natural history of MPGN (Tables 69.4 and 69.5) [70–84]. Antiplatelet therapy and immunosuppressive therapy have been tested in RCTs (Table 69.4) and in several uncontrolled trials, retrospective studies, and cases series (Table 69.5). Unfortunately, several of these trials and studies were performed before MPGN was known to be strongly associated with hepatitis C in adult patients, and the relevance of these trials to recommendations for current therapy is problematic. Three controlled trials have tested antiplatelet therapy, and an additional trial has tested antiplatelet therapy in combination with cyclophosphamide therapy [70,71,73,75]. Two studies concluded that antiplatelet therapy was beneficial, and two did not demonstrate efficacy of antiplatelet therapy (Table 69.4), but all of these studies probably included some patients with hepatitis C. Two controlled trials of prednisone versus placebo in children concluded that prednisone

therapy was beneficial, and follow-up biopsies in one study demonstrated decreased active disease (Table 69.4) [72,74]. In a trial of three groups that received either angiotensin converting enzyme (ACE) inhibitor therapy, calcium channel blocker therapy, or no additional therapy, in the patients with MPGN (also treated with diuretic therapy and beta blocker therapy), proteinuria and serum creatinine decreased with ACE inhibitor therapy, only creatinine decreased with calcium channel blocker therapy, and creatinine and proteinuria increased in the group that received no additional therapy [76].

Seven uncontrolled trials, retrospective studies, and case series using alternate-day prednisone therapy concluded that therapy was beneficial (Table 69.5) [77–84]. Four of these trials also incorporated pulse methylprednisolone into the treatment regimen for many patients [79–81,84]. An uncontrolled trial of prednisone,

azathioprine, chlorambucil, and/or cyclophosphamide concluded that triple therapy was more effective in reducing proteinuria [77]. A recent retrospective study that compared patients treated with oral prednisone and mycophenolate to patients that received no therapy reported that proteinuria decreased more in the treatment group [82]. A retrospective comparison of alternate-day prednisone therapy in children with type I or type III MPGN concluded that therapy was more effective in type I MPGN [84].

Recommendations for therapy of MPGN

Controlled trials, uncontrolled trials, retrospective studies, and case series have demonstrated that alternate-day prednisone therapy is beneficial in MPGN (Table 69.6). Thus, alternate-day prednisone therapy is indicated in children with MPGN and could be considered in adults with idiopathic MPGN. Because the studies to test the efficacy of antiplatelet therapy were performed before the association of MPGN with hepatitis C was known and because the results of these trials demonstrated mixed findings, recommendations for antiplatelet therapy are difficult to formulate, but antiplatelet therapy is probably not indicated in patients with MPGN. A previous review of evidence-based treatment recommendations concluded that a trial of antiplatelet therapy is indicated in adult patients [85]. Adequate control of blood pressure and therapy to decrease residual proteinuria with ACE inhibitors should be used in patients with MPGN when indicated.

70 Cystinosis

William G. van't Hoff

Nephro-Urology Unit, Great Ormond Street Hospital for Children, London, United Kingdom

Introduction and clinical course

Cystinosis is a disorder characterized biochemically by excess accumulation of cystine due to defective lysosomal efflux and clinically as the most common inherited cause of generalized proximal tubular dysfunction (renal Fanconi syndrome) in young children [1]. It is inherited in an autosomal recessive manner and is due to defective or absent function of cystinosin, the lysosomal proton-dependent cystine transporter, secondary to mutations in the *CTNS* gene [2,3]. Cystinosis is a rare condition, averaging approximately 1/150,000 births in the UK, but the incidence varies according to geographic region and ethnicity, being more common in populations with increased consanguinity.

