Foreword

The evidence-based approach to health care is assuming a greater role in informing patient care worldwide. This approach arises from a convergence of factors, including the easy availability of evidence-based resources that synthesize the evidence, as exemplified by the Cochrane database, the desire of practitioners to attain best practices in the face of an almost overwhelming volume of new biomedical information, and the realization that, in an environment of limited health care resources, the best evidence of effectiveness should be central to the determination of which specific treatments warrant full investment. On the most immediate level, best evidence should inform the rational care of individual patients by the practitioner. On a broader level, best evidence should also influence specific decisions by society on the provision of specific health care services. In each case, evidence forms one of the two main components of a medical decision, as described by David Eddy [1,2].

Because the term evidence-based medicine was first coined by Sackett and colleagues more than 15 years ago, the emphasis in evidence-based medicine has been on evidence as it informs the choices of individual patients and of practitioners caring for these individuals, where the choices are determined by the evidence and by the individual preferences of the patients but not, strictly speaking, by the relative value or cost-effectiveness of these interventions [3,4]. Although cost-effectiveness determinations naturally evolve from a consideration of the evidence, we have chosen in this first evidence-based medicine-centered textbook in nephrology to address the evidence principally from the perspectives of the patient and the individual practitioner, not the policy maker. It is our hope that this evidence-based nephrology textbook will provide a resource for practitioners, and therefore we have focused on the primary clinical evidence and, where available, systematic reviews of this evidence. Health economic assessments are considered in this text only insofar as such analyses and the policy choices they have engendered may influence the various current national and international management guidelines, such as the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative and the European Best Practice Guidelines.

What then is the potential for an evidence-based approach to nephrology for the individual practitioner and patient? As noted by Eddy [1], "different value judgments are unavoidable. Yet, a thorough and judicious assessment of the best evidence will promote treatment decisions that are: less arbitrary, better informed, more individualized, more transparent, and more broadly acceptable. The first contribution of evidence-based medicine is to change the anchor for the decision from the beliefs of experts to evidence of effectiveness." An important consequence of a comprehensive examination of the evidence broadly covering all clinical topics in nephrology as necessitated by this textbook is the exposure of the scope of evidence that informs the diagnosis and management of patients in our field, the laying bare, so to speak, of what is known and what is not known. Recently, Strippoli and coworkers evaluated the number of randomized controlled trials in nephrology compared to other fields in internal medicine [5]. They found that the number of randomized trials in nephrology was substantially lower than for other internal medicine subspecialties. In this evidence-based nephrology textbook, evidence from high-quality observational studies is considered in many cases in conjunction with the randomized controlled trials evidence, a reflection of the current state of the best available evidence that informs the practice of nephrology.

The examination of the totality of evidence should have the following principal outcomes. An explicit acknowledgment of the limited scope of the evidence, specifically, that it is rather incomplete in many areas, should permit a responsible challenge of opinion-based (even expert opinion) practice recommendations and should, thus, reduce the reliance on dogma. Identifying those areas of disease management for which there is only poor-grade evidence should suggest a research agenda. Because evidence-based medicine has traditionally emphasized patient-centered research, it is anticipated that an evidence-based approach will be more robustly patient centered.

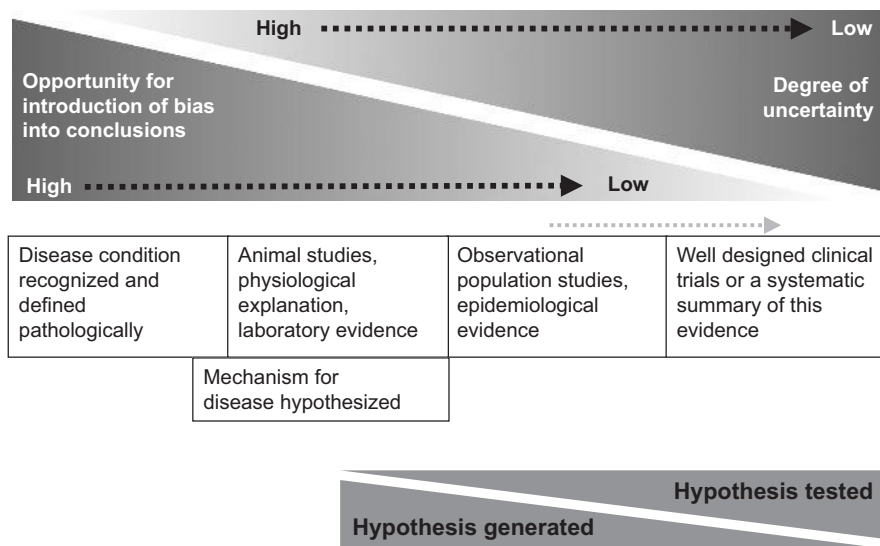
In the spirit of evidence-based medicine, we have embarked on this book with the following goals in mind. First, we wish to provide the student of nephrology with a single convenient source of clinical evidence that has been passed through an evidence-based filter. Second, we wish to provide a forum for the reasonable inclusion of data of multiple types as these determine best practice in nephrology, including high-quality observational and


Figure 1 The spectrum of clinical uncertainty.

epidemiological data, in particular where high-quality experimental data are lacking. Third, by uncovering the areas where evidence is lacking, we hope to help inform the hierarchy of need for clinical trials. We hope that this textbook reflects current best evidence and that it is sufficiently comprehensive to cover the major clinical questions encountered by nephrologists, including those caring for the transplant patient and the pediatric patient. In compiling a textbook we have had to make some editing choices for clarity and organization. There may be areas, we hope very few, that have not been covered as comprehensively as the majority of topics in this text. We have included very little discussion of some topics that are covered extensively in traditional nephrology textbooks, including discussions of the mechanisms of disease and/or pathophysiology that emerge from *in vitro* studies, unless a discussion of these is likely required to understand clinical evidence on treatment of the relevant renal disorder. Thus, the treatment of electrolyte disorders that typically occupies one-third of most textbooks in nephrology is confined to one rather brief section, as clinical trials evidence is entirely lacking for much of the dogma on this topic.

By definition a textbook is likely to be less up to date than an evidence-based medicine website that can undergo comprehensive updating in real time. The latter type of resource, as exemplified by the Cochrane database, requires a large investment of intellectual resources, and for this reason the promise of a truly comprehensive constantly updated review of all topics in nephrology has not been fully achieved to date. In the absence of such resources, we hope that this textbook, *Evidence-Based Nephrology,* will fill a substantial portion of this void. Furthermore, unlike the Cochrane database, which is almost exclusively focused on questions of therapy, we have also included comparisons of many of the current evidence-based guidelines and we have included a discussion of the evidence as it relates to diagnosis, prognosis, and risk identification. We begin with a discussion of the sources of this evidence and the qualities that differentiate high-quality evidence from that of lower quality. We acknowledge that inclusion of nonexperi-

mental evidence does not permit robust conclusions in the absence of a significant degree of clinical uncertainty. This general concept of a spectrum of clinical uncertainty, in which all clinical decisions are made along a continuum from higher degrees of uncertainty to lower degrees of uncertainty, is illustrated in Figure 1.

It is our hope that this evidence-based nephrology textbook will, by moving the practice of nephrology toward the right-hand end of this spectrum, result in better clinical decisions. In the true spirit of evidence-based medicine, we hope that this text will thus push the specialty toward greater reliance on less biased evidence and make explicit the fact that we will never be able to manage patients without some uncertainty.

We also wish to acknowledge, along with the benefits we have enumerated above, some of the risks of an evidence-based approach in developing a textbook. In sum, we do believe the practice of nephrology is far better off with an evidence-based approach based on the principles that we have tried to exemplify in compiling this text as the starting point of an understanding of our field. To the material detailed in the various chapters, we hope or rather expect that our evidence-based medicine-centered learners and readers will add, through their own judicious application of evidence-based medicine principles, their own new knowledge as it emerges from the medical literature. Additionally, we acknowledge that an evidence-based medicine text might be most up to date when first published but that new information will always emerge between editions; hence, a textbook like this can at best be only one of several resources for the evidence-based medicine practitioner. We hope this effort will provide a core resource for the evidence-based nephrology practitioner who is otherwise limited by time constraints from researching every question that may arise daily in the care of patients.

Introduction: Trials, Systematic Reviews, Grading Evidence, and Implications for Nephrology Research

Jonathan C. Craig

Why a trial (evidence)-based book

Readers of this book will be very familiar with the usual rationale for why randomized controlled trials (RCTs) should be central to routine clinical care [1]. Fundamentally, health care is about improving health outcomes, and an RCT is the study design which best estimates the true effects of interventions. Clearly, to practice good health care, other types of questions need to be addressed, diagnostic and prognostic questions in particular, and for these questions other study designs are needed. Inevitably in a book like this, some prioritization is needed, and because treatment questions are critical, results of relevant RCTs have been highlighted in all chapters.

The recent history of RCTs is interesting and was begun not in health care but in agricultural science by R. A. Fisher in 1935 [2]. Like many advances in biomedical science, innovators and leaders are always needed, and this came in the form of two eminent English scientists, Major Greenwood and Bradford Hill. Major Greenwood, as head of the Medical Research Council's (MRC) Statistical Committee, was able to convince the Therapeutic Trials Committee of the MRC in the 1930s to 1940s of the importance of RCTs. Bradford Hill took over Major Greenwood's position in 1945, and under his supervision the MRC's randomized trial of streptomycin was conducted in 1946 and published in 1948 [3]. Richard Doll, another major figure in the development of clinical trials during the 20th century, reflected upon the impact of this landmark study. The expert judgment of the Professor in deciding whether an intervention worked or not was rejected in favor of am explicit, quantitative, methodologically robust study design, the randomized trial [4].

The history of RCTs has also been marked by critics who typically suggest that observational studies are more "real world," and because they are larger, follow patients for longer time periods, are more inclusive, they are at least as valid as RCTs for evaluating whether interventions work, and they are probably more valid [5–10]. This debate occurred during the so-called outcomes research movement in the 1980s, but it was comprehensively decided in favor of trial-based evaluation of interventions, given that for the past 20 years major research funders, guidelines groups, regulators, and purchasers of health care had almost universally accepted the trial as the most valid study design to evaluate the effects of interventions, with observational studies a clear second [11]. Recently, this debate has been reignited, largely it would seem, to lower the barrier for new drugs and devices for the purposes of approval and subsidization [12].

The fundamental flaw of observational studies is that the allocation of interventions to patients is not random [13–16]. Consequently, any difference in outcomes between the patients who did and those who did not receive the intervention may be due to differences in patient characteristics, and unfortunately these differences can never be reliably and completely adjusted for, despite regression analysis, propensity scores, and the other statistical methods. A large-scale empirical comparison of the results of trials and observational studies was commissioned by the National Health Service and published as a Health Technology Assessment report [17]. The conclusion was clear. Most of the time, the results of observational studies and trials are concordant, but sometimes they are not, and the results of trials cannot be predicted with certainty based upon observational studies. There are many examples, tightness of glucose control in type 2 diabetics being a recent one. Contrary to observational studies, which have consistently shown tight glucose control improves macrovascular and microvascular outcomes, the ACCORD [18] and ADVANCE [19] studies showed no improvement in macrovascular outcomes, and in ACCORD, an increased all-cause mortality was reported. Studies like these reaffirm the importance of proper evaluation of interventions in RCTs, even though they are expensive and take time. The conduct of trials will become increasingly important when the marginal gains in health care become smaller and the potential harms and costs, greater.

Why a systematic review-based book

Decisions on treatment should be based upon all, and not just some, relevant RCTs. Currently, the Cochrane Renal Group has a register of RCTs in kidney disease that contains the records of about 10,000 trials and 12,000 publications arising out of those trials. The registry steadily increases at about 2000 trials/year. A simple Medline search would find only about two-thirds of these trials, because of problems in classification of the disease category and study design in the Medline coding. Also, about one-fourth of all trials in the registry come from handsearching, mainly from abstract compilations from the major nephrology and transplantation meetings. These studies may never be published (publication bias) or may be published relatively late (publication delay bias). Why systematic reviews of RCTs should form the basis of treatment recommendations and not just narrative reviews or a single trial chosen by an expert is beyond the scope of this introduction, but I will summarize the key points.

For clinicians it is easier to look at one systematic review than the many trials that are summarized in that review. Second, many trials are relatively underpowered, and a formal quantitative synthesis of the results may find a statistically significant benefit (or harm) that none of the component studies found. Meta-analysis provides a summary estimator of treatment effects, where appropriate, and this is necessary to inform practice, to ensure that benefits numerically exceed harms. Third, the variabilities in populations and interventions in a systematic review may increase the applicability of the findings. For example, interleukin 2 receptor antagonists have a remarkably homogeneous effect in reducing acute rejection despite the variability in baseline immunosuppression used [20]. Critics of meta-analyses argue that like should only be kept with like, and that "apples and oranges" should never be combined. Actually, it is often only in a context of a meta-analysis that there can be formal testing of whether treatment effects vary according to prior beliefs. Fourth, systematic reviews may minimize and/or highlight the various publication biases that might occur. One publication bias, the tendency for so-called "negative studies" not to be published, can be minimized if a comprehensive search of the "grey literature" (meeting abstract compilations, etc.) is conducted. The opposite bias, duplication bias, is where one study, typically one that is favorable to an intervention, is published multiple times and this is not disclosed to readers. Some "salami slicing" is reasonable, when studies are extremely large and report many outcomes. Many is not, particularly when the net effect is to mislead clinicians into thinking an intervention is more effective than it really is because of multiple, undisclosed publications. Finally, systematic reviews can highlight an outcomes reporting bias. It has been shown that trialists frequently change their primary outcomes during the trial, and this tends to favor the intervention under evaluation [21,22]. Trialists may only report what is improved with an intervention and not what is most important to a patient or what they said they would do at the inception of a study. These observations have led to calls for public disclosure of trial protocols. Systematic reviews can highlight these potential biases by demonstrating discrepancies in the number of trials reporting important outcomes. For example, many trials of calcineurin inhibitors did not report diabetes, acute rejection, or graft survival [23].

Why a book which "GRADEs" evidence

Most evidence-based textbooks and guidelines only evaluate the study design. Randomized trials become the proxy for evidence, when the reality is much more complex. What about when the trials are poorly done? What about when the wrong outcomes are measured? What about when the benefits are evaluated but the harms are not? Recently, the GRADE group, an open, multidisciplinary, international group of researchers and policy makers, developed a comprehensive approach to evidence, which forms the basis of this book [24–26]. Many of the chapters in this book have one or more evidence profile tables, with the simple two-tier (strong or recommend, weak or suggest) recommendations developed by GRADE. Full details of the process are provided elsewhere, but in short, GRADE begins with a systematic review of the available evidence. The overall evidence supporting an intervention, against the comparator intervention, is assessed. Domains considered are the study design (RCTs, observational studies, etc.), study quality (for RCTs this would include allocation concealment, blinding, intention to treat, loss to follow-up), consistency (are all the studies reporting the same results or are they different, and are the differences unexplained), and directness. Directness concerns whether the results of the trials can be generalized to the patient group being considered for the intervention and whether the outcomes being assessed are relevant or of a surrogate or unimportant nature. These four domains are considered in evaluating the overall strength of the evidence for the intervention being evaluated. Importantly, both benefits and harms are given equal consideration, and so even if there was high-quality evidence of the benefits of an intervention, if the quality of data for the adverse effects was very low, then the overall quality of evidence would also be rated as very low. Conceptually, evidence is rated as high quality when the evidence is so robust that no new studies could be justified because the benefits and harms are clear. The GRADE framework is a net clinical benefit, a benefit–harm framework, informed by the quality of the evidence. The evidence profile is then converted into a treatment recommendation after considering the quality of the evidence, values and preferences, local applicability considerations, and the benefit–harm trade-off in the patient group being considered for treatment. Conceptually, a strong recommendation would be equivalent to a recommendation that most clinicians and patients would follow if well-informed.

Clearly, judgment is required, but GRADE requires that such judgments be explicit and incorporate all of the relevant domains. GRADE reinforces the notion that, although trials are essential for evidence-based health care, they are insufficient. Observational studies are often needed to quantify the baseline risk values of

individuals for outcomes that are averted by an intervention and to quantify the harms of rare events. GRADE also reinforces the importance of systematic reviews as the first step in the recommendation process.

Why evidence-based nephrology is a work in progress

More and better trials are needed

It has been shown that the number of trials in kidney disease lags behind all other specialties, and the standard quality reporting domains of allocation concealment, blinding, and intention to treat analysis are low and not improving [27]. Nephrology patients deserve the same quality of evidence-based care as patients with cancer. This can only occur when the standard of clinical care is for participation in a trial of a new promising intervention versus the current standard of care that is large enough to answer the question and in which simple outcomes that matter to patients are measured in all participants, both benefits and harms. This model of a large, simple trial, which has been adopted so successfully in cardiology and oncology, is a long way from the current model in nephrology [28]. The typical current model is a small trial (presumably because of large per-patient recruitment costs or a lack of a cohesive recruiting network) and one that sometimes compares a new intervention against a nonstandard, clinically inferior intervention [29]. Superiority is typically demonstrated, but such trials have questionable ethics and give results with uncertain policy relevance where the best standard care is expected to be the comparator. Trials may also be short term (months), and not all patient-relevant outcomes are reported, suggesting outcomes reporting bias in which only favorable outcomes are reported. In nephrology trials, the generic call for mandatory registration of trials and study protocols, and for complete reporting of all outcomes, both harmful and beneficial, should be heeded [21,22]. The nephrology community needs to follow the example of other disciplines and develop a consensus on what outcomes should be reported in trials and what definitions should be used [30].

More and better systematic reviews are needed

To date, the nephrology community has summarized in systematic reviews only about 1000 of the available 10,000 trials. In short, we are only about 10% of the way towards the goal of up-to-date systematic reviews of all RCTs. Readers of this book will notice that not all chapters have tabulated evidence summaries based on the GRADE methods. Reasons for this are many but include the absence of existing systematic reviews in areas of high clinical importance.

Although the focus on interventions is justifiable, ideally we need systematic reviews of all diagnostic tests used in nephrology and, some would argue, we equally need systematic reviews of prognosis studies. This can only be achieved with much larger-scale cooperation across the peak nephrology bodies and among researchers and clinicians than has occurred to date. Until this

occurs, and the relevant reviews are done, unnecessarily duplicative and unethical studies will continue, and needed studies will go undone. Research will be dominated by commercial interests and not patient needs.

More and better recommendations are needed

Not all authors in this book have used the GRADE system. This is to be expected, given the absence of existing systematic reviews and lack of familiarity with the GRADE process, which is still in development.

One critical lack is an almost complete absence of evidence about the values and preferences of patients with chronic kidney disease, which is needed to inform and assign weights to recommendations. Researchers tend to assume that they can correctly assign priorities to outcomes that reflect the values held by patients but, when evaluated, this has not been the case for other chronic diseases. A qualitative research agenda needs to be developed around patient perspectives of research and health care in nephrology.

In conclusion, this book has been deliberately ambitious. If readers are better informed by better evidence compared to their pre-reading state, then the goal of the book will have been achieved. A bonus will be if this book prompts a better evidence base that will make whatever subsequent editions of this book that appear more comprehensive, valid, and useful to clinical decision makers [31].

1   Epidemiology of Kidney Disease

1 Epidemiology of Chronic Kidney Disease

William M. McClellan[1] **& Friedrich K. Port**[2]
[1] Emory University School of Medicine, Atlanta, USA
[2] Arbor Research Collaborative for Health, Ann Arbor, USA

Introduction

End-stage renal disease (ESRD) is defined by the cessation of effective kidney function and the substitution of renal replacement therapy (RRT), such as hemodialysis, peritoneal dialysis, or kidney transplantation, for native kidney function to sustain life. During the last 3 decades, an epidemic of ESRD has occurred in both industrialized and developing countries [1,2]. The epidemic increase in ESRD was initially attributed to the dissemination and adoption of RRT with the attendant extension of productive life. Although there is evidence that the rate of increase in ESRD incidence has abated in the USA, continuing increases in ESRD incidence rates after access to RRT becomes available to an entire population of a particular country have been documented by registries throughout the world [3].

The public health impact of the epidemic of ESRD is substantial. In the USA, it is estimated that the lifetime risk of being treated for ESRD is 2.5% for white men, 1.8% for white women, 7.3% for black men, and 7.8% for black women [4]. Life expectancy among individuals treated for ESRD is substantially shortened, and treatment is punctuated by frequent hospitalizations and progressive disability [3]. The economic costs of the epidemic are substantial as well, and the per-patient cost of care can exceed by severalfold the costs incurred by age-, gender-, and ethnicity-matched individuals in the general population. Furthermore, these costs only partially capture the full economic burden of ESRD, which includes the costs of chronic disability, premature mortality, and diminished quality of life.

Given the population cost burden of this epidemic of ESRD, it is increasingly recognized that strategies must be designed to increase the early detection and care of the antecedent diseases that contribute to this epidemic of end-organ failure [5,6]. There are multiple causes of kidney injury that result in ESRD, and the

evidence-based diagnosis and management of these conditions are discussed in detail in subsequent chapters of this textbook. Common to each, however, is a continuum of progressive decline in kidney function that leads to a syndrome of chronic kidney disease (CKD), which is characterized by hypertension, anemia, renal/metabolic bone disease, nutritional impairment, neuropathy, impaired quality of life, and reduced life expectancy and which culminates in ESRD. The purpose of this chapter is to describe the definition of CKD and the measurement of the population-based health burden of CKD across the continuum of disease, from mild impairment to ESRD, as an essential foundation for the evidence-based management of kidney disease. Problems inherent in using biomarkers and prediction equations to define kidney function and detect CKD are discussed in chapter 2. The epidemiology of CKD is discussed in chapter 4, and risk factors associated with progressive loss of kidney function can be found in chapter 3. Chapter 2 examines how surveillance systems have been used to measure and improve the care of patients receiving RRT.

Definition of chronic kidney disease

CKD can be defined as the persistence for 3 or more months of structural and/or functional abnormalities of the kidney [7]. This definition replaces previous case definitions that described variable degrees of impaired kidney function [8,9]. The rationale for adopting a uniform case definition of CKD includes the need for 1) improved comparability across observational and clinical studies, 2) an improved capability for uniform comparisons of kidney disease incidence and prevalence, and 3) improved communications about diagnosis and treatment of kidney disease. The most important anticipated benefit of a common terminology is more effective communication with patients and the public.

The "structural" abnormalities used to define CKD are 1) microalbuminuria or overt proteinuria; 2) an abnormal urinary sediment as evidenced by the presence of red blood cells (RBCs), RBC casts, white blood cells (WBCs), WBC casts, tubular cells, cellular casts, granular casts, oval fat bodies, fatty casts, or free

Table 1.1 Prevalence of decreased kidney function and CKD in the noninstitutionalized US population

Kidney function				Albuminuria Within Each Level of GFR (%)				CKD			
Estimated GFR (mL/min/1.73 m²)	n	Prevalence (%)	N (1,000s)	None	Micro-albuminuria	Macro-albuminuria	Persistence of Micro-albuminuria (%)	Stage	Prevalence (%)	N* (1,000s)	N† (1,000s)
>90	10,183	64.3	114,000	90.8	8.7	0.5	53.9	1	3.3	5,900	10,500
60–89	4,404	31.2	55,300	87.2	11.7	1.2	72.7	2	3.0	5,300	7,100

fat; and 3) abnormal findings on imaging tests, including ultrasound, intravenous pyelogram, computer tomography, magnetic resonance imaging, and nuclear scans. Overt proteinuria is defined as an increased urinary concentration of albumin and other proteins detected by routine laboratory measures (e.g. urine dipstick test for protein), and microalbuminuria is an increased albumin excretion that can be detected only by laboratory methods more sensitive than the standard protein assay that uses the urine dipstick.

The functional component of the definition of CKD uses creatinine-based estimates of clearance derived from the Modification of Diet in Renal Disease (MDRD) glomerular filtration rate (GFR) estimating equation or the Cockcroft–Gault creatinine clearance equation [10]. The derivation and use of these multivariate prediction equations are discussed in chapter 5. At present, no single method of GFR estimation is strongly recommended. Clinicians should choose a method that is appropriate for their population to determine the estimated GFR (eGFR) and assign a stage of kidney disease, always cognizant that failing to account for the modification of the complex association between serum creatinine and GFR by age, gender, and race is likely to lead to misclassification of kidney function and attendant errors in clinical decision making.

The available estimating equations are imprecise at higher levels of GFR, and there is great interest in revising them or identifying better filtration markers that will improve our ability to measure kidney function across the continuum of kidney performance from normal to ESRD [10]. The inherent imprecision of all methods of estimating GFR led to the decision to rank the degree of impaired kidney function into more global stages (levels) by the eGFR in the following manner:

Stage 1: eGFR >90 mL/min/1.73 m² (with structural abnormalities)

Stage 2: 60–90 mL/min/1.73 m² (with structural abnormalities)

Stage 3: 30–59 mL/min/1.73 m²

Stage 4: 15–29 mL/min/1.73 m²

Stage 5: <15 mL/min/1.73 m²

In addition to these eGFR ranges, the persistence of structural abnormalities for at least 3 months is necessary to assigning CKD stages 1 and 2, and stages 3–5 of CKD are defined by persistent impairments for greater than 3 months in the eGFR alone.

This staging algorithm is illustrated by using data from the US population aged 20 years and older (Table 1.1). The prevalence of CKD based on eGFR and presence and degree of proteinuria CKD is estimated to be 11% of the US population [7]. Over 50% of the prevalent disease is due to the presence of proteinuria among individuals with stage 1 (3.3%) and stage 2 (3.0%) CKD, and this proteinuria is largely due to microalbuminuria. Among individuals with stages 3–5 CKD, which are defined by eGFR alone, 85% of individuals have stage 3 disease (4.3%).

Kidney disease: improving global outcomes

The definition of CKD was reviewed at the 2004 "Kidney Disease: Improving Global Outcomes (KDIGO)" Controversies Conference [11]. Two further modifications were proposed to better
Figure 1.1 Secular trends in mortality attributed to various causes illustrating discontinuities in trends with changes in ICD classification of cause of death. (Reprinted with permission [13].)

Note : Age-adjusted rates per 100,000 U.S. standard populattion, area "Technical Notes" "Essential" (primary) hyperien aion and Hypertension renal disease.

adapt the staging algorithm for international use: 1) clinical judgment should be used to decide the relevance of nonproteinuric markers of kidney damage prior to diagnosing CKD in individuals without either proteinuria or reduced GFR; 2) individuals with a transplanted kidney should be considered as having CKD irrespective of other structural or functional markers. The KDIGO modified the CKD risk stratification by adding the letter T to denote CKD in a transplanted kidney and recommended that stage 5 CKD be modified by the letter D to denote RRT by dialysis [11].

International Classification of Diseases and kidney diseases

The *International Classification of Diseases* (ICD) classifies each condition that has given rise to the chain of events leading to death (underlying cause of death) as recorded on death certificates. The ICD is used by national vital statistics registries. At present, it provides the only uniform population-based case definition for international comparisons of the burden of disease attributable to earlier stages of CKD and, as such, is an important actuarial tool in defining the health burden of CKD across populations and, with certain limitations described below, temporally. The Ninth Revision of the ICD (ICD-9), used between January 1, 1979 and December 31, 1998, was replaced by ICD-10 on January 1, 1999 [12].

Revisions of the ICD reflect the evolution of disease classification and emergence of new diseases, and they resolve administrative issues that have stemmed from a particular version of the codes. Clinicians should be aware that ICD revisions often introduce changes in the classification of an underlying cause of death. Comparisons of death rates due to specific causes, such as kidney disease, across different ICD revisions can be facilitated by using comparability ratios that relate rates from different time periods. The comparability ratio relating rate computed from ICD-9 (ICD-9 codes 580–589) and ICD-10 (ICD-10 codes N00–N07, N17–N19, and N25–N27) data is estimated to be 1.23, indicating that the new ICD-10 coding will result in a 23% increase in classification of deaths due to kidney disease compared with the ICD-9 codes [12]. This version-to-version difference is due, in part, to a change in the classification of ESRD from an unspecified disorder of the kidney in ICD-9 to ESRD (N18.0), a subcategory of kidney failure (N17–N19) in ICD-10.

Secular trends in kidney disease as an underlying cause of death need to be interpreted with these changes in mind. This can be illustrated by trends in kidney disease as a cause of death in the USA (Figure 1.1), which declined between 1958 and 1978 and then increased substantially until the end of the century [13]. The transition from ICD-9 to ICD-10 in 1998 is represented by the discontinuity in the trend line for deaths due to nephritis, nephrotic syndrome, and nephrosis.

The Clinical Modification of ICD-9 (ICD-9-CM) is used administratively in the USA and was modified in 2005 to reflect the new nomenclature for CKD. ICD-9-CM code 585, "Chronic renal failure," was dropped, and seven new four-digit codes were introduced to code for the presence of CKD [14]. These new codes reflect the National Kidney Foundation (NKF) CKD staging definitions:

585.1: Chronic kidney disease, stage 1
585.2: Chronic kidney disease, stage 2 (mild)
585.3: Chronic kidney disease, stage 3 (moderate)
585.4: Chronic kidney disease, stage 4 (severe)
585.5: Chronic kidney disease, stage 5
585.6: End-stage renal disease
585.9: Chronic kidney disease, unspecified

Furthermore, in 2006, the ICD-9-CM nomenclature for codes 403 and 404, denoting kidney complications of hypertension, were changed from "renal disease" to "kidney disease" and from "renal failure" to "chronic kidney disease." A revision of the clinical modification of ICD-9 to reflect the ICD-10 coding conventions is currently being developed.

The standardized ICD nomenclature provides some uniformity of data that allows descriptions of population-to-population differences in death rates attributed to kidney disease. This standard nomenclature stands in contrast to the information reported by national ESRD registries that collect and report information on the occurrence of stage 5D CKD (see chapter 2). A report by Maisonneuve *et al.* found substantial variability in the definition and classification of primary causes of ESRD throughout the world [15]. Comparisons of the burden of CKD based on ICD-related mortality statistics also avoid the skewing of prevalence rates based on ESRD rates that would be introduced by the variable coverage of ESRD registries in economically developing countries.

The use of international comparisons of kidney disease burden can be illustrated by considering the proportionate mortality attributed to kidney disease throughout the world. Kidney disease is the 9th leading cause of death in the USA [6] and the 12th leading cause of death worldwide [16]. The burden of mortality due to kidney disease in different world regions was recently reported by the Global Burden of Disease Report [17]. Age- and gender-adjusted proportionate death rates for genito-urinary diseases, which include nephritis and nephrosis, benign prostatic hypertrophy, and other genito-urinary system diseases, vary from less than half of to 50% greater than those observed in high-income regions of the world (Figure 1.2) [17].

There are multiple potential explanations for this region-to-region variability in the overall mortality burden due to kidney disease. Regional differences in the prevalence of risk factors for kidney injury and progressive loss of kidney function, access to health care, detection and treatment of kidney disease, and diagnostic convention could contribute to the observed variability. The main point of international comparisons is that a better understanding of the source of variation is essential for better control of CKD and its risk factors through public health measures and may lead to important generalizable insights into the reasons for the occurrence and progression of CKD.

Functional and etiologic diagnoses for CKD

CKD is a nonspecific diagnosis that describes the presence and degree of structural and functional abnormalities of the kidney. CKD does not identify the cause for the injury and/or impaired kidney function. Thus, the stage of CKD is an incomplete clinical description of the underlying disease process, and identification of CKD should also lead to a clinical diagnosis that includes a cause (etiology) for the kidney disease and the stage of CKD. For example, a diagnosis for CKD might be stated as "stage 3 CKD due to diabetes," "immunoglobulin A nephropathy with stage 4 CKD," or "stage 2 CKD of unknown etiology."

At present, the best estimates for the relative contributions of specific etiologies to the total burden of CKD within populations are derived from the proportionate, cause-specific incidence of ESRD within a population (see below). These estimates, however, have a number of limitations. Most important is the possibility that variations in survival and progression to stage 5 CKD among individuals with kidney disease due to different causes might alter the patterns of disease and the proportionate health burden over the course of CKD. It is also likely that there are substantial regional and ethnic variations within and between groups with respect to specific causes of initial kidney injury. It is likely that many individuals with prevalent kidney disease will have a number of competing risk factors associated with the initiation and progression of kidney disease, and the precise temporal relationship between these and the etiology of the initial kidney injury remains obscure. Finally, systematic studies to estimate the risk of kidney injury among individuals with less common forms of stage 5 CKD remain to be conducted.

Figure 1.2 Proportion of all deaths attributed to genito-urinary causes (ICD-9 codes 580–611 and 617–629 or ICD-10 codes N00–N64 and N75–N98). These codes include nephritis and nephrosis, benign prostatic hypertrophy, and other genito-urinary system diseases. Regions in the Global Burden of Disease study were defined as high-income countries (HIC), East Asia and Pacific (EPA), sub-Saharan Africa (SSA), Latin America and the Caribbean (LAC), Europe and Central Asia (ECA), Middle East and North Africa (ME/NA), and South Asia (SA). Data were derived from regional tables for deaths by cause, sex, and age. (Reprinted with permission [17].)

Prognostic importance of the stage of CKD

As discussed in chapter 2, the classification of CKD using the NKF stages provides substantial prognostic and diagnostic information concerning 1) outcomes (progression to ESRD and mortality) [18,19] and 2) ocurrence of intercurrent morbidity (ischemic heart disease, stroke, and peripheral vascular disease) [20–28]. Further, the stage of CKD is predictive of the prevalence of complications associated with impaired kidney function (anemia, bone disease, and nutritional and functional status) (Table 1.2).

Table 1.2 CKD stage characterizations and risk factors associated with progressive kidney disease

Characteristic or risk factor	Stages 1 and 2	Stage 3	Stage 4	Stage 5
CKD stage characterization				
Description	Chronic kidney damage with normal to mildly decreased GFR	Moderate GFR loss	Severe GFR loss	Kidney failure
GFR (mL/min/1.73 m^2) [2]	≥60	30–59	15–29	<15 or dialysis
Prevalence [7]	6.6%	4.3%	0.2%	0.2%
Proteinuria [45]	8.1%	23.3%	63.4%	–
Cardiovascular risk factors				
Hypertension [7]	40%	55%	77%	75%
Diabetes [45]	3.1–6.5%	16.8%	22.8%	–
C-reactive protein >0.21 mg/dL [44]	25–30%	48.7%	57.7%	–

Complications of CKD and CKD stages

Complications that develop in CKD are listed in Table 1.2. The diagnosis and management of these complications are discussed in greater detail in the sections Prognostic importance of the stage of CKD and Complications of CKD and CKD stage of this text. Some of the important CKD-specific associations between the development of comorbidities and CKD stage that have emerged from epidemiologic studies are described in brief below.

Disordered metabolism of 25(OH)-vitamin D, phosphorous and calcium balance, and serum parathyroid hormone levels are well-documented for stage 5 CKD [1] and are noted to begin at or before stage 3 CKD. LaClair *et al.* studied patients with stage 3–5 CKD and found that 25(OH)-vitamin D deficiency was present in 71% and 83% of these patients, and parathyroid hormone levels outside of the recommended normal range were present in 64.6% and 69% of individuals with stages 3 and 4 of CKD [32]. Interestingly, geographic locations characterized by lower latitudes were inversely associated with an intact parathyroid hormone level. A recent study by Binkley *et al.* questioned the role of sun exposure on 25(OH)-vitamin D deficiency because deficiency remains relatively common even in sun-exposed individuals [33]. The prevalence of elevated serum phosphorous levels and low albumin-adjusted serum calcium levels increases with increasing stage of CKD. Analyses of data from a cohort study of left ventricular hypertrophy and anemia by Levin *et al.* estimated that the prevalence of a serum phosphorous level greater than 4.5 mg/dL increased from less than 5% among individuals with stage 3 CKD to 20% of those with stage 4 CKD; comparable prevalence estimates for a serum calcium level of less than 8.5 mg/dL were less than 5% and 8% [34]. In contrast to these observations, Hsu *et al.* found that age-, gender-, and race-adjusted femoral bone density among National Health and Nutrition Survey III (NHANES III) participants was unchanged among individuals with mild and moderate kidney disease [35].

Abnormalities of calcium and phosphorous metabolism are associated with increased risks of death and cardiovascular disease. Kestenbaum *et al.* reported that patients with CKD in the Veterans Affairs medical system with an elevated serum phosphorous level were at increased risk for all-cause mortality (hazard ratio [HR] per 1 mg/dL increase, 1.33; 95% confidence interval [CI],

1.15–1.54) [36]. Menton *et al.* reported that, after adjusting for other risk factors, cardiovascular disease but not all-cause mortality rates were marginally associated with increased serum phosphorous among participants in the MDRD study (adjusted HR per 1 mg/dL increase, 1.27; 95% CI, 0.94–1.73) [37]. Similarly, the calcium–phosphorus product was marginally associated with cardiovascular disease, but not all-cause mortality (HR, 1.22; 95% CI, 0.89–1.66; P = 0.23) in the MDRD participants. Among individuals with stage 5 CKD, the association between disorders of mineral metabolism, including elevated serum phosphorus and calcium levels and hyperparathyroidism, are well-documented and are estimated to account for 17.5% of the population attributable risk for proportionate mortality.

Astor *et al.* used the NHANES III data to determine the association between GFR and the prevalence of anemia, defined as hemoglobin less than 12 g/dL for men and less than 11 g/dL for women [38]. The prevalence of anemia increased from 1% among individuals with no CKD to 5.2% of individuals with stage 3 CKD and 44.1% of those with stage 4 CKD.

As the stage of CKD increases, functional impairment and magnitude of diminished quality of life reported by patients increase as well [39,40]. A recent report from the Chronic Renal Insufficiency Cohort study compared standard disease-specific measures of quality of life, the Kidney Disease Quality of Life Short Form 36, and general measures, including the SF-12 Physical and Mental Health Short Form, the Health Utilities Index 3, and the Time Trade-Off score among individuals with CKD [39]. The Chronic Renal Insufficiency Cohort study investigators observed a strong inverse association between stage of CKD and baseline measures of disease-specific and general quality of life. Furthermore, among individuals with CKD of stage 4 or greater who were tested sequentially over 2 years, progression of CKD was associated with further impairment of quality of life [40].

There is also evidence that the prevalence of cognitive impairment increases with increasing stage of CKD and that individuals with impaired kidney function at any level are at increased risk of developing cognitive impairment [41–43]. A report from the Health, Aging, and Body Composition study found that baseline cognitive function measured by the Modified Mini-Mental State Exam was inversely associated with degree of impaired kidney function, which declined from a total score of 87.5 among individuals without CKD to 86.9 among those with a GFR between 45 and 59 mL/min/1.73 m^2 and to 84.7 for those with a GFR less than 45 mL/min/1.73 m^2, with a score of less than 80 indicative of cognitive impairment [42]. After controlling for other risk factors, both individuals with a GFR between 45 and 59 mL/min/1.73 m^2 (odds ratio [OR], 1.32; 95% CI, 1.03–1.69) and those with a GFR of less than 45 mL/min/1.73 m^2 (OR, 2.43; 95% CI, 1.38–4.29) were at an increased risk of developing dementia during follow-up.

Individuals in the Cardiovascular Health Cognition Study underwent a three-stage evaluation for dementia that included an assessment of dementia risk, neuropsychological testing on high-risk patients (and a sample of other study subjects), and neurological and psychiatric evaluation for those classified as abnormal on the neuropsychological tests [42]. Subjects with an increased serum creatinine of $\geq$ 1.3 mg/dL for women and $\geq$ 1.5 mg/dL for men were found to be at increased risk of developing incident dementia during follow-up (OR, 1.37; 95% CI, 1.06–1.78). Of interest from this study, these associations were observed only among individuals who were healthy at baseline and were observed for vascular-type but not Alzheimer's-type dementia.

Descriptive epidemiology of CKD

Prevalence of Stage 1–4 CKD

The epidemiology of CKD is not well understood. NHANES is an ongoing series of surveys of representative samples of the US population conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention. These surveys are cross-sectional, complex, random samples of the US population, and they have been analyzed to provide CKD prevalence estimates. The prevalence of CKD among adults aged 20 years and older in the USA based on NHANES III data is estimated as 11%, with 6.3% of the population in the combined stages 1 and 2 CKD, 4.3% in stage 3 CKD, and 0.2% of the population in each of stage 4 and stage 5 CKD (Table 1.1).

Microalbuminuria, defined as an albumin–creatinine ratio of 17–250 mg/g in men and 25–355 mg/g in women, is present in 10.5% of the population on initial screening and persists over time on repeated measures in the same individual in 63.2%, whereas overt proteinuria (albumin–creatinine ratio of >250 mg/g for men and >355 mg/g for women) is present in 1.1% of the population [45]. Proteinuria increases in prevalence with decreasing GFR and is found in 0.5% of individuals with an estimated GFR greater than 90 mL/min/1.73 m^2, 1.2% of those with stage 3 CKD, and 7.2% of those with stage 4 CKD.

There is substantial heterogeneity in the prevalence of stage 3 and 4 CKD across subgroups of the US population. CKD stages 3 and 4 are more prevalent among women (5.3%) than men (3.6%), and prevalence increases from 0.2% among individuals age 20–39 years to 7.5% of individuals age 60–69 years. The non-Hispanic white population has the highest prevalence of stage 3 and 4 CKD in the US population (5.0%), compared with the non-Hispanic black population (3.3%) and Mexican–Americans (1.0%). CKD stage 3 and 4 prevalence is higher among individuals with diabetes (15.1%) and those with treated (17.5%) and untreated (7.9%) hypertension.

Comparisons of CKD estimates between the US population and other countries are difficult to make for several reasons. The measure of kidney function needs to be based on a standardized measure of kidney function that has been validated within each population. A standard classification needs to be applied to each population. Estimates need to be adjusted for differences in the underlying demographic characteristics (age, gender, and ethnicity) of the respective populations.

CKD prevalence estimates currently available in the literature are shown in Table 1.3 [46–57]. There is substantial variability

Table 1.3 Prevalence estimates for Stage 3 and 4 CKD by world region

* Serum creatinine >1.8 mg/dL.

across the studies in the age strata studied, classification methods, and methods of estimating GFR. Despite these variations, it is possible to discern the substantial drop-off in prevalence between stage 3 and stage 4 CKD across these varied populations; the estimated prevalence of CKD stage 4 is consistently less than 0.5% among nondiabetic populations. It is also evident that stage 3 and 4 CKD is a substantial public health problem across the world, exceeding 4% prevalence in all but one population. Finally, the population-to-population variability in prevalence suggests that, similar to the risk for cardiovascular disease, population-specific risk factors for CKD may exist.

CKD and race

The lifetime risks of incidence of ESRD, based on 1993–1995 US Renal Data System (USRDS) data, for 20-year-old white men has been estimated to be 1.98%, 1.67% for white women, 5.49% for black men, and 6.31% for black women, and these cumulative incidences increased further during the 1990s [4]. The racial disparity is reflected in age-adjusted ESRD rates, which are 3.8- to 4-fold higher among black people compared with white people [3]. The excess ESRD incidence for the black population stands in stark contrast to the prevalence data of stage 3 and 4 CKD estimated from the NHANES III population-based sample of the US population [58]. These studies report that CKD among adults age 20 years and older is found in 5.0% of the white population and 3.4% of the black population [58]. These racial disparities persisted after controlling for age, hypertension, and diabetes. Analyses of

the REGARDS cohort study showed that these disparities are particularly evident in stage 3 CKD. As GFR declines, the black–white prevalence gap diminishes and crosses in stage 4 CKD such that the prevalence among Black people with advanced stages of CKD becomes consistent with the observed ESRD incidence rate disparities [59].

The disparity in black and white population ESRD incidence rates persists after accounting for differences in the prevalence of hypertension [60] and diabetes [61] in the at-risk population. Factors associated with these racial disparities in ESRD incidence include access to health care, poverty, and community poverty [62–64]. Tarver-Carr and her associates used follow-up data from NHANES II to examine risk factors associated with racial differences in the incidence of all-cause ESRD [65]. They reported a 2.7-fold-higher ESRD incidence for black people compared with white people. Adjustment for a number of sociodemographic factors (poverty status, educational attainment, and marital status) explained 12% of the excess ESRD risk among black people, and adjusting for life-style factors (smoking status, physical activity, alcohol use, and body mass index) explained an additional 24% of the excess risk. Models that adjusted for prevalent diabetes mellitus, hypertension, and cardiovascular disease and baseline values of systolic blood pressure and serum cholesterol levels explained 32% of the excess risk. When all of these factors were controlled, the adjusted relative risk was 1.95 (95% CI, 1.05–3.63), accounting for 44% of the excess risk. Furthermore, the excess risk among black people for ESRD reported by Tarver-Carr and her colleagues was much greater among middle-aged than among older adults [65].

The unexpected reversal of prevalence of CKD among black individuals compared with the white population and the failure of multiple risk factors to explain the observed disparities in ESRD incidence are consistent with observations that black people with the same degree of impaired kidney function are at increased risk of progressive kidney failure [62–69]. Hsu *et al.* recently examined this possibility in an ecologic analysis of NHANES III and USRDS data [70,71]. They estimated that, despite a comparable prevalence of CKD, 5% of black people and 1% of white people in the US population will develop ESRD over a 5-year period, which is consistent with the progression hypothesis.

Incidence and prevalence of stage 5 CKD

Stage 5 CKD is defined by a GFR of <15 mL/min/1.73 m^2 and has two phases. The first phase is treated conservatively without dialysis, and the second, slightly later phase involves the initiation of RRT—either dialysis or kidney transplantation. The latter has been called stage 5D, or ESRD, which is defined by its treatment [11]. Whereas there is ample information available about patients treated with RRT, epidemiological information about stage 5 prior to starting dialysis is quite limited.

During the earlier phase of stage 5 CKD, conservative therapy includes the same factors discussed in chapter 3 for stage 4 but requires much closer monitoring of laboratory data and clinical symptoms of uremia. Symptoms or laboratory abnormalities are the main indications for starting dialysis. The optimal time for initiation of dialysis therapy has been a focus of many debates, as reports appear to be conflicting. Collins *et al.* showed that late stages of CKD are associated with a high risk of mortality even before starting dialysis [72]. Therefore, it appears reasonable that early initiation of dialysis will save lives. Retrospective analyses of mortality risk after initiation of dialysis, by level of kidney function at the start of dialysis, suffer from a major bias: patients who are started on dialysis with relatively higher levels of kidney function tend to be older and frailer, whereas those who start with poorer kidney function tend to be otherwise healthier with relatively few comorbidities. Thus, due to selection bias, retrospective data may falsely suggest that a later start is associated with better survival on dialysis. Prospective studies that randomize patients to early versus late start are scarce, but they appear to suggest that earlier start of dialysis is associated with better outcomes after dialysis [73]. Such studies must consider the lead time bias, which can be avoided by studying survival not from the start of dialysis but from the time of randomization to early versus late start. This takes into account mortality risk while being treated without dialysis for those randomized to a later start. As with stage 4, various causes of CKD have different rates of loss of kidney function, which needs to be considered in such studies, for example, by stratified randomization. The contributors to the recent NKF Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines reviewed the available evidence on optimal RRT start time in great detail [7]. These guidelines do not offer a specific level of GFR to indicate the need for starting dialysis but suggest that impairment of nutritional status is one of several key indications for the initiation of

dialysis therapy. The evidence regarding when to initiate dialysis therapy and what dialysis modality results in the best outcomes is reviewed in detail in chapters 7 and 8 of this textbook.

There is a wealth of epidemiologic information available about the later stage 5D of CKD (i.e. for patients who have started RRT, usually with dialysis). Numerous national and regional registries have relatively complete information on patients undergoing RRT. Patients initiating dialysis should be viewed as survivors of stage 4 CKD and the earlier phase of stage 5 CKD. This applies to numerous retrospective studies on patient management during the months prior to the start of dialysis.

The Dialysis Outcomes and Practice Patterns Study (DOPPS) inquired from patients how long they had seen a nephrologist prior to starting dialysis and found (among those surviving to dialysis) that, for each of the 12 DOPPS countries, about 66.8–82% had seen a nephrologist for more than 4 months and 8.4–20.6% had seen one for less than 1 month prior to starting dialysis. Patients who received longer pre-ESRD nephrology care were sixfold more likely to have a permanent vascular access rather than a catheter in use, and they were more likely to have an arteriovenous fistula rather than a graft [74].

Incidence

The number of patients starting RRT per year has been increasing steadily since maintenance dialysis became available in 1960, with roughly a doubling in the annual number of new patients during each decade in the 1970s, 1980s, and 1990s [75]. Thus, the incidence has been growing at an exponential rate. Each registry has shown clearly that this rate of growth has been substantially lower for younger patients and highest for the oldest age group. This epidemic of dialysis-requiring CKD may have several causes, although it may be difficult to quantify the role of each contributor. Causes may be categorized into three major groups: 1) patient selection, 2) competing risk, and 3) increased incidence of advanced CKD.

Selection of patients to RRT

The steep increase in incidence for older age groups suggests that very elderly patients and those with particularly severe comorbid conditions were likely not offered dialysis therapy in earlier years and have been increasingly offered RRT in each subsequent decade. In fact, in the early 1970s, a common exclusion for dialysis was age over 60 or 65 years and presence of any systemic disease, such as diabetes or lupus erythematosus. Such patients did have stage 5 CKD but were not counted in registries because registries dealt only with patients who actually received dialysis therapy. The "epidemic" of ESRD was defined only by its treatment.

Competing risks

There is clearly a high mortality risk among patients with earlier stages of CKD, and most individuals with stage 3 and 4 CKD die before starting RRT [18,19]. In fact, impaired kidney function is now recognized as one of the most important risk factors for coronary artery disease, and these risks persist into stage 5 CKD [20].

Substantial improvements in the treatment of heart disease and in survival have occurred in recent decades, which may have allowed such patients to survive to advanced stages of CKD and to the need for dialysis, whereas in earlier eras, these same patients would have died from heart disease during an earlier stage of CKD. A recent analysis by Muntner *et al.* investigated the possibility that the increase in ESRD between 1978 and 1991 could be attributed to increased survival among individuals with diabetes, myocardial infarction, and stroke [76]. They estimated that changes in the numbers of persons in the US population with these conditions could account for slightly over 40% of the increased ESRD incidence (diabetes, 27.6%; myocardial infarction, 4.8%; stroke, 7.9%). These results suggest that some, but not all, of the increase in ESRD in the USA is due to improved care and survival among high-risk groups.

True increase in incidence of CKD

It is also possible that the increased incidence of ESRD reflects increases in the underlying prevalence of CKD. There are potential reasons for more CKD to occur, but these are somewhat speculative. The incidence of type 2 diabetes mellitus has doubled from the 1970s to the 1990s, according to the Framingham study [77]. The availability of nonsteroidal anti-inflammatory drugs without prescription has likely increased their widespread use and the potential for nephrotoxic injury. Greater intensity of medical care may have led to greater exposure to potentially nephrotoxic agents, such as antibiotics and chemotherapeutic agents. Specifically, the growth in nonrenal organ transplantation has been associated with a substantial incidence of CKD and ESRD [78].

Influence of race on incidence of ESRD

Incidence rates for newly treated ESRD differ markedly by race and ethnic group. Incidence is highest among African Americans and among indigenous populations of North America, Australia, and New Zealand [7,78]. Diabetes as the cause of ESRD is also particularly high in these populations. Low incidence rates are recorded in developing countries, but this may reflect more limited availability of dialysis therapy, rather than less CKD. Japan and the USA have relatively high overall incidence rates. The USA also has a particularly high fraction of incident patients with diabetes as the cause of their kidney failure. It is surprising that incidence rates of RRT and of the fraction with diabetes are substantially lower among Europeans than among white Americans, since the latter are mostly of European descent [7,79]. As ESRD incidence rates continue to rise everywhere, European rates have been similar to those observed in the USA nearly a decade earlier. As the rates of increase gradually level off in the USA, one may speculate that rates in Europe and the USA will eventually become more similar.

Trends in incidence

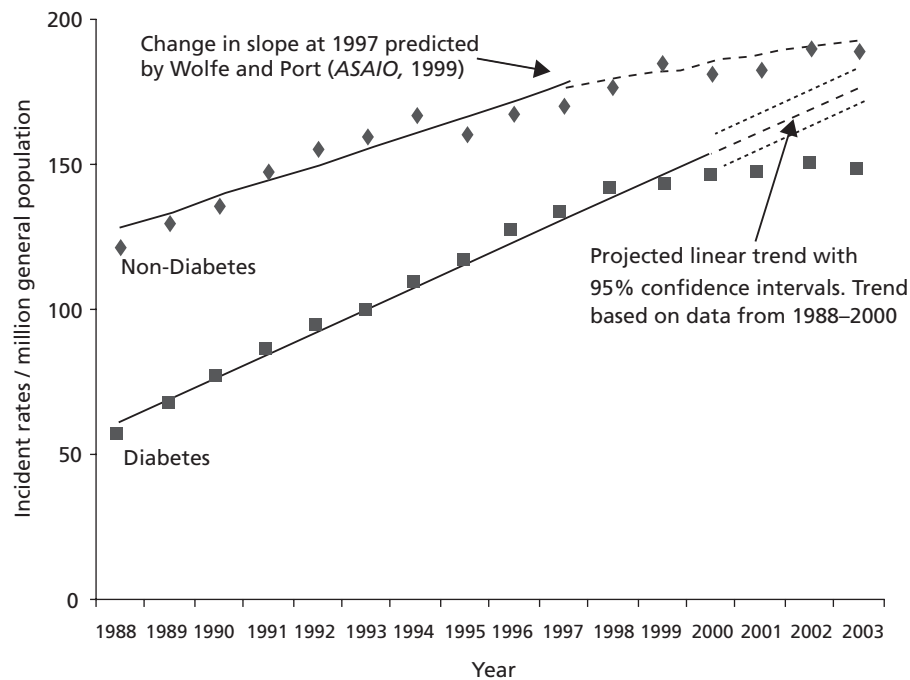
The first indication of a significant slowing of the rate of rise in the incidence of stage 5D CKD was noted by Wolfe and Port for nondiabetic patients, according to USRDS data for the year 1997 [80]. More recent USRDS data confirm the earlier change in trend for nondiabetic patients and show that, for patients with diabetic ESRD, the annual rise in incidence rates has also significantly slowed in more recent years. This is shown in Figure 1.3 by the evidence that, since 2001, annual incidence rates for diabetic patients have been below the projected 95% CI of prior years. USRDS data


Figure 1.3 USRDS data showing trends for non-diabetic and diabetic patients.

Table 1.4 Comorbid conditions for representative samples of prevalent and incident hemodialysis patients by geographic region in 2002–2003 based on DOPPS-II

Comorbid condition	Prevalent cross-section (%)			Incident prevalent cross-section (%)[a]		
	Europe (*n* = 3938)	Japan (*n* = 1805)	US (*n* = 2260)	Europe (*n* = 230)	Japan (*n* = 75)	US (*n* = 162)
CAD	44.3	25.2	61.1	40.8	14.9	60.7
Cancer	12.9	6.0	11.9	18.9	10.4	15.8
Cardiac (other than CAD or CHF)	40.1	31.7	31.1	31.1	17.5	29.7
Cerebrovascular	16.5	14.6	19.1	13.8	14.3	15.4
CHF	24.5	16.4	40.1	24.7	25.6	44.0

Note: Analyses are weighted for dialysis facility size.

also show that the age group of patients that shows essentially no increase in incidence now extends beyond childhood and adolescence to also include young adults [80]. Despite these encouraging trends, it is important to note that there continues to be an increase in the incidence rate overall, even in the USA. The epidemic may have slowed in the USA, but it continues to be a major concern. Recent reports from non-US ESRD registries indicate that similar trends may be emerging throughout the world [81].

Prevalence

Data on the true prevalence of stage 5 CKD are lacking, except for the detailed registry data on those treated with dialysis or transplant. The number of patients undergoing RRT at the end of a year (point prevalence) and the number at any time during a year (period prevalence) are much higher than the number starting RRT during the year (incidence). Prevalence rates have been rising steeply over time. Prevalence of a disease increases if patient survival increases at a constant incidence rate or if the incidence rises at a constant survival rate. Thus, the prevalence rate corresponds to the product of the incidence and survival rates. For RRT, both a rise in the incidence (Figure 1.1) and an improvement in survival have been well-documented in the USA [82]. The issues described above related to incidence also apply to prevalence of treated ESRD, except where modified by differences in survival for certain groups. Because of the lower survival rates for the oldest age groups, their relative rate of rise in prevalence is not as steep as that observed for incidence. Worldwide, more than a million patients were undergoing ESRD therapy at the beginning of the millennium, and this number continues to grow.

Comorbidity in stage 5D CKD patients

Patients starting RRT usually have numerous comorbid conditions. International data from the DOPPS indicate that, at the initiation of hemodialysis, the vast majority of patients carry a diagnosis of hypertension. Heart disease, particularly coronary artery disease and congestive heart failure, lead the list of serious conditions. Other major factors are noted in Table 1.4 both for incident and for a cross-section of prevalent hemodialysis patients. With diabetes as a leading cause of ESRD, it is noteworthy that the prevalence of comorbidities is even higher in diabetic patients than in nondiabetic patients. Compared with patients on dialysis for over 1 year, incident hemodialysis patients (<30 days) are more markedly anemic [82], and almost half of them have phosphorous levels above the guideline level of <5.5 mg/dL (DOPPS unpublished information). Patients starting ESRD with peritoneal dialysis may have a positive selection because greater independence and ability to learn self-care may select healthier patients. On the other hand, difficulties with vascular access or lack of prior nephrologic care may select higher-risk patients to peritoneal dialysis [84]. Transplant recipients have substantially less comorbidity, largely due to patient selection. This has been documented by the finding that the mortality risk for wait-listed transplant candidates on dialysis is substantially lower than for all dialysis patients who are not (yet) wait-listed [85].

Comparisons of treatment modalities for ESRD and for patient groups need to consider differences in case mix (i.e. comorbidities and demographics). This can be accomplished in part through statistical adjustment for those factors that are recorded. The DOPPS and other studies showed that a long list of factors needs to be considered to allow meaningful comparisons between treatments,

patient groups, regions, or centers. Some factors, such as age, cancer, and diabetes, may be considered as givens, whereas others, such as control of anemia, phosphorus, and malnutrition, may be modifiable. Studies of the latter factors, while adjusting for the former, have the potential to identify ways to improve patient care and longevity. This has been the focus of observational studies, such as the DOPPS, and of panels that review evidence to develop practice guidelines, such as the K/DOQI.

Survival after initiation of RRT

Morbidity and mortality are high in late stages of CKD and remain high among those who survive to the start of dialysis therapy. After initiation of dialysis, mortality depends largely on patient characteristics and comorbid conditions, particularly age and diabetes. Comparative studies of treatment modalities have clearly identified that kidney transplantation provides superior outcomes [85], and even more so when from a living donor [86]. Studies of the mortality risk for peritoneal dialysis versus hemodialysis have been somewhat inconclusive, as no large randomized studies of these dialytic treatment options have been performed and patient selection may influence the outcomes. Age may serve as an example for important differences in patient selection; compared with patients treated with hemodialysis, those treated with peritoneal dialysis are on average younger in the USA and older in Italy [87]. Thus, selection practice may explain some of the conflicting comparative survival results of peritoneal dialysis versus hemodialysis from different countries. In the USA, peritoneal dialysis appears to be associated with lower mortality risk in the first 1 or 2 years of dialysis, followed by a higher mortality risk. This early benefit of peritoneal dialysis, particularly among nondiabetic patients, may be related to greater preservation of residual kidney function with peritoneal dialysis [88]. These issues are reviewed in detail in the chapters in part 6 (hemodialysis) and in part 7 (peritoneal dialysis) of this textbook.

Differences in ESRD patient survival for Europe, Japan, and the USA have been found to be based largely on registry data, after adjusting for age and diabetes [89]. Subsequent study of hemodialysis patients, based on the DOPPS, confirmed these significant differences, albeit of a lesser magnitude, when allowing for greater adjustments for case mix and achieving better death ascertainment [90]. A more recent analysis of the DOPPS II data indicated that the mortality difference between the USA and Europe was confirmed but suggested that it could be largely explained by differences in vascular access [91].

Further studies of hemodialysis patients have indicated that several treatment factors are associated with mortality risk. The DOPPS pointed to a large number of factors that may be modifiable. Specifically, significantly lower mortality risk was associated with less catheter use and greater arteriovenous fistula use [92] as well as greater compliance with guidelines for Kt/V, hemoglobin, albumin, phosphorus, and calcium and avoiding large interdialytic fluid weight gains [93]. Additionally, the DOPPS analyses suggest

that better quality of life indicators [94], less depression [95], and better nutrition [96] are strongly associated with longer survival.

The mortality risk has been shown to be relatively high in the early phase after initiation of dialysis. According to the DOPPS, this risk is elevated for the first 4 months and then appears to level off [97]. Among survivors to subsequent years, the mortality risk appears to show a gradual increasing trend by the fifth year compared with the second year [98].

Among causes of death, those related to atherosclerotic heart disease and congestive heart failure are dominant. Infection deaths are strongly associated with catheter use for vascular access. Withdrawal from dialysis precedes death in about 20% of deaths in the USA, about half of them due to failure to thrive and half following acute complications [99]. Withdrawal from dialysis is practiced differently in different countries; for example, much lower rates have been reported in Japan and Italy and much higher rates have been reported in the USA [100].

Hospitalization may serve as a proxy for morbidity. On average, dialysis patients are hospitalized nearly twice yearly [7]. Modifiable factors associated with higher case mix-adjusted hospital admissions include more severe anemia and hyperphosphatemia [83,101]. Cardiac problems account for most admissions, and these same laboratory abnormalities are associated more prominently with cardiac admissions. Catheter use for vascular access is strongly associated with greater risks of hospitalization for infections [102].

Dialysis therapy is successful overall in prolonging life. However, survival of patients on dialysis is similar to survival of patients with serious malignancies, such as colon or prostate cancer [103]. A greater focus on modifiable practices may influence better outcomes. A recent study strongly suggested a causal relationship between practice and outcomes by showing that dialysis facilities that improved their compliance with guidelines for dialysis dose and anemia control had improvements in their patients' survival during the same time period compared with those with little change in treatment, where outcomes did not improve [82]. Transplantation clearly provides a better quality of life [104] and longer survival than dialysis in virtually all patient groups [85].

[2]Wake Forest University School of Medicine, Winston-Salem, USA

Definition of surveillance

The US Centers for Disease Control and Prevention (CDC) defines surveillance as "the ongoing, systematic collection, analysis, interpretation, and dissemination of data regarding a health-related event for use in public health action to reduce morbidity and mortality and to improve health" [1]. Data obtained through surveillance may be used for public health action, program planning and evaluation, measuring the burden of disease in specified populations, monitoring the quality of care patients receive, and evaluating trends in outcomes of care [1–4].

Chronic kidney disease (CKD) patients have a unique set of medical comorbidities that can affect morbidity and mortality rates, including anemia, renal osteodystrophy, and blood pressure. In addition, several process measures, such as dose of dialysis, type of vascular access, and markers of nutritional status, are associated with morbidity and mortality. Data from a number of surveillance systems have demonstrated that there is marked variation in the care of patients with CKD. This variation in care offers opportunities for the improvement in the care of patients, and surveillance systems provide an excellent mechanism to identify these variations in care [5–7]. In this chapter, we describe several sentinel surveillance systems in place for these medically complex patients, including governmental systems, such as the US Renal Data System (USRDS) and the End-Stage Renal Disease Clinical Performance Measures (ESRD-CPM) Project Database in the USA, and private systems, such as the Dialysis Outcomes and Practice Patterns Study (DOPPS) and the National Kidney Foundation (NKF) Kidney Early Evaluation Program (KEEP).

US ESRD surveillance systems

There are two national surveillance systems in the USA for patients with ESRD. These are the USRDS and the ESRD-CPM Project Database.

USRDS

The USRDS, a national registry of ESRD patients in the USA, was created in 1988 with funding from the National Institute of Diabetes and Digestive and Kidney Diseases. Patient-level data are supplied by the Centers for Medicare & Medicaid Services (CMS), the Organ Procurement and Transplant Network (OPTN), and proprietary databases. Until 2002, when their program was terminated, the CDC also provided the USRDS with facility-level data on reuse practices, water treatment, antibiotic use, hepatitis levels, and rates of human immunodeficiency virus infection and AIDS. Data from these sources have been integrated and compiled in a format suitable for biomedical and economic research analyses.

From the USRDS, an Annual Data Report is produced each year that provides information on the characterization of the total kidney disease patient population and the distribution of patients by sociodemographic characteristics across treatment modalities, the incidence and prevalence of ESRD, hospitalization, transplantation, and mortality rates, and economic analyses.

The USRDS database (more information may be obtained at http://www.usrds.org) contains the following information:
• Demographic, diagnosis, and treatment history for all Medicare beneficiaries with ESRD
• Medicare enrollment and entitlement data, including historical information on Medicare secondary payor status and employee group health plan status

- CMS paid claims records
- CMS Standard Information Management System data maintained by the ESRD Networks and used for patient tracking
- CMS ESRD Annual Facility Survey data
- Dialysis facility ownership status
- CMS ESRD CPM data
- CMS minimum data set to determine which ESRD beneficiaries are nursing home residents
- Medicare 5% enrollment and utilization data, used to estimate numbers of persons with CKD, diabetes, and/or heart disease in the general Medicare population
- OPTN wait list information, transplant events, and posttransplant follow-up
- MEDSTAT Marketscan databases
- CDC surveillance data (historical; data collection was terminated in 2002).

Researchers interested in obtaining data from the USRDS may complete a study request form online, following the processes outlined on the USRDS website (http://www.usrds.org/request.asp).

The ESRD-CPM Project Database

CMS's Health Care Quality Improvement Program is a national surveillance system designed to monitor the quality of care provided to beneficiaries. Since 1994, CMS, in collaboration with the 18 ESRD Networks (regional organizations contracted by CMS to perform quality oversight activities to ensure the appropriateness of services and protection for dialysis patients), has conducted an annual data collection to assess the quality of care of US dialysis patients. The data collection effort was known as the ESRD Core Indicators Project from 1994 to 1999. In response to the Balanced Budget Act of 1997, CMS sought the broad participation of the nephrology community in the development of CPMs based on NKF's Dialysis Outcome Quality Initiative (DOQI) clinical practice guidelines [8–11]. In 1999, the ESRD Core Indicators Project was merged with the ESRD-CPM development effort. Since 1999, the ESRD-CPM Project has collected quality-of-care information in the areas of anemia management, hemodialysis adequacy, peritoneal dialysis adequacy, and vascular access for hemodialysis patients. Although not an official CPM, information is also collected on serum albumin. (Reports and data collection forms may be found at http://www.cms.hhs.gov/CPMProject.)

Annually, each ESRD Network validates the census of ESRD patients within their geographic region. The following groups of patients have been included in the project:

- A nationally representative 5% sample of adult (≥ or 18 years or older) in-center hemodialysis patients, stratified by the 18 ESRD Networks (1994 to present)
- A nationally representative 5% sample of adult peritoneal dialysis patients (1995 to present)
- The identified universe of pediatric in-center hemodialysis patients, ages 12 to under 18 years (2000–2001)
- The identified universe of pediatric in-center hemodialysis patients, ages 0 to under 18 years (2002 to present)

- The identified universe of pediatric peritoneal dialysis patients, ages 0 to under 18 years (2005 to present).

Data are collected on in-center hemodialysis patients from October to December of the year prior to the study year (i.e. October–December 2004 for the 2005 study year) and for the peritoneal dialysis patients from October of the year prior to the study year to March of the study year (i.e. October 2004–March 2005 for the 2005 study year). The data are aggregated, analyzed, and reported annually in the ESRD-CPM Annual Report. Every facility in the country receives the Annual Report and is able to compare their performance against regional and national findings for their adult hemodialysis patients. For adult peritoneal dialysis patients and for all pediatric patients (hemodialysis and peritoneal dialysis patients), national comparison findings are provided.

ESRD Network and treatment center quality improvement activities

A primary function of the ESRD surveillance system is to promote practice-based quality improvement activities designed to remedy less-than-adequate care [5]. These activities facilitate the translation of information about facility-specific, guideline-based performance measures into activities to improve care. Although each Network designs its own intervention activities, these interventions are typically directed at treatment centers needing improvement, rather than the system of treatment centers, and include dissemination of relevant guidelines (national, Network, and facility feedback reports on quality of care; distribution of management algorithms; workshops on methods to improve the quality of care in the treatment center) and continued supervision of poorly performing treatment centers [6]. Network-specific interventions that were subsequently found to be independently associated with an increased rate of improvement in care included workshop participation and continuing Network supervision of facilities selected for intervention [12]. Additional data suggest that changes in care documented by this surveillance system were associated with improved survival among ESRD patients [13].

Improvement has been noted in the areas of hemodialysis adequacy and in anemia management for adult hemodialysis and peritoneal dialysis patients. The percentage of in-center hemodialysis patients with a mean single-pool Kt/V of 1.2 increased from 74% in late 1996 to 91% in late 2004 (Figure 2.1). From 1997 to 2004, the percentage of adult in-center hemodialysis patients with a mean hemoglobin of 11 g/dL increased from 43% to 83%; for adult peritoneal dialysis patients, the increase was from 55% to 82% (Figure 2.2). Similar improvement has been noted for pediatric in-center hemodialysis patients. The percentage of pediatric patients with a mean single-pool Kt/V of 1.2 increased from 87% in late 2001 to 89% in late 2004. Sixty-two percent of pediatric patients had a mean hemoglobin of 11 g/dL in late 2001 compared with 67% in late 2004.

The NKF's Kidney Disease Outcomes Quality Initiative (K/DOQI) clinical practice guidelines for vascular access in 2001
Figure 2.1 Percentage of adult hemodialysis patients in the USA with mean single-pool Kt/V of ≥1.2, 1996–2004. Data are from the ESRD-CPM Project.

recommended that primary arteriovenous (AV) fistulae be constructed in at least 50% of all new kidney failure patients and that 40% of prevalent patients have a native AV fistula [14]. Trend data from the ESRD-CPM Project indicate only modest improvement toward attaining these goals. For the last quarter of 2004, 37% of incident and 39% of prevalent adult in-center hemodialysis patients were dialyzed with an AV fistula as their access (Figure 2.3).

Thus far, there have been 52 publications and 123 abstracts describing findings from the ESRD-CPM Project data. One of the

goals of *Healthy People 2010* [15] is to eliminate disparity for all groups. Data from the ESRD-CPM Project have been examined to determine whether disparity exists for groups of ESRD patients in regard to both processes of care and outcomes, such as subsequent hospitalization, transplantation, and mortality [16–20]. Other analyses linking the ESRD-CPM Project data with CMS administrative and claims data have examined the association of intermediate outcomes with hospitalization and mortality [7,21–24].

Other national ESRD surveillance systems

A number of other national or international registries for ESRD patients have been developed by either governmental or private agencies. The defining characteristic of these registries is that they have been voluntary and capture a variable fraction of the ESRD population. Some of the larger registries are presented below. The reader is referred to the websites of these organizations for additional information.

European Renal Association–European Dialysis and Transplant Association Registry

The European Renal Association–European Dialysis and Transplant Association (ERA-EDTA) Registry collects data on renal replacement therapy (RRT) via the national and regional renal registries in Europe. The 2003 annual report included information based on 55 registries from 27 countries. Section A of this report contains data on incidence and prevalence from 32 national and regional registries from 12 countries whose individual patient data are included in the ERA-EDTA Registry database (shown in dark gray in Figure 2.4) as well as data on patient survival, graft survival, and expected remaining lifetimes. Section B of the report provides aggregated data from 24 national and regional registries from 17 countries that were obtained via individual patient data, center questionnaire data, or information from health authorities (shown in light gray in Figure 2.4). Data in Section B are not included in the ERA-EDTA Registry database. These registries complete the tables themselves and return them to the ERA-EDTA Registry office for inclusion in the annual report(http://www.era-edta-reg.org/index.jsp) [25].

Canadian Organ Replacement Register

The Canadian Organ Replacement Register (CORR) is the national information system on renal and extrarenal organ failure and transplantation in Canada. The first Renal Failure Register was started in 1972. CORR collects data from hospital dialysis programs, regional transplant programs, organ procurement organizations, and kidney dialysis services offered at independent health facilities. The registry includes information on both renal and extrarenal transplantation. The most recent annual report provides data for a 10-year period (http://secure.cihi.ca/cihiweb/dispPage.jsp?cw_page=AR_5_E) [26].

Australia and New Zealand Dialysis and Transplant Registry

The Australia and New Zealand Dialysis and Transplant Registry (ANZDATA) is an organization set up by Kidney Health Australia and the Australia and New Zealand Society of Nephrology to monitor dialysis and transplant treatments. ANZDATA is funded by the Australian and New Zealand governments and Kidney Health Australia. All kidney specialists throughout Australia and New Zealand report patient information every 12 months to ANZDATA. The most recent annual report includes data from the calendar year 2004 (http://www.anzdata.org.au/) [27].

Other ESRD surveillance systems

DOPPS

DOPPS is a prospective, observational study that was initiated in 1996 (DOPPS I) with data from 308 hemodialysis units in seven countries (17,000 patients), including 145 facilities from the USA, followed by additional data from 62 facilities from Japan and 101 facilities from five European countries (France, Germany, Italy, Spain, and the UK). More than 12,800 patients were added in DOPPS II from 322 hemodialysis units from the seven DOPPS I countries as well as Australia, Belgium, Canada, New Zealand, and Sweden (Figure 2.5). DOPPS III was initiated in 2005, and the data collection effort includes parameters that allow for a better
Figure 2.4 Countries participating in the ERA-EDTA Registry. The 12 countries in dark grey provide individual patient data. The 17 countries in medium grey provide aggregated patient data from 24 national and regional registries [25].

understanding on how some dialysis facilities accomplish better adherence and achievement of K/DOQI targets than others.

For DOPPS I and II, the study design focused on five key elements: 1) within each country, random selection of dialysis units stratified by type of facility and geographic region, with facility sampling proportional to size within each stratum; 2) collection of demographic data, diabetes as the cause of ESRD, and mortality data for all chronic maintenance hemodialysis patients in each study dialysis unit (cumulative hemodialysis census); 3) collection of additional detailed patient data from a random selection of 20–40 patients within each dialysis unit at study entry (medical questionnaire) and at 4-month intervals throughout the study (interval summary); 4) collection of kidney disease quality-of-life information from this random sample as well as other data regarding a patient's medical care as indicated in a questionnaire completed by the patient at study entry and annually thereafter (patient questionnaire); and 5) collection of detailed facility practice information, assessed from patient data and from questionnaires completed annually by the dialysis unit's medical director (medical directors survey) and by the unit's nurse manager or designee

(unit practices survey) [28]. In DOPPS II, data were collected for both a cross-section of chronic hemodialysis patients and sequentially on 5354 new patients within 30 days of initiating dialysis. The latter cohort allowed for the determination of the practices, characteristics, and outcomes of patients since the initiation of chronic hemodialysis therapy.

Facilities chosen for participation in DOPPS were required to treat more than 25 hemodialysis patients to ensure that the facility was of sufficient size to obtain accurate estimates of facility practices and outcomes. Patients from each dialysis unit were chosen randomly. In addition, facilities were chosen so that there was a representative sample of dialysis units in each country. The implementation of these criteria allowed for the investigators to provide nationally representative results for in-center hemodialysis therapy.

The data collected in DOPPS II provide detailed information on sampled patients, including patient demographics and more than 70 other variables, including medical comorbidity, socioeconomic status, insurance coverage, laboratory values, medication use, hospitalization and outpatient events, vascular access use and

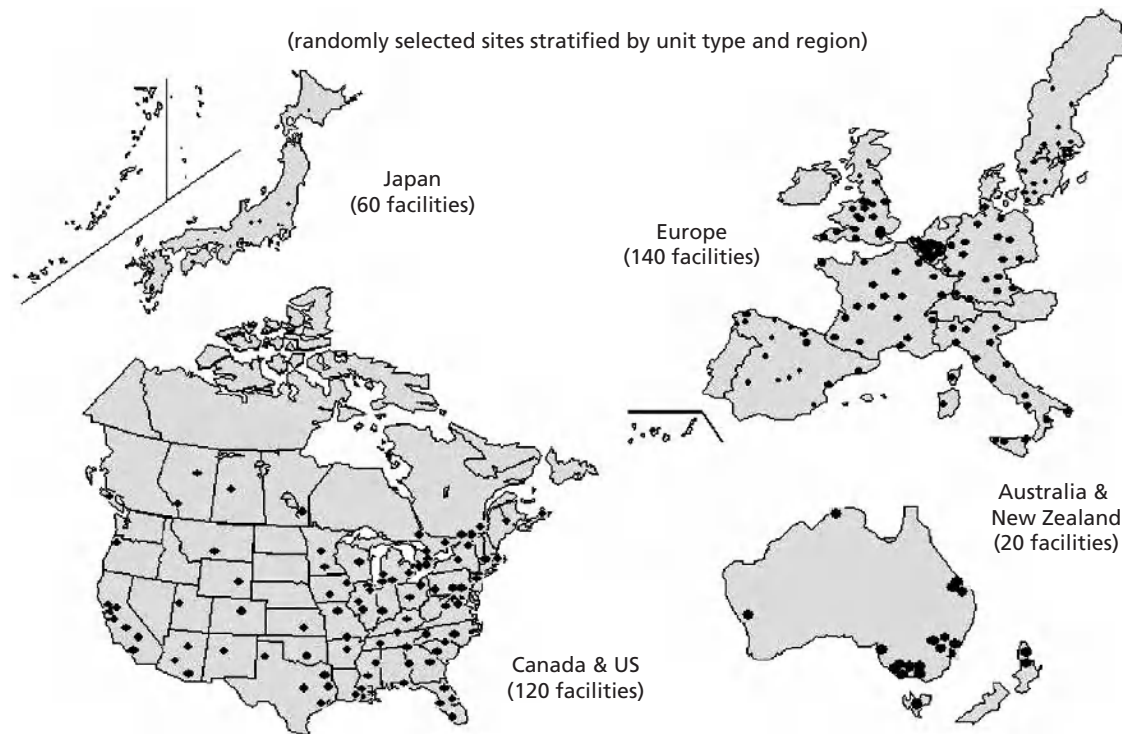
(randomly selected sites stratified by unit type and region)


Figure 2.5 Countries participating in the DOPPS [28].

vascular access procedures, dialysis prescription, delivered dialysis dose, residual kidney function, nutritional measures, aspects of medical care before ESRD, kidney transplant wait-listing, patient quality of life, physician-diagnosed and patient-reported measures of depression, date and cause(s) of death for patients who died during the study, and transfer to or from peritoneal dialysis or kidney transplantation.

This extensive database allows DOPPS investigators to analyze information on patient demographics, comorbidities, laboratory measures, and practice patterns for characterization of these data elements, as well as to determine cross-sectional associations and prospective associations with outcomes of interest. The database includes mortality data for more than 100,000 patients and detailed longitudinal data from almost 30,000 hemodialysis patients. This large database also allows for analyses of practice pattern variations in hemodialysis patients. Thus far, more than 70 publications have described findings from the DOPPS data [29].

Surveillance systems for CKD stages 1–4

There are few surveillance systems for stage 1–4 CKD that are available in the public domain. Difficulties with identifying patients with CKD have hampered efforts to develop surveillance systems. The October 2005 ninth revision of the *International Classification of Disease* (ICD-9) coding now includes specific codes for each of the five stages of CKD (ICD-9 codes 585.1–585.5). In addition, legislation in both British Columbia (Canada) and New Jersey (USA) now mandate that laboratories provide an estimate of glomeru-

lar filtration rate (GFR) based on serum creatinine levels. More widespread use of these specific CKD codes, in conjunction with more widespread use of automated estimates of GFR based on serum creatinine levels, will facilitate the development of additional surveillance systems. In the absence of these systems, mass screenings have substituted for surveillance systems in identifying patients with CKD.

KEEP

In the USA, the NKF developed the KEEP program to 1) evaluate the feasibility of detecting large numbers of previously unidentified persons with CKD or at high risk for CKD in communities with at-risk populations, and 2) determine the prevalence of selected risk factors and level of kidney function within that group.

The pilot study, KEEP 1, was conducted from 1997 to 1999 in 21 cities, and data from this study demonstrated that 71.4% of 889 individuals screened had at least one abnormal test value [30]. Since then, KEEP screening programs conducted by NKF affiliates had enrolled more than 37,000 individuals at the time of publication of the 3rd Annual Data Report from KEEP in 2005 [31]. Screenings are advertised through local media (radio and television stations and newspapers), announcements by clergy from the pulpit, flyers, posters, and information provided to dialysis patients, with an emphasis on minority communities [32]. Screening sites include churches, hospitals, health centers, schools, community centers, and dialysis units.

Consenting individuals completed a screening questionnaire, a self-report instrument that collects information regarding socio-demographic status (e.g. race and ethnicity, age, education), personal and family health history, and life-style behavior (e.g. smoking). Those persons with hypertension or diabetes or a first-order relative with hypertension, diabetes, or kidney disease were screened for kidney disease risk factors. Blood pressure, blood glucose, serum creatinine, hemoglobin, microalbuminuria, hematuria, pyuria, body mass index, and estimated GFR (eGFR) were obtained for these eligible persons. Those persons who did not meet eligibility criteria were given educational material and encouraged to maintain a healthy life-style [30].

At the completion of data collection, participants were given a copy of their test results that had been reviewed by a KEEP physician, educational materials and, if needed, a list of health care providers who could provide follow-up care. Approximately 2 months after the screening, participants who had been encouraged to see their physician were contacted to determine whether follow-up had occurred and whether abnormal test results had been corroborated.

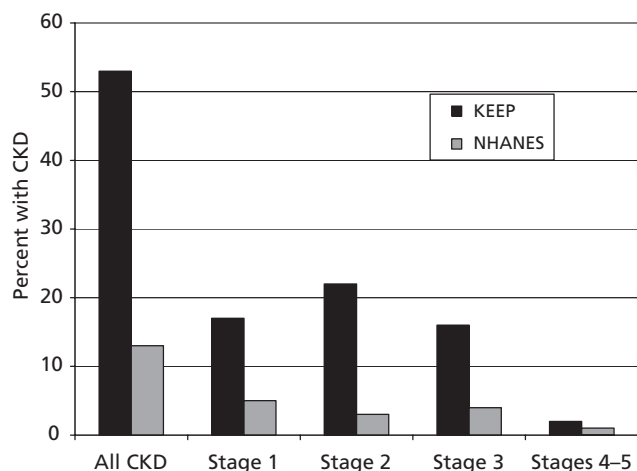
Although less than 10% of KEEP participants reported that they had kidney disease or kidney stones, more than 50% of participants had CKD as defined by NKF K/DOQI guidelines, compared with 13% of National Health and Nutrition Survey (NHANES) participants. CKD of stages 1, 2, and 3 was found in 16%, 22%, and 15% of KEEP participants, respectively, compared with <5% in each stage for NHANES participants (Figure 2.6). Among those patients with CKD (Figure 2.7), stage 2 CKD was noted in 41% of KEEP participants, with a range of 39–42% among different race and ethnic groups. Stage 3 CKD was found in 42% of the White population compared with 17–21% in other racial and ethnic groups [31].


Figure 2.6 CKD in KEEP and NHANES participants by CKD stage. CKD stages 1, 2, and 3 were found in 16%, 22%, and 15% of KEEP participants, respectively; occurrence of each stage was 5% or less in the NHANES population. Adapted from KEEP 2005 Annual Report, Figure 5.3.

Fifty-seven percent of KEEP participants returned the study follow-up form. Of these 14,441 participants, a total of 8244 saw a doctor, of which 51% were seen for hypertension and 48% for abnormal urine testing. A total of 3449 participants learned that they had anemia, 1605 participants learned that they had hypertension, and 741 participants learned that they had diabetes mellitus; all were started on a medical intervention [31].

The KEEP study demonstrates the high yield of a high-risk screening program in detecting previously unknown disease as well as the benefit of a screening program in tracking individuals with known clinical conditions to evaluate the control and progress of management of hypertension and diabetes, conditions that are well-recognized as risk factors for CKD.

Province of British Columbia

The British Columbia Renal Agency (BCPRA) and the British Columbia Ministry of Health Services have jointly developed a patient register to help identify and track the quality of care and status of patients at all stages of CKD, including at-risk populations. The register is supported by existing Ministry administrative data and the BCPRA's Patient Registration and Outcome Management Information System. This registry includes data from more than 30 nephrology (CKD and ESRD) units in British Columbia to provide information on individual patient management, nephrology unit management, continuous quality improvement and research, and outcomes-based planning.

As of October 2002, more than 2000 dialysis patients and 2600 CKD patients were registered in this database, which captures data on all patients seen by nephrologists. Once registered, patients are tracked over their entire clinical course; thus complete data, including medication lists, dialysis start dates, and death, are accessible. Demographic variables such as age, gender, and diagnosis of kidney disease are entered into the database as part of essential information. Diabetic status (either insulin-requiring or non-insulin-requiring) is entered as a comorbid condition, and the level of kidney function at the time of registration is also entered. Laboratory values including hemoglobin, transferrin saturation, and serum chemistries are all either manually entered or automatically uploaded from laboratory systems in the province. Changes in treatment status (from CKD to dialysis or transplant or death) are captured within the database, as it forms the basis of funding of kidney services. Any patient requiring erythropoietin therapy must have hemoglobin and transferrin saturation values entered into the database before the prescription for the drug can be processed. Other prescribed medications are also entered into the database [33]. Additional information about the British Columbia Renal Agency may be found on their website (http://www.bcrenalagency.ca/).

Okinawa (Japan) Screening Program

The Okinawa Screening program is a unique demonstration of a longitudinal cohort study of a community-based screening program that was first conducted in 1983. The study has provided

KEEP

NHANES 1999–2002
Figure 2.7 CKD in KEEP and NHANES participants by CKD stage and race and ethnicity. The percentage of KEEP participants with stage 2 CKD was similar across race and ethnicity groups, at 39–42%. Stage 3 CKD, however, was found in 42% of the white population but only 17–21% of other racial and ethnic groups. From KEEP 2005 Annual Report, Figure 3.35.

insights on the natural history of risk factors and longitudinal outcomes of the thousands of individuals who participated in the screening program. Over 10% of the adult population in Okinawa participated in the 1983 screening survey [34]. This program identified several key findings, including the following: 1) the strong association between dipstick proteinuria at baseline and increased risk of ESRD after 17 years of follow-up, even at levels of proteinuria of 1+ (odds ratio of 1.93 for ESRD) [34]; 2) a continuous increase in risk of ESRD with increasing body mass index, primarily in men [35]; 3) uric acid as an independent risk factor for ESRD [36] and other.