Children typically present with slow weight gain, poor feeding, recurrent vomiting, and features of dehydration and rickets. These features are not present at birth, possibly related to the normally low glomerular filtration rate in newborn babies, but develop progressively from 4 to 6 months of life. Rarely, patients can present in adolescence or adult life with proteinuria or chronic renal failure [1]. Laboratory findings include hypokalemia, hypophosphatemia, and a hyperchloremic metabolic acidosis. Urinary data include generalized aminoaciduria, proteinuria (characteristically including large amounts of low-molecular-weight proteins), phosphaturia, and bicarbonaturia [4]. The diagnosis can be confirmed clinically by demonstration of cystine crystals in the cornea via slit lamp examination; the fundus is often characteristically "blond." However, these ocular signs may be missed, and all suspected cases should have the leukocyte cystine concentration determined. This is a specialized assay, and careful coordination with accredited laboratories is necessary to provide an accurate result.

The effects of the Fanconi syndrome are profound. Children require huge volumes of water, electrolyte supplements, and medications to try to normalize their biochemical and volume status. Feeding difficulties and vomiting exacerbate the problem. Without specific treatment, children suffer progressive growth failure, bone deformity from rickets, and chronic kidney failure (the median age of renal replacement therapy for untreated children is between 9 and 10 years) [1]. Kidney transplantation is highly successful and cystinosis does not recur in the graft, although cystine may be seen in interstitial cells within graft biopsies as cystine continues to accumulate in the rest of the body. Virtually every body system is affected in the long term, and in untreated patients, death occurs in early adulthood, usually secondary to neurological involvement [1].

Treatment

The treatment of cystinosis can be divided into general and specific measures. The aims of general treatment are to replace the deficits and normalize the biochemical homeostasis. Specific therapies address the underlying metabolic disorder or its progress.

In the context of evidence-based therapy for conditions affecting many thousands of patients, many treatments used in cystinosis would be regarded as having "poor" evidence. Most importantly, the disorder is extremely rare, so that studies are difficult to undertake. This review will not address the use of replacement electrolyte supplements, such as sodium and/or potassium chloride, sodium bicarbonate, sodium and/or potassium citrate, and phosphate preparations. Administration of combinations of these are essential, often in large volumes, to make up for the severe urinary losses.

Cysteamine acts by undergoing disulfide exchange with cystine to form a mixed disulfide, which exits the lysosome via the lysine transporter [5]. This effect was discovered during an investigation of a range of sulfhydryl agents, and its mechanism of action confirmed its utility in cystinosis. It has not been subject to a randomized controlled trial (which, in addition to the rarity of cystinosis, would be hampered by the taste and smell of cysteamine), but there is other considerable evidence for its efficacy (Table 70.1). What remains unclear is whether the efficacy is purely related to

Table 70.1 Evidence ratings and recommendations for cystinosis studies.

Intervention	SR	Evidence rating			Comments	Recommendation			Comment
		High	Moderate	Low		I	II	III	
Cysteamine (Mercaptamine)	—		•		4 case series (approx 376 patients, some possible duplications); very consistent reduction in progression renal damage; small number case reports with inconsistent results	•			Only available treatment at present
Topical cysteamine eye drops	—	•			4 RCTs (64 patients, 34 vs. placebo, 30 vs. other agents); cysteamine improved symptoms and objective score of corneal cystine density	•			Only available treatment at present
Cysteamine for nonrenal tissues	—		•		3 case series (>100 patients; likely marked overlap) studying thyroid function, swallowing dysfunction, and neurological status; clear preservation of thyroid function, reduced score for swallowing dysfunction; Possible effect on neurological status		•		Only available treatment at present
Growth hormone	—			•	Case series in children with very severe growth reduction (78 patients: 52 CRF, 7 dialysis, 15 transplanted); increased height SDS in CRF prepubertal group		•		10 RCTs for other CKD show benefit, increased risk with impaired glucose intolerance
Indomethacin to reduce urinary losses	—			•	1 RCT and 2 case reports; RCT (39 patients) showed no significant effect on polyuria or growth (over 6 months); RCT underpowered; case reports indicated improved electrolyte status			•	Used in approximately 50% UK patients pretransplant
Carnitine replacement	—			•	2 case series, 11 and 6 patients; improved plasma (short term) and muscle levels (long term)			•	Low toxicity, unproven clinical benefit
ACE inhibitor for proteinuria	—			•	Case series (5 patients); 43% reduction in albuminuria, reduction in systolic BP			•	Effective for other CKD, increased risks of hypotension in cystinosis
Proton pump inhibitor (omperazole, esomeprazole)	—			•	2 case series (23 children); improved symptom score and reduced cysteamine-induced gastric acid hypersecretion		•		Vomiting and feeding symptoms often worse with cysteamine, proton pump inhibitors well-tolerated
Ineffectiveness of ascorbic acid	—	•			1 RCT (64 patients vs. placebo); stopped after 2 years, as no benefit and 8/11 deaths or ESRD on ascorbic acid, RR of adverse event 2.7, CI 0.8–11.5	•			No evidence of efficacy

* Systematic review of randomised controlled trials (RCT).