National Kidney Foundation of Singapore Screening Program

Similarly, the National Kidney Foundation of Singapore Screening Program is unique in its goal of developing a comprehensive multilevel strategy for the prevention of ESRD in the population. The design of the Singapore model includes 1) screening populations

at risk for CKD, 2) monitoring of standards of care for chronic diseases associated with CKD, 3) institution of a disease management program to facilitate management of patients with diabetes and hypertension, which are among the leading causes of ESRD in the country, and 4) longitudinal tracking of individuals who participated in the screening program [37]. Given Singapore's multi-ethnic population and high burden of chronic diseases that are associated with CKD, the Singapore program suggests that differences in risk for kidney disease exist across racial and ethnic subgroups. In particular, the program demonstrates that 1) the relationship between body mass index and proteinuria in this multi-ethnic population is J-shaped, 2) the association between blood pressure and proteinuria is continuous and begins to occur even at levels considered within the normal range for Western populations, 3) a family history of kidney disease is a risk factor for proteinuria, and 4) among its pediatric population, a low body weight was found to be predictive of proteinuria [37,38].

Altogether, these population-based studies suggest the possible use of a surveillance and screening program, not merely in identifying persons at increased risk for CKD but also to determine unique population-specific risk factors that may be modifiable. Longitudinal analyses of these populations should be performed in order to evaluate whether interventions aimed at these risk factors are effective in reducing the burden of CKD in the population.

Practice-based screening and quality management for CKD

Practice-based screening for CKD is a relatively undeveloped field. This is due to the difficulties in identifying patients with CKD based on ICD-9 codes (as discussed above) and the slow acceptance of the provision of automated estimates of GFR by local and national laboratories.

Quality management of both dialysis and nondialysis CKD patients has been facilitated by guideline development in key areas of CKD. In 1995, the NKF launched the DOQI to develop clinical practice guidelines for dialysis patients and health care providers. The goal of this project was to improve the quality of care delivered to all patients with kidney disease. The first set of guidelines for dialysis patients, in the areas of hemodialysis, peritoneal dialysis, anemia management, and vascular access, was published in 1997 [8–11]. These guidelines were updated in 2001 [14,39–41] and again in 2006 [42–45].

In 1999, the NKF developed guidelines for CKD patients who were not on dialysis. The rationale for this change was that early intervention and appropriate measures can prevent the loss of kidney function in some patients, slow the progression of the disease in many other patients, and ameliorate organ dysfunction and comorbid conditions in those patients who progress to kidney failure and ESRD. To reflect these expanded goals, the reference to "dialysis" in DOQI was changed to "disease," and the new initiative was termed the Kidney Disease Outcomes Quality Initiative (K/DOQI). The first of these K/DOQI guidelines, on the evalua-

tion, classification, and stratification of CKD, was released in 2002 [46].

CKD is defined in five stages, based on the estimated level of kidney function and the presence of other signs of kidney disease, such as proteinuria, as detailed in chapter 1 of this text. The GFR is estimated from equations using serum creatinine, patient demographics, and in some cases, other serum and laboratory data. This classification of CKD provides a framework for additional guidelines in CKD, where evaluation and management are linked to the level of kidney function. There are now K/DOQI guidelines for anemia (in 2006 for dialysis and nondialysis patients) [42], nutrition [47], hypertension [48], hyperlipidemia [49], bone and mineral metabolism [50], and cardiovascular disease [51]. Guidelines for the care of the CKD patient with diabetes mellitus published in 2007.

The process of guideline development follows several principles. First, guideline development is scientifically rigorous and based on a critical appraisal of the available evidence. This process is carried out by both an evidence review team and the workgroup members. Second, participants involved in developing the guidelines are from multiple disciplines. These participants include not only nephrologists, but also other internists, surgeons, nurses, dietitians, social workers, and other content experts as deemed appropriate by the workgroup. Third, the workgroups charged with developing the guidelines are the final authority on their content and evidence rating. The guidelines are evidence based whenever possible, and the rationale and evidentiary basis of each guideline are explicit. Each of the draft guidelines undergoes a peer review process where nephrologists and other content experts worldwide are asked to provide comments that are reviewed by the workgroup. Modifications to the guidelines are made by the workgroup prior to the publication of the guidelines.

These guidelines have been widely adopted. They were used as a template for national clinical performance measures in the USA that were developed and implemented by the Health Care Financing Administration (now named the Centers for Medicare & Medicaid Services). They have been translated into more than a dozen languages, and selected components of these guidelines have been adopted in various countries across the world. The new classification of CKD into five stages has been widely adopted in research and was adopted in a revision of the ICD-9 codes released in October 2005. Implementation tools for each of the guidelines are available from Kidney Learning System (http://www.kidney.org/professionals/KLS/). This NKF organization develops implementation tools by using information provided by workgroup members, other content experts, and Kidney Learning System staff.

Other guideline development organizations

A number of other national and international organizations have developed guidelines, and many of these guidelines are summarized at the website http://www.kdigo.org/welcome.htm. Although in general these guideline statements are similar to those developed by K/DOQI, there are differences not only in the targets

recommended for particular parameters but also in the evidence review and evidence-grading processes. It thus became evident that there would be benefits both in terms of a standard approach to guideline development worldwide; also, the potential duplication of effort among these many organizations led to the formation of an international guideline development group called Kidney Disease Improving Global Outcomes, or KDIGO. The stated goal of KDIGO, launched in 2003, is "to improve the care and outcomes of kidney disease patients worldwide through promoting coordination, collaboration and integration of initiatives to develop and implement clinical practice guidelines" [52]. The KDIGO website has a list of guideline statements from a number of national and international organizations that allows for the direct comparison of recommended targets among different guidelines.

Summary

A number of surveillance systems have been developed for patients with CKD. ESRD surveillance systems are well-established in many countries, and documentation of improvement in intermediate outcomes over time has been demonstrated. CKD surveillance systems are of more recent origin and are not prevalent in most developed countries. Additional efforts are needed to expand CKD surveillance programs. The development of guidelines in a number of areas of CKD should help to facilitate the choice of intermediate outcomes for these surveillance systems.

3 Risk Factors for Progression of Chronic Kidney Disease

Eberhard Ritz,[1] Danilo Fliser,[2] & Marcin Adamczak[3]

Evidence for progression of primary and secondary chronic kidney diseases

Etiology as a determinant of progression

In experimental studies, progressive loss of kidney function is consistently observed in many different animal models of chronic kidney diseases (CKD) [1]. In contrast, observational clinical data and available data from the recruitment phase prior to enrollment in controlled prospective studies have revealed that a considerable proportion of patients with CKD progress at a slow rate, and we know from our clinical observations that a substantial proportion of patients do not progress at all. One of the factors determining the rate of progression (i.e. the natural course of CKD) is the underlying renal disease. For example, progression is rather slow in membranous glomerulonephritis (GN) and immunoglobulin A (IgA) GN and more rapid in focal segmental glomerulosclerosis, autosomal-dominant polycystic kidney disease (ADPKD), and diabetic nephropathy, whereas in malignant hypertension and scleroderma fulminant progression is usually observed in the short term. Because controlled clinical trials with placebo treatment are ethically no longer permissible in patients with progressive CKD, historical data on spontaneous rates of progression are still of considerable interest [2–10].

Risk factors of progression

It is clinically useful to distinguish between modifiable and non-modifiable risk factors for progression of CKD (Table 3.1). Some modifiable risk factors of progression can be eliminated simply by avoidance, for example, smoking, nonsteroidal anti-inflammatory drugs (NSAIDs), or herbal medicines, whereas elimination of others, such as elevated blood pressure and proteinuria, necessitates aggressive treatment and strict control. The list of modifiable risk factors also includes recently discovered potential risk factors, such

as the endogenous nitric synthase inhibitor asymmetric dimethylarginine [11,12]. In diabetic patients glycemic control (as reflected by the level of HbA_{1C}) determines long-term cardiovascular (CV) risk [13,14] and also renal risk, particularly in the first years of the disease.

Although there is no controlled prospective evidence available on this point, it is plausible to assume that the earlier intervention starts, the greater the effect on retardation of progression. In support of this view are the observations in several studies that low baseline glomerular filtration rate (GFR) is a strong predictor of progression and the comparison of outcomes for diabetic nephropathy, hypertension, and renin–angiotensin–aldosterone system (RAAS) blockade between studies with early [15] versus late [16,17] interventions.

Confounding effect of cardiovascular prognosis on progression

It is of note that even in early diabetic or nondiabetic renal disease, the risk of death (mainly from cardiovascular causes) is greater than the risk of progress to end-stage renal disease (ESRD) [18] (Table 3.2), and results from several recent large clinical trials have revealed that even incipient renal failure is an important independent CV risk factor [19–28].

Assessment of CKD progression

Measurement of GFR

GFR can be assessed using different methods. The gold standard for measurement of true GFR is still inulin clearance, but iohexol, Cr-EDTA, or iothalamate clearances are valuable alternatives. These clearance measurements are cumbersome, however, and too expensive for use in clinical routine or epidemiological studies. Thus, estimates of GFR based on the measurement of serum creatinine are widely accepted, for example, the MDRD or Cockroft-Gault equation, but in the interpretation of literature one has to keep in mind that these estimates of GFR are not very accurate, particularly in the near-normal range [29,30]. Furthermore, the equations

Table 3.1 Some modifiable and nonmodifiable risk factors for progression of CKD.

Risk factor for CKD progression
Modifiable risk factors
Blood pressure
Albuminuria, proteinuria
Obesity, metabolic syndrome
Smoking
Glycemic control in diabetic patients
Use of NSAIDs
Herbal medicine (e.g. Chinese herbs)
Lead
Radiocontrast media
Some antibiotics and antiviral drugs (e.g. amino glycoside antibiotics)
Dyslipidemia?
Nonmodifiable risk factors
Age
Gender
Etiology of renal disease
Family history
Ethnicity

have not been validated for specific populations and ethnicities, for example, the very old, patients with a renal allograft, or African Americans or Asians. A major problem remains, because the results of the MDRD equation depend on the accuracy of serum creatinine measurement, which can vary considerably between laboratories, and this again has to be considered when evaluating the literature. Alternative possibilities are new indicators of GFR, such as serum cystatin C, that are not confounded by muscle mass or tubular transport of creatinine, etc. [29,31].

Quantification of albuminuria and proteinuria

Albuminuria is usually categorized as micro- or macroalbuminuria, but several important questions concerning the measurement of urinary albumin excretion rate have not been resolved: in which sample should albumin be measured, that is, in spot urine (with or without creatinine correction), morning urine, or 24-h urine, and which method should be used for the measurement, that is, immune detection or high-performance liquid chromatography [32].

Despite these unresolved methodological problems albuminuria, as a continuous variable, is an impressively powerful predictor of both renal and cardiovascular outcomes in nondiabetic [33] as well as in diabetic [34] individuals (Table 3.3).

The urinary protein excretion is measured as total urinary protein (Biuret); the upper limit is 150 mg/24 h. Confounders of proteinuria (and also of albuminuria) are physical exercise, fever, and orthostasis (particularly in lordotic young individuals). In patients with CKD proteinuria is an independent treatment target, in addition to blood pressure lowering, to prevent progression, and reduction of proteinuria is predictive for lower rate of progression and renal function (GFR) loss (see below).

Renal resistance index

Studies in kidney transplant recipients have indicated that an increased renal segmental arterial resistance index (RI) measured by Doppler ultrasound is associated with worse renal outcome [35]. In patients with type 2 diabetes mellitus, an increased RI is associated with the presence of established diabetic nephropathy, that is, a higher-grade albumin excretion rate accompanied by reduced creatinine clearance [36,37]. It has been speculated that assessment of RI in patients with CKD is an easy-to-assess indicator of progression [38]. Because biopsy studies are lacking, it is not clear whether a high renal RI in diabetic patients is merely the result of structural changes of renal vessels or changes of the elastic properties of larger vessels (e.g. aortic stiffness) also modify RI. As a result, studies using this index will not be considered in the following discussion of the clinical measures of progression in CKD.

Perspectives

The assessment of GFR is not an optimal index of renal function loss, because the remaining glomeruli compensate by increasing single-nephron GFR so that up to 40% of renal parenchyma may be lost without a change in whole-kidney GFR (Table 3.4). This may explain metabolic abnormalities in patients with primary renal disease compared to healthy controls despite normal or near-normal whole-kidney GFR, for example, elevated asymmetric dimethylarginine levels [39], insulin resistance [40], or dyslipidemia [41]. Thus, there is a need for novel indicators of kidney function, perhaps those assessing processes beyond perfusion and filtration. Moreover, apart from assessing steady-state renal function, there is

Table 3.2 Estimated GFR reductions and relative risks of death and of progression to ESRD.[a]

Patient group GFR (mL/min/1.73 m^2) and CKD stage	No. of patients	% on renal replacement therapy	% Mortality
60–89 without proteinuria	14,202	0.07	14.9
60–89 with proteinuria, CKD stage 2	1741	1.1	19.5
30–59, CKD stage 3	11,278	1.3	24.3
15–29, CKD stage 4	777	19.9	45.7

[a] The risk of death was greater than risk of progression to ESRD during the 5-year observation period of 27,998 patients who had estimated GFRs of less than 90 mL/min/1.73 m^2 (data are from reference 18). CKD stages 2, 3, and 4 are the stages of CKD according to the National Kidney Foundation K/DOQI) criteria.

also a need to monitor the activity of the kidney-specific processes underlying renal damage. Promising approaches are the measurement of podocyte excretion rates, urinary angiotensinogen excretion, and proteomic analysis of the urine [42–44]. Some of the more promising alternatives to GFR are listed in Table 3.4.

Prevention of progression of CKD

Prevention or delay of progression

Measures designed to reduce or prevent chronic kidney injury and the risk factors known to mediate this injury have been shown to reduce progression in controlled studies. However, to date, we do

Table 3.4 Limitations of GFR and potential alternative approaches to assess renal dysfunction beyond GFR.

Limitation or alternative approach
Limitations of GFR
• Whole-kidney GFR does not take into account partial compensation by single-nephron hyperfiltration
• GFR does not capture processes initiating and maintaining progressive loss of renal function
• GFR does not capture injury to tubular cells
Selected examples of parameters beyond GFR
• Podocyte count in urine
• Podocyte protein in urine
• Exosomes in urine
• Proteomic analysis of urine
• Tubular marker proteins in urine

not know whether any of these measures will completely abrogate the risk of progression to the hard end point of ESRD or merely delay its onset, valuable though this might be. If the evolution of the incidence of ESRD in type 1 and recently also type 2 diabetes is any indication, however, the observation of a progressive reduction of the incidence of ESRD in type 1 diabetes and its stabilization in type 2 diabetes is cause for cautious optimism. Recent evidence emerging from experimental models of kidney damage indicates that to a limited extent glomeruli with focal segmental glomerulosclerosis are capable of undergoing self-repair with reversal of glomerulosclerosis, presumably as long as the number of podocytes is not too seriously depleted [45,46]. Additionally, progressive loss of renal function after an episode of acute renal failure, particularly in the elderly, is now recognized as a potential cause for CKD. Thus, optimal management to prevent acute renal failure [47,48], including that from nephrotoxic injury, should reduce the burden of CKD [49]. These conditions and management options are detailed in section 3 of this book. Evidence from observational studies and from controlled clinical trials supports the efficacy of a number of therapeutic interventions that may ameliorate the development and progression of CKD. These measures are summarized in Table 3.5. These are discussed in the context of the CKD burden in populations and are detailed further in section 6 of this book.

Treatment strategies
Blood pressure lowering
In patients with CKD an important unresolved issue is which aspect of blood pressure should be targeted for control. Observational studies and post hoc analyses of intervention trials have documented that systolic blood pressure is more predictive of renal function loss than diastolic blood pressure or pulse pressure (the latter of which is also highly predictive for cardiovascular events) [50,51]. Currently poorly documented in kidney disease patients are the relative roles of casual blood pressure, home blood pressure, ambulatory 24-h blood pressure, night-time blood pressure, or blood pressure variability as predictors of renal outcome. Observational data indicate that, independent of time-averaged 24-h blood pressure, high nocturnal blood pressure is associated with more rapid loss of renal function in nondiabetic [52] and diabetic [53] patients.

Published guidelines propose a target blood pressure of below 130/80 mmHg for patients with CKD and diabetes [54–56]. The prospective controlled evidence for this recommendation is problematic, however. In the Modification of Diet in Renal Disease (MDRD) trial, which examined 840 patients with predominantly nondiabetic kidney disease, a nonsignificant trend was observed for the primary end point of less GFR loss during a mean observation period of 2.2 years in patients randomized to intensified blood pressure control (i.e. a target mean arterial blood pressure of 92 mmHg) compared to those randomized to usual blood pressure control (i.e. a target mean arterial blood pressure of 107 mmHg), or −2.8 versus −3.9 ml/min/1.73 m^2/year in patients with baseline GFR between 25 and 55 mL [57]. Closer inspection of the

Table 3.5 Interventions proposed to halt progression of CKD

Intervention	Strength of evidence[a]	Strength of recommendations[b]	Reference(s)
Blood pressure lowering	A	Is recommended	57–59, 62, 63
Reduction of proteinuria	A	Is recommended	16, 17, 58, 73–76
Blockade of RAAS			
With ACEi or ARB in conventional doses	A	Is recommended	15–17, 74, 88, 158, 159
Dose escalation and/or combination ACEI or ARBs if response unsatisfactory	Indirect	May be considered	91–93
Mineralocorticoid receptor blocker (spironolactone, eplerenone)	Indirect	May be considered[c]	98
Renin inhibitors	No evidence	Cannot yet be recommended	
Cessation of smoking	B	Is recommended	102, 104–107
Weight reduction in obese subjects	Indirect	Is recommended[d]	113, 116–120
Avoidance of NSAIDs and other nephrotoxic drugs	C	Is recommended	160–164
Reduction of salt intake	C	Should be considered	135
Low-protein diet	B	May be considered[c]	57, 141–157

Source: Based on ADA 2005 [158].

[a] Strength level A, randomized controlled clinical trials, may be assigned based on results of a single trial; level B, cohort and case–control studies, post hoc, subgroup analysis, or meta-analysis, prospective observational studies and registries; level C, expert opinion, observational studies, epidemiological findings, safety reporting from large-scale use in practice.

[b] "Is recommended," part of routine care, exception to therapy should be minimized; "Should be considered," majority of patients should receive the intervention; some discretion in application to individual patients should be allowed; "May be considered," individualization of therapy is indicated; "Is not recommended" (or cannot yet be recommended), therapeutic intervention should not be used.

[c] Until safety data are available, considered only if estimated GFR is normal and no hyperkalemia is present.

[d] Note of caution: because of the risk of malnutrition and the potential adverse impact on later outcome of dialysis, this is no longer advisable in advanced kidney failure.

[e] Is recommended particularly if protein intake is very high, as assessed by urinary urea excretion.

data revealed, however, that initially GFR decreased more in the group randomized to intensified blood pressure control (i.e. 3.4 ml/min/1.73 m^2 vs. 1.9 mL/min/1.73 m^2 for 4 months), an effect that was thought to be hemodynamically mediated. The subsequent decline in GFR in the intensified blood pressure control group, however, was less than in the control group. Further post hoc analysis has indicated that the benefit of blood pressure lowering was restricted mainly to patients with proteinuria of >1 g/24 h [58]. Patients with proteinuria of <1 g/24 h were mostly patients with ADPKD; it remains unclear whether they were less responsive to the intervention because of their underlying renal disease rather than because of the absence of significant proteinuria. The evidence from the MDRD study has become more solid with the results of a longer-term observation of these patients for a median observation period of 5.9 years. A significant and persisting, but not progressively widening, difference in the slowing of the decline in GFR has been observed in patients randomized to intensified blood pressure control versus usual care [59].

In contrast to the positive results from the MDRD long-term follow-up study, two large prospective studies, the African American Study of Kidney Disease and Hypertension (AASK) and the REIN 2 study [60,61], have found no significant difference overall between patients randomized to ordinary and lower blood pressure targets. It may not be appropriate, however, to consider all patients with advanced CKD as one homogenous group. In the AASK trial there was a tendency in patients with proteinuria above 300 mg/24 h to have a slower rate of loss of GFR at the lower blood pressure target, and this was most evident in the few patients with proteinuria above 1 g/24 h. This observation raises the issue as to whether one identical blood pressure target is appropriate for all patients with kidney disease irrespective of their rate of protein excretion. Post hoc analyses of two recent major clinical trials in patients with advanced diabetic nephropathy, the Irbesartan Diabetic Nephropathy Trial (IDNT) study [62] and the Reduction of Endpoints in Non-Insulin-Dependent Diabetes Mellitus with the Angiotensin II Antagonist Losartan (RENAAL) study [63], clearly show that at any given level of systolic blood pressure, renal end points, defined as a doubling of serum creatinine or ESRD, were progressively lower with lower achieved seated systolic blood pressure at 12 months (Figure 3.1) However, at systolic blood pressures below 120 mmHg all-cause mortality was higher by a factor of 3. It is unclear whether this higher observed mortality at the lowest treated blood pressures was caused by preexisting cardiac or other diseases or whether it was the result of too-aggressive antihypertensive treatment. This observation is reminiscent of the J-curve phenomenon, specifically, a paradoxical increase of mortality with aggressive lowering of diastolic blood pressure in hypertensive patients in general, presumably because of cardiac events. This finding was recently reiterated in the International Verapamil-Trandolapril Study (INVEST) in patients with known coronary
Figure 3.1 Achieved systolic blood pressure and progression of diabetic nephropathy (A) and all cause mortality (B) in patients with type 2 diabetes. From the IDNT study, post hoc analysis [63].

heart disease [64]. From these observations, it may be prudent not to lower systolic blood pressure below 120 mmHg or diastolic blood pressure below approximately 70 mmHg in kidney disease patients with known coronary heart disease.

Reduction of proteinuria

It has been known for a long time that proteinuria is a predictor of more rapid loss of renal function in patients with CKD [65]. Quite unexpectedly it has also been shown that the change in proteinuria during treatment is a powerful predictor of progression beyond that predicted because of any concomitant change in blood pressure [66,67]. This observation lends support to the hypothesis of

Remuzzi *et al.* [68] that proteinuria is a potent CKD progression promoter. Furthermore, the change in proteinuria predicts not only renal but also cardiovascular events, and this holds true both for patients with frank proteinuria and also in patients with microalbuminuria [69,70]. The conclusion of Khosla and Bakris [71] therefore seems justified, that proteinuria per se is an important therapeutic target apart from and independent of blood pressure. This recommendation has been integrated into the recent National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines [56]. Specifically, the K/DOQI guidelines recommend reduction of proteinuria to less than 1 g/24 h [56], and some authors have even recommended 0.3 g/24 h [72].
Figure 3.2 Progression: effects of current level of systolic blood pressure and current urine protein excretion. From reference 73 with permission of the publisher. Data show the relative risks for patients with a current urine protein excretion of 1.0 g/day or greater (223 events) and in patients with a current urine protein excretion of less than 1.0 g/day (88 events). Patients with a systolic blood pressure of 110–119 mmHg as the reference group. Single multivariable model including two levels for urine protein excretion, six levels for systolic blood pressure, and the interaction of current systolic blood pressure and current urine protein excretion. Covariates include assignment to angiotensin-converting enzyme inhibitor versus control group, sex, age, baseline systolic blood pressure, baseline diastolic blood pressure, baseline urine protein excretion, baseline serum creatinine concentration (<2.0 or 2.0 mg/dL [<177 or 177 μmol/L]), interaction of baseline serum creatinine and baseline urine protein excretion, interaction of baseline serum creatinine and current urine protein excretion, and study terms.

The evidence for this guideline recommendation in nondiabetic patients comes from clinical trials summarized by Jafar *et al.* [73] (Figure 3.2), including particularly the REIN [74,75] and AIPRI [76] studies for angiotensin converting enzyme inhibitors (ACEi), but also from the results of the RENAAL [16] and IDNT [17] studies for angiotensin receptor blockers (ARBs). As with MDRD trial, the attenuation of GFR loss in these trials was greater in CKD patients with proteinuria of >1 g/day [58]. In the REIN study mostly nondiabetic patients with advanced CKD were randomized to treatment groups after stratification according to baseline proteinuria (below 1 g/day, between 1 and 3 g/day, and above 3 g/day). The rate of progression in placebo-treated patients was greatest in patients with proteinuria above 3 g/day. They were also the ones who benefited most from RAAS blockade with ramipril, with the greatest attenuation of the rate of loss of GFR [74].

The validity of the assumption that, independent of blood pressure control, the combination of ACEi and ARBs can reduce proteinuria further compared to the monotherapies was supported by several recent studies [77,78]. Furthermore, in diabetic [79] as well as in nondiabetic patients [80], it has been noted that an inverse correlation exists between the initial reduction of proteinuria and the subsequent decline in GFR. For ARBs, post hoc analyses of two recent studies (RENAAL for losartan and IDNT for irbesartan) provided evidence that reduction of proteinuria predicts the occurrence of fewer renal end points, independent of the antihypertensive agent used (in the IDNT study irbesartan, amlodipine, or alternative antihypertensive medication was used) [62,63].

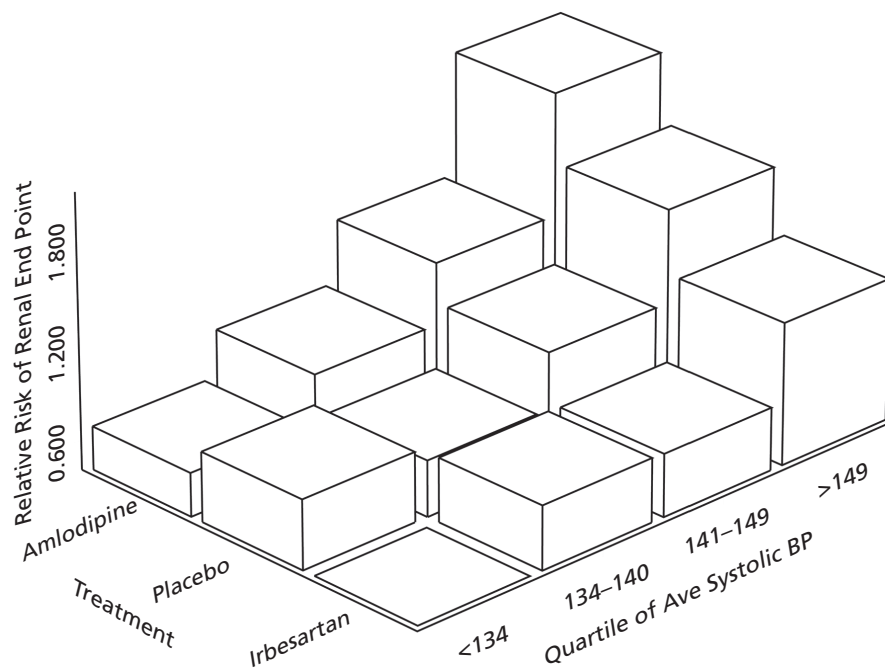
In nondiabetic individuals, an increased albumin excretion rate is a predictor of a future decrease in estimated GFR [80]. However, there is no controlled clinical trial evidence to date that a reduction of albumin excretion in the microalbuminuric range at baseline reduces the renal risk in nondiabetic patients. Such evidence is, however, available with respect to reduction of CV events [69]. In contrast, there is abundant evidence in diabetic patients that reduction of microalbuminuria is associated with less progression of diabetic nephropathy; the evidence initially arose from observational studies on patients with type 1 diabetes [82] and later from controlled clinical trials in patients with type 1 [83,84] and type 2 [85] diabetes. Additionally, the Bergamo Nephrologic Diabetes Complications Trial (BENEDICT) by Ruggenenti *et al.* [86] documented that it is not only possible to attenuate microalbuminuria but also to prevent its development in a large proportion of patients. In this study, administration to nonmicroalbuminuric patients with type 2 diabetes of trandolapril, but not verapamil, with attainment with both of equally intense lowering of blood pressure, reduced the onset of albuminuria over a median of 3.6 years of observation significantly from 10.0% for patients on placebo combined with control antihypertensive treatment compared to 6.0% for those on trandolapril. This question is currently


Figure 3.3 Progression of nephropathy in type 2 diabetes: influence of achieved systolic blood pressure, RAAS blockade with irbesartan, and their interaction. Data are from a post hoc analysis of the IDNT results (reference 62).

being investigated further in the ROADMAP study using the ARB olmesartan [87].

RAAS blockade

The US National Kidney Foundation recommends either ARBs or ACEi as first-line antihypertensive agents for the treatment of diabetic renal disease [56]. This recommendation is based largely on the findings from clinical studies demonstrating their renoprotective effects in patients with type 1 and type 2 diabetes and nephropathy (Figure 3.3) [15,16,17,88]. In addition to lowering blood pressure and reducing proteinuria, these clinical trials data support the view that blockade of renin, angiotensin, or aldosterone, the RAAS, might have direct and specific renoprotective effects. In normotensive patients with type 2 diabetes and microalbuminuria, treatment with enalapril for 5 years stabilized the decline in renal function (and reduced proteinuria) compared to placebo [85]. Similarly, in normoalbuminuric patients with type 2 diabetes and hypertension, treatment with enalapril for 6 years stabilized creatinine clearance and prevented the development of albuminuria [89]. These study results highlight the potential clinical impact of initiating RAAS blockade even before the onset of overt albuminuria in patients with type 2 diabetes.

One important question has yet to be resolved in large-scale clinical trials, specifically, whether increasing the dose of ACEi and/or ARBs above the level of maximal blood pressure lowering offers additional renoprotection through a direct RAAS inhibition in patients with nondiabetic or diabetic kidney disease. Studies in experimental models of kidney disease have documented increased intrarenal RAAS activity, and treatment with RAAS inhibitors resulted in significant attenuation of progression independent of the effect on systemic blood pressure [90]. Clinical evidence for a blood pressure-independent effect by RAAS inhibition on proteinuria as an accepted surrogate marker of progression comes from two recent small studies in patients with nondiabetic [91] and diabetic [92] CKD and from the much larger IRMA 2 study (Irbesartan in Patients with Type 2 Diabetes and Microalbuminuria) [93]. In the IRMA 2 study, 590 hypertensive patients with type 2 diabetes and microalbuminuria were randomized to the addition of either placebo to conventional antihypertensive treatment or the ARB irbesartan, at a dose of either 150 mg or 300 mg daily, and were followed for 2 years. The primary outcome was the time to the onset of diabetic nephropathy, defined by persistent albuminuria of >200 μg/min. In the 300-mg irbesartan treatment group 5.2% of patients reached the primary end point, whereas in the 150-mg Irbesartan group 9.7% developed persistent albuminuria, and in the placebo group 14.9% developed persistent albuminuria (hazard ratios: 0.30 [95% confidence interval 0.14–0.61] [$P < 0.001$] and 0.61 [95% confidence interval 0.34–1.08] [$P = 0.08$] for the two irbesartan groups compared to control, respectively). Because the average blood pressure during the course of the study was similar in both ARB treatment groups, the authors concluded that irbesartan has renoprotective effects independent of its clinical blood pressure effects. Importantly, serious adverse events were less frequent among the patients treated with irbesartan ($P = 0.02$) [93]. In the two smaller studies with ultra-high-dose ARB therapy no adverse effects were observed, including, notably, no effects on measured GFR [91,92].

When considering the role of each of the components of the RAAS in mediating the progression of nondiabetic and diabetic CKD, one must take into account recent data that support the view that aldosterone may be of importance as well. This is somewhat reminiscent of what has been shown for chronic congestive heart failure. There is experimental [94] as well as indirect clinical [95–98] evidence that aldosterone inhibition may be beneficial in arresting progression of CKD. Schjoedt *et al.* [98] evaluated the short-term effect of spironolactone on albuminuria in 20 diabetic patients with nephrotic-range albuminuria (>2500 mg/24 h) in a double-blind, crossover trial. Patients were randomly assigned initial treatment with either 25 mg of spironolactone once a day or placebo added to their baseline antihypertensive regimen, which included an ACEi or an ARB at maximally recommended doses. They found that spironolactone treatment significantly reduced proteinuria and concluded that inhibition of aldosterone may offer further renoprotection when added to recommended renoprotective strategies, including maximal RAAS blockade. Concerns remain with respect to the risk of hyperkalemia, particularly in patients with advanced CKD. Large prospective trials are necessary to evaluate the efficacy and safety of this approach. The preliminary clinical trials data described above indicate, however, that complete RAAS inhibition may not be accomplished even with high-dose ACEi and ARB monotherapy [91,92] or combination therapy [99], raising expectations for direct renin inhibitors. It remains to be proven whether this new class of antihypertensive agents that act by blocking "completely" the RAAS will confer renoprotection of greater magnitude than that observed with the ACEi and ARBs.

Smoking

In the general population cigarette smoking is associated with an increased risk of albuminuria and renal disease [100,101]. Smoking is also associated with an increased renal risk in nondiabetic and diabetic patients with CKD. Among patients with IgA GN (as a model of immunological renal disease) or ADPKD (as a model of nonimmunological disease) in a retrospective case–control study, Orth *et al.* [102] found that the risk of progressing to ESRD was significantly higher in smokers compared to nonsmokers, but the risk was markedly attenuated in patients on ACEi therapy. In diabetic patients it has been known for a long time that smokers have a higher risk of developing microalbuminuria and also progress more rapidly to overt nephropathy and renal failure [103–107]. According to Biesenbach *et al.* [106], smokers progress twice as fast to ESRD as nonsmokers. Although ACEi obviously attenuate GFR loss in smokers, they do not completely prevent it, even when target blood pressure values are reached [107]. Because no difference of proteinuria was observed in smoking compared to nonsmoking diabetic persons with renal disease, it has been concluded that vascular lesions are more important promoters of the excess CKD progression among smokers than the glomerular lesions of classical Kimmelstiel-Wilson glomerulosclerosis [108]. Regalado, Yang, and Wesson demonstrated in a prospective cohort an association of smoking with more rapid progression of CKD in hypertensive

patients in the absence of diabetes [109]. This risk appeared to be particularly important for African Americans in their cohort study. These data further support the notion that the risk of CKD from smoking is mediated through the effects of smoking on renal microvascular disease.

Is there evidence that cessation of smoking improves renal prognosis? Controlled studies to address this question would be unethical. In an observational study Sawicki *et al.* [104] compared progression in type 1 diabetic patients according to smoking habits. Progression was loosely defined as an increase in proteinuria or serum creatinine or a decrease in GFR. Progression was observed in 53% of the smokers ($n = 34$) but significantly less in exsmokers ($n = 24$; 33%) and nonsmokers ($n = 35$; 11%). Chuahirun *et al.* also demonstrated that markers of kidney injury in diabetic patients without overt nephropathy but with controlled hypertension on ACEi improved in a cohort of individuals who were successful in quitting smoking [110].

Obesity

In patients with morbid obesity a unique form of focal segmental glomerulosclerosis may be found with nephrotic proteinuria [111] and rapid progression to kidney failure [112]. In patients with various types of kidney disease, body mass index (BMI) is an independent predictor of proteinuria and loss of kidney function, particularly in IgA GN [113], in kidney transplant recipients [114,115], and in patients with unilateral renal agenesis or a remnant kidney [116]. In uninephrectomized individuals, for example, live kidney donors [117], the risks of proteinuria and loss of kidney function are higher if the individual is obese.

The question arises whether weight reduction improves indices of kidney damage. In severely obese patients without overt kidney disease but with hyperfiltration, Chagnac *et al.* observed normalization of GFR and reduction of albuminuria after gastroplasty following a decrease of BMI from 48 to 32.1 kg/m^2 [118]. In morbidly obese patients with chronic proteinuric nephropathy (including diabetic nephropathy and chronic glomerulonephritis), weight loss after caloric restriction with a decrease of BMI from 37.1 to 32.6 kg/m^2 reduced urinary protein excretion from 2.9 to 0.4 g/day [119]. The reduction of proteinuria was similar in magnitude to what is achieved with ACEi treatment [119]. The effect of weight reduction has also been studied in proteinuric patients with moderate obesity [120]. In such obese patients with chronic proteinuric nephropathies, a loss of 4.1% of body weight (BMI reduction from 33.0 to 31.6 kg/m^2) decreased proteinuria by 31.2% (from 2.8 to 1.9 g/day) [120]. However, in patients with advanced kidney failure on hemodialysis, a low BMI predicts poor CV survival, and the survival advantage progressively improves with higher BMI values extending into the range of morbid obesity [121]. It is therefore likely prudent to advise against weight reduction in patients with advanced stages of CKD, possibly CKD stage 3 or higher; however, the exact threshold of CKD where the risks of weight reduction outweigh the benefits cannot be determined from the clinical trial evidence currently available.

Salt intake

In the early decades of the past century low salt intake was a standard feature of the treatment of patients with renal disease [122]. With the advent of diuretics this aspect of management of renal patients was largely abandoned. However, in addition to the large body of clinical evidence that low dietary salt intake reduces blood pressure [123] and oxidative stress [124], low dietary salt has been demonstrated to attenuate proteinuria, renal function loss, glomerulosclerosis, and interstitial fibrosis in various experimental models of renal damage [125–131]. It is important to emphasize that the benefits of low salt intake could not be reproduced in the experimental model of uninephrectomized SHR rats by the administration of a diuretic [127]. This observation could have potential clinical importance.

In humans, evidence pointing to the renal benefit of dietary salt restriction comes from short-term studies on renal function that suggest a transient increase of filtration fraction as a surrogate marker of glomerular capillary pressure [132], which could be reversed by RAAS blockade and presumably represents evanescent counterregulation [133]. Reduction of proteinuria was seen in Black patients during short-term intervention [134]. Both a slowing of loss of GFR and cessation of further increases of proteinuria after reduction of sodium intake were reported from a retrospective analysis of an Italian series [135]. In particular because of its potential multiple health benefits, salt restriction as a public health measure directed towards individuals at risk for CKD and CKD progression is in great need of further well-designed human studies and constitutes a promising area of renal research.

Water intake

As Koranyi observed in the 19th century, reduced urinary osmolality (and hence the capacity to concentrate urine) is one of the first functional signs of renal dysfunction and primary kidney disease [136]. Both the capacity to concentrate urine and the capacity to excrete excess water are reduced in advanced renal disease. Because of the limited urine-concentrating capacity, and uncontrolled clinical observations that volume depletion may cause acute deterioration of renal function, it had been recommended conventionally that in patients with impaired renal function, the daily water intake should be above 1500 mL. As a safeguard against hyponatremia in these patients with limited excretory capacity for water, the daily water intake has usually been restricted to 3000 mL. Fishberg suggested that "if renal function is poor as revealed by the concentration test one should not restrict the fluid intake, because the elimination of a large volume of urine is the only safeguard of the patient with impaired concentrating power" [137]. Experimental studies by Bankir *et al.* [138,139] have provided evidence that water intake might attenuate progression. They reported that increased water intake in the animal renal ablation model attenuated progression in parallel with reduced vasopressin concentrations and less O_2-demanding solute transport in the ascending limb of Henle's loop. Until recently, no further human clinical trial

evidence was available to inform this question beyond the above recommendations, which are based largely on biological plausibility and customary practice. However, recent evidence from clinical trials in humans has seriously challenged the validity of these prior recommendations. Thus, in a retrospective analysis of data from the MDRD study, higher urine volumes and, by implication, higher water intakes in the steady state were associated with more adverse renal outcome, even when adjusted for a number of relevant confounders [140]. This has led to the competing recommendation that CKD patients should not be encouraged to ingest high water loads. The issue has remained controversial and is in need of controlled studies.

Protein intake

A recent observational study found that the risk of a progressive decline of renal function increases with increasing protein intake in women with moderate CKD [141]. A large randomized trial, however, failed to demonstrate that low-protein diets improved renal survival (MDRD), although several small studies with less rigorous end points showed better renal outcomes in those on low-protein diets among nondiabetic [142,143,144] as well as diabetic patients [145,146]. This finding was not consistent across all studies, however [147,148,149]. Several meta-analyses came to the conclusion that dietary protein restriction had a positive effect on renal outcomes despite significant heterogeneity between the studies [150,151,152]. The data are difficult to interpret, however, because observation periods and end points differed between the studies. The one study to address this issue which is regarded as definitive because of its size and study design was the MDRD study [57]. A total of 585 patients with moderate CKD (GFR, 25–55 mL/min) were randomized to a typical protein (1.3 g/kg/day) or low-protein (0.58 g/kg/day) diet (study A). In addition 255 patients with severe CKD (GFR, 13–24 mL/min) were randomized to a low (0.58 g/kg/day) or very low (0.28 g/kg/day) protein diet plus a mixture of ketoacids (study B). After an average of 2.2 years the intention-to-treat analysis showed no significant difference between the diets, although there was a trend toward a slower rate of GFR decline in the very low protein group in patients with advanced CKD [57]. A secondary analysis of the data from study B of the MDRD trial evaluating the achieved dietary protein intake found an inverse correlation between achieved total protein intake and GFR loss [153]. An achieved total protein intake lower by 0.2 g/kg/day was associated with a 1.15-mL/min/year reduced loss of GFR, equivalent to 29% of the mean GFR decline [153].

Although under properly supervision very low protein diets have been claimed to be nutritionally safe [154,155] and do not adversely affect function and structure of skeletal muscle [156], follow-up observations of the MDRD study have documented a nutritional decline in patients on protein restriction, which is a matter of considerable concern in view of the high mortality associated with reduced body weight observed in incident dialysis patients [157].

4 Epidemiology and Screening for Chronic Kidney Disease

Sylvia Paz B. Ramirez

Arbor Research Collaborative for Health, Ann Arbor, USA

Epidemiology of chronic kidney disease as a basis for a population-based system for surveillance and screening for kidney disease

Applying a standard system for the definition and classification of chronic kidney disease (CKD) is essential. Only through an established system that is consistently utilized can disease trends be tracked over time. To achieve this, the National Kidney Foundation in its Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines has proposed a staging classification for CKD, and these guidelines have been extensively described elsewhere [1]. The guidelines also provide an extensive review of the test characteristics of the various screening tests for CKD, and this is further discussed in chapter 2 of this textbook.

Screening for CKD serves two general goals. The first is to diagnosis and intervene early in the chronic phase of kidney disease in order to modify renal outcomes, particularly in high-risk populations. The second is to intervene in order to improve nonrenal outcomes, including cardiovascular outcomes and mortality. Numerous studies of a wide spectrum of populations have shown that low glomerular filtration rate (GFR) is clearly associated with cardiovascular disease and cardiovascular disease risk factors. For instance, systolic blood pressure, cholesterol levels, and the percentage of patients with low levels of high-density lipoproteins are more prevalent in patients with reduced GFR, as shown in the Heart Outcomes and Prevention Evaluation (HOPE) study and the Cardiovascular Health Study [2,3], the Hypertension Optimal Treatment Study [4], the Framingham and Framingham Offspring studies [5,6], and the Atherosclerosis Risk in Communities study [7]. Similarly, the prevalence of cardiovascular disease is higher in those with a decreased GFR [4,5,8,9]. The implications of CKD and proteinuria as risk markers for cardiovascular disease are not within the scope of this discussion; a more extensive analysis of

the cardiovascular implications of CKD is presented in chapter 5 of this textbook.

For screening and surveillance to be feasible, it is important to consider the following factors:
- The natural history of CKD, including the likelihood of disease progression based on the stage of CKD detected. Screening and surveillance become relevant only if it is clear that the associated abnormality increases the risk of disease progression. The natural history of disease is also relevant in determining the optimal interval of screening for a particular population.
- The target population for screening, as this determines the screening tool's success at identifying a true increase in risk for CKD and CKD progression (positive predictive value)
- Screening frequency or the interval between two successive screening tests.
- Ability of a screening program to impact clinical outcomes, including mortality, progression to end-stage renal disease (ESRD), and development of other comorbidities.

These factors will be described in detail in the following sections.

Impact of natural history of CKD on screening

Tables 4.1 and 4.2 present a summary of the published literature on the natural history of CKD in general and proteinuria in particular. As is evident from the literature, there is clear variability in the progression of CKD, particularly in the presence of clinical factors such as diabetes, hypertension, or proteinuria.

Table 4.1 reflects the annual decline in GFR, whereas Table 4.2 presents the likelihood of disease progression by degree of proteinuria. An extensive body of literature shows that the presence of elevated levels of albumin in the urine is associated with a significantly greater risk of development of progressive renal insufficiency and should be a component of surveillance and screening programs for CKD.

As shown in Table 4.1, the annual decline of GFR differs markedly by clinical history and presence of proteinuria. Based on the National Health and Nutrition Evaluation Survey (NHANES),

Table 4.1 Annual decline in GFR by clinical history.

Clinical history and GFR	References	Annual decline in GFR (mL/min/1.73 m^2)
No diabetes or hypertension No proteinuria, normal GFR	Coresh *et al.* 2003 [10] NKF Clinical Practice Guidelines 2000 (http://www.kidney.org/professionals/doqi/kdoqi/- 4_class_g1.htm)	Mean decrease, 1.0

in the absence of diabetes or hypertension, the average member of the adult US population is estimated to have an approximate annual decline in GFR of 1 mL/min/1.73 m^2 in the presence of normal renal function at baseline [10]. The degree to which renal function continues to decline beyond a certain GFR in the absence of hypertension, diabetes, or proteinuria is not known.

In the presence of hypertension, but without proteinuria, Agodoa and others [11] showed a GFR decline of 1.4 mL/min/1.73 m^2, and this deterioration increased significantly to approximately 3.9 mL/min/1.73 m^2 in the presence of proteinuria [12,13]. In the presence of diabetes, multiple studies have demonstrated an annual decline in GFR that increases from 1.1 mL/min/1.73 m^2 in

Table 4.2 Disease progression by degree of proteinuria.

Clinical history and [reference]	Predictor	Outcome	Population
No hypertension or diabetes			
Verhave *et al.* 2004 [20]	Elevated urinary albumin excretion	4.2% developed GFR <60 mL/min/1.73 m^2 after 4-year follow-up	The Netherlands, excluded those with GFR <60 mL/min/1.73 m^2 at baseline
Iseki *et al.* 2003 [21]	No proteinuria to trace 1+ proteinuria ≥ 2+ proteinuria	18-yr ESRD incidence 0.2% 18-yr ESRD incidence 1.4% 9.2%	Japanese

High risk for CVD Ishani *et al.* 2006 [22]	Proteinuria 1+ Proteinuria ≥2+	OR 3.1 (CI, 1.8–5.4) OR 15.7 (CI, 10.3–23.9)	12,866 men at high risk for CVD

Abbreviation: RR, relative risk.

the absence of baseline proteinuria and renal insufficiency [14–16] to 5.2 mL/min/1.73 m^2 among patients with proteinuria and renal insufficiency at baseline [17–19]. What these studies demonstrate is the following: 1) there is a background rate of deterioration of renal function, 2) this decline in renal function is dramatically hastened by the presence of diabetes and hypertension, and 3) the presence of proteinuria is an important marker for progression of CKD.

Table 4.2 is another representation of the clinical importance and natural history of proteinuria, as it presents the likelihood of progression to significant chronic renal insufficiency and ESRD based on clinical history and presence of proteinuria. As shown in Table 4.2, numerous studies support that albuminuria in and of itself, regardless of the level of GFR, is an important predictor of renal function decline. In the absence of hypertension or diabetes, the PREVEND study (Prevention of Renal and Vascular End-Stage Renal Disease), a longitudinal study initiated in 1997 that looked at the impact of albuminuria in the development of renal and cardiovascular disease in the general population, showed that the presence of an elevated urinary albumin excretion was associated with development of renal insufficiency 4 years after follow-up [20]. The study identified older age, higher blood pressure, serum cholesterol and serum glucose, degree of albuminuria, and relatively lower GFR as predictors of significant renal insufficiency in a population without known risk factors for CKD. Similarly, Iseki and colleagues in an 18-year longitudinal study of the general population of Okinawa revealed a significant stepwise increase in the incidence of future ESRD based on a screening dipstick proteinuria [21]. As shown in Table 4.2, the presence of dipstick-positive proteinuria of 2+ or greater is associated with a 9.2% incidence of ESRD, and even with lower degrees of proteinuria (1+), there was an increased risk of ESRD compared to patients with dipstick-negative proteinuria. The increased risk of ESRD associated with proteinuria was even higher in a population at high risk for cardiovascular disease [22]. As shown in the MRFIT study (Multiple Risk Factor Intervention Trial), which included 12,866 men who were at high risk for heart disease, the presence of a single dipstick proteinuria of 1+ was associated with an odds ratio (OR) of 3.1 (confidence interval, 1.8–5.4) for development of ESRD in over 25 years of follow-up. When dipstick proteinuria was 2+ or greater, the associated OR was 15.7 (confidence interval, 10.3–23.9). A similar predictive power of proteinuria in the development of ESRD in other populations considered at high risk for development of ESRD will be discussed extensively below. These studies unequivocally show the relationship between proteinuria and subsequent development of ESRD.

Less clear is the relationship between normal levels of albuminuria and microalbuminuria on the development of CKD. Indeed, although there are numerous studies that show that microalbuminuria is associated with an increase in both all-cause and cardiovascular mortality in apparently healthy populations [23–25], as well as in those with existing cardiovascular risk factors in the HOPE trial [26] or hypertension in the LIFE and AASK trials [27], studies that show an association between lower levels of albumin-

uria and renal outcomes have only been recently published. In the PREVEND study, for instance, high-normal levels of urinary albumin were found to be associated with an increased risk of chronic kidney disease in the general population [20].

Thus, published evidence on the natural history of CKD unequivocally demonstrates the relationship between high levels of albuminuria and progression to CKD, supporting the use of this measure in a surveillance and screening system. Whether this is of value in the general population or only in high-risk populations is further discussed below. Finally, because there is no evidence on the use of normoalbuminuria or microalbuminuria for screening in the general population, this does not appear to be justified at present.

Impact of other factors on development of a surveillance and screening system

A second consideration in developing a surveillance and screening system is to define the target population. If CKD were extremely infrequent in a population, then screening would not be productive. A screening test's likelihood of truly detecting an individual at increased risk for CKD, or the positive predictive value, depends on the proportion of the screened population with CKD [28,29]. Indeed, a screening program's positive predictive value can be improved by focusing on the population at increased risk, that is, the group of individuals with a higher prevalence of CKD. A summary of the published literature identifying the populations at increased risk for CKD is presented in the next section.

Another important factor to consider is the screening frequency, or the interval between two successive screening tests. This, too, depends primarily on the incidence rate of CKD in the target population. For a low-risk population with a low incidence of CKD, high frequencies of screening will yield a lower number of identified cases and, as a consequence, the potential for a reduction in the number of cases of ESRD will be low.

Finally, evaluating a screening program for CKD in terms of its ability to impact on the number of ESRD cases, or the development of cardiovascular and all-cause morbidity and mortality, is complex. Even a randomized study that evaluates the effects of a screening program is difficult for a variety of reasons, as summarized by McClellan and others [30], including the feasibility and cost of the study and the unique biases associated with screening programs. In particular, when comparing survival curves between screened and unscreened populations, it is certain that longer survival will be observed in the screened population [28,29]. This is due to three factors: 1) lead time bias, with which patients are detected earlier than they would have been based on clinical symptoms; 2) length time bias, with which patients with a longer preclinical, and likely less-aggressive, kidney disease course are more likely to be detected by screening programs; and 3) selection bias, with which patients who are relatively healthy have a greater tendency to participate in screening programs. Indeed, the improved outcomes that may be attributed to early detection and early intervention with screening

Table 4.3 Older age and risk of CKD.

Data source [reference]	Study population	Exposure	End point	Results
Patel *et al.* 2005 [32]	VA, retrospective longitudinal cohort, 48% with CKD at baseline	GFR (stage of CKD)	Mortality rate, 3-yr follow-up	Mortality in those without CKD, 4.7 deaths/100 person-yrs; increased w/ progressive CKD to 20.1 deaths/100 person-yrs if GFR 15–29 mL/min/1.73 m^2

programs are difficult to separate from these inherent biases of screening programs.

High-risk populations for CKD

Elderly

Older age is significantly associated with mortality regardless of the presence of preexisting disease [31]. Several studies have demonstrated an increased risk of CKD progression in older populations. Working with the Veterans Administration (VA) population, Patel and others evaluated the 3-year mortality rate of older patients with or without CKD [32]. As shown in Table 4.3, the mortality rate increased with worsening degree of baseline GFR. Furthermore, the authors noted that the risk in the VA population, previously reported to have a greater illness burden than the general population [33], is greater than that observed using a community-based population, with a sevenfold-greater risk of death among those with relatively higher GFR levels in the VA population [34]. Similarly, the Cardiovascular Health Study, a longitudinal cohort study of elderly persons in four communities in the USA demonstrated the high prevalence of a condition that the authors identified as "preclinical disease" in the elderly community. The term preclinical disease was likened to prediabetes by those authors, in that the constellation of clinical characteristics is associated with a high rate of progression to CKD [35]. The study further noted that in this older population, there was a value in the use of cystatin C as a predictor for future CKD. In the absence of any other evidence of CKD, those elderly patients with elevated cystatin C concentrations were found to have a fourfold-increased risk for developing CKD on follow-up. These studies demonstrate the elevated risk of CKD associated with older age.

Hypertension

Hypertension as a risk factor for CKD has been clearly established. As shown in Table 4.4, CKD is highly prevalent in patients with treated essential hypertension. An analysis of the NHANES data showed that reduced GFR was present in 51.4% of screened adults with hypertension and on no medications and in 64.4% of screened

adults with hypertension and receiving medications [10]. An analysis of the SHEP study (Systolic Hypertension in the Elderly Program) demonstrated a relative risk of 2.4 for a decline in kidney function among SHEP participants (placebo group) in the highest quartile of systolic blood pressure compared to those in the lowest quartile [36]. Perneger and colleagues, by integrating several population studies, estimated a rate of 14.6/100 patients for the development of CKD in hypertensive patients with normal baseline renal function [37]. Similarly, Segura and colleagues observed a deterioration in creatinine clearance (CrCl) to less than 60 mL/min/1.73 m^2 in 14.6% of a hypertensive population with baseline normal renal function [38]. Indeed, more recent studies have demonstrated an increased risk of CKD among patients with essential hypertension, in contrast to the earlier thought that the prevalence of CKD in the presence of essential hypertension is quite low [39].

Cardiovascular disease

Innumerable studies have documented the increased risk of cardiovascular disease in the presence of CKD [40,41]. This is discussed in chapter 5. Similarly, in addition to the strong relationship between hypertension and ESRD, cardiovascular disease in and of itself is also known to increase the risk for CKD, resulting in a vicious cycle given that CKD is known to amplify cardiovascular disease [42]. Using the HOPE study findings, which was a randomized trial designed to test the use of an angiotensin converting enzyme inhibitor (ACEi) and vitamin E in patients at high risk of cardiovascular events (Heart Outcomes and Prevention Evaluation Study), Mann and colleagues evaluated the predictive value of low levels of albuminuria that were below the cutoff used to define microalbuminuria for the development of clinical proteinuria and several cardiovascular outcomes [26]. Their analysis showed that in the individuals with established risk factors for cardiovascular disease, even low levels of albuminuria were significantly associated with development of clinical proteinuria. The relative risk for developing higher-grade proteinuria was 17.5 in both diabetic and nondiabetic patients. In fact, other findings of the HOPE study included that one of every three patients with diabetes developed microalbuminuria, and of these, one of five developed nephropathy

Table 4.4 Hypertension and cardiovascular disease as risk factors for CKD.

Data source [reference]	Study population	Exposure	End point	Results
Coresh et al. 2003 [10]	NHANES III cross-sectional survey	Hypertension (among others)	Presence of CKD	51.4% of those with hypertension on no medication and 64.4% of those with hypertension and on medication had reduced GFR
Young et al. 2002 [36]	Placebo arm of the Systolic Hypertension in the Elderly Program	Elderly men and women; blood pressure	Risk of decline of kidney function	2.4 adjusted RR for decline in kidney function in the highest quartile of SBP compared to lowest quartile
Perneger et al. 1993 [37]	Integrated analysis of several population studies	Four national databases (US Census, NHANES, Hypertension Detection and Follow-up Program trial, USRDS)	Abnormal serum creatinine	14.6/100 patients (over 13 yrs follow-up)
Segura et al. 2004 [38]	Patients with essential hypertension and normal renal function at baseline	Observational cohort study looking at relationship between blood pressure and CKD	CrCl <60 mL/min/1.73 m^2	Mean follow-up of 13.2 yrs, 14.6% developed renal insufficiency
Mann et al. 2004 [26]	Heart Outcomes and Prevention Evaluation (HOPE) study, a randomized trial designed to test use of an ACEi and vitamin E in patients at high risk of cardiovascular events	Normoalbuminuria (below microalbuminuria cutoff, >2 mg/mmol)	Clinical proteinuria	Baseline microalbuminuria predicted clinical proteinuria with RR of 17.5 in both diabetic and nondiabetic patients over 4.5-year follow-up; baseline microalbuminuria also increased RR of primary outcome of MI, stroke, or CV death (RR, 1.83)
McClellan et al. 2004 [44]	Medicare fee-for-service patients with primary diagnosis of AMI and a primary diagnosis of CHF	Presence of preexisting cardiovascular disease as defined by AMI and CHF diagnoses	Presence of CKD (defined as MDRD eGFR <60 mL/min/1.73 m^2	CKD in 51.7% of AMI and 60.4% of CHF patients; CKD increased risk of death in yr 1 for CHF patients (OR 1.6) and AMI (OR 3.1); increased risk of progression to ESRD among those with CKD

Abbreviations: ACEi, angiotensin converting enzyme inhibitor; AMI, acute myocardial infarction; CHF, congestive heart failure; RR, relative risk.

[43]. McClellan and others also demonstrated the increased risk of progressive CKD among patients with cardiovascular disease [44]. Using the Medicare database, those authors evaluated the relationship between CKD as defined by a reduced estimated GFR of <60 mL/min/1.73 m^2 in Medicare patients with a discharge diagnosis of either acute myocardial infarction or congestive heart failure. The study revealed that not only was there a high prevalence of previously undetected CKD in these two patient groups, but also there was an increased risk of ESRD among patients with CKD in addition to their cardiovascular disease, and they had an increased risk of death within 1 year after discharge.

That the presence of cardiovascular disease is a risk factor for CKD is most clearly apparent with the inclusion of kidney disease screening in the guidelines for the management of cardiovascular disease [45]. This advisory acknowledges the strong correlation between the risk factors and the occurrence of cardiovascular disease and CKD, and strongly recommends the routine screening of patients with cardiovascular disease for evidence of kidney disease.

Table 4.5 Diabetes and risk of CKD.

Data source	Study population	Exposure	End point	Results
Kramer et al. 2003 [48]	Type 2 diabetes mellitus in NHANES	Albuminuria	Low GFR	In 30% of adults with type 2 diabetes and normoalbuminuria, GFR was low
MacIsaac et al. 2004 [49]	Type 2 diabetes mellitus, cross-sectional survey of outpatients of a hospital	Albuminuria	Low GFR	In 39% of adults with type 2 diabetes and normoalbuminuria, GFR was <60 mL/min/1.73 m^2

Table 4.6 Family history and risk of CKD.

Data source [reference]	Study population	Exposure	End point	Results
Jurkovitz et al. 2002 [50]	Voluntary screening of family members of patients with ESRD	Family history	CrCl <60 mL/min, proteinuria	13.9% of family members had a CrCl <60 mL/min; 9.9% had proteinuria of ≥1+
Freedman et al. 2001 [51]	4365 incident dialysis patients treated in a single year	Incident dialysis patients	Family history of ESRD	20% of patients reported having a first- or second-degree relative with ESRD
Ferguson et al. 1988 [52]	Matched case–control study of dialysis patients matched to controls residing in area surrounding dialysis centers	History of CKD in a first- or second-degree relative	Risk of ESRD	History of CKD in first- or second-degree relative was associated with increased risk for being a prevalent ESRD patient
Bergman et al. 1996 [108]	First -degree relatives of patients with hypertensive ESRD	Relative of ESRD patient	Renal abnormality	Evidence for CKD was seen in 65% of participating families
O'Dea et al. 1998 [53]	Patients with ESRD	ESRD	Family history of ESRD	28% of patients had a first-, second-, or third-degree relative with CKD, compared with 15% of comparison spouses
Lei et al. 1998 [54]	First-degree relatives of new ESRD patients	Family member of ESRD patient	ESRD	OR of ESRD was 1.33 (CI, 0.7–2.6) for one first-degree relative with CKD, 10.4 (2.7–40.2) for two or more first-degree relatives

Diabetes

Diabetes is well-recognized to have reached epidemic proportions worldwide. In fact, an analysis by Jones and others suggested that the increase in incident ESRD over recent years is directly attributable to the combination of the rise in the incidence and prevalence of diabetes, as well as an increased risk in developing ESRD among patients with diabetes [46]. That there is a clear and established relationship between diabetes and CKD is well-documented, and this has been the subject of extensive review elsewhere [47]. Rather than providing a review of the overwhelmingly convincing data documenting the increased risk for nephropathy in diabetes, it is important to point out a novel finding presented by Kramer and others (Table 4.5). In their analysis of adults in their study with type 2 diabetes mellitus, 30% were found to have a low GFR in the absence of proteinuria [48]. That a reduced GFR can exist in diabetic patients in the absence of albuminuria was also shown in a study in Australia in which 39% of adults with type 2 diabetes had a GFR of <60 mL/min/1.73 m^2 despite having a normal albumin excretion level [49]. These studies provide evidence that for patients with diabetes, screening for nephropathy requires testing for both albuminuria and reduced GFR. Whether those diabetic patients who present only with reduced GFR in the absence of albuminuria follow a different clinical course and require different interventions deserves further study.

Family history

Several studies have demonstrated that individuals with a family history of CKD are at greater risk for kidney disease compared to those without any family history (Table 4.6). Among family members of patients with ESRD, it was shown that 13.9% had reduced CrCl (below 60 mL/min) and 9.9% had proteinuria of 1+ or greater on voluntary screening [50]. In another study, 20% of incident dialysis patients were reported to have a first- or second-degree relative with ESRD [51]. In a case–control study of dialysis patients matched to controls residing in areas surrounding dialysis centers, it was also shown that compared to controls, those with a family history of CKD was a significant predictor for being a prevalent ESRD patient [52]. That a family history of CKD is associated with CKD has been shown in both black and white patients [53]. Finally, the association between family history and CKD appears to be dose dependent. Lei et al. showed that the OR for ESRD was 1.3 for those with a single first-degree relative with CKD but that the odds dramatically increased to 10.4 in the presence of two or more first-degree relatives [54]. These studies demonstrate the association between CKD and a positive family history, arguing for targeted screening for CKD among individuals with such a family history.

Race and ethnicity

Evidence for race and ethnicity as risk factors for CKD is extensive (Table 4.7). To begin with, the US Renal Data System (USRDS) has shown that certain racial and ethnic groups have a higher age- and gender-adjusted risk of ESRD compared to the white population [55]. Factors that potentially account for the racial disparity in CKD include true biologic differences in risk and disease progression [56], a higher prevalence of low birth weight in certain racial and ethnic groups, which evidence reveals is a risk factor not only for CKD but also for hypertension and diabetes [57], and socio-economic factors leading to differential quality of and

access to health care [58]. Low birth weight as a partial explanation of the observed racial difference is of interest [59]. As discussed in a separate section below, evidence exists that suggests an association between low birth weight and risk of CKD. Furthermore, the prevalence of low birth weight is up to twofold higher among African Americans compared to white and Hispanic groups [60]. Together, these suggest the potential contribution of prenatal and postnatal characteristics in the subsequent development of CKD.

Another contributing factor to the excess burden of CKD in certain racial and ethnic groups is the higher rates of predisposing factors to kidney disease development and progression, including higher rates of diabetes mellitus, hypertension, and glomerulonephritis [61]. With diabetes, for instance, African Americans, Hispanics, and Native Americans are recognized to have markedly higher rates of diabetes mellitus compared to white people. Similarly, as shown by the NHANES data, 34% of African Americans have hypertension, compared to 29% in the white population and 21% in Hispanic populations [62], and more African Americans develop hypertension-related ESRD compared to white people [63]. Socio-economic factors that lead to disparities in access to care have also been documented, with 31% of the African American population living below the federal poverty level compared to 11% of the white population [64].

As shown in Table 4.7, racial differences in the prevalence and risk for CKD are striking. Using the NHANES data, Jones and colleagues showed that the prevalence of albuminuria in African Americans is 50% higher compared to other racial and ethnic groups [65]. Interestingly, clear differences in various Asian ethnic groups have also been demonstrated in Hong Kong and Singapore [66,67]. The NHANES data were also used in an analysis that showed that the higher incidence of ESRD in African Americans is partly attributable to a faster rate of progression of CKD compared to that in other racial groups [56].

Racial differences in the rate of ESRD were also demonstrated in the health screening of the integrated health care system of Kaiser Permanente, in which Blacks and Asians were found to have significantly higher age-adjusted rates of ESRD compared to Whites [68]. The differences between black and white populations were similarly demonstrated in the MRFIT study, although the racial difference identified by this study was significantly attenuated by adjustments for multiple confounding factors [63]. Even the risk of developing ESRD secondary to diabetes appeared to have racial differences, as shown by Karter *et al.*, who found that Asians had an adjusted risk of 1.85 for developing diabetic ESRD compared to white people [69].

Analyses from the REGARDS cohort study, which aims to identify risk factors that lead to an increased mortality rate from stroke among black patients, has provided additional insight into the question of race and CKD risk. In this analysis of racial differences in the prevalence of CKD among participants in this cohort, there was a clear shift in the black/white OR with advancing degrees of renal insufficiency. In particular, the OR for a GFR between 50 and 59 mL/min/1.73 m^2 was 0.51, with fewer blacks than whites

having this degree of renal insufficiency, whereas at a GFR of <10 mL/min/1.73 m^2, the OR had flipped to 4.19, with a significantly greater odds for Black patients to have a more advanced degree of renal insufficiency compared to White patients [70].

Thus, for numerous reasons, it is evident that certain racial subgroups are at markedly greater risk for the development or more aggressive progression of CKD. Screening programs aimed to identify those at increased risk can potentially lead to earlier and more aggressive intervention. Although such an approach is theoretically appropriate, no published studies exist that demonstrate the clinical benefit gained from taking part in a screening program. Even if a randomized controlled trial for screening were performed, as stated in the earlier section of this chapter, unique screening-specific biases would need to be teased out from the true benefit gained from taking part in a screening program.

Other risk factors for CKD

Data exist on several other clinical features that may place individuals at increased risk for CKD. As summarized in Table 4.8, these factors include obesity, low birth weight, and the presence of metabolic syndrome. In Sweden for instance, Ejerblad and colleagues demonstrated that a body mass index (BMI) of 25 kg/m^2 or greater at the age of 29 years was associated with a threefold-increased risk of having an elevated serum creatinine [71]. Indeed as shown in Table 4.8, obesity as a risk factor for CKD was seen whether CKD was defined as a decline in GFR or as the presence of microalbuminuria and whether this was evaluated in a cohort study or in a cross-sectional study.

There is also significant evidence that low birth weight is associated with CKD. In nondiabetic populations, Yudkin and others showed an association between low ponderal index (weight for height) and an increased OR for microalbuminuria [72]. Among Pima Indians with type 2 diabetes, it was also shown that both extremes of BMI were significantly associated with albuminuria, with an OR of 2.3 for albuminuria among those with low birth weight compared to those with normal birth weight [73]. A similar increased risk for nephropathy in low birth weight women with type 1 diabetes was also reported by Rossing and colleagues [74]. Finally, low birth weight was also shown to be associated with ESRD, with an OR of 1.4 for developing ESRD among those with a birth weight of <2.5 kg compared to those with normal birth weight [75]. These studies potentially show that obesity and low birth weight should be increasingly recognized as risk factors for CKD, and these factors should be considered in developing screening and surveillance programs.

Patterns of awareness and treatment of stage 1–4 CKD in the general population

There is growing evidence that the detection and treatment of earlier stages of diabetic [47] and nondiabetic kidney disease [76,77] can delay, if not prevent, further progression of kidney injury, and this evidence has been incorporated into clinical practice

Table 4.7 Race and ethnicity and risk of CKD.

Data source [reference]	Study population	Exposure	End point	Results
Jones *et al.* 2005 [46]	National Health and Nutrition Evaluation Survey (US, multiethnic)	Race	Albuminuria	Prevalence of albuminuria 50% higher in African Americans than in non-African Americans
Li *et al.* 2005 [66]	Population-based screening program (Hong Kong, Chinese)	Predictors of urinary abnormalities	Urinary abnormalities	Prevalence of 5% for proteinuria
Chadban *et al.* 2003 [110]	Cross-sectional study, Australians of European descent and Asians	Predictors of urinary abnormalities	Urinary abnormalities	Prevalence of 2.4% for proteinuria, 16% with either proteinuria, hematuria, or reduced GFR
Ramirez *et al.* 2003 [67]	Cross-sectional study, multiethnic	Clinical and demographic factors	Urinary abnormalities	Prevalence of 1.1% for proteinuria
Hsu *et al.* 2003 [56]	National Health and Nutrition Evaluation Survey and US Renal Data System (US, multiethnic)	Race	Development of ESRD	More aggressive disease and increased rate of progression of CKD contributes to higher incidence of ESRD in African Americans
Hall *et al.* 2005 [68]	299,168 adult members of an integrated health care delivery system who underwent screening in 1964 and 1985 (Kaiser Permanente) (US, multiethnic)	Race and ethnicity	Incidence of ESRD	Age-adjusted rate of ESRD 14.0/100,000 PY in Asians (10.5–18.5); 7.9/100,000 PY in whites (6.5–9.6); 43.4/100,000 PY in blacks (36.6–51.4)
Klag *et al.* 1997 [63]	Men screened for entry into MRFIT study	Race and ethnicity	Incidence of ESRD	Age-adjusted ESRD incidence 13.9 and 44.2/100,000 yrs for white and black populations, respectively, after adjustments RR reduced to 1.9 in blacks vs whites
Karter *et al.* 2002 [69]	Prospective cohort study of 62,432 diabetic members of a health insurance plan (US, multiethnic)	Race	Risk of ESRD and other diabetic complications	Adjusted risk of 1.85 (1.4–2.4) for diabetic ESRD among Asians compared to whites
McClellan *et al.* 2006 [70]	Nationally representative, population-based cohort of individuals $\geq$45 yrs old	Race	GFR	Distribution of GFR significantly different between black and white participants, whereas CKD more prevalent among white than black participants at relatively lower grades of CKD; odds of lower GFR for blacks vs whites increased with more advanced degrees of CKD
Toto 2004 [103]	AASK, prospective randomized controlled trial of use of antihypertensive regimens in 1100 nondiabetic African American adults (US)	Effect of aggressive blood pressure vs usual blood pressure lowering in African Americans with hypertensive nephrosclerosis using three different regimens	Rate of decline of GFR	No difference in rate of decline and renal outcomes between blood pressure groups or between antihypertensive regimens; those assigned to ramipril had significantly lower ESRD and composite renal outcome

Abbreviation: PY, person-years.

guidelines [50,78,79], and the contemporary management of CKD is discussed in section 6 of this textbook.

Despite the well-documented benefits of early detection and treatment of CKD, population-based studies have found that awareness of impaired kidney function among individuals with CKD is minimal, and this lack of awareness should be considered a potential risk factor for progressive CKD. Analyses of the NHANES data found that 8% of participants with stage 3 CKD responded that they had been told by a health care provider that they had "weak or failing kidneys" (excluding kidney stones, bladder

Table 4.8 Other potential risk factors for CKD.

Risk factor and data source [reference]	Study population	Exposure	End point	Results
Obesity				
Ejerblad *et al.* 2006 [71]	Population-based case–control study of incident moderately severe CKF in Sweden	BMI at age 25 and highest lifetime BMI	Creatinine >3.4 in men, >2.8 in women	BMI $\geq$25 kg/m^2 at age 29 associated with 3-fold increased risk of CKD; BMI $\geq$30 among men and $\geq$35 in women anytime during lifetime had a 3- to 4-fold increased risk High BMI increased risk of GFR in 5th or lower percentile; each unit increase in BMI SD was associated with 1.2-fold increased risk for new-onset kidney disease
Fox *et al.* 2004 [111]	Framingham Offspring cohort	BMI	GFR	A continuous increase in risk of ESRD with increasing BMI primarily in men; higher BMI associated with higher degrees of albumin excretion, primarily in men
Iseki *et al.* 2004 [21]	Okinawa longitudinal cohort study	BMI	CKD	BMI $\geq$30 associated with RR of 1.77 for CKD; after adjusting for diabetes and other predictors, remained significant at 1.57
Cirillo *et al.* 1998 [112]	Population-based cohort study	Predictors of albuminuria	Microalbuminuria	Higher baseline BMI associated with increased risk for CKD, OR of 1.45 in those with BMI >26.6 vs those with BMI <22.7
Hallan *et al.* 2006 [113]	Cross-sectional survey of Nord-Trondelag County (HUNT Study); 30,485 men and 34,708 women	BMI	CKD	Each 1 unit increase in BMI was associated with 5% increase in CKD risk
Gelber *et al.* 2005 [114]	Physicians Health Study, cohort study of 11,104 healthy men	BMI	GFR	Those with weight gain >10% had increase in CKD risk to 1.27 compared to those with weight that remained within 5% of their baseline
Low birth weight				
Yudkin *et al.* 2001 [72]	Community-based populations	BW, length, and ponderal index	Albuminuria	Those in the lowest third for ponderal index had an OR of 3.1 for microalbuminuria compared to those in highest third for ponderal index
Nelson *et al.* 1998 [73]	Pima Indians with type 2 diabetes	BW	Albuminuria	As compared to those with normal BW, those with low BW had an OR of 2.3 and those with high BW had an OR of 3.2
Rossing *et al.* 1995 [74]	Type 1 diabetes	BW percentile	Nephropathy	Among women with IDDM, 75% had evidence of nephropathy among those whose BW was $\leq$2.7 kg (10th percentile) compared to 35% in those with BW $\geq$4 kg (90th percentile)
Lackland *et al.* 2002 [75]	Medicaid beneficiaries in a US region	BW	ESRD	Among those with BW <2.5 kg, OR for developing ESRD was 1.4 compared to those with normal birth weight

Abbreviations: CRF, chronic kidney failure; BW, birth weight; IDDM, insulin-dependent diabetes mellitus.

infections, or incontinence) [78]. Awareness of CKD increased as the stage of CKD increased and was higher among individuals with albuminuria and among women [78]. Similar low levels of awareness of impaired kidney function and proteinuria have been reported for other high-risk populations [50].

The lack of reported awareness among individuals with stage 3–4 CKD is consistent with reports that clinicians frequently fail to recognize evidence of injury and impaired kidney function among their patients [79,80] and that patients in North America and Europe with CKD may not be referred early for specialist care [81,82], which may be associated with less than optimal care of CKD [83]. There is evidence that the care of CKD patients by both primary care physicians and kidney specialists is characterized by

inadequately managed hypertension [84] and anemia [85] and under prescription of cardiovascular medications [86,87] as well as routine preventive care [88]. Recently there has been interest both in Europe and North America in the role of clinics dedicated to the management of CKD [89] with growing evidence that such care is better in quality [84,90,91] and may be associated with improved outcomes, including delayed progression of CKD [92–94].

Cost-effectiveness analyses for CKD screening

Another important consideration in determining the appropriateness of a screening program is its cost-effectiveness [30]. Because

of the lack of studies that evaluate the effectiveness of screening programs in improving clinical and economic outcomes, the limited number of publications that have addressed the issue of cost-effectiveness of screening have largely been based on computer simulation models. Furthermore, the focus of the literature is on cost-effectiveness of screening for nephropathy in the context of diabetes mellitus.

Diabetic nephropathy

Without exception, all studies on the cost-effectiveness of screening for nephropathy in patients with diabetes, whether type 1 or type 2, have been based on simulation models as summarized in Table 4.9. Simulation models are subject to a number of limitations, including dependence on key assumptions, such as the rate of progression of various stages of CKD as well as the efficacy of treatment in reducing the risk of progression. Nevertheless, the findings of the cost-effectiveness analyses for screening for diabetic nephropathy are overwhelmingly in favor of either one of two strategies: routine screening for microalbuminuria followed by treatment, or routine treatment with an ACEi or angiotensin receptor blocker (ARB) upon diagnosis of diabetes mellitus. Clearly dominated, that is, not deemed to be cost-effective, is screening for gross proteinuria.

Studies that have evaluated the cost-effectiveness of screening for diabetic nephropathy are shown in Table 4.9. Of further importance for study is the routine treatment of patients with diabetes with antiproteinuric therapy. Golan and others, modeling patients with newly diagnosed type 2 diabetes mellitus, demonstrated that routine treatment had the lowest progression to ESRD or death and had a marginal cost-effectiveness of only $7500 for every quality-adjusted life year (QALY) compared to the strategy of screening for microalbuminuria followed by treatment [95]. Similarly, Kiberd and Jindal showed that routine treatment with ACE inhibitors 5 years after diagnosis of type 1 diabetes produced the longest life expectancy, more quality-adjusted life years, and had the lowest cost of care if ACE treatment were assumed to reduce microalbuminuria development by 26% [96]. These analyses raise the question of whether there is a potential value in designing a clinical trial that compares routine treatment with ACEI or ARB on diagnosis of type 2 diabetes, or after several years of having type 1 diabetes, with the current standard of care that includes annual screening for microalbuminuria.

Nondiabetic nephropathy

In contrast to screening for type 1 and 2 diabetic nephropathy, cost-effectiveness studies for the screening for proteinuria in a nondiabetic population are extremely limited. Boulware and colleagues examined the cost-effectiveness of annual screening for proteinuria in the absence of diabetes mellitus [97]. In this study, routine screening with a urine dipstick test during annual physical examination tests was compared with incidental testing or testing during symptom development. The authors demonstrated that in the absence of diabetes or hypertension, routine screening for proteinuria was not within the range considered cost-effective, with an estimated cost of $282,818/QALY gained. Only in patients

60 years or older did screening in the absence of hypertension or diabetes approach a cost-effectiveness range, with $53,372/QALY gained. In contrast, routine screening in the presence of hypertension was highly favorable, with a cost of $18,621/QALY gained, and this was cost-effective even with screening at 30 years of age. Screening in patients with diabetes was cost-saving, with a savings of $217 and gain of 0.1 QALY/person. Indeed, this analysis suggests the value of screening high-risk populations, in that screening for proteinuria only in the presence of hypertension, diabetes, or older age is cost-effective. This is in marked contrast to the findings of Craig *et al.* who showed that a single opportunistic dipstick screening results in significant cost savings [98]. The differences in the conclusions of these two analyses demonstrate the limitations of simulation models given that analyses are sensitive to model assumptions, including reliability and reproducibility of screening tools and the natural history of disease progression [99]. Another important shortcoming of existing cost-effectiveness studies is the failure to account for the benefit gained from preventing the cardiovascular outcomes of proteinuria. Thus, these evaluations of the cost-effectiveness of screening using simulation models only highlight the lack of appropriately designed studies to evaluate the outcomes of screening for CKD.

Discussion and recommendations for future research

Evidence for improving population outcomes through the implementation of population-based CKD screening programs is not convincing. However, the value of surveillance systems in tracking trends of disease and overall disease burden should be considered. In addition, though definitive randomized clinical trials evaluating the effectiveness of screening programs in reducing ESRD rates may not be feasible, review of the extensive literature on the outcomes of CKD in populations at high risk, such as those in certain clinical and demographic subgroups, warrants the consideration of targeted screening and intervention among high-risk populations.

Other important questions on the value of screening for CKD in the population remain, including 1) determining the optimal time to initiate screening in high-risk populations, 2) identifying an appropriate screening frequency that balances cost and utility of screening, 3) determining whether it is truly clinically feasible and appropriate to treat all diabetic patients upon diagnosis with an ACEi or ARB rather than to perform screening for evidence of early or overt nephropathy, 4) performing follow-up of programs that focus on screening high-risk populations, and 5) defining the harms and costs of screening.

In evaluating the true increase in risk for CKD in certain demographic and clinical populations, additional studies on the following aspects should be considered, as summarized by Ramirez [99]: 1) continued evaluation and examination of clinical biomarkers and genetic markers for the occurrence and progression of CKD, 2) development of race- and ethnicity-specific prediction

Table 4.9 Cost-effectiveness analysis of screening for diabetic nephropathy.

Data source [reference]	Comparison groups	Diabetes type and population	Outcome
Kiberd *et al.* 1999 [115]	Annual screening for microalbuminuria 1 yr after diagnosis of diabetes and then treatment with ACEi, vs treat all with ACEi 1 yr after diagnosis	Type 2, Pima Indians	If routine ACEi treatment reduced development of microalbuminuria by 9% and reduced progression of microalbuminuria to macroalbuminuria by 50%, cost per life year gained was $15,000
Herman *et al.* 2003 [117]	Treatment with losartan for hypertension and nephropathy, vs conventional antihypertensive treatment (non-ACEi, non-ARB)	Type 2 diabetes with nephropathy and hypertenison; analysis of the RENAAL clinical trial	Treatment with losartan resulted in reduction in ESRD days by 33.6 over 3.5 yrs, translating to net cost savings per patient of $3522 over 3.5 yrs
Palmer *et al.* 2004 [118]	Early treatment with irbesartan (microalbuminuria only), late treatment with irbesartan (overt diabetic nephropathy) vs standard antihypertensive treatment (non-ACEi, non-ARB)	Type 2 diabetes with nephropathy and hypertension; analysis of the IDNT data	Compared to standard therapy, early irbesartan treatment resulted in savings of $11.9 million; late irbesartan resulted in savings of $3.3 million for every 1000 patients
Golan *et al.* 2000 [95]	Routine treatment with ACEi, screening for microalbuminuria or screening for gross proteinuria	Patients with newly diagnosed type 2 diabetes	Routine treatment of newly diagnosed diabetes had lowest progression to ESRD or death, screening for gross proteinuria had lowest benefit and highest cost; marginal cost-effectiveness of routine treatment was $7500 per QALY compared with screening for microalbuminuria
Kiberd & Jindal 1998 [96]	Screening for microalbuminuria then treatment, routine ACEi treatment 5 yrs after diagnosis, vs a risk-based strategy in which high-risk patients received routine treatment and low-risk patients received treatment only upon abnormalities	Type 1 diabetes	Routine treatment with ACEi 5 yrs after diagnosis produced longest life expectancy, more QALYs, and had lowest associated cost if routine drug therapy reduced microalbuminuria development by 26%.
Siegel *et al.* 1992 [120]	Screening for microalbuminuria then treatment vs screening for gross proteinuria and treatment	Type 1 diabetes	Screening for microalbuminuria and treatment cost $7900 to $16,500 per QALY, within range considered cost-effective
Borch-Johnsen *et al.* 1993 [121]	Screening and intervention program vs no screening	Type 1 diabetes	Increase in life expectancy by 4–14 yrs depending on effectiveness of ACEi treatment, estimated 33–67% effectiveness
Kiberd *et al.* 1999 [116]	Screening for microalbuminuria vs screening for gross proteinuria and hypertension	Type 1 diabetes	Screening for microalbuminuria would produce an additionally QALY at an incremental cost of $27,042 compared to screening for gross proteinuria and hypertension
Palmer *et al.* 2000 [119]	Modeled seven different complications of diabetes; evaluated nephropathy management including screening for microalbuminuria and then treatment	Type 1 diabetes	Screening for microalbuminuria and treatment dominate altenatives, as this was both cost-saving and life-saving
Dong *et al.* 2004 [122]	Treatment with ACEi immediately following diagnosis of type 1 diabetes vs treatment after onset of microalbuminuria	Type 1 diabetes	Routine treatment with ACEi following diagnosis is cost-effective; estimated cost per QALY gained is $13,814 if onset of diabetes is 20 yrs and HbA1c is 9%; cost is $39,350 per QALY gained if onset is at 25 yrs and HbA1c is 7%
Rodby *et al.* 1996 [123]	Compared treatment of diabetic nephropathy with captopril vs placebo	Types 1 and 2 diabetes, reanalysis of clinical trial (Collaborative Study Group)	Treatment with captopril was cost-savings with benefit of $32,550 direct costs saved for IDDM and $9900 direct costs saved for NIDDM per patient

Abbreviations: IDDM, insulin-dependent diabetes mellitus; NIDDM, non-insulin-dependent diabetes mellitus.

equations for the occurrence and progression of CKD, 3) an evaluation of the generalizability of intervention strategies across populations, 4) development of a CKD surveillance model (and not just an ESRD registry), among others. Both the KDIGO position statement and the ISN Consensus Workshops on Prevention have also released similar position statements on additional studies required in the field of kidney disease surveillance, screening, and prevention [100,101].

In establishing a severity stage classification for chronic kidney disease (CKD), the goal of the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (K/DOQI) was to develop a public health approach to the disease aimed at facilitating epidemiological studies and clinical trials as well as the application of clinical practice guidelines [1]. Although this classification did not aim at predicting renal risk, albuminuria and glomerular filtration rate (GFR) cutoff levels set to define CKD stages reflect a graded increase in the risk of major renal and cardiovascular outcomes, including progression to end-stage renal disease (ESRD) and premature death [1,2].

Recommendations for evaluating individuals at risk mainly rely on urine albumin measurement and equation-estimated GFR. In this chapter, we will first very briefly describe the reference methods for these two measures as well as issues related to their use in specific subgroups. In the second part, we will review the main studies providing risk estimates of ESRD as well as of all-cause mortality and cardiovascular events associated with CKD, with special emphasis on variations by age, gender, and race.