[a] Evidence rating based on number of studies, study design, study quality, and consistency of results. No intervention was rated with a high evidence rating.

[c] Recommendations based on efficacy, trade-offs between benefits and harms, quality of evidence, and availability of medication. I, recommend; II, suggest; III, no recommendation possible.

cystine depletion or to other mechanisms as well (cysteamine is a radio-protective agent, and it may affect free radical production and other thiols in cystinotic cells). Cysteamine (Cystagon) has been licensed for use in cystinosis.

Cystinosis is a multisystem disorder, so responses to drugs shown to be beneficial in other chronic kidney disease (CKD) cannot necessarily be extrapolated. For instance, the bone disease in cystinosis children is caused by a combination of profound hypophosphataemic rickets, renal osteodystrophy, endocrinopathy, and potentially a direct effect of cystine accumulation on bone.

The $ctns^{-/-}$ mouse manifests severe bone disease but has no evident renal tubulopathy. The multisystem dysfunction needs to be considered when assessing the risk–benefit ratio of a drug, such as growth hormone. Likewise, angiotensin converting enzyme (ACE) inhibition can have profoundly adverse effects in cystinosis due to the chronic intravascular volume depletion.

Cystinosis patients who develop end-stage renal failure receive dialysis or transplantation as with other noncystinosis conditions. Graft survival is good in cystinosis; the disease cannot recur in the graft, although cystine crystals may be detected in the interstitium

of graft biopsies [5-7]. However, because cystine continues to accumulate in other nonrenal tissues, cysteamine therapy is generally advised in posttransplant patients [1].

Recommendations for optimal management

Optimal management should initially correct the biochemical and intravascular volume abnormalities evident at presentation. However, achieving stable biochemistry can take months, and cysteamine should be started as soon as the diagnosis is confirmed. Cysteamine should be given in four divided doses throughout 24 h; better cystine depletion occurs in those who can manage a strict 6-h regimen, but this may not be realistic for all families [8,9]. The recommended dose is 1.3 g/m^2/day, but new patients should be commenced at lower doses (e.g. one-fourth of the maintenance dose) with increases every week. Breath smell, nausea, and vomiting are frequent adverse effects, but tolerance can develop. A proton pump inhibitor can reduce the gastrointestinal effects [10,11]. The leukocyte cystine level is considered the best marker of tissue cystine depletion, and the aim is a level (taken 4–6 h after the last dose) of <1 nmol $^1/_2$ cystine/mg of protein [1]. The determination of leukocyte cystine is difficult. Careful discussion with a specialized metabolic laboratory is vital, as difficulties with the assay tend to cause artificially low results, which may lead to inadequate dosing [7]. After stabilization, the cystine level should be checked 3–4 times/year. The maximal dose is 1.95 g/m^2/day. For patients over 12 years old or over 50 kg, the recommended dose is 2 g/day. A small number of European patients (six so far, and mostly on high doses) have experienced an Ehlers Danlos-like skin reaction, in one case with fatal complications. Families should be asked to report immediately to their physician any unexpected circumscribed hemorrhagic or bruising rash.

Expert nutritional support is needed in view of the extreme fluid requirement, poor feeding, and vomiting that are so prevalent with cystinosis. In Europe, many physicians advocate indomethacin (2–3 mg/kg/day in divided doses) to reduce urinary losses and use of growth hormone in those who fail to respond to conventional treatments. Cysteamine eye drops are clearly beneficial and may even reverse corneal crystal deposition. After transplant, cysteamine therapy is logical to minimize the long-term sequelae of cystinosis.