Estimation of GFR

GFR has been considered the best indicator of global kidney function for many years [3–6]. It can be measured using slightly different methods, each of which has advantages and limitations. All of these are based on measurement of renal or plasma clearance of an exogenous tracer, such as inulin, which is historically the gold standard, radiolabeled molecules ($[^{51}Cr]$EDTA, $[^{125}I]$iothalamate, and ^{99m}Tc-DTPA), or radiocontrast agents (iohexol and iothalamate). However, these GFR measurements can only be performed in specialized centers, and they are much too time-consuming and costly for routine use in monitoring kidney function. Thus, in clinical practice, GFR has to be estimated using endogenous filtration markers. Creatinine, which is an amino acid derivative with a molecular mass of 113.12 Da, is by far the most widely used one, although it does not fulfill all the criteria of an ideal filtration marker. In particular, creatinine production depends on muscle mass and to a lesser extent on protein intake. As a consequence, serum creatinine concentration is thus influenced by factors such as gender, age, ethnicity, and diet. In addition, although creatinine is principally eliminated by glomerular filtration, urinary excretion is in part mediated by tubular secretion, especially in subjects with reduced renal function. Different equations have been developed that provide an estimation of GFR based on serum creatinine concentration and on subject characteristics, such as age, gender, ethnicity, or body weight. They have been derived by using regression techniques to model the observed relationship between serum creatinine concentration and measured GFR in study populations. Up to now, two creatinine-based equations have been extensively studied and are widely used: the historical Cockcroft-Gault formula [7] and the abbreviated Modification of Diet in Renal Disease (MDRD) study equation [8,9]. The results of the main studies that assessed the performance of these formulas have been recently reviewed by Coresh *et al.* [10] and are summarized in Table 5.1.

The Cockcroft-Gault equation, which was developed to be an estimation of creatinine clearance rather than measured GFR, has several limitations. It tends to systematically overestimate GFR in subjects with low GFR and in subjects with high body mass index, while it tends to underestimate GFR in the elderly [11–14]. For example, in a cohort of subjects with GFR higher than 60 mL/min/1.73 m^2 and older than 65 years, on average the Cockcroft-Gault formula underestimated GFR by 14.5 mL/min/1.73 m^2 in men and by 10.7 mL/min/1.73 m^2 in women [12]. By contrast, the MDRD formula tends to perform better than

Table 5.1 The main studies that have analyzed the performance of the Cockcroft-Gault and MDRD formulas adapted from [10].

Abbreviations: RS, research study; CP, clinical practice; Tx, transplant; CVD, cardiovascular disease; mGFR, mean GFR (in mL/min/1.73 m²); SCr, serum creatinine.
[a] An "m" following the bias value indicates the value is the median.

the Cockcroft-Gault equation in these subgroups of patients, and it appears to be reasonably accurate in most CKD patients. The major limitation of the MDRD formula seems to be an underestimation of GFR in subjects with high GFR. This has been shown by analysis of different cohorts, including potential kidney donors [15,16], diabetic patients without CKD [17], or subjects with and without CKD [11,18]. However, it should be stressed that, at high levels of GFR, a small relative error in serum creatinine measurement will induce a large error in estimated GFR and that the uncertainty of the estimate increases with the absolute value of the GFR. This can be depicted by plotting the interquartile range of measured GFR as a function of estimated GFR (Figure 5.1). It emphasizes the fact that variability of serum creatinine measurements among clinical laboratories can lead to very significant differences in GFR estimation, particularly in subjects with high GFR, and the necessity to calibrate creatinine assays [19,20]. Recently, initiatives have been developed to standardize serum creatinine measurements and im-

prove their accuracy through the preparation of high-level certified reference materials set by isotope–dilution mass spectrometry (IDMS) [21]. A slightly modified IDMS-MDRD formula is now available that should be used with calibrated serum creatinine assays [22], since the formula has been validated on a large external set of data collected through the CKD-EPI collaborative study [23].

Cystatin C, a 13-kDa protein, is an alternative endogenous filtration marker. Its main advantage is the relative stability of its production, which is mainly independent of muscular mass variations. During the past few years, some predictive equations to estimate GFR have been developed. Two sets of equations issued from the CKD-EPI collaborative study have been proposed: one using cystatin alone as a GFR marker, and a second using both creatinine and cystatin [24]. This combined approach slightly improves the predictive performance of the formula. The main recent GFR predictive equations are summarized in Table 5.2.
Figure 5.1 Predicted values of the measured GFR as a function of the estimated GFR value using the MDRD formula. Solid lines represent the upper and lower boundaries of the 95% confidence interval of the measured GFR values for each value of eGFR. The dotted line represents the mean measured GFR value for each value of eGFR [12].

Table 5.2 GFR prediction formulas recently developed based on large data sets of patients (900–3400 independent patients).

GFR marker, method (reference lab or reference material)	eGFR formula [reference]
Creatinine, Jaffe colorimetric (Cleveland Clinic Foundation)	Abbreviated MDRD (four variables) [9] SCr (mg/dL): $eGFR = 186 \times (SCr)^{-1.154} \times (age)^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if Black})$ SCr (μmol/L): $eGFR = 32{,}789 \times (SCr)^{-1.154} \times (age)^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if Black})$
Creatinine, Jaffe colorimetric (Mayo Clinic Clinical Lab)	Mayo quadratic [15] SCr (in mg/dL; SCr with a constant value of 0.8 mg/dL if measured creatinine < 0.8 mg/dL): $eGFR = \exp[1.911 + (5.249/SCr) - (2.114/SCr^2) - (0.00686 \times age) - (0.205 \text{ if female})]$
Creatinine, Jaffe colorimetric calibrated to IDMS-standardized Roche enzymatic assay (IDMS, NIST 914a)	Abbreviated MDRD refitted for IDMS standardization [22] Scr (mg/dL): $eGFR = 175 \times (SCr)^{-1.154} \times (age)^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if Black})$ SCr (μmol/L): $eGFR = 30{,}850 \times (SCr)^{-1.154} \times (age)^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if Black})$
Cystatin C, nephelometry (Dade-Behring/Siemens)	CKD-EPI cystatin alone [24] SCys (mg/L): $eGFR = 127.7 \times (SCr)^{-1.17} \times (age)^{-0.13} \times (0.91 \text{ if female}) \times (1.06 \text{ if Black})$
Creatinine and cystatin C, nephelometry for SCys (Dade-Behring/Siemens) and Jaffe colorimetric calibrated to IDMS-standardized Roche enzymatic assay (IDMS, NIST 914a) for SCr	CKD-EPI combined SCr and SCys formula [24] SCr (mg/dL) and SCys (mg/L): $eGFR = 177.6 \times (SCr)^{-0.65} \times (SCys)^{-0.57} \times (age)^{-0.20} \times (0.82 \text{ if female}) \times (1.11 \text{ if Black})$ SCr (μmol/L) and SCys (mg/L): $eGFR = 3271 \times (SCr)^{-0.65} \times (SCys)^{-0.57} \times (age)^{-0.20} \times (0.82 \text{ if female}) \times (1.11 \text{ if Black})$

Abbreviations: BSA, body surface area; SCr, serum creatinine; SCys, serum cystatin; NIST, National Institute of Standards and Technology.

It is worth noting that although similar in structure to risk prediction equations, such as the Framingham risk function [25], currently utilized GFR equations do not provide an estimate of risk directly; that is, calculated GFR is not expressed as a risk estimate for future events. However, the combined cystatin and creatinine equation may be a first step in integrating relative risk in GFR prediction formulas, because cystatin on its own has been recognized as an independent risk marker for cardiovascular morbidity and overall mortality [26].

Assessment of proteinuria

Timed versus untimed urine sample

Measurement of proteins in a 24-h urine collection has long been considered the gold standard for quantitative assessment of proteinuria. However, collecting urine over such a long period of time is quite burdensome, and reliable 24-h urine collections are quite difficult to obtain. This has prompted the National Kidney Foundation and KDIGO to recommend using protein/creatinine or albumin/creatinine ratios obtained in untimed urine samples to quantitatively assess proteinuria or albuminuria. Although the excretion rate of creatinine in the urine varies according to age, gender, ethnicity, and body size, and although protein and albumin excretion rates may vary throughout the day, different studies have shown a strong correlation between protein and albumin excretion rates and protein/creatinine and albumin/creatinine ratios in a spot urine sample. In 2005, Price *et al.* performed a systematic review of studies comparing 24-h protein excretion and protein/creatinine ratios assessed in a random spot urine sample [27]. Their analysis of 20 studies showed that the correlation coefficient between the two values was above 0.90 in 14 studies of 20 and above 0.80 in 16 studies of 20.

Albuminuria versus proteinuria

In adults, the National Kidney Foundation K/DOQI guidelines recommend measurement of albuminuria rather than proteinuria, because it is a more sensitive marker of CKD due to diabetes, hypertension, or glomerular disease [1]. In addition, it seems logical to measure a well-defined protein that is filtered in increased amounts even when glomerular lesions are minimal rather than a mixture of proteins that include albumin but also proteins that are normally filtered by the glomerulus and reabsorbed by tubular cells, such as low-molecular-weight proteins, and proteins that are normally produced by tubular cells and excreted in the urine, such as uromodulin. However, the usefulness of albuminuria for diagnosis of CKD has been mostly demonstrated in patients with diabetes and kidney disease. In these patients, albuminuria provides the earliest clinical evidence of nephropathy and is an early predictor of patients at higher risk of progressive loss of renal function, both in type 1 and type 2 diabetic patients [28–31]. In the general population, the PREVEND study has provided evidence that at low level albuminuria are also a risk factor for subsequent impairment of renal function. In this large epidemiological study that included more than 80,000 subjects with a mean follow-up of 4 years, an albumin/creatinine ratio above 30 mg/g at inclusion was an independent risk factor for an estimated GFR (eGFR) of <60 mL/min/1.73 m^2 at 4 years [32].

Threshold values

The threshold used to define proteinuria is usually 300 mg/day or 200 mg/g of creatinine [1], which roughly correspond to protein concentrations that are detected by dipstick analyses. Although this threshold appears not to be grossly flawed on clinical grounds, one can question the fact that it is not higher than the limit used to define "clinical albuminuria" or "macroalbuminuria" [1].

Regarding albuminuria, the Third National Health and Nutrition Evaluation Survey showed that, in a very large cohort of subjects, about 95% of those less than 50 years of age had an albumin/creatinine ratio of less than 3 mg/g [33]. Because creatinine excretion rate varies according to gender and ethnicity, it may seem necessary, for the sake of precision, to define gender-specific cutoff values for albuminuria as defined by this ratio. However, due to the greater complexity that such modifications would introduce, the inherent uncertainty in assay precision, and the existence of other factors influencing importantly creatinine excretion rate besides gender, a KDIGO position paper did not advocate using gender-specific cutoff values for diagnosis of CKD and considered 30 mg/g as the threshold level [34]. Furthermore, this threshold is consistent with the recommendations of JNC-7 and recommendations from the American Diabetes Association [35]. However, when assessing albuminuria, it is important to remember that verification of increased albumin excretion requires at least two out of three positive tests on independent determinations.

Mortality and ESRD risk associated with CKD

There are numerous studies that have linked CKD to all-cause mortality and cardiovascular events in various populations, including cohort studies and cohort analyses of randomized trials, but those linking CKD to the risk of ESRD are scarce [36,37]. With a few exceptions, risks associated with GFR level or albuminuria have been analyzed separately.

GFR level and risk for progression to ESRD

In most studies, renal replacement therapy (RRT) is used as a surrogate outcome for ESRD. Therefore, ESRD risk estimates are influenced by geographic variations and trends over time in access to treatment. Based on data from the US Renal Data System 2000 annual report, the cumulative lifetime risk of developing ESRD requiring RRT was estimated by gender and race in 20-year-old Americans as follows: 7.3% and 7.8% in African American men and women and 2.5% and 1.8% in white men and women [38]. Because RRT incidence rates are 2 to 3 times lower in Europe and Australia than in the USA [39,40], cumulative risks are likely to be reduced proportionally in these countries.

Table 5.3 Cumulative 5- and 10-year incidence rates of competing risks for kidney failure and death in patients with CKD stage 3 (n = 3047)

Patient age and incidence data category	No. of cases (%) or incidence (95% CI)

[a] Kidney failure was defined as irreversible CKD stage 5 or initiation of RRT.

Available studies have consistently shown that at any stage of CKD the risk of death is greater than the risk of progression to ESRD. Some studies have also shown that the magnitude of both risks, i.e. death or ESRD, stratified by CKD stage varies importantly with age, gender, and race.

In a large cohort of 28,000 health maintenance organization members (>17 years old; mean age, 66 years), Keith *et al.* [41] showed that the percentages of patients reaching RRT, either transplant or dialysis, over a 5-year observation period versus those dying were 1.1 versus 19.5%, 1.3 versus 24.3%, and 19.9 versus

45.7% for those patients at baseline with CKD stages 2, 3, and 4, respectively. Moreover, among patients with comparable levels of eGFR, older patients have higher rates of death and lower rates of treated ESRD than younger patients [42].

Table 5.3, adapted from Eriksen and Ingebretsen [43], displays the 5- and 10-year competing risks of true ESRD and death in a population-based cohort of 3047 Norwegian patients (>20 years old; median age, 75 years) with persistent CKD stage 3 at baseline, identified from all serum creatinine levels measured in a geographically defined population. The 10-year risk of ESRD, defined as

CKD stage 5, that is, either an eGFR of less than 15 mL/min/1.73 m^2 or RRT, was 4%, 13 times lower than the risk of death in this cohort. The risk of ESRD was 3 times higher in men than in women and twice as high in patients less than 69 years old than in older patients. As expected, the relative risk of death versus ESRD increased strongly with age, from 2.4 (17% vs. 7%) among the youngest age group to 28 (84% vs. 3%) in the oldest group. Compared with the general population, the standardized incidence rate ratios of ESRD and death for CKD patients in this Norwegian population were 36.6 and 3.1, respectively, among those younger than 69 years but only 3.7 and 2.2, respectively, in the oldest age group. Similar results with regard to the risk of progression to ESRD versus mortality according to age were observed in a retrospective cohort from England [44].

The competing risks of death versus ESRD were examined in advanced CKD stages in a population-based inception cohort of 920 Swedish adults aged 18–74 years with CKD stage 4 or stage 5 not on dialysis. Of this cohort, 8% started RRT within 6 years, only 10% died before initiating RRT, but 42% were dead by 6 years [45]. These findings taken together favor the conclusion that premature death rather than denial of RRT explains the higher risk of death versus ESRD for patients with earlier stages of CKD.

Finally, ecologic studies linking data on the CKD prevalence derived from nationally representative population-based surveys with the RRT incidence derived from national renal registries have shown that the 5-year risk of treated ESRD is 5 times higher in African Americans with stage 3 plus CKD (5%) than in their white counterparts (1%) [46] and 2.5 times higher in US whites than in Norwegians [40]. Causal interpretation of these results should nevertheless be made with caution, as ecologic associations based on aggregate measures may not accurately reflect true associations at the individual level [47].

GFR level and risk for all-cause mortality and cardiovascular events

Studies linking GFR level with mortality have been extensively reviewed by Tonelli *et al.* and Vanholder *et al.* [36,48]. Despite variations in design, study populations, event rates in controls, and definitions of CKD, more than 90% of the studies found an increased risk of all-cause and cardiovascular mortality with decreasing GFR, both before and after adjustment for potential confounders [36]. An independent graded association between a reduced eGFR and the risk of death and *de novo* or recurrent cardiovascular events was consistently observed in cohorts of patients with heart failure [49,50], cardiovascular disease or high cardiovascular risk [51,52], and hypertension [53], as well as in the general population [54–63].

In a cohort of 1,120,000 health plan members, Go *et al.* [57] showed that the age-standardized rates for death from any cause and for cardiovascular events, defined as any hospitalization for coronary heart disease, heart failure, ischemic stroke, or peripheral arterial disease, increased substantially with progressively lower GFR. Taking patients with an eGFR of ≥60 mL/min/1.73 m^2 as the reference, and after adjustment for demographics and several comorbidities, the risk of death strongly increased as GFR declined, from a 17% increase in risk with an eGFR of 45–59 mL/min/1.73 m^2 to 80%, 220%, and nearly 500% increases for GFRs of 30–44, 15–29, and <15, respectively. The adjusted risk of any cardiovascular events followed a similar pattern, with a 43% increase in risk for a GFR of 45–59 mL/min/1.73 m^2 and 100%, 180%, and 240% increases for GFRs of 30–44, 15–29, and <15, respectively. However, O'Hare *et al.* [62] demonstrated using a different study population that whereas severe reductions in eGFR were associated with an increased risk for death in all age groups, very moderate reductions in GFR (50–59 ml/min/1.73 m^2) were not associated with significantly increased risk among those older than 65 years.

In a pooled analysis of data from four large US community-based longitudinal studies including 22,634 individuals, Weiner *et al.* [60] found that CKD was an independent risk factor for all-cause mortality but not for myocardial infarction or stroke. However, there was a significant interaction between kidney function and race. In African Americans, CKD defined as an eGFR of <60 mL/min/1.73 m^2 was associated with a more than a 100% increase in risk of myocardial infarction and 83% increase of all-cause mortality, whereas in whites the risk of all-cause mortality only was significantly increased by 31%. Reduced kidney function was also associated with increased risk for incident heart failure [64]. Finally, in a large cohort of participants in the MONICA Augsburg survey, the authors investigated the gender-specific association of CKD with cardiovascular mortality and incident myocardial infarction. After adjusting for common cardiovascular disease risk factors, they found similar hazard ratios for both events in men and women [63].

Proteinuria and risk for ESRD and cardiovascular outcomes

Urinary protein (or albumin) excretion of 300 mg/24 h (300 mg/g urinary creatinine) or greater is a major and well-established determinant of progressive kidney failure in patients with glomerular, diabetic, and hypertensive nephropathies. Numerous clinical studies have shown a strong graded relationship between proteinuria level and the risk of either 50% decrease in GFR, ESRD, or death. Moreover, there is evidence that treating proteinuria in these patients improves renal outcome [65–67]. These studies are reviewed and discussed in detail by Ritz in chapter 3.

In contrast, studies investigating the link between the presence of proteinuria at screening and the risk for poor renal outcomes in the general population are scarce. In a 17-year follow-up of 106,177 participants in a community-based mass screening in Japan, Iseki *et al.* [68] showed that a positive dipstick proteinuria (1+ or greater) was associated with a relative risk for developing ESRD of 1.9 in men and 2.4 in women, compared with participants with no or trace proteinuria. Similarly, in the PREVEND study, which was a large population-based cohort of 6894 adults aged 20–75 years from the city of Groningen, the Netherlands, participants with baseline screened macroalbuminuria (>300 mg/24 h), which was present in 0.6% of the general population, had faster

annual declines in GFR (7.2 mL/min/1.73 m^2/year) than controls without albuminuria (2.3 mL/min/1.73 m^2/year) [69]. The 4-year follow-up of this study was not long enough, however, to evaluate the risk of the progression to ESRD.

The significance of microalbuminuria, in the range of 30–300 mg/24 h (30–300 mg/g urinary creatinine), as an early marker of renal injury and a predictor of progressive CKD is less clear [70]. Microalbuminuria was initially defined as a range of dipstick-negative albuminuria predicting future overt nephropathy in patients with type 1 diabetes mellitus [71]. Its predictive value was later extended to patients with type 2 diabetes mellitus. In the UK Prospective Diabetes Study (UKPDS), a randomized clinical trial including 5097 patients with newly diagnosed type 2 diabetes and a median follow-up of 10.4 years, the annual probability of progression from stage to stage of kidney injury (incidence) was estimated as follows: 2%/year from no nephropathy to microalbuminuria, 2.8% from microalbuminuria to macroalbuminuria, and 2.3% from macroalbuminuria to elevated serum creatinine or RRT [72]. The annual probability of not progressing to a more advanced stage of nephropathy or death was 93.8% for patients with microalbuminuria, and the estimated median duration in this stage was 10.9 years. For patients with microalbuminuria, the annual death rate, 3%/year, was similar to that of progressing to macroalbuminuria, but for those with macroalbuminuria, the annual death rate of 4.6% was twice as high as that of progressing to worse nephropathy. Relative to patients with no nephropathy, those with microalbuminuria, macroalbuminuria, or an elevated serum creatinine or RRT had a 2.2-fold, 3.4-fold, and 13.9-fold increased risk of death, respectively.

Although similarly robust evidence of progression from microalbuminuria to overt nephropathy and ESRD are lacking in other segments of the population, there is increasing evidence that microalbuminuria is associated with GFR decline in the general population as in patients with hypertension [70]. Data from the PREVEND study showed that an elevated urinary albumin excretion predicted *de novo* development of chronic kidney failure defined as an eGFR of <60 mL/min/1.73 m^2 [32]. In the African American Study of Kidney Disease and Hypertension (AASK), there was a graded relationship between continuous level of albuminuria and the risk of either a 50% decrease of GFR, ESRD, or death, starting in the microalbuminuric range [67].

Both micro- and macroalbuminuria are well-established risk factors for cardiovascular outcomes, including fatal and nonfatal coronary heart disease, chronic heart failure, and stroke. Multiple studies and secondary analyses of large databases have shown strong independent associations of albuminuria with an increased risk for these events, as reviewed by Basi *et al.* [70]. This association is well-documented in patients with diabetes or hypertension [39-41], as well as in nondiabetic, nonhypertensive individuals from either selected or unselected populations [56,73–78].

It is evident from all these studies that microalbuminuria is definitely a major predictor of cardiovascular risk in all individuals and of progressive renal disease in diabetic patients. Whether it also predicts poor renal outcomes in nondiabetic populations

is likely, albeit not yet proven. These results are important from a public health perspective of primary prevention of both cardiovascular disease and ESRD, as albuminuria is a potentially modifiable risk factor. Lowering of albuminuria by either an angiotensin converting enzyme inhibitor or an angiotensin II receptor blocker is indeed associated with a better renal and cardiovascular outcome in patients with overt proteinuric nephropathy as well as in diabetic patients with microalbuminuria [65,66,81]. However, robust clinical trials evidence that similar treatment of nondiabetic individuals with microalbuminuria [75], a condition that can affect from 6 to 20% of all adults depending on the population, is beneficial, safe, and cost-effective to prevent cardiovascular and renal diseases is currently not available.

2   Acute Kidney Injury

6 Definition, Classification, and Epidemiology of Acute Kidney Disease

Eric A. J. Hoste,[1,2] **Ramesh Venkataraman,**[1] **& John A. Kellum**[1]

[1]The Clinical Research, Investigation, and Systems Modeling of Acute Illness Laboratory, Department of Critical Care Medicine, University of Pittsburgh, School of Medicine, Pittsburgh, USA
[2]Intensive Care Unit, Ghent University Hospital, De Pintelaan 185, Belgium

Introduction

The concept of acute renal failure (ARF) has undergone significant reexamination in recent years. Mounting evidence suggests that acute, relatively mild dysfunction of the kidney, manifest by changes in urine output and blood chemistries, portends serious clinical consequences [1]. Although the term acute renal failure is relatively new, its first description as *ischuria renalis* was by William Heberden in 1802 [2]; it has nonetheless become entrenched in our medical lexicon. During the first World War the syndrome was named "War Nephritis" [3] and was reported in several publications. The syndrome was then largely forgotten until the second World War, when Bywaters and Beall published their classical paper on crush syndrome [4]. It is Homer W. Smith who is credited for the introduction of the term acute renal failure, in a chapter on "Acute renal failure related to traumatic injuries" in his textbook *The Kidney—Structure and Function in Health and Disease* (1951). The same year, an entire issue of the *Journal of Clinical Investigation* was dedicated to ARF [5].

Thus, it should come as little surprise that in most reviews and textbook chapters [6,7], the concept of acute kidney dysfunction still emphasizes the most severe forms, with severe azotemia and often with oliguria or anuria. It has only been in the past few years that moderate decreases of kidney function have been recognized as potentially important, e.g. by the SOFA score [8] and in studies on radiocontrast-induced nephropathy [9].

However, not only has there been a lack of consensus regarding the concept of ARF, but also there has been, until very recently, no consensus on the diagnostic criteria or clinical definition of ARF. Distressingly, this has resulted in multiple different definitions being used. For example, a recent survey revealed the use of at least 35 different definitions of ARF in the literature

[10]. Along with differences in patient characteristics, this lack of uniformity in the diagnosis has probably contributed to the wide variation in the reported incidence and outcome of ARF (incidence ranges between 1 and 31% [11,12], and mortality is between 28 and 82% [12,13]). Obviously if one study defines ARF as a 25% or greater rise in serum creatinine while another study defines ARF based on the need for renal replacement therapy (RRT), the two studies will not describe the same cohort of patients. A linear correlation between the degree of kidney dysfunction and the outcome of acute kidney dysfunction has been described; the more strict the definition of ARF, the greater the mortality [10].

Another element that has emerged in recent years is the observation that small decrements in kidney function are important. For example, Levy *et al.* [9] found that a 25% increase in serum creatinine after administration of radiocontrast was associated with a worse outcome in those patients experiencing the decrement in function compared to those patients who did not experience a 25% or greater increase in serum creatinine. Chertow *et al.* [14] defined hospital-acquired acute kidney dysfunction as an increase of serum creatinine of >0.3 mg/dL and found that this was independently associated with mortality.

Similarly, Lassnigg *et al.* [15] saw, in a cohort of patients who underwent cardiac surgery, that acute kidney dysfunction, defined as an increase of serum creatinine of ≥0.5 mg/dL or a decrease greater than 0.3 mg/dL, was associated with decreased survival.

The reasons why small alterations in kidney function lead to increases in hospital mortality are unclear. Possible explanations include the untoward effects of acute kidney dysfunction, such as volume overload, retention of uremic compounds, acidosis, electrolyte disorders, increased risk for infection, and anemia [16]. Although, acute kidney dysfunction could simply be colinear with unmeasured variables that lead to increased mortality, multiple attempts to control for known clinical variables have led to the consistent conclusion that kidney dysfunction is independently associated with adverse outcome. Furthermore, more severe kidney dysfunction tends to be associated with even worse outcome compared to milder abnormalities.
Figure 6.1 RIFLE classification scheme for AKI. The classification system includes separate criteria for serum creatinine (SCreat) and urine output (UO). The criterion that leads to the worst possible classification should be used. Note that RIFLE-F is present even if the increase in SCreat is <3-fold, as long as the new SCreat is ≥4.0 mg/dL (350 µmol/L) in the setting of an acute increase of at least 0.5 mg/dL (44 µmol/L). The shape of the figure denotes the fact that more patients (high sensitivity) will be included in the mild category, including some without actually having kidney failure (less specificity). In contrast, at the bottom, the criteria are strict and therefore specific, but some patients will be missed. From Bellomo *et al.* [17]; used with permission.

From acute kidney failure to acute kidney injury

As with many conditions in acute medicine, early detection affords a better opportunity to intervene. Furthermore, milder forms of renal dysfunction have clinical importance and therefore staging (mild to severe) is desirable in order to better describe the syndrome. For these reasons, the Acute Dialysis Quality Initiative (ADQI), an international consensus group comprised of nephrologists and intensivists with expertise in acute kidney dysfunction, proposed the RIFLE criteria to define and stage acute kidney dysfunction (www.ccm.upmc.edu/adqi/ADQI2) [17]. The acronym RIFLE stands for the three severity stages of *r*isk, *i*njury, and *f*ailure (in order of increasing severity) and the two outcome stages of *l*oss and *e*nd-stage kidney disease. The three severity stages are defined on the basis of either increases in serum creatinine or decreases in urine output (Figure 6.1), where the more severe of either criterion is used. The two outcome criteria, loss and end-stage kidney disease, are defined by the duration of loss of kidney function.

The RIFLE criteria were published as a workgroup document on the ADQI website in June 2003 and published online May 2004 and in print August 2004 [17]. Since then multiple studies have been published using the RIFLE criteria [18–29] (Table 6.1), with the majority published within the past 12 months. In addition, the Acute Kidney Injury Network (AKIN) organized two conferences endorsed by critical care and nephrology societies from around the world with the aim of developing a broader consensus on the definitions and terminology for ARF. In particular, this group has proposed the term acute kidney injury (AKI) to define the entire spectrum of acute kidney dysfunction from its earliest and mildest forms to the need for RRT. We will therefore adopt this term for new studies, as we have previously [1,24], although we will continue to use ARF when describing older studies.

Epidemiology of AKI

In one Spanish multicenter study, Liaño *et al.* defined ARF as a sudden rise in serum creatinine concentration to >177 µmol/L in patients with normal kidney function, or a ≥50% rise in serum creatinine in patients with previous mild to moderate chronic kidney failure (serum creatinine <264 µmol/L) [30]. In this study, a collaborative prospective protocol with 98 variables was developed to assess all ARF episodes encountered in the 13 tertiary care hospitals in Madrid, Spain. An overall incidence of ARF of 209 cases per million population (pmp)/year; (95% confidence interval [CI], 195–223) was reported. The incidence of acute tubular necrosis (ATN) was 88 cases pmp (95% CI, 79–97), prerenal ARF was 46 pmp (95% CI, 40–52), acute onset chronic kidney failure presenting as ARF was 29 pmp (95% CI, 24–34), and obstructive ARF was 23 pmp (95% CI, 19–27). In 187 cases, mortality was attributed to underlying disease, and thus corrected mortality due to ARF was 26.7%. Dialysis was required in 36% of patients and was associated with a significantly higher mortality (65.9 vs. 33.2%; $P < 0.001$). More recently, in a prospective study of adult patients admitted in 43 Spanish intensive care units (ICUs), ARF was defined as a creatinine level of ≥2 mg/dL or oliguria and a urine volume of <400 mL/24 h in patients with normal baseline function, and in patients with chronic kidney disease, ARF was defined as a 100% increase in serum creatinine, excluding patients with a baseline creatinine of ≥4 mg/dL [31]. This study found an incidence of ARF of 5.7%, with 55% of cases occurring on admission. Mortality was 42.3% during the ARF episode, and recovery

Table 6.1 Studies in which the RIFLE criteria for AKI were used.

Study [reference]	Cohort	Aim of study	AKI defined by GFR (1) or by UO and GFR (2)	Outcome criteria	Occurrence of AKI	No. patients with max RIFLE score/total patients in subgroup
Herget-Rosenthal [18]	85 ICU patients, initial normal GFR	Evaluate cystatin C vs creatinine	1	No	44/85 (51.8%)	R: 3/85 (3.5%) I: 13/85 (15.3%) F: 28/85 (32.9%)

Lopes [28][b]	126 burn patients	Incidence and outcome of AKI	2	No	35.7%	R: 14.3% I: 8.7% F:: 12.7%
Ahlstrom [29]	658 ICU patients, classified w/in 3 days of ICU admission	Evaluation of different scoring systems, including RIFLE criteria, for hospital mortality	2	Yes	52.0%	R: 168/658 (25.5%) I: 100/658 (15.2%) F: 74/658 (11.2%) L: 1/658 (0.2%)

Abbreviations: NA, not applicable or not available; BSI, bloodstream infection; ECMO, extracorporeal membrane oxygenation.

[a] Patients were classified at inclusion in the study (on admission to the ICU or at the start of CRRT).

[b] Patients were classified on occurrence of maximum RIFLE class during the first 10 days of hospital admission.

of kidney function occurred in 85.6% of the survivors. Four other large epidemiological surveys, in which a less sensitive but more specific definition of ARF was used, i.e. ARF defined by the need for RRT, found an incidence of approximately 100 pmp/year. The incidence in Australia ranged from 80 to 134 pmp/year [32,33], in Finland an incidence of 80 pmp/year was found [34], and recently,

Bagshaw *et al.* reported an incidence of severe ARF defined as needing new RRT of 110 pmp/year in a Canadian population [35].

Recent retrospective data suggest that there is a rise in the incidence of ARF in the USA, while mortality rates are declining [36,37]. Different definitions or coding of ARF may hamper correct interpretation of these findings. However, this limitation seems

unlikely based on the study by Waikar *et al.* [37]. Those authors evaluated the accuracy of administrative codes for ARF for applications in clinical epidemiology and health services research by comparing codes of the *International Classification of Diseases*, 9th Revision, Clinical Modification (ICD-9-CM) from hospital discharge records against serum creatinine-based definitions of ARF [38]. The study revealed that 4.2% of discharges received a code for ARF. In comparison to a diagnostic standard of a 100% change in serum creatinine, ICD-9-CM codes for ARF had a sensitivity of 35.4%, specificity of 97.7%, positive predictive value of 47.9%, and negative predictive value of 96.1%. Compared with reviews of medical records, ICD-9-CM codes for ARF had a positive predictive value of 94.0% and negative predictive value of 90.0%.

AKI defined by the RIFLE criteria

An overview of studies using the RIFLE criteria for AKI is presented in Table 6.1.

All studies used the severity grading criteria of risk, injury, and failure, but only three studies [19,20,29] also used the outcome criteria loss and end-stage kidney disease. Two of these studies were in a cohort of AKI patients defined by the need for RRT. Ahlstrom *et al.* [29] and Bell *et al.* [20] classified both severity grades and outcome classes. However, all patients included in the study by Bell and colleagues were treated with chronic RRT for AKI. These subjects therefore had severe AKI, and thus represent only a subgroup of the overall population.

Severity grading was performed according to the RIFLE criteria on creatinine and urine output criteria in 8 of the 11 studies that reported on severity grading [20–24,26,28]. However, Lin *et al.* [26] used different urine output criteria cutoffs than those of RIFLE. The three remaining studies defined severity of AKI based only on change of serum creatinine level and not on urine output [18,25,27]. The reasons for this were diverse. Herget-Rosenthal compared assessment of glomerular filtration rate (GFR) by serum creatinine and cystatin C levels. Uchino retrospectively evaluated hospital-wide cases, which prevented assessment of urine output [25]. In addition, the study by Heringlake was a large prospective study on practice patterns in cardiac surgery in German cardiovascular centers [27], and urine output was not collected. Interestingly, one group chose to use the Cockcroft-Gault equation for assessment of creatinine clearance, rather than use a change in serum creatinine levels, as all other authors did [21]. When the baseline serum creatinine level is unknown in a patient without a history of chronic kidney insufficiency, ADQI proposed back-calculation of the "baseline" serum creatinine concentration using the four-variable Modification of Diet in Renal Disease (MDRD) study equation, assuming a GFR of >75 mL/min/1.73 m^2 [17]. This was done in only four studies [24–26,29]. Kuitunen also used the MDRD formula, however not for assessment of a baseline creatinine level but for assessment of GFR [22].

Most studies used the RIFLE criteria to assess the occurrence of AKI in specific cohorts. However, two studies used the RIFLE criteria for other specific purposes. Herget-Rosenthal evaluated whether a serum level of cystatin C is a better marker for GFR than

a serum creatinine level [18], and Hoste used the RIFLE outcome criteria as a secondary outcome parameter in a study on the impact of bloodstream infection in AKI patients treated with RRT [19].

The occurrence of AKI defined by RIFLE criteria in various different cohorts ranged from 15.4 to 78.3% (Table 6.1). This is higher than is generally accepted when the classic terminology of ARF is used. The large study by Uchino demonstrated that almost 18% of hospitalized patients in a large tertiary care hospital had an episode of AKI as defined by RIFLE using serum creatinine criteria [25]. This is much higher than the incidence of 4.9% reported in a hallmark study using data from 1979 [39] or 7.2% in a follow-up study that used data from 1996 [40]. Although the definition of AKI used in these earlier studies differs from the RIFLE criteria, the sensitivity seems comparable. Hou and Nash defined AKI as a rise in serum creatinine of >0.5mg/dL for patients with a baseline of <1.9 mg/dL, >1.0 mg/dL for patients with a baseline between 2 and 4.9 mg/dL, and >1.5 mg/dL for patients with a serum creatinine level of >5.0 mg/dL [39]. An explanation for the higher rates of AKI could be that the RIFLE criteria are more sensitive, especially for patients with acute or chronic disease. Alternatively, the three cohorts may have had different baseline characteristics and/or different comorbidities. The trend of increasing incidence for the same definition suggests that the latter explanation seems more plausible. Increasingly, patients are now older, suffer from more comorbidities, such as diabetes or cardiovascular disease, and are more frequently exposed to diagnostic and therapeutic procedures with potential to harm the kidneys.

Two large studies in cardiac surgery patients using the RIFLE criteria indicated that the incidence of AKI after cardiac surgery is about 15–20% [22,27]. This is a considerably higher incidence than the incidence of AKI of <8% that is generally accepted in this specific cohort of patients [11,41–44]. In a single-center, tertiary care, general ICU setting, two out of three patients experienced an episode of AKI [24]. This was comparable to the 52% incidence found by another group in a study that included two different ICUs from the same hospital [29] and considerably higher than the incidence of renal dysfunction generally reported (generally ranging from about 5% [45] up to 31% in specific patient subgroups [12,46]). Finally, small studies in specific groups of patients, such as patients with cardiogenic shock on extracorporeal membrane oxygenation, liver transplantation, or burns, also demonstrated high ICU period prevalence rates for AKI, with rates of 78, 64, and 35.7%, respectively [23,26,28].

In summary, the RIFLE criteria for AKI are more sensitive than more traditional definitions of ARF. The incidence of AKI defined by the RIFLE criteria is much higher (2–10 times higher) than the incidence of more traditionally defined ARF, but the incidence for both appears to be increasing.

Outcomes in AKI

Most studies, with few exceptions, have reported a stepwise increase of mortality for increasing RIFLE class. One exception is

Table 6.2 Mortality outcome of AKI defined by RIFLE criteria and by individual RIFLE severity grades after correction for other comorbidities.

Study [reference]	Statistical test used	RIFLE criterion	OR (for LR) or HR (for CPH) (95% CI)	P value
Kuitunen [22]	LR	AKI	2.616	<0.001
Hoste [24]	CPH	AKI	1.7 (1.28–2.13)	<0.001
	CPH	Risk	1.0 (0.68–1.56)	0.896
		Injury	1.4 (1.02–1.88)	0.037
		Failure	2.7 (2.03–3.55)	<0.001
Uchino [25]	LR	Risk	2.536 (2.152–2.988)	<0.0001
		Injury	5.412 (4.547–6.442)	<0.0001
		Failure	10.124 (8.318–12.32)	<0.0001
Lopes [28]	LR	Risk	5.6 (1.2–26.8)	<0.001
		Injury	6.2 (1.1–47.8)	0.008

Abbreviations: LR, logistic regression analysis; CPH, Cox proportional hazard analysis; OR, odds ratio; HR, hazard ratio.

the study by Bell *et al.* [20], who included only patients who were treated with CRRT, suggesting that these patients already had severe AKI. In all other studies, increasing severity classes of AKI indeed had worse outcomes. In four studies, multivariate analyses were performed to assess the impact of AKI defined by RIFLE after correction for other comorbidities (Table 6.2). AKI defined by RIFLE criteria was associated with increased mortality in all four studies.

Limitations of the RIFLE criteria

Use of the urine output criterion of the RIFLE criteria has been more controversial and less widely used compared to the creatinine criterion. Although decreased urine output has a high specificity and sensitivity for acute kidney dysfunction, the urine output criteria have significant limitations. First, sensitivity and specificity may be lost when diuretics are used. The use of diuretics is not explicitly addressed in the RIFLE criteria, although their use is common practice with AKI patients worldwide (with reported utilization rates ranging between 59 and 70%) [47,48]. The urine output criterion can only be accurately assessed in patients with urinary catheters. Thus, the use of urine output criterion may be limited to an ICU cohort. However, these data should also prompt reconsideration of the need for monitoring urine output and improved rigor in this monitoring in most hospital settings outside of the ICU or operating room. Another limitation of the urine output criterion is that there are many reasons that might interfere with exact measurement of urine output, such as mechanical issues, including obstruction of the urinary bladder catheter by debris or blood clots and kinking of the catheter. Finally, the sensitivity of the urine output criterion for risk, injury, and failure may not be well-calibrated with the respective creatinine criteria. In other words, at-risk patients defined by the creatinine criterion may be more severely ill compared to at-risk patients defined by the urine output criterion. This could be one explanation for the different impact of increasing RIFLE class on mortality in the two large studies by Hoste (creatinine and urine output criteria) [24] and Uchino (creatinine criterion only) [25]. Baseline mortality in non-AKI patients was comparable. However, mortality for patients in the risk, injury, and failure groups was much higher in the cohort studied by Uchino compared to the cohort studies by Hoste, despite the fact that the latter was derived from a hospital-wide population and the former a general ICU population.

Another limitation of the RIFLE criteria is the need for a baseline creatinine level in order to calculate the proportional decrease of kidney function. A proportional increase in serum creatinine better represents changes in kidney function compared to a severity gradation based completely on specific cutoffs, as in the SOFA score [8]. A patient who has an increase of serum creatinine from 0.5 to 1.1 mg/dL has a 120% decrease of kidney function and this would be classified as RIFLE injury; however, this same patient would have a renal SOFA score of 0. Baseline serum creatinine levels are, however, not always known in patients who are admitted to the emergency department or ICU. And if there are data, what is the correct baseline? For example, a serum creatinine level after a 1.5-week hospitalization period in an elderly patient with pneumonia may be falsely low due to loss of muscle mass and decreased creatinine production [49]. Creatinine at admission is probably less biased by loss of muscle mass; however, it may be elevated already due to early kidney dysfunction. In patients without a history of chronic kidney disease, back-calculation of a "baseline" creatinine level using the MDRD equation has been proposed; however, this can only provide an approximate value, and the validity of this equation across all populations has been questioned. The MDRD equation was validated in a large data set of US patients with moderate to severe chronic kidney insufficiency and was not validated in patients with near-normal kidney function, in patients with underlying diabetes mellitus, or in the very elderly. However, recent reports from different parts of the world suggest general validity in other groups of patients and ethnicities [50–52].

Another issue was raised by Herget-Rosenthal *et al.* [18]. These authors demonstrated that serum cystatin C levels allow for an earlier determination of AKI than serum creatinine. Although serum creatinine has its limitations, it has been the biomarker of choice for evaluation of kidney function for many years. Recently, other biomarkers for detection of AKI have emerged.

Biomarkers of renal tubular injury

Several serum and urinary markers, such as neutrophil gelatinase-associated lipocalin (NGAL) [53,54], kidney injury molecule-1 (KIM-1) [55], cysteine-rich protein 61 (also called CCN1) [56], spermidine/spermine $N(1)$-acetyltransferase [57], cystatin C [18,58], and urine interleukin-18 (IL-18) [59–61], have been identified as potential markers of early tubular injury (see Table 6.3).

Table 6.3 Potential biomarkers in early detection and surveillance of AKI.

Biomarker	Study	Patients	Results	Comments
Cystatin C	Villa *et al.* [62]	50 critically ill patients	Serum cystatin C correlated better with GFR than did serum creatinine	1/cystatin C versus C_{Cr}: $r = 0.832$, $P < 0.001$ 1/creatinine versus C_{Cr}: $r = 0.426$, $P = 0.002$
	Herget- Rosenthal *et al.* [18]	85 patients at high risk to develop AKI	Increase in blood level of cystatin C significantly preceded that of creatinine	Serum cystatin C increased by $\geq 50\%$, 1.5 ± 0.6 days earlier than creatinine
	Ahlstrom *et al.* [58]	202 consecutive adult ICU patients	Serum cystatin C was as good as plasma creatinine in detecting AKI in intensive care patients	Cystatin C had poor predictive value for hospital mortality
NGAL	Mishra *et al.* [53]	71 children undergoing cardiopulmonary bypass	NGAL in urine at 2 h after cardiopulmonary bypass was the most powerful independent predictor of acute renal injury	NGAL conc in urine at 2 h had area under ROC curve of 0.998; sensitivity was 1.00 and specificity was 0.98 for a cutoff value of 50 μg/L
KIM-1	Han *et al.* [55]	6 patients with biopsy-proven ATN	For each unit increase in normalized KIM-1 there was a >12-fold-higher risk for the presence of ATN (odds ratio, 12.4; 95% CI, 1.2–119)	Small study with questionable statistical and clinical relevance
IL-18	Parikh *et al.* [59]	Nested case–control study within Acute Respiratory Distress Syndrome Network trial (400 urine specimens from 52 patients and 86 controls)	Urine IL-18 levels of >100 pg/mL are associated with increased odds of AKI of 6.5 (95% CI, 2.1–20.4) in the next 24 h	On multivariable analysis, urine IL-18 on day 0 was independent predictor of mortality

Of these markers, cystatin C has been evaluated most extensively. Cystatin C is a nonglycosylated protein that is produced at a constant rate by nucleated cells. Its low molecular mass (13.3 kDa) and positive charge at physiological pH levels facilitate its glomerular filtration. Following filtration, it is reabsorbed and almost completely catabolized in the proximal renal tubule. Because of its constant rate of production, its serum concentration is determined by glomerular filtration. For these reasons, cystatin C has the potential to be a useful marker in detecting AKI. Villa *et al.* conducted an evaluation of serum cystatin C concentration as a real-time marker of AKI in critically ill patients and demonstrated that cystatin C correlated better with GFR than did creatinine and was diagnostically superior to creatinine (receiver-operating characteristic [ROC] area under the curve for cystatin C, 0.927; 95% confidence interval, 86.1–99.4; ROC area under the curve for creatinine, 0.694; 95% confidence interval, 54.1–84.6) [62]. Subsequently, Herget-Rosenthal and coworkers evaluated early detection of AKI by cystatin C and showed that the increase in blood levels of this marker significantly preceded that of creatinine [18]. Moreover, according to the R, I, and F criteria of RIFLE, cystatin C detected renal dysfunction 2 days earlier than did creatinine. It also predicted the long-term need for RRT in patients with AKI moderately well. A subsequent study evaluated serum cystatin C as a marker of kidney function in ARF and its power in predicting survival of ARF patients [58]. Serum cystatin C, plasma creatinine, and plasma urea were measured in 202 patients upon admission to the ICU, daily during the first 3 days, and 5–7 times a week during the rest of the ICU stay. In this study, serum cystatin C showed excellent positive predictive value for ARF in critical illness. However, it was not clinically useful in predicting mortality.

Using a genome-wide interrogation strategy, investigators have identified NGAL as one of the most strikingly up-regulated genes and overexpressed proteins in the kidney after ischemia [54,63]. The clinical applicability of NGAL in AKI was demonstrated by Mishra *et al.*, who studied 71 children undergoing cardiopulmonary bypass [53]. Serial urine and blood samples were analyzed by Western blotting and enzyme-linked immunosorbent assay for NGAL expression. Using multivariate analysis, the investigators found that the urinary NGAL 2 h after cardiopulmonary bypass was the most powerful independent predictor of acute renal injury. The study also revealed that for the concentration of NGAL in the urine at 2 h, the area under the receiver-operating characteristic curve was 0.998, sensitivity was 1.00, and specificity was 0.98, using a cutoff value of 50 μg/L.

KIM-1 is a type 1 transmembrane protein whose expression is markedly up-regulated in the proximal tubule in the postischemic kidney in rat models. In a pilot study, Han *et al.* evaluated the appearance of KIM-1 in the urine of 40 patients with acute (23 patients) or chronic (9 patients) kidney failure and normal kidney function (8 patients) and the tissue expression of KIM-1 in kidney biopsy specimens from 6 patients with biopsy-proven ATN [55]. The investigators found that there was extensive expression of KIM-1 in proximal tubule cells in biopsies from the six patients with confirmed ATN. Moreover, when adjusted for age, gender,
Figure 6.2 Relationship between outcome and RIFLE class across different studies. See text for details. Adapted from Hoste *et al.* [64].

and length of time between the initial insult and sampling of the urine, these investigators found that for subjects in this small cohort, a 1-unit increase in normalized KIM-1 was associated with a 12-fold risk (odds ratio, 12.4; 95% CI, 1.2–119) for the presence of ATN.

IL-18 has been shown to be an important mediator of inflammation. Urine IL-18 levels have been shown to increase in patients with ATN, both in animal models and human studies [59–61]. In humans, IL-18 was shown to have a sensitivity and specificity of >90% for diagnosis of established kidney injury [59]. In this study, on multivariable analysis, the urine IL-18 concentration was an independent predictor of mortality.

Large human trials evaluating the usefulness of various biomarkers for early detection of AKI are lacking. However, theoretically such biomarkers could play an important role in the diagnosis and management of AKI. Currently available serum markers for other disease processes, such as troponin-I and brain natriuretic peptide, have correlated fairly well with the degree of the underlying disease. Serum brain natriuretic peptide levels also decline with adequate response to therapy. Theoretically, serial measurement of a biomarker could potentially help clinicians identify early disease and/or follow the response to treatment once disease is advanced. With ongoing research, an analogous biomarker for AKI is perhaps not too far in the future. In addition, further research exploring

the value of biomarkers in terms of prognosticating for patients with AKI (both survival and renal recovery) will be necessary.

Conclusions

Small changes in kidney function in hospitalized patients are important and impact outcomes, hence the shift of terminology from ARF to AKI. RIFLE criteria provide a uniform definition of AKI and are increasingly used in the literature. RIFLE severity grades represent patient groups with increasing severity of illness, as illustrated by the increasing proportion of patients who die or require treatment with RRT.

7 Pre-Renal Failure and Obstructive Disease

Kevin W. Finkel

Division of Renal Diseases & Hypertension, University of Texas Medical School, Houston, USA

Introduction

Pre-renal azotemia is the most common form of acute renal failure (ARF) in hospitalized patients and, if uncorrected, can lead to ischemic parenchymal damage and acute tubular necrosis (ATN) [1,2]. The clinical syndrome of pre-renal failure is characterized by intact tubular function with impaired filtration function because of renal hypoperfusion and usually manifests as low urine volume, reduced urinary concentration of sodium (UNa) and fractional excretion of sodium (FeNa%), and an elevated ratio of blood urea nitrogen to serum creatinine (Cr).

Pre-renal failure is the result of either true volume depletion, as occurs with hemorrhage or excessive diuresis, or "effective" volume depletion in circumstances such as congestive heart failure (cardiorenal syndrome), liver failure with ascites (hepatorenal syndrome), and sepsis. The etiologies for pre-renal failure are outlined in Table 7.1. In both instances decreased intravascular volume causes baroreceptor stimulation and enhanced adrenergic output, leading to systemic and local regulatory mechanisms aimed at restoring normal perfusion pressure.

At the level of the kidney, a complex interplay between neuroendocrine and vasoactive agents initially compensates for decreased perfusion pressure. Specifically, angiotensin II causes preferential vasoconstriction of the efferent arteriole, increased proximal tubular reabsorption, elevation of glomerular hydrostatic pressure, and a reduced glomerular ultrafiltration coefficient. Because of angiotensin II preferential constriction of the efferent arteriole, with mild to moderate volume depletion, the glomerular filtration rate (GFR) is maintained. With severe volume depletion, frank ischemic ATN may ensue. Since the GFR in such situations is dependent on relative efferent arteriolar vasoconstriction, the use of angiotensin II antagonists, such as angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs),

can precipitate ATN. The vasoconstrictor effects of angiotensin II are opposed by endogenously produced prostaglandins and nitric oxide. When used acutely in pre-renal failure, nonsteroidal anti-inflammatory drugs lead to unopposed vasoconstriction and worsening of renal function.

In response to decreased renal perfusion, activation of the renin–aldosterone axis and release of antidiuretic hormone also occur, increasing sodium and water retention in an attempt to restore intravascular volume. These temporizing physiologic measures are necessary to maintain perfusion pressures in the face of frank volume depletion but are ineffective in sepsis and clearly deleterious in conditions such as heart failure with pulmonary edema.

Given this background, pre-renal failure is not a simple case of hypovolemia that can be corrected by administration of intravascular crystalloid or colloid. Treatment must, by necessity, be directed at the underlying pathophysiology that has triggered the compensatory physiologic response common to all etiologies. Therefore, an evidence-based approach to the treatment of pre-renal azotemia requires a review of the available data in several subgroups of patients and cannot take a "one size fits all" approach.

Diagnosis

Many causes of pre-renal failure are clinically obvious. With reliance on history, physical examination, and certain laboratory findings, patients with true volume depletion are often easily identified and can be treated with aggressive volume repletion. Such patients demonstrate orthostatic hypotension, tachycardia, dry mucous membranes, low urinary output, and poor skin turgor. Although much has been made of the utility of urinary indices in ARF (*vide infra*), they are unnecessary in such situations, and patients promptly respond to volume resuscitation. Likewise, the argument over using colloid or crystalloid in these patients is moot, as simple crystalloid solutions have proven very effective. It is only in the complex patient, usually in an intensive care unit (ICU), that such controversies are more germane. In essence, one is trying to differentiate the patient with pre-renal failure physiology

Table 7.1 Causes of pre-renal failure.

Decreased Cardiac Output	Redistribution/Vasodilation
Myocardial infarction	Cirrhosis
Congestive heart failure	Nephrotic syndrome
Pericardial tamponade	Pancreatitis
Positive pressure ventilation	Sepsis
Pulmonary embolism	Crush injuries
	Intestinal obstruction
Hypovolemia	**Vascular Disease**
Hemorrhage	Renal artery stenosis
Diuresis	Atheroembolism
Diarrhea	Vasculitis
Excessive sweating	Aortic aneurysm dissection

who will not benefit (or be frankly harmed) by fluid resuscitation from one who will quickly recover with crystalloid or colloid infusion. For example, a patient with cirrhosis of the liver and ARF has clinical and laboratory findings consistent with pre-renal failure. Will volume repletion reverse the renal failure because true volume depletion is present, or is it hepatorenal syndrome? In both scenarios the kidneys are underperfused, but administration of fluid will only help in the former and be deleterious in the latter. In the liver failure patient measurement of the central venous pressure (CVP) or pulmonary artery occlusion pressure (PAOP) could be used as a guide to therapy, or the clinical response to an infusion of saline, as recommended by the Second International Ascites Club [3]. Yet, none of these diagnostic methods has been subjected to rigorous scientific analysis. Similarly, in the patient with septic shock, on multiple vasopressors and positive pressure ventilation, early ARF may be pre-renal failure in nature but aggressive fluid resuscitation may only serve to aggravate hypoxemia by worsening acute respiratory distress syndrome (ARDS). Indeed, in the recently published Fluids and Catheter Treatment Trial by the ARDS Network group, a fluid-conservative treatment strategy targeting a CVP of 3 or a PAOP of 7 decreased the number of ventilator days and ICU length of stay without any increase in the incidence of ARF or need for dialysis [4].

CVP and PAOP

Although physicians often rely on CVP and PAOP to guide fluid administration and determine whether or not a patient has true volume depletion, there is little evidence that such measurements are clinically useful. Although there are no trials that have assessed the utility of these measurements specifically for determining the reversibility of pre-renal failure, one can reasonably extrapolate from available data regarding their ability to predict improvement in stroke volume, cardiac output, and urine output.

The CVP and PAOP are frequently used as means of determining cardiac preload and volume status. However, their use has been criticized because of poor ability to predict which patients will have improvement in their hemodynamic status when given fluid resuscitation [5]. As reviewed by Michard and Teboul, in three of five

trials assessing the ability of CVP to predict fluid responsiveness in critically ill patients, defined as an improvement in either stroke volume or cardiac output, there was no significant difference in the baseline CVP measurements between responders and nonresponders. The two remaining studies reported lower baseline values of CVP in responders; however, the marked overlap of individual CVP levels did not allow for the identification of a discriminatory cutoff value. Likewise, baseline PAOP was not significantly lower in responders versus nonresponders in seven of nine studies. Three studies reported a significant difference in the baseline PAOP between the groups, being higher in responders in a single study and lower in responders in two studies. However, in none of the studies could a cutoff PAOP value be found that predicted the hemodynamic response to volume expansion. In normal subjects, Kumar and associates demonstrated a lack of correlation between initial CVP and PAOP values and both end diastolic volume and stroke volume [6]. Furthermore, changes in both parameters following 3-L saline infusion did not correlate with changes in end diastolic volume and cardiac performance.

In addition, numerous randomized controlled trials (RCTs) and meta-analyses assessing the benefit of pulmonary artery catheters (PAC) in a variety of clinical circumstances have been reported [7–9]. In a meta-analysis of 13 RCTs, the use of PAC neither increased overall mortality and hospital days nor conferred any benefit [10]. Likewise, in an RCT of 676 patients with shock mainly from sepsis, ARDS, or both, early use of PAC did not significantly affect mortality or morbidity, including the need for dialysis [11]. Therefore, in critically ill patients with multiple reasons for pre-renal failure (sepsis, capillary leak with third spacing, positive pressure ventilation, hypoalbuminemia, cardiac dysfunction, and liver disease), measurement of CVP and/or PAOP does not improve outcome and has poor predictive value for improvement in renal function.

Urine output

The development of oliguria (urine output of less than 400 mL/day) does not assure the presence of pre-renal failure. It occurs in both pre-renal failure states and numerous other causes of ARF, including ATN, obstructive nephropathy, glomerulonephritis, and atheroembolic disease. Despite the compensatory mechanisms invoked in response to decreased renal perfusion that increase salt and water retention by the kidneys in pre-renal failure states, higher urine outputs can ensue in the face of underlying chronic kidney disease, salt wasting states such as adrenal insufficiency and cerebral salt wasting, concomitant use of diuretics, osmotic diuresis, and the presence of nonreabsorbed anions, such as ketones and bicarbonate in the urine.

Urinalysis

Urinalysis is often used to differentiate various causes of ARF. In pre-renal failure, the urine is concentrated and the urinary sediment is bland. Bland urinary sediment, however, does not allow for discrimination between true and effective volume depletion. Furthermore, patients with pre-renal failure can have abnormal sediment if they have a pre-existing renal disorder, bilirubin in the

Table 7.2 Urinary indices in ARF.

Index and range	No. of patients with condition/total no. of patients		
	Pre-renal failure	Oliguric ATN	Nonoliguric ATN
Urine Na (mEq/L)			
<20	18/30 (60%)	0/24 (0%)	2/13 (6%)
20–40	12/30 (40%)	14/24 (59%)	11/31 (35%)
>40	0/30 (0%)	10/24 (41%)	18/31 (59%)
FeNa%			
<1	27/30 (90%)	1/24 (4%)	4/31 (12%)

urine (causing granular casts), or microscopic hematuria and bacteriuria from an indwelling bladder catheter. The utility of the urinalysis in differentiating pre-renal failure from acute kidney injury (AKI) has been called further into question by the results of two recent systematic reviews on the urinary findings in sepsis-related AKI (human and experimental animal studies). These systematic reviews demonstrated substantial heterogeneity between studies and suggested that the scientific basis for the use of urinary microscopy in septic AKI and, by extension, to differentiating ATN from pre-renal failure is weak [12,13].

Urinary indices

The measurement of UNa and calculation of the FeNa% has been routinely recommended as a means to differentiate oliguric pre-renal failure from oliguric ATN, as shown in Table 7.2. In the sentinel study reported by Miller *et al.* a UNa concentration of less than 20 mEq/L had an 80% sensitivity and specificity for differentiating pre-renal failure from ATN in the face of oliguria [14]. The FeNa% performed even better, with a sensitivity and specificity of 98 and 95%, respectively. The utility of either measurement was significantly less in the absence of oliguria. However, there are numerous exceptions to the general rule [15–17]. Both UNa and FeNa% can be low, suggestive of pre-renal failure with ARF from rhabdomyolysis, radiocontrast nephropathy, acute glomerulonephritis, multiple myeloma, amphotericin B toxicity, and early obstructive nephropathy. More to the point, the finding of renal sodium avidity does not allow one to discriminate between true and effective volume depletion nor reliably predict reversibility with volume administration.

It is also important to point out that in the study by Miller *et al.* patients were excluded if they had an elevated baseline creatinine (>1.6 mg/dL), received any diuretic within the preceding 24 h, had evidence of underlying adrenal or liver disease, or had glucosuria or bicarbonaturia [14]. Also, the percentage of patients with sepsis was not described, nor was the actual cause of ATN provided. With only 85 patients included in the study, it is probable that in the medically complex patient these indices have lower sensitivity and specificity or predictive powers than the paper actually suggests.

The use of diuretics can increase urinary sodium loss even in the face of pre-renal failure, thus negating the utility of the FeNa%. Since the fractional excretion of urea (FeUN%) is primarily dependent on passive forces, it is less influenced by the administration of diuretics and may be useful in the evaluation of ARF. A group of 102 patients with ARF was divided into three subgroups: pre-renal failure, pre-renal failure treated with diuretics, and ATN. The FeNa% was low in 92% of prerenal failure patients and 48% of pre-renal failure patients receiving diuretics. Both groups had similar and significantly lower FeUN% values than the ATN patients [18].

Treatment

In the patient with clinically obvious volume depletion, adequate fluid resuscitation can be achieved by the administration of crystalloids, such as normal saline or lactated Ringers solution. Such patients often show remarkable improvement in their renal function over a short period of time.

In the complex or critically ill patient, the situation is more challenging. In this population, it is difficult to accurately determine intravascular volume and whether the pre-renal failure is due to true or effective volume depletion, while concern is great for the potential harm of indiscriminant fluid administration in the face of acute lung injury or frank ARDS. There is also debate on what type of fluid, colloid versus crystalloid, is best for volume resuscitation in such patients. Although not specifically done to address pre-renal failure, review of recent clinical trials in these areas can provide some type of general guideline.

Goal-directed hemodynamic management and fluid therapy

Previous observational nonrandomized studies had shown that patients who survived critical illness had higher values for cardiac index and oxygen delivery than those who died and that those values were higher than normal physiologic levels [19,20]. Two studies of surgical patients showed significant decreases in mortality associated with therapy directed at increasing hemodynamic parameters to supraphysiologic values, whereas no benefit was seen in patients with sepsis and mixed groups of critically ill patients [21–24]. Subsequently, two RCTs assessed the benefit of goal-directed hemodynamic therapy in critically ill patients. In one trial of 100 patients randomized to dobutamine or placebo, there were no differences in mean arterial pressure or oxygen consumption despite higher cardiac index and oxygen delivery in the treatment group [25]. In fact, the treatment group had a significantly higher mortality rate than the placebo group. In another trial of 762 patients randomized into one of three intervention groups, hemodynamic therapy aimed at achieving supranormal values for cardiac index or normal values for mixed venous oxygenation saturation did not reduce morbidity or mortality [26].

More recently, Rivers and colleagues reported their experience with early goal-directed therapy in the treatment of severe sepsis

and septic shock [27]. Patients with severe sepsis or septic shock were randomly assigned upon arrival to the emergency center to either 6 h of early goal-directed therapy or standard therapy prior to admission to the ICU. Active intervention aimed at achieving a central venous oxygen saturation of 70% included saline boluses targeted to a CVP level of 8–12 mmHg, vasopressor agents to maintain a mean arterial pressure greater than 65 mmHg, transfusion to a hematocrit of 30%, and dobutamine. Although the patients assigned to active intervention received more fluid and blood products in the initial 24-h period, they experienced a significantly reduced rate of organ failure and death.

Finally, the ARDS Clinical Trials Network assessed optimal fluid management in patients in the ICU with acute lung injury [4]. In this RCT, 1000 patients were assigned to either a conservative or liberal strategy of fluid management using explicit protocols applied for 7 days. The mean cumulative fluid balances in the conservative versus liberal groups were −136 ml and 6992 mL, respectively. Although there was no difference in mortality, the conservative group had significantly reduced ventilator and ICU days and improved oxygenation. Importantly, conservative fluid management did not increase the need for RRT.

Crystalloid versus colloid fluids

The putative superiority of colloid over crystalloid fluids in the resuscitation of the critically ill patient has been a source of considerable controversy. Aggressive hydration with crystalloid solutions such as normal saline can worsen interstitial edema and pulmonary function. Colloidal solutions, such as various starches and human albumin, might appear to be attractive alternatives, but there is little solid evidence of their superiority in clinical trials. Systematic reviews of randomized controlled trials comparing crystalloids with colloids have yielded conflicting results. Some trials have found an increased mortality rate associated with the administration of human albumin and hydroxyethyl-starch, while others have not [28–31]. More recently, a large, randomized, controlled prospective trial of albumin versus saline in almost 7000 critically ill patients found no benefit of one over the other [32]. Specifically, there was no demonstrable effect on mortality, renal function, or the frequency of renal replacement therapy. Of note, patients with cirrhosis were excluded from this trial, and limited data suggest that albumin is useful to prevent ARF in cirrhotic patients with spontaneous bacterial peritonitis [33].

Summary

In the complex medical patient, pre-renal failure can occur from either true or effective volume depletion. Since both circumstances share the same physiologic derangements, clinical parameters such as urine output and urinary electrolytes do not have any discriminatory power between the two. It is also difficult to predict which patients will benefit from volume resuscitation based on measurement of the CVP or PAOP. Often, the only way to determine if the renal failure is reversible is to provide an empiric "fluid challenge" and assess the clinical response. With regard to approaching the critically ill patient who may be functionally pre-renal failure, fluid management is dependent on timing. Early intervention with goal-directed therapy, resulting in a positive fluid balance in the first 24 h, is associated with reduced organ failure. In patients already in the ICU with lung injury, a conservative fluid approach improves pulmonary function without adverse renal effects.

Cardiorenal syndrome

Cardiorenal syndrome is a recently recognized constellation of findings in patients with combined cardiac and renal dysfunction. Such patients have pulmonary edema refractory to diuretics, recurrent hospitalizations, progressive renal failure, and markedly reduced quality of life. However, no explicit diagnostic criteria have been adopted, as yet, for cardiorenal syndrome. It is nonetheless a common medical condition. The prevalence of chronic kidney disease (GFR of ≤ 60 mL/min) in the US population is estimated to be 16 million adults. In these patients, cardiac failure is frequently present and a major cause of mortality [34,35]. Likewise, the development of renal dysfunction in heart failure patients has a significantly negative impact on prognosis. In the Evaluation of Losartan in the Elderly (ELITE) study, comparing an ACE inhibitor to an ARB in the treatment of heart failure, nearly 30% of patients experienced worsening renal function [36]. In the Studies of Left Ventricular Dysfunction trial, risk factors for renal failure included older age, low ejection fraction, use of diuretics, low systolic blood pressure, and diabetes mellitus [37]. Patients who develop worsening renal function have increased hospital length of stay, higher costs, and higher mortality rates [38].

The pathophysiology of cardiorenal syndrome is incompletely understood. It is not simply a "low cardiac output" syndrome, since up to as many as one-half of patients have cardiac ejection fractions greater than 40%, and several studies could not find a correlation between worsening renal function and ejection fraction [38,39]. More than likely, cardiorenal syndrome is the result of a complex interplay between local and systemic neuro-humoral systems, such as the renin–angiotensin–aldosterone system, sympathetic nervous system, natriuretic peptides, nitric oxide, prostaglandins, endothelin, and inflammatory mediators. It is not surprising, therefore, that traditional methods for treating heart failure prove either ineffective or exacerbate renal dysfunction and have prompted interest in novel therapies, such as isolated ultrafiltration.

Treatment of cardiorenal syndrome

Determining the best evidence-based treatment of cardiorenal syndrome is a challenging clinical problem, since most heart failure trials have excluded patients with impaired renal function. Furthermore, as mentioned, cardiorenal syndrome is not simply a low-flow problem that corrects with traditional therapies used in congestive heart failure. Each organ dysfunction appears to interact in such a way that traditional measures may be rendered ineffective.

Diuretics

The role of diuretics in cardiorenal syndrome is controversial. Often, they are not effective in achieving the desired fluid removal and weight loss. In heart failure trials, 20% of patients treated with intravenous diuretics fail to lose weight or actually gain weight during their hospitalization [40]. This diuretic resistance has been shown to be an independent marker of poor outcome. Aggressive attempts to overcome the resistance with higher diuretic doses, continuous infusion, or addition of a second diuretic agent acting distally to a loop diuretic often are associated with worsening renal function, an independent risk factor for mortality [41].

Loop-diuretic resistance results from the interplay of several factors, including poor intestinal absorption, decreased delivery to the kidney, increased sodium absorption proximal and distal to the loop of Henle, and excess sodium intake. Strategies to overcome resistance include adding an additional diuretic agent that acts at another site, increasing the dose and frequency of the diuretic, and changing from intermittent to continuous infusion. However, a Cochrane review comparing continuous to intermittent bolus diuretic for congestive heart failure was unable to confirm any superiority from this maneuver [42]. Addition of hyperoncotic (>5%) albumin has also been advocated as a means of increasing diuresis. In analbuminemic animals, addition of albumin increases salt excretion [43]. However, albumin did not improve diuresis in a small trial of humans with nephrotic syndrome [44].

ACE inhibitors and ARBs

ACE inhibitors and ARBs have clearly been shown to improve survival in patients with heart failure [45]. Most studies, however, excluded patients with significant chronic kidney disease (Cr $\geq$ 2.0 mg/dL).

The Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS) included severe heart failure patients with creatinine values less than 3.5 mg/dL [46]. In the subgroup with Cr greater than 2.0 mg/dL, use of an ACE inhibitor significantly improved outcome. Nevertheless, in CONSENSUS 30% of all patients experienced an increase in their serum Cr, although few patients needed to stop the medication.

In order to avoid precipitating acute renal dysfunction, ACE inhibitors and ARBs should be started at low doses in patients who are considered not to be volume depleted and who are off of any nonsteroidal anti-inflammatory agents.

Natriuretic peptides

B-type natriuretic peptide (BNP) is produced by the myocardial ventricles in response to increased stress. BNP results in arterial and venous vasodilation, increased sodium excretion, and suppression of the renin–angiotensin–aldosterone system.

Nesiritide, a synthetic BNP, was assessed in heart failure patients in the Vasodilation in the Management of Acute Congestive Heart Failure trial [47]. Compared to intravenous nitroglycerine, nesiritide significantly lowered PAOP at 1 h, although there was no difference in the degree of dyspnea. Nesiritide was equally effective in patients with or without renal dysfunction (Cr > 2.0 mg/dL) [48].

In another trial nesiritide was given to patients with recent increases in baseline Cr associated with congestive heart failure exacerbation (mean Cr increase from 1.5 to 1.8 mg/dL) [49]. Compared to placebo, there were no changes in urine output, sodium excretion, glomerular filtration rate, or effective renal plasma flow. This finding suggests that nesiritide is ineffective in cardiorenal syndrome.

More concerning are recent reports that the use of nesiritide in congestive heart failure may be associated with an increased risk of acute renal dysfunction and mortality. In a meta-analysis of five randomized trials including 1,269 patients, the use of nesiritide was significantly associated with the development of acute renal dysfunction (an increase of Cr of $\geq$ 0.5 mg/dL) [50]. Furthermore, in three RCTs that reported mortality rates, the use of nesiritide was associated with a hazard ratio for death of 1.8 ($P = 0.057$) [51].

Ultrafiltration

Ultrafiltration (UF) for therapy-resistant chronic volume overload is an increasingly utilized treatment modality. With the advent of technology that allows for low blood flow and ultrafiltration rates, and also venous access through a peripheral location, the use of isolated UF will likely become commonplace in the treatment of cardiorenal syndrome.

The Ultrafiltration Versus IV Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure trial compared UF and intravenous diuretics in 200 patients [52]. Compared to patients who received diuretics, patients randomized to UF lost more weight and, at 90 days, had less rehospitalization and unscheduled clinic and emergency center visits. However, overall mortality rates were equal in both groups. In addition, there is justified concern if isolated UF becomes more prevalent outside the research environment that excessive UF rates may result in hypotension and worsening renal function.

Obstructive nephropathy

Urinary tract obstruction should always be considered in the differential diagnosis of ARF. Regardless of cause, obstruction of urinary flow leads to renal impairment, which early in the course of the condition is reversible if the obstruction is alleviated. Tubular function is initially affected; however, prolonged obstruction leads to tubular damage and parenchymal atrophy.

Clinical manifestations of urinary tract obstruction vary depending on the location, duration, and degree of obstruction. In patients with complete bilateral obstruction or with an obstructed solitary kidney, anuria (<50 mL urine output in 24 h) can be the presenting feature, whereas in patients with partial obstruction, the urinary output can vary from oliguria to polyuria. Although pain is more likely to be associated with acute blockage, obstruction may be totally asymptomatic and occur without overt clinical manifestations or suggestive laboratory findings. Therefore,

obstructive nephropathy should always be considered as a cause of renal failure when an obvious pre-renal failure or intrinsic renal cause is not identified. The location of obstruction is anatomically divided into upper and lower urinary tract at or below the level of the bladder. Common causes of lower urinary tract obstruction include urethral strictures, prostatic hypertrophy, and neurogenic bladder.

Diagnosis of urinary tract obstruction can be difficult. Anuria, flank pain with a palpable mass, or a palpable bladder are obvious clues. The laboratory evaluation can be helpful. Hyperkalemia with a nonanion gap metabolic acidosis is suggestive of a renal tubular acidosis associated with obstruction [53]. The urinary sediment may be bland or demonstrate crystals or hematuria, depending on the etiology of the obstruction. Patients may have very dilute urine due to the presence of an acquired form of nephrogenic diabetes insipidus [54].

Ultrasonography is the most useful test for the presence of obstruction. Although hydronephrosis is usually demonstrated, there are circumstances when hydronephrosis is not seen despite urinary tract obstruction: 1) early in the course of obstruction (12–24 h) when the collecting system is relatively noncompliant; 2) in the face of severe volume depletion when glomerular filtration is severely depressed; and 3) when the collecting system is encased by retroperitoneal lymphadenopathy or fibrosis [55,56].

Conversely, the finding of hydronephrosis on ultrasound does not prove the presence of obstruction, since it is also seen in high urinary flow states such as diuretic use and diabetes insipidus, pregnancy, previous obstruction, and congenital megaureter. In a series of 192 patients with ARF, hydronephrosis unrelated to obstruction was noted in 11% of patients [57].

Although ultrasound is the preferred imagining modality for initial assessment of obstruction, its use has been supplanted by noncontrast helical computed tomography (CT) scan in the evaluation of flank pain and nephrolithiasis. In a single-center study of 864 patients evaluated for flank pain, 34 underwent both helical CT scan and ultrasound [58]. Compared to helical CT, ultrasound was found to have a sensitivity and specificity for renal stones of 81 and 100%, respectively, although the sensitivity for ureteric stones was only 46%. In the same study, the sensitivity and specificity for the detection of hydronephrosis were 93 and 100%, respectively.

In another study, 181 consecutive patients with acute flank pain underwent a combination of helical CT, ultrasound, and unenhanced radiography [59]. When compared with the diagnostic accuracy for ureterolithiasis of combined ultrasound and unenhanced radiography, helical CT had greater sensitivity (92% vs. 77%) and negative predictive value (87% vs. 68%).

Treatment of obstruction and its timing is dependent on the etiology. Patients with small stones (>5 mm) can be managed conservatively with aggressive hydration and pain control in the absence of infection. Bladder catheterization should be performed if there is reason to suspect that bladder outlet obstruction is present; possible clues to this diagnosis include suprapubic pain, a palpable bladder, or an older man with unexplained renal failure. Measurement of a urinary postvoid residual is often advocated in the

detection of outlet obstruction but has not been subjected to any rigorous evaluation. Nor is there a standard method of measurement or definition. Up to one-third of patients with bladder outlet obstruction demonstrated by urodynamic testing do not have an elevated postvoid residual [60]. Upper tract obstruction is relieved with either percutaneous nephrostomy tubes or ureteral stenting, depending on cause, availability, and local expertise.

The duration and severity of obstruction are the major determinants for the recovery of renal function after its correction. The longer the duration of obstruction, the less likely are the chances for complete renal recovery. There are few published data on the relationship between duration and obstruction and renal recovery rates. The variability is likely related to the severity and cause of obstruction, the presence of underlying chronic kidney disease, and concurrent infection. Case reports, however, have documented renal recovery after correction of obstruction lasting 12 months [59].

Postobstructive diuresis

Postobstructive diuresis occurs when there is correction of complete bilateral obstruction or complete obstruction of a solitary kidney. It involves the production of a large volume of urine that results from a defect in urine-concentrating ability, impaired reabsorption of urinary sodium, and solute diuresis from the retained urea and intravenous administration of sodium-containing solutions [62]. Although numerous textbooks discuss the proposed pathogenesis and treatment of postobstructive diuresis, there is very little information in the medical literature that describes its clinical course or outcome other than case reports and case series. There certainly are no RCTs. Patients with relief of complete obstruction are considered at risk for developing postobstructive diuresis and should be carefully monitored. It has been recommended for patients without pulmonary edema, congestive heart failure, or altered consciousness from uremia that urine losses be replaced by oral intake. Intravenous replacement fluids are given only if the patients develop orthostatic hypotension, tachycardia, hyponatremia, or a urine output of more than 200 mL/h [63]. On the other hand, in high-risk patients with altered sensorium, congestive heart failure, or pulmonary edema, replacement of half the hourly urine output with half-normal saline has been recommended. If the patient is hyponatremic, normal saline should be used instead. None of these recommendations has been subjected to any rigorous clinical trial. Nonetheless, they do appear to be prudent and reasonable based on clinical experience.

8   Hepatorenal Syndrome

Andrés Cárdenas & Pere Ginès

Liver Unit, Institut de Malalties Digestives i Metaboliques, Hospital Clinic, University of Barcelona, Barcelona, Spain.

Renal failure in the setting of cirrhosis is a common complication that accounts for major morbidity and mortality. A frequent cause of kidney dysfunction in patients with advanced cirrhosis is hepatorenal syndrome (HRS), which occurs in the absence of parenchymal kidney disease. HRS is defined as functional renal failure characterized by renal vasoconstriction and a low glomerular filtration rate (GFR) that develops in patients with advanced cirrhosis and ascites; however, it occasionally occurs in patients with alcoholic hepatitis or acute liver failure [1–4]. There are two types of HRS, as previously defined by the International Ascites Club: type 1 HRS is the acute form and is associated with very poor prognosis, and type 2 HRS is a chronic form that develops slowly over weeks with a better survival rate [1]. Although advances in medical therapy are very promising, liver transplantation remains the treatment of choice in suitable candidates. Uncontrolled studies demonstrate that the use of splanchnic vasoconstrictors, such as terlipressin, midodrine, and norepinephrine, in combination with albumin as a plasma expander or the use of a transjugular intrahepatic portosystemic shunts (TIPS) are effective in improving renal function in cirrhosis. HRS can be prevented in the setting of spontaneous bacterial peritonitis (SBP) with intravenous albumin and in alcoholic hepatitis with oral pentoxifylline [3,5]. This chapter will review the pathogenesis, clinical features, therapy, and prevention of HRS.

Pathogenesis

The main characteristic of HRS is the presence of renal vasoconstriction [6,7]. This vasoconstriction occurs late in the natural history of patients with cirrhosis and ascites and is a consequence of a continuous process where several underlying mechanisms, including changes in systemic arterial circulation, increased portal pressure, impaired cardiac function, and activation of systemic

and renal vasoconstrictor factors, act on the renal circulation and lead to functional renal failure without histological damage of the kidneys.

Arterial vasodilation

Portal hypertension due to an abnormal liver architecture and increased intrahepatic resistance of blood flow is the main factor responsible for the development of splanchnic arterial vasodilation. This vasodilation occurs mainly due to the production of nitric oxide and other vasodilators (calcitonin gene-related peptide, substance P, carbon monoxide, and endogenous cannibinoids) as a consequence of endothelial stretching and possibly bacterial translocation [8]. Plasma volume accumulates in the splanchnic bed, causing a compensatory response due to a fall in central blood volume with activation of systemic vasoconstrictor and antinatriuretic systems, such as the renin–angiotensin–aldosterone system (RAAS), the sympathetic nervous system (SNS), and arginine vasopressin (AVP), accounting for sodium and water retention and in advanced stages, renal vasoconstriction as the kidney senses a relative hypovolemic state (Figure 8.1) [9–11]. The ongoing action of such vasoconstrictor factors acting on the kidney eventually leads to HRS. This occurs because although in the early stages of cirrhosis renal blood flow may be kept within normal limits due to the effect of local renal vasodilators, with time circulating vasoconstrictors overcome the effect of renal vasodilators, leading to severe renal vasoconstriction and reduction in GFR [7,12]. In some patients precipitating factors such as bacterial infections worsen circulatory dysfunction and may trigger renal vasoconstriction [5,13]. At this stage, the stimulation of the RAAS, SNS, and AVP is so intense that their vasoconstrictor effects cannot be overcome, and HRS develops.

Reduced cardiac output

Circulatory dysfunction in cirrhosis has been the classic defining pathophysiological alteration that leads to HRS; however, recent evidence suggests that a reduction in cardiac output may play a role as well [14]. As discussed above, a complex interplay between the splanchnic, systemic, and renal circulation takes place once
CIRRHOSIS

Portal hypertension

Increased splanchnic nitric oxide → Splanchnic Arterial Vasodilation ← SBP, bacterial infections, LVP, Alcoholic hepatitis

Arterial underfilling

Decreased total systemic vascular resistance

Decreased effective arterial blood volume

Sodium and water retention

Stimulation of vasoconstrictors: *RAAS , SNS , AVP*

Central hypovolemia & impaired cardiac function

Increase in plasma volume

Fall in cardiac output

Development of severe renal vasoconstriction

Hepatorenal Syndrome

Figure 8.1 Pathogenesis of HRS in cirrhosis. Extrahepatic nitric oxide production is secondary to endothelial stretching and bacterial translocation. The main precipitating factors are SBP, other bacterial infections, large volume paracentesis (LVP) without plasma expanders, and alcoholic hepatitis. Splanchnic vasodilation arising from portal hypertension, an increased plasma volume, and a decreased cardiac output seem to play an equally important role in the decreased renal perfusion leading to HRS.

portal hypertension is established. In the initial stages of cirrhosis in the process of progressive vasodilation, both intravascular volume and cardiac output increase to maintain systemic hemodynamic homeostasis. However, with progression to decompensated cirrhosis a patient's clinical status may worsen, for instance, due to a bacterial infection. A consequent decrease in cardiac output and effective arterial blood volume may occur, thereby reducing renal perfusion and possibly contributing to the development of HRS. Two studies suggested that the development of HRS occurs in the setting of a reduction in cardiac output and that the progression of circulatory and renal dysfunction in cirrhosis is not only due to splanchnic vasodilation but also to a fall in cardiac output [15,16]. In the first study of 23 patients with SBP, the 8 patients who developed renal failure had a significantly reduced cardiac output compared to those that did not develop renal failure [15]. In the second study, 66 patients with cirrhosis and ascites were longitudinally followed. Twenty-seven patients (41%) developed HRS, and in all cases cardiac output at the time of HRS was significantly decreased compared to the cardiac output in the same patients measured before the occurrence of HRS [16]. These studies support the concept that HRS occurs in the setting of worsening circulatory function with a significant decrease in cardiac output in the setting of marked splanchnic vasodilation [15,16] (Figure 8.1). The exact pathogenic mechanisms that cause this decrease in cardiac output are not completely understood and therefore deserve further investigation.

Clinical features

HRS occurs in about 10% of hospitalized patients with cirrhosis and ascites [17]. The probability of developing HRS in patients with cirrhosis and ascites is 18% at 1 year and 39% at 5 years of follow-up [17]. Individuals who have HRS for the most part exhibit clinical features of advanced cirrhosis, and most have high model for end-stage liver disease (MELD) and Child-Pugh scores, along with low arterial blood pressure and severe urinary sodium retention (urine sodium, ≤10 meq/L) [17,18]. The MELD score is a mathematically derived score calculated from serum bilirubin, serum creatinine, and the international normalized ratio for prothrombin time used for organ allocation by liver transplant centers in the USA [19]. Spontaneous dilutional hyponatremia (serum sodium, ≤130 meq/L) is commonly present in patients with HRS due to an increased solute-free water retention because of elevated levels of AVP [20]. Serum creatinine levels are elevated and in fact define HRS; however, they are usually lower than those seen in noncirrhotic patients with acute renal failure, due to a reduced muscle mass and low endogenous production of creatinine in cirrhosis [21–23]. The two types of HRS as previously defined by the International Ascites Club [1] are shown in Table 8.1. In type 1 HRS renal function deteriorates with an increase in serum creatinine to a level higher than 2.5 mg/dL in less than 2 weeks. This type of HRS, if not treated, is associated with a very poor

Table 8.1 Clinical types of HRS.

Type 1: Rapid and progressive impairment of renal function, defined by a doubling of initial serum creatinine to a level higher than 2.5 mg/dL or a 50% reduction of the initial 24-h creatinine clearance to a level lower than 20 mL/min in less than 2 weeks.

Type 2: Impairment in renal function with serum creatinine of >1.5 mg/dL that does not meet criteria for type 1.

prognosis, with a median survival time of 2 weeks (Figure 8.2) [16,17]. In type 2 HRS there is a steady decline in renal function, and serum creatinine levels usually range between 1.5 and 2.5 mg/dL [1]. Most patients with type 2 HRS have a median survival time of 6 months if they do not receive a transplant (Figure 8.2) [17,18,23].

Type 1 HRS may develop spontaneously, but in many cases it is precipitated by bacterial infections, such as SBP or sepsis, acute alcoholic hepatitis, and large-volume paracentesis without albumin expansion [3,5,13,24]. Bacterial infections and SBP precipitate type 1 HRS in 10–30% of patients with advanced cirrhosis and ascites despite resolution of the infection [5,13,25]. Therapeutic paracentesis (≥5 L) without albumin expansion may precipitate type 1 HRS in nearly 15–20% of cases [24]. Renal failure may occur in up to 10% of cirrhotic patients with gastrointestinal bleeding, but in most cases it is due to acute tubular necrosis (ATN) and not HRS [26]. Contrast medium for radiological procedures does not seem to be associated with an increased risk of kidney failure in patients with cirrhosis and ascites [27].

Clinical diagnosis

The diagnosis of HRS is based on specific clinical criteria that aim to exclude other causes of kidney failure that are not functional. The diagnostic criteria proposed by the International Ascites Club for

Figure 8.2 Probability of survival of patients with cirrhosis according to type of HRS. (From Alessandria *et al.*, 2005 [18], with permission.)

Table 8.2 Diagnostic criteria of HRS.

Major criteria[a]
- Chronic or acute liver disease with advanced hepatic failure and portal hypertension
- Low GFR, as indicated by a serum creatinine concentration greater than 1.5 mg/dL or 24-h creatinine clearance of <40 mL/min
- Exclusion of shock, ongoing bacterial infection, volume depletion, or use of nephrotoxic drugs
- No sustained improvement in renal function (decrease in serum creatinine to 1.5 mg/dL or less) despite stopping diuretics and volume repletion with 1.5 L of isotonic saline
- No proteinuria or ultrasonographic evidence of obstructive uropathy or parenchymal renal disease

Minor Criteria
- Urine volume lower than 500 mL/day
- Urine sodium lower than 10 mEq/L
- Urine osmolality greater than plasma osmolality
- Urine red blood cells less than 50 per high power field
- Serum sodium concentration lower than 130 mEq/L

Source: Adapted from reference 1.
[a]Only major criteria are necessary for the diagnosis of hepatorenal syndrome.

the diagnosis of HRS are outlined in Table 8.2 [1]. Unfortunately, it seems that in clinical practice HRS is not accurately diagnosed, as evidenced by two retrospective studies. In one study, 59% of patients with cirrhosis and kidney failure labeled as having HRS fulfilled the proposed criteria [28]. Another report from a large tertiary care center indicated that out of 140 patients diagnosed as having HRS only 29% met the diagnostic criteria and the majority of misdiagnosed cases were due to ATN and sepsis-related renal failure [29].

Common causes of renal failure in cirrhosis that should be excluded before the diagnosis of HRS is made include pre-renal failure secondary to volume depletion, ATN secondary to shock, drug-induced renal failure (mainly from nonsteroidal anti-inflammatory agents or aminoglycosides), and glomerulopathies in patients with viral hepatitis [30,31]. In cases of pre-renal failure, renal function usually improves after plasma volume expansion with an intravenous dose of 20–40 g of albumin. Proteinuria (>500 mg/day) and/or ultrasonographic abnormalities of the kidneys indicate parenchymal renal disease and preclude the diagnosis of HRS.

Management

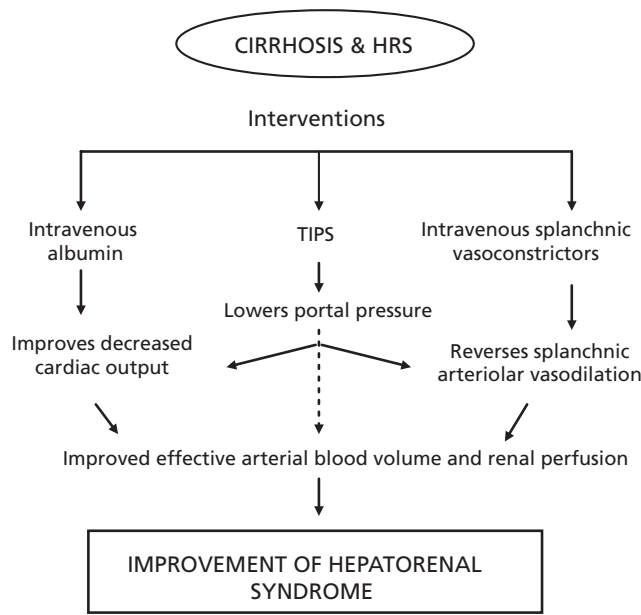
When considering treatment, the type of HRS must always be taken into account, as the two types differ in time course and prognosis. In type 1 HRS patients, current practice supports their hospitalization in a closely monitored acute care unit. A central line may be helpful in assessing volume status after patients receive plasma expansion when ruling out other causes of renal failure, but the utility of central pressure monitoring has yet to be established with


Figure 8.3 Possible mechanism of action of the different therapies for HRS. Therapies that improve renal function are vasoconstrictors, such as terlipressin, midodrine, or norepinephrine (which act by ameliorating arterial vasodilation) combined with albumin (which improves circulatory function). TIPS may reverse HRS by reducing portal pressure as well as increasing effective arterial blood volume.

an randomized, controlled trial (RCT) in this specific patient population. Patients with type 2 HRS can be managed as outpatients.

Given that patients are frequently malnourished and require a sodium-restricted diet, a nutritionist should be a part of the team taking care of the patient. In patients with dilutional hyponatremia, fluid restriction of 1 L/day is recommended, as pharmacological therapy is not yet available for this condition [20]. Apart from routine hematological and biochemistry blood tests, all patients must undergo a diagnostic paracentesis to rule out SBP and have blood cultures performed to rule out other bacterial infections, as prompt treatment of infections may result in improvements in renal function. Diuretics need to be stopped, because they can worsen renal failure and may cause electrolyte disturbances. Finally, probably the most important aspect of providing care to patients with HRS is assessment of candidacy for orthotopic liver transplantation (OLT).

In patients that are candidates for OLT, all efforts should be made to improve renal function in order to obtain a better outcome after transplantation. Current available therapies for type 1 HRS include the use of splanchnic vasoconstrictors, albumin, and TIPS. A summary of the therapeutic interventions available for HRS is outlined in Figure 8.3.

Pharmacological therapy

Systemic vasoconstrictors given with plasma expansion are currently the most-used form of pharmacologic therapy for HRS [2,12,32–50]. Splanchnic vasoconstrictors are used in conjunc-

tion with albumin because they counteract the intense vasodilation of the splanchnic circulation and improve effective arterial blood volume, which in turn supresses the endogenous vasoconstrictor factors responsible for HRS (Figure 8.3). Vasoconstrictor therapies used in HRS include vasopressin analogues (ornipressin and terlipressin) and α-adrenergic agonists (midodrine and norepinephrine). Albumin has been used concomitantly with these vasoconstrictors as a means of improving effective arterial blood volume and therefore further suppressing endogenous vasoconstrictor factors (RAAS and SNS) responsible for the intense renal vasoconstriction in HRS [35,39,40,42,43,47–50]. In addition, albumin administration by expanding circulating blood volume may increase cardiac preload and cardiac output, which may improve effective arterial blood volume leading to improved GFR [51] (Figure 8.3).

Terlipressin

Vasopressin analogs have a marked vasoconstrictor effect in the splanchnic circulation and therefore have been used for treating patients with portal hypertension-related complications, such as bleeding gastroesophageal varices. Ornipressin, although effective in HRS, caused significant ischemic side effects in about one-third of patients and was abandoned [32,33,52]. Terlipressin, a safer synthetic analog of vasopressin with fewer side effects (approximately <10% of cases) has been succesfully used in the past decade, and one randomized and several nonrandomized studies indicate that it reverses renal failure in type 1 HRS [35–37,39–46,50]. The administration of terlipressin and intravenous albumin improves renal function, with a reduction of serum creatinine and improvement in GFR in aproximately 60% of patients with type 1 HRS (range, 42–92% initial response rates in the reported clinical trial) [35–37,39,46,50] (Table 8.3). The dose of terlipressin ranged from 0.5 to 1 mg every 6–12 h in two studies [42,43]. In other studies, the administered dose was an intravenous bolus of 0.5 mg every 4 h, and it was increased in a stepwise fashion to 1 mg every 4 h and 2 mg every 4 h every 3 days if a significant reduction in serum creatinine level (≥1 mg/dL) was not observed during each 3-day period [35,39]. Also in another study terlipressin, administered as a continuous intravenous infusion starting at 2 mg/day with an increase every 2 days (in a stepwise manner to 4, 6, 8, and 12 mg/day if no significant reduction in serum creatinine [≥30%] was observed), was found to be efficacious when given in combination with albumin [50].

The dose of albumin administered in most studies was 20–40 g/day [35,39,40,42,43,50]. In most cases renal function starts to improve within 48–72 hours. The end point of treatment is a reduction in serum creatinine to a value less than 1.5 mg/dL, and in general this takes between 1 and 2 weeks. In four studies of patients with type 1 HRS, the recurrence of HRS among initial responders after stopping treatment ranged between 17 and 64% [36,39,42,50]. In the study with the highest rate of recurrence (64%), albumin was not administered with terlipressin [36]. In the other studies with lower recurrence rates (17–55%), albumin was administered at the doses described above, and in most cases

[a] The definition of response varied between studies; however, in all studies it was defined as a marked decrease in serum creatinine.

[b] Recurrence of HRS after treatment withdrawal in responder patients; the definition of recurrence also varied between studies.

[c] Many patients presented with self-limited abdominal cramps and/or diarrhea during the administration of the first doses of terlipressin, which were not counted as severe side effects.

[d] Received concomitant albumin as plasma expander.

[e] NR, not reported.

[f] An RCT.

[g] Mean transplant-free survival in complete responders.

a repeat course of terlipressin with albumin was effective in decreasing serum creatinine [39,42,50] if HRS recurred after completion of the first course. Short-term (15 days to 1 month) survival among patients responding to terlipressin has ranged from 40% to 80% [35–37,39,42,50] (Table 8.3). In the one RCT that compared terlipressin-based therapy to customary care, survival at 15 days was 40% in the terlipressin group and zero in the control [42]. Survival was seen only in those who demonstrated improvement in renal function. Although the data on this therapeutic approach are encouraging, there is undoubtedly a need for additional prospective RCTs assessing the role of terlipressin and albumin in improving renal function in HRS.

Midodrine, octreotide, and norepinephrine

The use of midodrine (an α-adrenergic agonist) in association with octreotide, an inhibitor of the release of glucagon, and albumin also may improve renal function in cirrhotic patients with HRS. However, available data are so far limited to only two nonrandomized observational cohort studies with a total of 19 patients [47,48]. In these two studies there was improvement in renal function and GFR with suppression of renin, aldosterone, norepinephrine, and AVP to normal or near-normal levels in 73% of cases (15/19 patients). Overall survival in these two cohorts was 58% at 3 months. In the second, larger study, long-term survival was seen only in patients who had undergone either a TIPS procedure or a liver transplant [48]. In the earlier of these cohort studies, the administered dose of midodrine was between 7.5 mg orally three times daily with an increase to 12.5 mg three times daily if needed and octreotide at 100 µg subcutaneously three times daily with an increase to 200 µg three times daily if needed [47]. In addition, 20–40 g of in-

travenous albumin was given daily [47]. In contrast, in the second study the investigators used midodrine at 2.5 mg daily combined with a continuous intravenous infusion of octreotide of 25 µg/h (previous bolus injection of 25 µg/h) and 50 g/day of intravenous albumin [48]. Interestingly, another study showed that octreotide was ineffective when administered alone [53]. The administration of a continuous infusion of norepinephrine (0.5–3 mg/h) for 5 days combined with intravenous albumin resulted in a significant improvement of renal function in a cohort of 12 cirrhotic patients with type 1 HRS [49]. Improvement in renal function was observed in 10 patients in association with an increase in mean arterial pressure and a marked reduction in renin and aldosterone levels [49]. Unfortunately, there is scarce rigorous clinical trials' evidence on these therapeutic regimens for HRS; only two of these trials are formal RCTs and both are of very small size. Despite the fact that the available data from observational and cohort studies are promising, more rigorous randomized controlled studies are needed in order to determine if any of these interventions have a beneficial role in HRS (Table 8.4) in terms of long-term renal function preservation, overall survival, and/or transition to OLT.

Aim of pharmacological therapy

The most important objective when treating HRS is to reverse renal failure in order to provide a successful bridge to OLT, so that suitable candidates can undergo transplantation with less morbidity and side effects to posttransplant medications and have similar survival as patients without HRS. Patients with HRS treated sucessfully with terlipressin and albumin before OLT have a similar posttransplantation outcome and survival as patients transplanted without HRS [54]. In four cohort studies, patients that responded

Table 8.4 Treatment of type 1 HRS patients with oral midodrine (Mido) and subcutaneous or intravenous octreotide (oct), octreotide intravenous infusion alone, intravenous norepinephrine, and TIPS.

Treatment [reference]	Response[a] (%)	Recurrence[b] (%)	Response control group	Side effects[c]	1-month survival (%)	1-month survival in control group (%)
Mido + Oct [47][d]	5/5 (100)	0/5 (0)	1/8	3/5	80	15
Mido + Oct, TIPS [48]	10/14 (71)	4/14 (29)		NR	50	
Norepinephrine [49]	10/12 (83)	NR		2/12	50	
Oct [53][d,e]	2/7 (61)	NR	2/9	NR	28.5	55

Abbreviations: Mido, midodrine; Oct, octreotide; NR, not reported.

[a]The definition of response varied between studies; however, in all studies it was defined as a marked decrease in serum creatinine.

[b]Recurrence of HRS after treatment withdrawal in responder patients; definition of recurrence also varied between studies.

[c]Patients presented with self-limited tingling, abdominal cramps, and/or diarrhea during the administration of the first doses of midodrone–octreotide.

[d]Patients received concomitant albumin as plasma expander.

[e]Crossover study of placebo and octreotide.

to therapy of HRS with terlipressin plus albumin or octretide, midodrine, and albumin had an increased survival compared to those who did not respond [37,39,48,50]. Whether this observed increase in survival after transplant in responders is a direct effect specific to a particular pharmacological therapy or rather simply a result of the identification of a less-ill patient group cannot be determined from these studies.

Nonpharmacological therapy

Liver transplantation

In the past OLT was the only available effective therapy for patients with HRS, and it continues to be the treatment of choice for HRS in candidate patients. The survival of cirrhotic patients with HRS treated by OLT is 85% at 1 year and 73% at 3 years, although the presence of HRS is associated with increased morbidity and early mortality after transplantation [55]. In fact, patients with HRS who undergo transplantation have more complications, spend more days in the intensive care unit, and have a higher in-hospital mortality rate than transplanted patients without antecedent HRS. Transplantation for type 1 HRS is limited by the fact that many patients die before the operation because of their advanced liver disease, a short average survival time after onset of HRS, and a prolonged waiting time for transplantation in most liver transplant centers [56]. Therefore, since patients with type 1 HRS have a very poor prognosis, this group of patients should be given higher priority for transplantation [56]. In fact, the implementation of the MELD score in the USA has placed patients with HRS at a higher priority level for liver transplantation due to the fact that creatinine is a strong variable in the mathematical model [19]. In addition, the MELD score provides a good estimate of prognosis in patients with type 2 HRS [18].

TIPS

TIPS is a nonsurgical intervention performed percutaneously that creates a connection (by means of a prosthetic shunt) within

the liver between the portal and hepatic vein, thereby reducing portal pressure. This method has been used as an alternative therapy to surgical shunts for cirrhotic patients bleeding from esophageal or gastric varices who are refractory to endoscopic and medical treatment. The rationale for using TIPS in HRS is based on the fact that reduction of portal pressure improves circulatory function and supresses RAAS and SNS activity (Figure 8.3).

There are scarce data regarding the use of TIPS in HRS. Four uncontrolled studies indicate that TIPS may improve renal function and GFR as well as reduce the activity of RAAS and SNS in patients with cirrhosis and HRS [48,57–59]. Improvement in renal function observed in these uncontrolled studies after TIPS placement alone was slow and successful in approximately 60–70% of patients [48,57–59]. Studies assesing TIPS for type 1 HRS have only included patients with preserved liver function and excluded those with a history of hepatic encephalopathy, Child-Pugh scores of ≥12 or serum bilirubin of >5 mg/dL. A combined approach using the combination of vasoconstrictors with TIPS in 14 patients for the treatment of type 1 HRS revealed that those with preserved liver function (Child score, <12) who responded to oral midodrine plus intravenous octreotide and albumin and then had a TIPS performed had an excellent outcome, with renal function that continued to improve and completely normalize [48]. Nonetheless, this study included a limited number of patients, was uncontrolled for either aspect of the intervention, and was associated with an overall mortality of 50% at 2 months. Thus, larger studies using this approach are required in patients with type 1 HRS before the efficacy of this combined approach can be accepted.

Dialysis

The use of hemodialysis and peritoneal dialysis is ineffective in HRS because patients are prone to develop significant side effects, including arterial hypotension, coagulopathy, and gastrointestinal

bleeding [60,61]. Although dialysis is not routinely recommended in HRS, it may be a temporary option in patients who have exhibited no response to vasoconstrictors or TIPS or in those who develop severe volume overload, metabolic acidosis, or refractory hyperkalemia. Data on the extracorporeal albumin dialysis (MARS) system seem to be promising. This system uses a cell-free albumin-containing dialysate that is recirculated and perfused through charcoal and anion exchange columns connected to a hemodialysis machine, enabling the removal of albumin-bound substances, such as bilirubin, bile acids, and cytokines [62]. In a prospective RCT of 19 patients with Child C cirrhosis and type 1 HRS, there was a decrease in serum bilirubin and serum creatinine levels and an improvement in serum sodium, urine volume, mean arterial blood pressure, and mortality when the data were analyzed using parametric statistical tests for the 13 patients who underwent MARS versus the 5 patients who received hemofiltration and customary care [62]. In a recent systematic review of MARS compared to conventional therapy in patients with severe liver failure, a meta-analysis of the four RCTs identified and that included the only RCT in patients with HRS failed to demonstrate a survival benefit from MARS in liver patients in general [63]. A survival advantage was demonstrated only when nonrandomized trials were included in the review. MARS should, therefore, still be considered an experimental treatment, and further controlled studies are clearly needed before advocating its use in the management of patients with type 1 HRS. An alternative approach to MARS, Prometheus, is currently undergoing clinical evaluation and comparison to MARS [64].

Prevention

The two clinical scenarios in which prevention of HRS has been successful are SBP and alcoholic hepatitis. In SBP, intravenous albumin (1.5 g/kg at diagnosis of infection and 1 g/kg 48 h later) prevents the development of HRS because it counteracts an enhanced arterial splanchnic vasodilation triggered by the infection, causing an even more reduced effective arterial blood volume with additional activation of vasoconstrictor systems [5]. In one study, the incidence of HRS in patients with SBP not administered albumin was 33% and only 10% in those that received albumin [5]. In addition, there was less in-hospital mortality in those receiving albumin (10%) than in those not receiving albumin (29%) [5]. However, it seems that other plasma expanders, such as intravenous hydroxyethyl starch, are not effective in preventing renal failure in the setting of SBP [65]. In patients with acute alcoholic hepatitis, oral pentoxifylline (400 mg three times daily for 1 month) also reduces the incidence of (8% in pentoxiphylline vs. 35% in placebo) and mortality (24% in pentoxiphylline vs. 46% in placebo) of HRS [3]. There have been no follow-up studies confirming these results nor studies to evaluate their generalizability to other clinical settings; however, these two methods of prevention are widely accepted in the clinical setting.

9 Acute Tubular Necrosis

Jay L. Koyner & Patrick T. Murray
Section of Nephrology, University of Chicago, Chicago, USA.

Introduction

The incidence, etiology, and outcomes of acute kidney injury (AKI) vary greatly, depending on the chosen definition and specific population being studied. In the majority of hospitalized patients, AKI is usually the result of prerenal azotemia (reversible renal insufficiency caused by renal hypoperfusion) or acute tubular necrosis (ATN) [1,2]. ATN is a form of AKI that results from injury (ischemic or toxic) to the tubular epithelial cells. In recent case series ATN has accounted for 45–63% of AKI cases hospitalized [3,4]. Furthermore, a study based upon the Program to Improve Care in Acute Renal Disease found ischemic (nonnephrotic) ATN to be the most common cause of AKI, occurring in over 40% of all patients [5]. It should be noted that sustained prerenal azotemia has been shown to be a major predisposing factor towards the development of ischemic ATN [6]. In hospitalized patients, ATN commonly results from a variety of ischemic (hypotension, sepsis, etc.) and nephrotoxic (pharmacologic, radiocontrast, rhabdomyolysis, etc.) insults, often in additive or synergistic combinations [7]. ATN results in intrinsic renal parenchymal injury characterized by tubular cell apoptosis and necrosis, which leads to impairment of renal function.

Diagnosis

The diagnosis of ATN (nephrotoxic or ischemic) may be distinguished from that of prerenal azotemia via serum markers (plasma electrolytes, blood urea nitrogen, and creatinine) and evaluation of urine electrolytes, osmolality, and sediment [8,9]. The tubular dysfunction of ATN may be associated with an elevated urine sodium concentration and a fractional excretion of sodium (FeNa) {[(urine sodium/plasma sodium)/(urine creatinine/plasma creatinine)] × 100} greater than 1%. Additionally, owing to tubular

damage that results in the impaired ability to concentrate and dilute urine, isosthenuria is present [10]. Of course there are exceptions to these findings; in the setting of chronic kidney disease or following recent diuretic use, the diagnostic accuracy of urine chemistries to distinguish prerenal azotemia versus ATN decreases. Additionally, ATN in the setting of rhabdomyolysis, hemolysis, sepsis, or heart failure has been shown to be associated with urine sodium of less than 10 mEq/L and a fractional excretion of sodium of less than 1% [11–13]. As such, one must use caution when attempting to make a diagnosis of ATN based solely on laboratory data. Fortunately, ATN does have characteristic urinary sediment that includes renal tubular epithelial cells and granular and muddy brown casts, but these findings may be transient or unrecognized by an inexperienced observer. Despite years of investigation, no "gold standard" for the diagnosis of ATN exists. Thus, the diagnosis must rely on a combination of data from the patient's history, physical examination, and laboratory studies, including urine sediment. The utility of various diagnostic strategies to differentiate pre-renal azotemia from ATN are discussed in further detail in chapter 3.

Pathophysiology

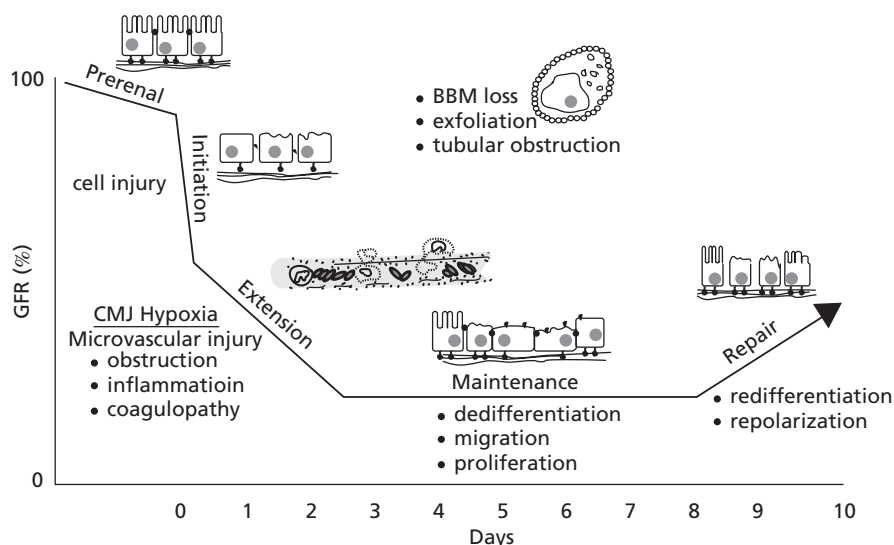
Although there is still much to be discovered in the complex biology of ATN, there are increasingly sophisticated experimental data characterizing the pathophysiology of this syndrome (Figure 9.1). Current evidence suggests that the course of ischemic ATN has several phases: prerenal, initiation, extension, maintenance, and repair. Tubular cell structure and function are severely impaired during the renal hypoperfusion of the initiation phase. Eventually, the tubular basement membrane is denuded by the sloughing of tubular cells. This sloughing leads to cast formation and intratubular obstruction, which results in a decrease in glomerular filtration rate (GFR) [12,13]. Additionally, this permits glomerular filtrate back-leak, which leads to a further decrease in GFR [14]. In the extension and maintenance phases of ATN, several inflammatory cytokines and chemokines promote vasoconstriction, contributing


Figure 9.1 The serial phases of ischemic ATN. (Reprinted from Sutton *et al.* [16] with permission of the publisher.)

to a milieu that promotes renal hypoperfusion, medullary congestion, and generalized tissue injury [14,15]. Lastly, when successful, the repair phase (which is an area of extremely active investigation) consists of death and exfoliation of the proximal tubular cells. These cells are then repopulated and eventually mature and regain their differentiated character [1]. Although ATN is a complex and poorly understood syndrome, a broad spectrum of research initiatives are currently in progress to further our understanding of its pathogenesis and pathophysiology to inform the timing and targeting of prophylactic and therapeutic efforts to improve patient outcomes.

Outcomes

In the early stages of ATN there is an opportunity to correct insults (ischemic or nephrotoxic) that have caused the initial damage. Provided this adjustment is made, renal function will generally improve, although it may not return to preinsult level. It should be noted, however, that severe and acutely irreversible loss of renal function may occur in the setting of ATN. When such a loss of function does occur, it often requires initiation of renal replacement therapy (RRT) and is associated with much higher morbidity and mortality. Severe acute irreversible loss of function with ATN is most likely in the setting of preexisting renal disease and/or repeated ischemic or nephrotoxic insults [16].

Several studies have attempted to gain a clinical understanding of factors that contribute to patient mortality in ATN. Chertow *et al.* [17] performed a multicenter prospective study that followed over 250 patients with "early ATN." They documented a 60-day mortality rate of 36%. Additionally, multivariate analysis identified the following independent predictors of death in acute renal failure (ARF) (with relative risks in parentheses): mechanical ventilation (1.86), male gender (2.01), oliguria (<0.4 L/day) (2.25),

chronic immunosuppression (2.37), acute stroke or seizure (3.08), and acute myocardial infarction (3.14). Similarly, in a multicenter, prospective, controlled trial that evaluated the use of biocompatible hemodialysis membranes, Parker and colleagues showed that the severity-of-illness scores (APACHE) within 24 h of the initiation of RRT for ATN can predict patient survival and recovery of renal function [18]. Despite several recent advances in critical care and renal replacement therapy, recent studies show that AKI from ATN still carries a 35–70% mortality rate, depending on the center and patient population studied [19,20]. Given the severe adverse impact from ATN, it is imperative that clinicians employ as many clinically effective preventative strategies as possible in patients known to be at increased risk for development of ATN by virtue of their demographic characteristics or their risk of exposure to ischemia or nephrotoxicants.

Preventive strategies

Ischemic events (vascular and cardiothoracic surgeries, sepsis, and hypotension) and exposure to several known potential nephrotoxicants (aminoglycosides, amphotericin B, and rhabdomyolysis) are part of the everyday experience of modern medicine. As such, several trials have been performed to determine if any preventative strategies are successful when the clinician is faced with the potential of an ATN-inciting agent or event. This section seeks to describe the studies currently available that inform best practices with regards to preventive strategies and that provide guidance for our current evidence-based recommendations.

Prevention of ATN from aminoglycosides
Despite their severe toxicities, aminoglycosides are still a mainstay of the treatment of life-threatening gram-negative bacterial infections. Nephrotoxicity occurs in 10–20% of patients,

whereas ototoxicity occurs in 3–10% [21–22]. Briefly, the nephrotoxicity stems from the proximal tubular damage the drugs induce after being freely filtered at the glomerulus and absorbed into the proximal tubular cell from the tubular lumen. The potential for tubular damage persists as long as 4 weeks after a single dose because of prolonged intracellular aminoglycoside accumulation; this may account for the observations of nephrotoxicity several days after the drug has been discontinued. It should be noted that aminoglycosides may also affect the distal nephron. This damage normally manifests itself as a defect in the concentrating ability of the kidney (polyuria) as well as severe magnesium wasting [24]. Despite the elucidation of several risk factors for developing aminoglycoside nephrotoxicity (duration of treatment, concurrent diuretics or nephrotoxins, elevated plasma drug trough levels, and liver dysfunction) [24–23], severe nephrotoxicity still occurs. Accordingly, several studies have been performed to evaluate strategies to minimize this potentially devastating side effect.

Over 60 trials have been conducted that have explored the benefit of altering the dosing schedule for aminoglycoside antibiotics. Traditionally, these drugs were dosed three times daily, but concerns over the dose exposure led to trials investigating the utility of once-a-day dosing. Due to the inherent differences in both the protocols and results of the clinical trials, no fewer than four meta-analyses have been performed in the hopes of clarifying some of the contradicting aspects of these studies [24–30]. Each of these works analyzed 20–42 randomized clinical trials; it should be noted that 10 studies were included in all four of these meta-analyses. Blaser *et al.* [27] reported improved clinical efficacy (89.5% vs. 84.7%; $P < 0.001$) as well as improved bacteriological efficacy (88.6% vs. 83.4%; $P < 0.01$) with once-a-day dosing but found no statistical improvement based on toxicity rates. Barza *et al.* [29] found a reduced incidence of nephrotoxicity (from 7.7% to 5.5%) with daily dosing but no significant change in the patient's clinical course. The largest of these studies, Hatala *et al.* [30] reported equivalence with regard to bacteriologic cure and a statistical "trend" toward reduced mortality and toxicity with once-daily dosing (risk ratio for nephrotoxicity, 0.87; 95% confidence interval [CI], 0.60–1.26). Lastly, Munckhof *et al.* [28] compared 20 trials involving 2881 patients and concluded that clinical efficacy improved 3.5% ($P = 0.027$) with once-daily dosing but that there were no differences in terms of the bacteriologic efficacy or toxicity rates. Taken together, these data have led to the commonplace use of daily aminoglycoside dosing in clinical practice, even though none of these meta-analyses reported a statistically robust renal advantage with daily dosing regimens. A recent systematic review in the Cochrane Database comparing aminoglycoside-based treatment regimens in patients with cystic fibrosis demonstrated a reduced renal toxicity benefit to once-daily dosing in children but not in adults with cystic fibrosis [31].

Unfortunately, there are still several grey areas where the safety and efficacy of aminoglycoside dosing remains unclear, including in the elderly, the morbidly obese, and those with chronic kidney disease (CKD). Additionally, in the face of the ever-growing threat of antibiotic resistance, several studies have also sought to facilitate further reductions in drug exposure by evaluating regimens that entail dosing less frequently than once daily. Although no large randomized trials or meta-analyses exist, studies like the prospective controlled trial by Bartal *et al.* raise the question of whether all patients should receive aminoglycosides doses on an individual pharmacokinetic basis (according to personalized trough levels drawn in response to daily drug administration) [32].

Prevention of ATN from amphotericin B

Amphotericin B, an effective therapeutic agent in treating systemic and invasive mycoses, induces nephrotoxicity in 20–80% of patients, depending on a variety of factors, including the dose, total drug exposure, and the population being investigated, as well as the definition of AKI that is used [33,34]. Despite recent advances and new agents to treat fungal infections, amphotericin B still remains an often-used agent for hospital-acquired ATN. All too often ATN arises with concomitant use of amphotericin B and another nephrotoxic agent (aminoglycosides, calcineurin inhibitors, etc.) [35]. It should be noted that amphotericin B nephrotoxicity can take on several forms besides ATN (as measured by increased serum creatinine); these other symptoms include hypokalemia with urinary potassium wasting and hypomagnesemia with urinary magnesium wasting (due to increased distal tubular membrane permeability), as well as nephrogenic diabetes insipidus or type 1 (distal) renal tubular acidosis [36]. In addition to decreasing some of the concomitant risk factors (drug dosage and avoidance of concomitant nephrotoxins), several other preventative measures have been investigated.

Prevention of ATN from amphotericin B by saline (volume expansion)

Animal models have suggested that, in part, the nephrotoxicity of amphotericin B stems from its ability to enhance tubuloglomerular feedback [37]. Because volume expansion (salt loading) has been shown to decrease the sensitivity of tubuloglomerular feedback, it has been used in an attempt to lower the rates of amphotericin B nephrotoxicity. Several studies have attempted to evaluate the utility of volume expansion prior to amphotericin B administration. A review by Anderson [38] compiled the results from five studies (120 total patients) that investigated the use of volume expansion. Anderson concluded that supplementing dietary intake of sodium chloride before amphotericin B therapy is initiated "will likely" prevent nephrotoxicity. This statement is based in large part on the results from the only prospective, double-blind placebo-controlled trial among the five studies included in the Anderson review. In that study, Llanos *et al.* looked at 20 individuals in Peru being treated with thrice-weekly amphotericin B for mucocutaneous leishmaniasis [39]. They found that serum creatinine rose and creatinine clearance decreased in those individuals who received the usual care compared to those who received intravenous saline prior to amphotericin administration ($P < 0.05$). Overall it is difficult to enthusiastically endorse volume expansion, as adequate trials have not been performed, but based on current data

there appears to be minimal harm in giving patients a saline load prior to amphotericin B administration.

Prevention of ATN from amphotericin B: lipid-based formulations

Because of the dose-limiting nephrotoxicity of conventional amphotericin B, several other formulations have been tried. Additionally, co-administration of a wide variety of therapeutic agents, including dopamine [40], has been investigated in the hopes of reducing amphotericin B nephrotoxicity, but these efforts have generally been disappointing.

The results of studies with lipid-based formulations of amphotericin B are more promising. Human studies have shown that there is likely an equal or decreased incidence and severity of AKI with the administration of lipid-based formulations of amphotericin B [41–44]. To date there have been few randomized trials demonstrating unequivocal superior efficacy and safety of lipid-based formulations compared to standard amphotericin B when the latter is given under optimal conditions. Walsh *et al.* [44] conducted a randomized double-blind multicenter trial in 687 patients that compared liposomal amphotericin B with conventional amphotericin B as empiric antifungal therapy. They showed that liposomal amphotericin B was as effective as conventional amphotericin B when used as empirical antifungal therapy and that it was associated with fewer breakthrough fungal infections, less infusion-related toxicity, and less nephrotoxicity (16.6% had a threefold increase in baseline serum creatinine with convention amphotericin B compared with 8.2% with liposomal). Wingard *et al.* performed a double-blind randomized controlled trial (RCT) that compared two doses of liposomal amphotericin B (3 and 5 mg/kg/day) with amphotericin B lipid complex in 244 neutropenic patients [45]. They found significantly lower rates of nephrotoxicity in those who received liposomal amphotericin B compared to amphotericin B lipid complex. In a systematic Cochrane review of this topic that included literature through April 2000, Jonhansen and Gotzche [46] noted that all lipid-based preparations appeared to decrease the occurrence of nephrotoxicity, but conventional amphotericin was rarely administered under optimal conditions and, therefore, they concluded that it was not clear that lipid-based formulations conferred any benefit. Moreover, it should be noted that under optimal clinical conditions, as achieved in the clinical trials, AKI still occurs with the lipid-based formulations and is more likely to occur in the setting of concurrent patient exposure to other nephrotoxic agents [42,44]. Overall, although large-scale and long-term outcome trials comparing lipid formulations of amphotericin B to the conventional formulation have not been performed, it appears that the former may cause less nephrotoxicity.

Prevention of ATN from rhabdomyolysis

Rhabdomyolysis and its associated myonecrosis often results in ATN and oliguric AKI. The ATN associated with rhabdomyolysis is often multifactorial. Volume depletion (renal ischemia), renal tubular obstruction from heme pigment casts, and tubular injury

from the free iron (released from dying muscle) all contribute to the development of ATN. As many as 50% of all patients with traumatic rhabdomyolysis develop ATN [47], but this number can vary greatly depending on the clinical cause of the rhabdomyolysis as well as the definition used to indentify cases of rhabdomyolysis and of AKI. Current standard therapy for treating rhabdomyolysis, regardless of its cause (which can be quite varied), involves aggressive fluid resuscitation with saline and then, once volume repletion is achieved, urinary alkalinization. The vast majority of studies on prevention of rhabdomyolysis-induced ATN involve trauma patients (natural disaster or accidental). Due to the nature of this type of injury, large-scale RCTs in humans have not been performed to evaluate the recommended therapeutic interventions.

Prevention of ATN from rhabdomyolysis with saline resuscitation

Saline resuscitation is the first step in interrupting the pathophysiology of rhabdomyolysis-induced ATN. The damaged and dying muscles sequester large volumes of water and sodium, which results in rapid intravascular hypovolemia if aggressive fluid resuscitation is not initiated [48]. Although mostly retrospective, human studies have indicated that in order to maintain adequate intravascular volume in traumatized patients at risk for rhabdomyolysis, it is important to start the fluid resuscitative effort prior to the extraction of the patient from the scene of the crush injury [49]. The rationale behind this is to restore intravascular volume prior to the release of heme pigment from injured muscle into the circulation and thus help to prepare the kidneys in advance of the crush relief. In a small retrospective study, this technique was shown to decrease the rate of ATN requiring RRT [50]. The ultimate goal of fluid administration is to initiate a volume diuresis, thereby washing out any obstructing heme pigment casts in the setting of massive fluid sequestration into injured muscle tissue. Overall, the observational trials data support the conclusion that the benefits of attempting saline resuscitation outweigh the risks for fluid overload and pulmonary edema, and as a result it should be attempted in patients presenting with rhabdomyolysis.

Prevention of ATN from rhabdomyolysis with mannitol and bicarbonate

In the setting of a successful saline resuscitation, several studies have attempted to show an additional benefit from initiating a forced alkalinization of the urine. This is often performed through the administration of a combination of mannitol and bicarbonate in intravenous solutions. The rationale behind this treatment is that urine alkalinization prevents the precipitation of the heme pigment casts and thus prevents tubular obstruction and AKI. Additionally, it is thought that it helps to prevent the dissociation of free iron from myoglobin [51]. Animal models have shown that in the setting of experimental traumatic rhabdomyolysis a combination of 0.9% saline, sodium bicarbonate, and mannitol reduces tissue injury (via oxidant stress) and restores renal blood flow, better than either 0.9% saline alone or hypertonic saline [48]. Unfortunately, these animal data have not been replicated in human studies. The

literature supporting the use of urinary alkalinization in patients suffers from the same deficiencies as the saline resuscitation studies. It is limited to retrospective, nonrandomized studies. Furthermore, these observational studies offer conflicting results with regards to the utility and effectiveness of urinary alkalinization in preventing ATN from rhabdomyolysis [50,52–54]. These studies vary in size from 15 patients to 382 patients, the largest of which (Brown *et al.*) did not demonstrate any improvement in the ATN or mortality rates in those individuals with rhabdomyolysis (creatine kinase level greater than 5000 U/L) treated with bicarbonate and mannitol [53]. The use of these agents cannot be recommended on the basis of any proven effectiveness reported in the current body of literature. Additionally, multiple toxicities and complications can occur with the administration of these agents (e.g. worsening of hypocalcemia, hypokalemia, hyperosmolality, mannitol-induced proximal tubular damage, systemic alkalosis) necessitating close monitoring of electrolytes, intravascular volume status, and serum and urine pH whenever this intervention is used.

Prevention of ischemic and postoperative ATN

Patients exposed to hypotension, regardless of the etiology (surgery, sepsis, hypovolemia, drug induced, etc.) are at risk for developing ischemic ATN. As mentioned above, the pathophysiology of ATN is complex, but much of what we know is based on animal and clinical models of ischemic ATN. Combining insights obtained from animal models with the availability of well-defined patient cohorts that are at high risk for postoperative ATN, several studies have been conducted to investigate the prevention (and therapy) of ATN in the perioperative setting. However, the majority of these controlled investigations have focused on patients with established ATN rather than those in the early initiation phase prior to clinically overt renal failure. Additionally, it should be noted that although several interventions evaluated in the aforementioned animal models showed dramatic effects in their ability to minimize injury and dysfunction, their translation to human studies and clinical practice has been negligible. These interventions include the use of loop diuretics, dopamine, and fenoldopam. The evidence supporting the role of these interventions in human ischemic ATN prevention and treatment is outlined below. A recent systematic review of loop diuretics, dopamine, calcium channel blockers, angiotensin converting enzyme inhibitors, and fluid therapy as renoprotective strategies for patients undergoing surgery has been published by the Cochrane Library [55].

Loop diuretics

In animal models of ATN, loop diuretics minimize the extent of renal damage and dysfunction [56]. As a result they have been extensively investigated as a means of preventing ATN in patients at risk. Randomized controlled trials comparing diuretic infusion to placebo and other agents (e.g. dopamine) have been performed, and the results have been varied. In 1996, Hager *et al.* [57] randomized 121 patients to receive low-dose infusions of furosemide (1 mg/h) or placebo throughout their intensive care
unit (ICU) stay following major thoraco-abdominal or vascular surgery. They found that there was no difference in serum creatinine or creatinine clearances nor incidence of AKI. It should be noted that no patient in this study (regardless of study arm) developed AKI requiring RRT. Subsequent studies have demonstrated a potential deleterious effect of loop diuretics. In a double-blind, placebo-controlled trial, Lassnigg *et al.* randomized 123 patients to furosemide, dopamine, or saline during and after cardiac surgery [58]. They described an increased rate of AKI (defined as a 0.5-mg/dL increase in serum creatinine) in those patients receiving the diuretic infusion (6 of 41) compared to those receiving saline (0 of 40) ($P < 0.01$). In light of the data reviewed, indicating that loop diuretic administration in patients with established acute renal failure might result in poorer outcomes [59–61] and the finding that loop diuretic administration does not reduce the incidence or duration of AKI and RRT, their routine use in patients at risk of ATN cannot be recommended.

Dopamine

Dopamine, when infused at low doses, has the ability to dilate both the afferent and efferent arterioles in experimental models and has been investigated extensively as a preventative tool in ATN. In the best study of low-dose dopamine therapy for ATN, the ANZICS group performed a randomized, double-blind, controlled trial in 328 critically ill patients with early signs of renal dysfunction (not specifically ATN), comparing dopamine (2 μg/kg/min) with placebo [62]. They found no difference between the groups in the primary end point (peak serum creatinine during study drug infusion) ($P = 0.93$) or with a variety of secondary end points, including development of RRT-requiring ATN ($P = 0.55$), length of ICU stay ($P = 0.67$), or hospital-based mortality ($P = 0.66$). Although this study may not have been a "pure prevention" trial, other more conventional prophylaxis trials have been performed with dopamine therapy. Marik [63] performed a meta-analysis of the kidney-protective effects of low-dose dopamine and found 21 RCTs that had compared low-dose dopamine to placebo and, after a quality review, Marik included 15 studies in the final analysis. Nine of these 15 studies involved postoperative or ischemia-related ATN; none of these demonstrated a significant beneficial effect of low-dose dopamine in preventing renal injury. Two additional meta-analyses [64,65] have been conducted that have included but were not limited to studies investigating dopamine on postoperative or ischemic ATN. Both of these meta-analyses failed to find a benefit from low-dose dopamine. The recent analysis by Friedrich *et al.* [66] included 61 trials (more than 40 of which involved postoperative or ischemic insults) encompassing over 3300 patients. Their analysis demonstrated that dopamine may offer "transient improvement in renal physiology" (as measured by urine output during the first 24 h of infusion) but no improvement in survival, need for RRT, or incidence of AKI (Figures 9.2 and 9.3).

Despite the robust clinical trials literature, use of dopamine persists in clinical practice because of the perceived beneficial effects of dopamine on renal perfusion in patients with AKI. The basic premise of this physiological argument has not been tested

Favors Dopamine   Favors Control

Weight refers to the contribution of each study to the overall estimate of treatment effect. The pooled estimate is calculated by using a random-effects model. The summary relative risk is calculated on the natural logarithm scale. The weight of each study is calculated as the inverse of the variance of the natural logarithm of its relative risk. The size of the symbol denoting the point estimate does not represent the weighting of the study. See the Methods section for a discussion of the weighting. ANZICS = Australian and New Zealand Intensive Care Society; n/n = numbers of deaths/patients randomly assigned; RR = relative risk.

in humans until recently. Recently, Lauschke *et al.* demonstrated that "low-dose" dopamine may have a deleterious effect on renal perfusion, specifically in those patients with AKI [66]. They conducted a prospective, double-blind, randomized controlled crossover trial in 40 patients (30 with AKI and 10 without). The patients received, in randomly assigned sequence, alternating doses of dopamine (2 μg/kg/min) or placebo and had renal resistive and pulsatility indices measured during four 60-min study periods. Patients with AKI (doubling of baseline serum creatinine or a value above 2.0 mg/dL) demonstrated an increase in resistance indices from baseline ($P < 0.01$) in response to dopamine. This study was the first to demonstrate that dopamine adversely affects renal perfusion and hemodynamics in patients with AKI and that this response differs from that observed in patients without AKI. Robust RCTs and meta-analyses of these RCTs demonstrate no renal or survival benefit from the administration of dopamine to prevent AKI in patients at risk. On the basis of these clinical trials data, dopamine cannot be recommended as an intervention to prevent ischemia-related ATN in the medical or surgical ICU patient.

Fenoldopam

Fenoldopam, a selective dopamine 1 receptor agonist, has been investigated for renoprotective uses because, like dopamine, it has been shown in low doses to increase renal blood flow in animal models without significant systemic adverse hemodynamic effects [67]. Several RCTs have evaluated the potential prophylactic effects of fenoldopam in preventing ATN in the settings of radiocontrast exposure [68,69], sepsis [70], liver transplantation [71], and cardio-aortic surgery [73–75].

In a prospective randomized placebo-controlled trial, Halpenny *et al.* studied 31 hemodynamically stable post-cardiovascular surgery patients administered either fenoldopam or placebo immediately postoperatively. They assessed renal function in patients who were sufficiently stable to remain on fenoldopam or placebo at 0–4 and 4–8 h and then on days 1, 2, 3, and 5 postoperatively. They reported their findings for the first three time periods only, during which they observed improved renal function in the fenoldopam group [73]. The long-term benefits and clinical importance of these data are unclear. In a second prospective randomized double-blind controlled study, Halpenny *et al.* [74] studied 28 individuals

Weight refers to the contribution of each study to the overall estimate of treatment effect. The pooled estimate is calculated by using a random-effects model. The summary relative risk is calculated on the natural logarithm scale. The weight of each study is calculated as the inverse of the variance of the natural logarithm of the point estimate of its relative risk. The size of the symbol denoting the point estimate does not represent the weighting of the study. See the Methods section for a discussion of the weighting. ANZICS = Australian and New Zealand Intensive Care Society; n/n = numbers of patients requiring renal replacement therapy/patients randomly assigned; RR = relative risk.

undergoing aortic cross-clamping and the effects of intraoperative administration of fenoldopam. Plasma creatinine concentration increased significantly from baseline on the first postoperative day in the placebo group ($P < 0.01$) and not in the fenoldopam group, but no subsequent data were reported, and the utility of this small pilot study in informing care is, therefore, limited. Caimmi *et al.* [75] randomized 160 patients with CKD (serum creatinine > 1.5 mg/dL) undergoing hypothermic cardiopulmonary bypass to receive intraoperative and postoperative fenoldopam (0.1–0.3 μg/kg/min) or conventional care. They found that fenoldopam was correlated with a shorter duration of mechanical ventilation, shorter ICU stays, and a lower immediately postoperative serum creatinine. Unfortunately, once again there was no report of effects on long-term postoperative renal function compared to placebo. In the last of these studies, Bove *et al.* [76] randomized 80 patients undergoing cardiac surgery to receive an infusion of either fenoldopam or dopamine for the 24 h following the induction of anesthesia. The merits of using dopamine as a control aside, this study failed to show any incremental improvement or benefit on renal outcomes from the fenoldopam infusion compared to dopamine.

Morelli *et al.* [71] conducted a randomized, double-blind, placebo-controlled trial of 300 patients with sepsis in which pa-

tients received fenoldopam (0.09 μg/kg/min) or placebo for the entire length of their ICU stay. They found that prophylactic fenoldopam decreased the rate of renal failure (serum creatinine > 300 μmol/L) compared to placebo (29 vs. 51 patients; $P = 0.006$). Additionally, they noted a decrease in the length of ICU stay with fenoldopam (10.6 ± 9.3 days vs. 13.4 ± 14.0 days; $P < 0.001$). These promising data for sepsis suggest that a larger trial should be conducted for this indication.

Although some of these studies report benefits from the use of fenoldopam for prevention of ATN, the data do not support the clinical use of fenoldopam for this purpose at this time, particularly given the potential risk of fenoldopam-induced hypotension, pending further confirmatory prospective studies.

N-Acetylcysteine

N-acetyl-cysteine (NAC) is thought to potentially protect patients from contrast-associated nephropathy because of its anti-inflammatory properties and through modulation of oxidative stress as an oxygen free radical scavenger [77]. NAC has therefore been tested in the setting of increased oxidative stress and renal ischemia associated with either cardiopulmonary bypass (CPB) or cross-clamping of the aorta for abdominal surgery where NAC has been administered prior to the onset of overt renal injury in

order to reduce postoperative AKI. Seven RCTs have evaluated the renoprotective effects of intra- and/or postoperative NAC infusion in patients at risk for ischemic and oxidative stress-related ATN from cardiac or aorta surgery [78–84]. No systematic review of the literature has been performed to date that summarizes this literature. Fisher *et al.* in a post hoc analysis of an RCT of NAC in cardiac surgery reported a significantly greater decline in calculated creatinine clearance in patients receiving placebo compared to those who received NAC [78]. In an RCT of 295 high renal risk coronary artery bypass graft patients that compared high-dose NAC (2400 mg/24 h) versus placebo, Burns and collegues were unable to demonstrate kidney-protective effects from NAC [79]. They conducted a post hoc analysis of those patients with baseline renal dysfunction (Cr > 1.4 mg/dL) and reported a non-significant trend toward less renal dysfunction in this subset of patients when they received NAC. Ristikankare *et al.* randomized 80 subjects with CKD undergoing elective cardiac surgery and CPB to receive either NAC intra- and postoperatively or placebo [80]. They evaluated biomarkers of tubular damage (*N*-acetyl-beta-D-glucosaminidase) and serum cystatin C and creatinine clearance during the first 5 days postoperatively and observed no protective effect on renal function with NAC [80]. In a second study from the same institution, Hynninen *et al.* evaluated whether NAC administered intraoperatively afforded renoprotection from ischemic ATN for patients with normal baseline renal function undergoing abdominal aortic surgery and aortic cross-clamping [81]. They measured serum creatinine and cystatin C and urinary NAG levels. They were unable to demonstrate any renoprotective effect with NAC administration. In a small study of Brazilian patients, Macedo also was unable to demonstrate renoprotective effects from NAC during abdominal aortic surgery [82]. In the most recent studies, Haase *et al.* investigated the effects of high doses of NAC (300 mg/kg over 24 h by continuous infusion) on renal function in a high-risk group of patients undergoing cardiac surgery with CPB. In this RCT there was no difference in the two groups in terms of serum creatinine or cystatin C level or urinary NAG during the 5-day postoperative follow-up period [83]. Thus, only one RCT demonstrated a small potential benefit from prophylactic NAC administration, one reported a trend toward a benefit in individuals with CKD, and the remainder of studies reported to date have demonstrated no benefit in patients at risk for ischemic ATN associated with cardiac or abdominal surgery. These studies are mostly small and, therefore, not sufficiently powered to preclude a small beneficial effect. At this time, however, routine use of NAC in cardiac and aortic surgery as a renoprotective strategy cannot be recommended.

Modulation of mechanical ventilation settings

Positive-pressure mechanical ventilation alters renal perfusion and function through a variety of mechanisms [76,85]. In patients with decreased effective circulating blood volume, increased intrathoracic pressure promotes a decrease in venous return from the periphery and may cause hypovolemic shock. Positive pressure ventilation, even in the absence of hypovolemia, alters neuro-hormonal

systems (stimulates increased sympathetic outflow, activates the renin–angiotensin–aldosterone axis, increases nonosmotic vasopressin release, and decreases atrial natriuretic peptide release). Overall these effects promote systemic and renal vasoconstriction, decreased renal blood flow, and lower GFR. Hypercapnia and severe hypoxemia (PaO_2 < 40 mmHg) have similarly been shown to result in renal vasoconstriction and decreased blood flow [85]. Overall, in critically ill patients with compromised circulatory function, it is well-documented that diminished systemic and renal perfusion (ATN) are common adverse outcomes of respiratory failure requiring mechanical ventilation.

Several studies have shown that fluid administration and the use of vasoactive drugs (dopamine, fenoldopam) can improve the renal hypoperfusion and decreased GFR associated with positive pressure ventilation [86–88]. Recently, ventilator-induced pulmonary and systemic inflammation have been identified as risk factors for ARF, in addition to known hemodynamic and neurohormonal mechanisms of ventilator-induced renal injury. Evidence from large-scale randomized trials suggests that the proinflammatory effects of positive pressure ventilation, specifically those of lung-injurious ventilatory strategies, may be a source of AKI [85,89–91]. The ARDSNet Tidal Volume Trial demonstrated that patients assigned to the lower tidal volume group experience an increased number of ventilator-free days, improved survival, and less AKI (defined as serum creatinine > 2.0 mg/dL) (20 ± 11 vs. 18 ± 11 days; $P = 0.005$) [90]. Additionally, in an RCT, Ranieri *et al.* [91] demonstrated that lower tidal volumes and higher PEEP (lung protective strategy) caused less systemic inflammation compared to standard care, and this correlated with fewer patients with organ system failures, including less AKI at 72 h postadmission. Overall, recent developments have shown that combinations of hemodynamic and lung-protective ventilatory strategies are the best current approach to minimizing ventilator-induced AKI. Hopefully, the widespread adoption of these guidelines will result in a decrease in AKI in critically ill patients.

Other agents

Over the years several additional agents have been investigated as potential preventative measures. The adenosine agonist theophylline has been studied in the setting of radiocontrast nephropathy [92] as well as following cardiovascular surgery [93]. In RCTs of 80 and 56 patients, respectively, theophylline was shown to be ineffective at preventing ATN. Similarly, mannitol has been compared to standard hydration in a wide variety of settings for ATN prophylaxis. Although some data support its use in the perioperative kidney transplant setting (discussed in chapter 51), in several small RCTs mannitol failed to prevent ATN following cardiovascular surgery [94], vascular surgery [95], and biliary tract surgery [96].

Pharmacologic therapy of established ATN

Several classes of agents have been investigated as potential therapeutic options for established ATN, but the results have been disappointing.

Therapy of established ATN with loop diuretics

Loop diuretics are often used during the management of ATN in the hopes of "converting" oliguric ATN to a nonoliguric state. Several decades ago, two small RCTs (with 58 and 66 patients) showed no benefit from increasing urine output with loop diuretics on the duration or severity of AKI [62,97]. Recently, there has been a renewed interest in this phenomenon, and several new investigations have sought to redefine the role of loop diuretics in the setting of established ATN. Cantarovich *et al.* found that high-dose furosemide (25 mg/kg/day), in the setting of established AKI, showed no impact on patient survival or renal recovery rate, despite increasing total urine output [98]. In this prospective, randomized, double-blind, placebo-controlled multicenter trial of 338 patients with AKI requiring RRT, there was no between-groups difference in the total time on RRT (11.4 ± 8.6 vs. 12.4 ± 8.7 days; not significant) despite achieving 2.0 L of urine output with furosemide administration. Furthermore, Mehta *et al.* evaluated a multicenter retrospective cohort of 552 patients with AKI in the intensive care unit setting. They found that diuretic use in critically ill patients was associated with an increased risk of death and nonrecovery of renal function [60]. In contrast, Uchino *et al.* examined diuretic use in 1743 patients with AKI at 54 centers [99]. Overall, 64% of that cohort received diuretic therapy, and extensive multivariate analysis found that diuretic use was not associated with any increase in mortality. Regrettably, due to lack of randomization and other confounders, the latter cohort studies are not definitive. In summary, the current literature does not support the use of loop diuretics as therapy for ATN to hasten renal recovery or improve mortality, but when clinically indicated it appears that their use to control fluid balance remains justified.

Therapy of established ATN with dopamine

As previously mentioned, although several meta-analyses have examined the role of dopamine in the setting of ATN, many of these results have combined prevention and therapeutic trials. For instance, in the Friedrich *et al.* meta-analysis of 61 randomized trials, only 6 trials studied dopamine as a treatment option for those with established renal dysfunction [66]. Of these six, only four investigated dopamine use in the setting of potential ATN (critical illness and congestive heart failure). The remaining two studies measured dopamine's performance in the settings of preeclampsia and contrast nephropathy [66]. The largest of the included trials was the ANZICS trial [63], which as previously mentioned examined 328 patients with two or more manifestations of systemic inflammatory syndrome in a 24-h period and at least one indicator of early renal dysfunction (decreased urine output or changes in serum creatinine). Patients received dopamine (at 2 μg/kg/min) or placebo until one of the study end points was met (death, RRT, 24 h postresolution of systemic inflammatory syndrome or adverse event). In the end, low-dose dopamine did not confer any clinically significant protection from renal dysfunction; there was no observed difference in the primary outcome of peak serum creatinine during the study ($P = 0.93$), RRT rate ($P = 0.55$), length of ICU stay ($P = 0.67$), or in-hospital mortality ($P = 0.66$). Similarly, a sys-

tematic review by Kellum and Decker [100] looked at dopamine use in a total of 17 RCTs. They concluded from their systematic review that "the use of low-dose dopamine for treatment or prevention of acute renal failure cannot be justified . . . and should be eliminated from routine clinical use." It should be noted that this meta-analysis did not formally distinguish between prevention and therapeutic trials. Based on these findings as well as those from the prevention trials discussed above, the use of dopamine as a therapeutic option in the setting of ATN cannot be endorsed.

Therapy of established ATN with fenoldopam

In addition to investigation as a prophylactic agent for radiocontrast nephropathy [101] and sepsis-induced renal dysfunction, fenoldopam has been studied as therapy for established ATN [102,103]. Tumlin *et al.* studied 155 ICU patients with early ATN and randomized them in a double-blind fashion to receive fenoldopam or 0.45% saline. They demonstrated that fenoldopam patients tended to have lower mortality ($P = 0.068$) and a decreased need for RRT. Unfortunately, the study was underpowered, and the 11% difference in RRT-free survival did not reach statistical significance. A secondary post hoc analysis of the trial data by these authors supported the view that in the subsets of patients without diabetes and those recently undergoing CV surgery improved outcomes might have been achieved with fenoldopam. The authors recommended that a larger multicenter trial with stratification for diabetes mellitus be performed to further explore the potential therapeutic utility of fenoldopam in the setting of early ATN [104].

Similarly, Brienza *et al.* [105] recently published their study of 110 ICU patients with AKI, comparing therapy with 4 days of fenoldopam with low-dose dopamine. Although this study was randomized, the investigators were not blinded, and the use of low-dose dopamine as a control arm was less than ideal. Nevertheless, the study showed that the mean serum creatinine as in the fenoldopam group was lower than that of the dopamine group after the 4-day infusion period (1.56 vs. 1.81 mg/dl). There was, however, no difference observed in the rate of RRT in either group. The clinical significance of this slightly lower serum creatinine after the 4-day infusion period remains unclear. Based upon the results of these two studies, a larger, multicenter, randomized, double-blind, placebo-controlled trial of fenoldopam therapy for ATN, stratified for subpopulations such as diabetic status, seems warranted.

Therapy of established ATN with natriuretic peptides

The natriuretic peptides (NP) are a family of hormones and pro-hormones that work in concert with the renin–angiotensin–aldosterone axis to maintain salt and water homeostasis. Atrial natriuretic peptide (ANP), which promotes afferent arteriolar vasodilation and efferent arteriolar vasoconstriction, leading to an increase in GFR [104], is the best-studied in this family. ANP and its analogs have been studied as treatment for ATN in several settings, including radiocontrast nephropathy [105], post-cardiac surgery [106], and generalized ATN (sepsis, nephrotoxin reaction, etc.) [107].

In a multicenter randomized, double-blind, placebo-controlled trial, Allgren *et al.* looked at anaritide (a synthetic analog of ANP)

in 504 patients with preexisting ATN [108]. They concluded that anaritide did not improve the overall rate of RRT-free survival; however, they reported some possible benefit for the subset of individuals with oliguric ATN. Only 73% of those with oliguric ATN required RRT in the anaritide arm compared to 92% receiving placebo. To evaluate this possibility, Lewis *et al.* conducted a randomized, double-blind, placebo-controlled trial of 222 patients with oliguric ATN and found no improvement in the dialysis-free survival time after a 24-h infusion of ANP (200 ng/kg/min) [108]. It should be noted that 36% of those studied by Lewis *et al.* received radiocontrast agent as the precipitating source of their ATN and that hypotension was more common in the ANP-treated subjects.

Looking at ANP exclusively in the post-cardiac surgery setting, Sward *et al.* found that administering 50 ng/kg/min of ANP to patients with early postoperative renal dysfunction decreased the requirement of RRT and improved dialysis-free survival [106]. In this prospective, double-blind, randomized placebo-controlled trial of 61 patients, only 8 patients (28%) receiving anaritide required RRT or died in the first 21 postoperative days, compared to 17 (57%) in the placebo arm (hazard ratio, 0.35; $P = 0.017$).

However, these studies have dosing discrepancies; the Allgren and Lewis studies that failed to show a benefit in RRT-free survival dosed ANP at 200 ng/kg/min (resulting in more hypotension in the experimental arm), compared to 50 ng/kg/min in the Sward *et al.* study. The duration of ANP treatment was also different. Thus, the possibility exists that the negative results from the former, high-dose studies might be the result of ANP-induced hypotension or some other confounder. As such, more trials investigating the use of "low-dose" anaritide are needed in order to fully evaluate the utility of these agents as ATN therapy.

Recent meta-analyses of brain natriuretic peptide (BNP; nesiritide) trials in the setting of congestive heart failure have generated some controversy. Sackner-Bernstein *et al.* in a meta-analysis of five trials with 1269 patients found nesiritide doses of 0.03 μg/kg/min significantly increased the risk of renal dysfunction (serum creatinine increase > 0.5 mg/dL) compared to non-inotrope-based controls or compared to all control groups (including inotropes) [109]. This association with renal dysfunction was noted at doses as low as 0.015 μg/kg/min compared to controls; however, there was no noted difference in dialysis rates. In a separate meta-analysis by the same authors, nesiritide showed a trend toward increased 30-day mortality [110]. Although none of the studies analyzed was performed with renal function as a primary end point, the use of nesiritide for the prevention or treatment of AKI in patients with CHF is not supported by the current literature.

Therapy of established ATN: other modalities

As previously mentioned, the pathophysiology of AKI is an active area of investigation, and several potential therapeutic agents have been identified in experimental models of AKI. Unfortunately, their role in clinical practice remains unclear [111]. Insulin-like growth factor 1 (IGF-1) showed a great degree of promise in early basic science studies and animal models. Yet, despite this early promise, several clinical trials have failed to demonstrate an appreciable beneficial effect. Among these studies is the multicenter, randomized, double-blind, placebo-controlled trial conducted by Hirschberg *et al.* [112]. In this trial, 72 patients were randomized to receive either recombinant human IGF-1 (rhIGF-1) or placebo. In this RCT, rhIGF-1 did not hasten recovery from AKI. Among the other negative studies, Hladunewich *et al.* performed a randomized placebo-controlled trial in 44 patients with delayed graft function immediately following cadaveric kidney allografts (a commonly used model for postischemic ATN) and compared the use of IGF-1 to placebo [113]. Patients receiving twice-daily infusions of IGF-1 for the first six postoperative days achieved no significant improvement in their renal function, as measured by day 7 inulin clearance ($P = 0.67$). IGF-1 is one agent on a long list of potential therapeutic agents that have shown promise in animal models, but to date none has demonstrated a clear benefit in clinical practice.

Summary

ATN is an all-too-common and serious complication for hospitalized patients. Its course is extremely variable, often necessitates that patients undergo RRT, and carries a very high mortality rate. Despite countless trials to investigate potential preventative and therapeutic agents, to date there exist few proven effective interventions for ATN.

10 Radiocontrast Nephropathy

Brendan J. Barrett & Patrick S. Parfrey

Division of Nephrology and Clinical Epidemiology Unit, Faculty of Medicine, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

Introduction

Iodinated contrast media are commonly employed to enhance aspects of radiographic images during diagnostic or interventional radiological procedures. The contrast media are injected intravascularly, into either an artery or vein. As discussed below, the route of administration and population studied may be important determinants in the potential for kidney injury and its prevention. Most of the recent literature on contrast-induced nephropathy has been in the setting of cardiac angiography and percutaneous coronary intervention. Estimates of risk, the mechanism of kidney injury, and the impact of preventive therapies may differ according to the population studied.

Definition of contrast-induced nephropathy

After exposure to intravascular iodinated contrast medium, sensitive tests of kidney function have identified mild, transient changes in most cases [1]. Clinically important injury, or contrast-induced nephropathy (CIN), is less common. There is no single satisfactory definition of CIN. CIN is often defined as an acute change in kidney function, occurring after contrast injection and in the absence of other potential causes of acute renal failure. Change in kidney function is usually recognized as a rise in serum creatinine in terms of either a fixed (e.g. 0.5 mg/dL [44 μmol/L]) or relative (e.g. 25%) change following contrast. Despite the prevailing definition, contrast solution may be a contributory rather than a sole cause of acute kidney failure. Concomitant insults may include low blood volume, surgery, atheroembolic disease, and other nephrotoxins. There is no specific diagnostic marker for CIN in humans, and these concomitant insults to the kidney may contribute indepen-

dently to a portion of the higher rate of acute renal failure seen after cardiac angiography.

The clinical importance of minor, usually transient, changes in serum creatinine is debatable. Although a 25% increase in serum creatinine following contrast exposure has been associated with prolonged hospital stay, adverse cardiac events, and higher mortality both in hospital and in the long term [2–7], these associations may be explained at least in part by comorbidities, acuity of illness, or by alternate causes of acute kidney failure, such as atheroembolism. However, the fact that interventions, such as prophylactic hemofiltration and *N*-acetylcysteine (NAC), have been found to reduce both the occurrence of CIN and premature death in some studies leaves open the possibility that minor acute changes in kidney function may in some way contribute to the other adverse outcomes [8–10].

Burden of disease

CIN was reported in one recent cohort study to be the third most common cause of acute renal failure in hospitalized patients [11]. In this study, contrast was assumed to be the cause of the renal failure if administered within the prior 24 h and no other major kidney insult was identified. The reported incidence of contrast nephropathy, however, varies among studies due to differences in definition, background risk, type and dose of contrast, imaging procedure, and the frequency of other potential causes of acute renal failure.

The presence or absence of background risk factors and the type of imaging procedure are the most relevant factors influencing the incidence of CIN. Preexisting renal function is a major determinant of risk for CIN [2]. In one study of patients undergoing coronary angiography, serum creatinine rose by more than 25% in 14.5% of cases (95% confidence interval [CI], 12.9–16.1), while 0.77% required dialysis [2]. Baseline estimated creatinine clearance was below 47 mL/min (0.78 mL/s) in all cases requiring dialysis, many of whom were close to end-stage kidney disease prior to angiography [2]. Registry data suggest an incidence of

nephropathy requiring dialysis after percutaneous coronary intervention of 0.44% [12]. In the absence of preexisting renal disease, the incidence is much lower. In a large clinical trial, only 8% of patients whose baseline serum creatinine was below 1.5 mg/dL (135 μmol/L) had an increase in serum creatinine of more than 0.5 mg/dL, and none had a rise of more than 1 mg/dL [13]. All of the above incidence rates were derived from studies of cardiac angiography. The literature on risk following intravenous injection of modern contrast agents for routine diagnostic computed tomography, for example, is more sparse. The frequency of minor changes in serum creatinine after intravenous contrast would appear to be much lower than the frequency reported after cardiac angiography. The importance of the background level of kidney function on the incidence rate of acute change in kidney function has recently been reemphasized [14].

Risk stratification of patients

The first steps in reducing the risk for kidney injury are to identify modifiable risk factors, to estimate the magnitude of risk, and to review the indications for contrast. Table 10.1 lists the major factors that have been associated with an increased risk for CIN. Most risk factors can be detected with a routine history and physical examination. Some risk factors, like hypovolemia, can be at least partially corrected prior to administration of contrast agent. The risk for decline in kidney function after contrast rises exponentially with the number of risk factors present [4,5,22]. Validated risk prediction models, such as the one shown in Table 10.2 and

Table 10.1 Risk factors for the development of radiocontrast nephropathy.

Risk factor	Comment [references]
Preexisting kidney disease	Risk inversely related to level of kidney function [2,12]
Diabetes mellitus	Less of a factor on its own but interacts with presence of kidney disease [2,15,16]
Heart failure or reduced systolic function	Seen with NYHA class III/IV pulmonary edema or LVEF <40% [10,16,17]
Hypotension	[16,17]
Low hematocrit	[17,18]
Older age	[16,17]
High dose of contrast	"Tolerable" dose may depend on level of kidney function [12,19,20]
High-osmolality contrast	Risk only clearly shown in presence of preexisting kidney disease [13,21]
Route of administration, cardiac angiography	Higher rates of CIN reported after cardiac angiography than after i.v. exposure [13,14]

Abbreviations: NYHA, New York Heart Association; LVEF, left ventricular ejection fraction.

Table 10.2 Risk prediction scores for acute decline in kidney function following percutaneous coronary intervention.

Risk factor	Score
Systolic pressure <80 mmHg for >1 h and requiring inotropic of intra-aortic balloon pump support within 24 h of procedure	5
Use of intra-aortic balloon pump	5
Heart failure, New York Heart Association class III/IV and/or history of pulmonary edema	5
Age >75 yrs	4
Hematocrit <39% for men, <36% for women	3
Diabetes	3
Contrast media volume	1 (for each 100 ml)
Serum creatinine >1.5 mg/dL or eGFR[a] <60 mL/min/1.73m^2	4 or 2 (for eGFR 40–60) 4 (for 20–40) 6 (for <20)

Source: adapted from Mehran et al. [16].
[a]Formula for eGFR: 186 × (serum creatinine [mg/dL])$^{-1.154}$ × (age)$^{-0.203}$ × (0.742 [for women]) × (1.21 [for African Americans]).

illustrated in Table 10.3, have been developed for those undergoing percutaneous coronary intervention [16].

It is not necessary to measure serum creatinine for every patient prior to contrast, but this should be done prior to intra-arterial use and in patients with a history of kidney disease, proteinuria, kidney surgery, diabetes, hypertension, or gout [23]. Patients with reduced kidney function may be more easily recognized if estimated creatinine clearance or estimated glomerular filtration rate (eGFR) is determined from the serum creatinine, using either the Cockroft-Gault [24] or MDRD [25] formula [eGFR = 186 × (serum creatinine, in mg/dL)$^{-1.154}$ × (age)$^{-0.203}$ × (factor of 0.742 if female) × (factor of 1.21 if African American). It should be noted that the

Table 10.3 Association of total risk prediction score with specific risks related to acute decline in kidney function.

Total risk score[a]	% of patients with indicated total risk score who will:	
	Have a serum creatinine rise >25% or 0.5 mg/dL	Require dialysis
≤5	7.5	0.04
6–10	14.0	0.12
11–16	26.1	1.09
≥16	57.3	12.6

[a]The total risk score is determined by addition of the scores for each element (illustrated in Table 10.2).

Cockroft-Gault formula progressively overestimates GFR as GFR reaches lower levels whereas the MDRD formula yields an estimate corrected to a body surface area of 1.73 m^2, which may not be appropriate in judging the impact of drug exposure (e.g. contrast agent) for an individual. Alternate imaging modalities not requiring contrast should be considered in those patients with any risk factors. High-dose gadolinium chelates should not be substituted for iodinated radiocontrast medium in patients at risk for CIN, as the former have been shown to be at least as nephrotoxic as the latter medium when used in this fashion and recently have been associated with the occurrence of nephrogenic systemic fibrosis [26]. Serum creatinine should be measured again at 24–72 h postcontrast in patients at risk for CIN, but estimates of GFR should not be calculated at that time, as the estimating equations rely on kidney function being stable and are not valid when kidney function is changing acutely. Because of the risk of lactic acidosis when CIN occurs in a patient with diabetes mellitus who receives metformin, it is recommended that metformin be stopped at the time of contrast injection and held until CIN has been excluded [27,28]. The balance of risks and benefits associated with interrupting a patient's ongoing therapy with diuretics, angiotensin converting enzyme inhibitors, or angiotensin receptor blockers in patients at risk for CIN has not been thoroughly studied [29]. It is generally recommended that nonsteroidal anti-inflammatory drug therapy be interrupted, but empirical data on which to base this recommendation are lacking.

Preventive interventions

No full Cochrane reviews have been published for preventive interventions for CIN. Meta-analyses of the impact of *N*-acetylcysteine and theophylline have been published and are discussed below. A general systematic overview of the prevention of CIN has recently been published [30]. The preventive approaches discussed below generally have been evaluated in randomized clinical trials as discussed in the relevant sections.

Contrast agent
Contrast media can be classified in a number of ways, including by osmolality, viscosity, and ionicity. High-osmolality agents, such as sodium diatrizoate, have largely been abandoned because of their greater general toxicities. Studies comparing the nephrotoxicities of contrast agents are presented in Table 10.4. In a meta-analysis of comparative trials, an increase in serum creatinine of more than 0.5 mg/dL (44 μmol/L) following administration of contrast in patients with reduced kidney function was less frequent with low- as opposed to high-osmolality medium (odds ratio, 0.61; 95% CI, 0.48–0.77) [21]. In that analysis, the results for subgroups in trials examining the intervention in particular patient populations were qualitatively similar but statistically significant only for intra-arterial injection of contrast and in those patients with preexisting renal impairment. Due to the small number of events, no conclusion could be reached about the need for dialysis.

More recently, trials have compared the nephrotoxicity of low-osmolal media, such as iohexol or iopamidol, to the iso-osmolal agent iodixanol. The results have not been consistent. Only one trial of patients with diabetes with renal impairment and undergoing cardiac angiography suggested a benefit with iodixanol [31]. Results of further trials are awaited. Thus, either low- or iso-osmolal medium could be used at this time for patients at risk for CIN.

The nephrotoxicity of iodinated radiocontrast agents seems to be dose related. This feature of contrast solution was not always clear from the early observational studies, because exposure to contrast was based on the volume injected (in milliliters). However, different contrast agents have different concentrations of iodine, and iodinated media are largely excreted through the kidney. It has been shown that the area under the curve as a measure of contrast exposure is closely estimated by dividing the amount (in grams) of iodine injected by the creatinine clearance [20]. The related measure, the maximum radiographic contrast dose, in milliliters, can be determined from the following formula: [(5 ml) × body weight in kilograms]/(serum creatinine in mg/dL). A value of >1.0 for the ratio of volume of contrast actually received to the calculated maximum radiographic contrast dose strongly predicts nephropathy requiring dialysis [12]. These studies support the recommendation that limiting the volume of iodinated contrast injected to the minimum required to complete the diagnostic or therapeutic procedure reduces the risk for CIN.

Fluid administration
Administration of fluids is recommended to reduce the risk of CIN. However, data to support a specific fluid regimen are lacking, and the optimal fluid regimen remains unclear. Studies evaluating prophylactic fluid therapy are summarized in Table 10.5. Three small trials compared prolonged intravenous (i.v.) fluid prophylaxis to regimens involving oral fluid with or without brief supplemental i.v. fluids administration [36,38,39]. The results were not entirely consistent, but the trend favors prolonged i.v. therapies. Isotonic saline was slightly better than 0.45% saline in a large trial of patients with well-preserved kidney function [37]. Almost all participants in these trials had received intra-arterial contrast. Based on this evidence the best recommendations at present are to ensure that patients receiving contrast are in a state of optimal volume and hydration as determined by clinical assessment. Fluid restriction prior to exposure to i.v. contrast should be limited to those cases where this is truly necessary. For cases at risk for CIN, particularly those undergoing cardiac angiography, it is recommended that fluids such as 0.9% saline be continued intravenously for at least 6 h after contrast, in the absence of data showing that a shorter duration or oral fluid supplementation is comparable.

Bicarbonate
Alkalinization of tubular fluid has been proposed to reduce the rate of CIN. The mechanism of any benefit might include reduction of pH-dependent free radical generation in the kidney. In the only reported trial to date, which involved 119 patients, 81%

Table 10.4 Trials comparing risk of CIN following exposure to contrast agents of various osmolalities.

Study [reference]	Route of contrast	Contrast agent #1	Contrast agent #2	No. of participants	Mean baseline kidney function	Outcome measure	Results, contrast #1 vs. contrast #2	95% CI or P value
Barrett 1992 [21]	i.a.	Various LOCM	Various HOCM	3000	NA	SCr increase =0.5 mg/dL at 24–72 h	OR 0.62	CI 0.0–1.3

Abbreviations: i.a., intra-arterial; p.o., per os; CrCl, creatinine clearance; NS, not significant.

of whom were undergoing cardiac angiography, isotonic sodium bicarbonate resulted in a lower frequency of a 25% increase in serum creatinine within 2 days compared to that following 0.9% saline infusion [40]. However, the trial was terminated early due to a lower than expected rate of "events" in the bicarbonate group, but the timing of the interim analysis and the stopping rules were not prespecified, and the P value for the difference in event rates was higher than generally used to prematurely terminate a trial. Additionally, visual inspection of Figure 3 from the study report raises the concern that the apparent, albeit small, benefit from bicarbonate versus saline might be due, at least in part, to a loss of one tail of the distribution of patients in the bicarbonate arm of this study. Although it may be reasonable to use a bicarbonate infusion judiciously in an effort to reduce the rate of CIN, the results of this trial require replication before bicarbonate-containing solutions can be recommended as the fluid of choice.

N-Acetylcysteine

NAC might reduce the nephrotoxicity of contrast through antioxidant and vasodilatory effects [41]. Data from trials evaluating the impact of prophylactic NAC on CIN risk are presented in Table 10.6. The results of an initial trial were dramatic, but the event rate, defined as a rise in serum creatinine of >05. mg/dL in the controls, was unexpectedly high for patients given low-dose intravenous low-osmolality contrast [62]. Subsequent trials have largely involved patients with reduced kidney function undergoing cardiac angiography. Some have shown benefit and others not; many are limited by low power and a lack of blinding. The dose of NAC employed in most trials has not been chosen based on pharmacologic principles. Two trials comparing doses of NAC suggested that higher doses may be required, especially if higher doses of contrast are being employed [10,45]. Several meta-analyses of trials of NAC have been reported. The trials included in these analyses vary, but more recent and comprehensive meta-analyses suggest some benefit with NAC (pooled odds ratio range, 0.54–0.73 for contrast nephropathy, defined variably as elevations of serum creatinine) [64–68]. However, this estimate must be interpreted with caution, given the heterogeneous results of the individual trials and the possibility of publication bias, with small negative studies underrepresented. Also, the effect of NAC on outcomes other than minor changes in serum creatinine is largely unknown. Indeed, studies in healthy volunteers have suggested that NAC might have an effect on creatinine levels unrelated to an effect on GFR [69]. However, in a recent trial involving patients undergoing primary angioplasty following myocardial infarction, NAC showed a dose-related improvement in CIN (defined as a serum creatinine rise), and there was a parallel beneficial effect on the in-hospital death rate [10].

Theophylline

Theophylline and aminophylline have the potential to reduce CIN through antagonizing adenosine-mediated vasoconstriction. These drugs have been tested in several small trials. Recent meta-analyses found that the mean rise in serum creatinine was significantly but slightly lower at 48 h after contrast administration among those receiving active therapy than among the placebo group, but the clinical importance of this finding is not clear, and there was significant heterogeneity among studies with regard to changes in serum creatinine [70,71]. There is potential for adverse effects with theophylline, and the optimal dose for prevention of CIN has not been established. Further studies are warranted.

Other pharmacological agents

Several other interventions have been proposed to reduce the risk of CIN, but data are limited to support them. Forced diuresis with furosemide, mannitol, dopamine, or a combination of these compounds given at the time of the contrast exposure has been associated with similar or higher rates of CIN compared to prophylactic fluids alone [72–75]. Negative fluid balance might underlie some of the observed detrimental outcomes from these pharmacological interventions.

Generally small randomized trials of vasodilation with dopamine, fenoldopam, ANP, calcium channel blockers, prostaglandin E_1, or a nonselective endothelin receptor antagonist failed to show a reduction in rate of CIN compared to fluid therapy alone [75–80].

Two small studies of captopril as a prophylactic agent yielded opposite results. In the first trial serum creatinine rose by more than 0.5 mg/dL (44 µmol/L) in two (6%) patients given captopril for 3 days versus 10 (29%) given placebo ($P < 0.02$) [81]. In the second study CIN was reported to occur in five (8.3%) patients given captopril versus one (3.1%) given placebo ($P = 0.02$) [82].

Ascorbic acid as an antioxidant has been tested in a single randomized trial with patients undergoing cardiac angiography [83]. Serum creatinine rose by 25% or more than 0.5 mg/dL (44 µmol/L) within 2–5 days in 11 (9%) cases given ascorbic acid versus 23 (20%) given placebo ($P = 0.02$) [83]. However, these results are difficult to interpret, as the baseline serum creatinine level was lower in the placebo group and both groups reached a similar creatinine level postcontrast [83].

Prophylactic renal replacement therapy

Hemodialysis during or shortly after contrast has not been shown to prevent CIN [84–86]. However, in an initial trial involving patients with advanced kidney disease (mean creatinine clearance, 26 mL/min) undergoing cardiac procedures, those randomized to prophylactic hemofiltration in an intensive care unit before and after contrast had a 25% increase in serum creatinine in three (5%) cases versus 28 (50%) cases given fluid alone ($P < 0.001$) [8]. Death in hospital was also less frequent in the hemofiltration group (2 versus 14%; $P = 0.02$) [8]. These results were replicated in another trial by the same investigators, in which they further demonstrated that the effects of hemofiltration limited to the postcontrast period were not significantly different from those with saline alone [9]. The change in serum creatinine during and soon after hemofiltration is affected by creatinine removal. This biases the primary outcome of the proportion suffering a 25% increase in serum creatinine within a time unspecified by the investigators.

Table 10.6 Trials of NAC for prevention of CIN.

Study [reference]	Contrast osmolality, route	Intervention regimen (NAC dose)	Control regimen	Co-intervention(s)	No. of participants	Mean baseline SCr (mg/dL)	Definition of CIN	Results	P value
Azmus 2005 [42]	Multiple, i.a.	600 mg p.o. b.i.d. (1 day pre/1.5 days post)	Placebo	1 L 0.9% saline i.v. (pre/post)	414	1.3	Increased SCr ≥25% or 0.5 mg/dL by 48 h	7.1% vs. 8.4%	NS
Baker 2003 [43]	Iso, i.a.	150 mg/kg i.v. pre + 50 mg/kg in 0.9% saline 4 h post	1 ml/kg/h 0.9% saline (12 h pre/12 h post)	None	80	1.8	Increased SCr ≥25% at 2–4 days	5% vs. 21%	0.045

Table 10.7 Recommendations to reduce risks for CIN.

1. Assess overall risk–benefit balance for the proposed contrast-requiring procedure

2. Assess kidney function prior to contrast injection by eGFR or creatinine clearance from serum creatinine in those due to have intra-arterial contrast and in those at increased risk of either preexisting reduced kidney function or with other risk factors for CIN

3. Consider whether a non-contrast-requiring procedure would provide the necessary diagnostic or therapeutic result(s)

4. Attempt to correct any modifiable risk factors prior to administration of contrast, including optimization of fluid volume status

5. Avoid use of high-osmolality contrast agents in those at risk for CIN

6. Use the lowest dose of contrast compatible with adequate completion of the diagnostic or therapeutic procedure

7. In patients at risk for CIN, where possible administer i.v. fluids, either 0.9% saline or isotonic sodium bicarbonate, beginning at least 1 h preoperative and continuing for at least 6 h post-contrast injection. The usual rate of administration is at least 1 mL/kg/h, but care is required in those at risk for fluid overload or pulmonary edema, and fluid status and balance must be clinically monitored during fluid administration.

8. Consider the use of NAC in patients at risk for CIN. The optimal dose is unclear, but doses of 1200 mg twice a day for 48 h, beginning prior to contrast injection, may be appropriate, especially if higher doses of contrast are likely to be required.

9. Consider prophylactic hemofiltration before and after contrast in patients with advanced preexisting kidney disease

10. Reassess kidney function by measurement of serum creatinine between 24 and 72 h post-contrast injection in those at risk for CIN

The mechanism of benefit, if any, to the kidney remains speculative. Marenzi *et al.* [9] suggest controlled high-volume administration as one possibility, but their protocol for hemofiltration should leave the patient in neutral, not positive, fluid balance. Alkalinization by bicarbonate in the hemofiltration replacement fluid is another possible mechanism. In both trials, hemofiltration, especially pre- and postcontrast together, was associated with reduced in-hospital cardiovascular mortality, but the mechanism by which this might occur is unclear. Given the resource implications, prophylactic hemofiltration should be considered a preventive option only for those at highest risk due to advanced kidney disease. Further studies are indicated to best define the group of patients who might benefit and the magnitude of this benefit.

Conclusions and recommendations

CIN remains a concern for patients with risk factors, including those with preexisting kidney disease, who must undergo cardiac procedures with iodinated radiocontrast. It is not clear that the same magnitude of risk applies to patients undergoing other radiocontrast-requiring procedures, particularly computer tomography with i.v. contrast. Data on risk from other contrast agents, such as gadolinium, in this patient population have not been as robustly assembled, and therefore evidence-based recommendations for prevention of nephrotoxicity from this second class of agents are not possible at this time.

Many different measures have been suggested to reduce the risk for CIN from iodinated contrast. Many of the trials of prophylaxis suffer from methodologic flaws. In most instances the dramatic apparent efficacy of preventive interventions was observed in initial trials with very small sample sizes and was not replicated in subsequent larger studies. Despite the limitations in the evidence base, some recommendations can be made to prevent kidney injury associated with radiocontrast agents. These are summarized in Table 10.7.

11 Miscellaneous Etiologies of Acute Kidney Injury

Kamalanathan K. Sambandam & Anitha Vijayan

Washington University School of Medicine, Renal Division, St. Louis, USA

Introduction

This chapter will review some of the less frequent causes of acute kidney injury (AKI): acute interstitial nephritis, atheroembolic renal disease, renal myeloma, crystalline nephropathies, and renovascular syndromes. Due to the relative rarity of these conditions, there are few randomized controlled trials to guide management. However, several observational and retrospective studies provide some insight into the clinical features, natural histories, and therapeutic responses.

Acute interstitial nephritis

Definition, etiology, and pathogenesis

Acute interstitial nephritis (AIN) represents a hypersensitivity reaction that causes AKI by immune-mediated tubular injury with interstitial infiltration and glomerular sparing. In one large case series, AIN was the predominant finding in 2.4% of all native kidney biopsies and in 10.3% of those biopsies performed in cases of AKI. There has been a documented increase in the incidence over a 12-year period, perhaps as a result of more liberal prescribing practices and the expanding drug armamentarium [1].

The localization of inflammatory injury to the renal tubules may occur through diverse mechanisms, including molecular mimicry with tubular epitopes or deposition of immunogenic portions of the inciting agent at the renal interstitium, either alone or as a hapten [2]. Similar to other hypersensitivity reactions, it is not dose dependent, there is recrudescence in disease activity upon re-exposure to compounds with similar biochemical structure, and there is often multiorgan involvement. Cell-mediated immunity plays a major pathogenic role, as evidenced by large numbers of T cells found in the interstitial infiltrates as well as occasional gran-uloma formation. Immune complexes or anti-tubular basement membrane antibodies are infrequently noted [3,4], suggesting that humoral immunity may also be involved.

The major causes of AIN are drugs, infections, and systemic diseases (Table 11.1). When AIN was first described by Councilman in 1898, it reportedly occurred in the context of scarlet fever and diphtheria [6], and prior to the advent of antibiotics, infections were the most common cause of AIN. However, in a recent analysis of three series totaling 128 cases from 1968 to 2001, drugs were the leading etiology (71%). Other causes included infections (16%), idiopathic (8%), tubulointerstitial nephritis with uveitis syndrome (TINU) (5%), and sarcoidosis (1%) [7]. Among drug-induced AIN, nonsteroidal anti-inflammatory drugs (NSAIDs; including salicylates and cyclooxygenase-2 [COX-2] inhibitors) and antibiotics were responsible for 44% and 33% of the cases, respectively [1,7].

Clinical features

In the 1960s, methicillin was a leading cause of AIN, with up to 17% of patients that received prolonged courses of the drug developing the disease [8]. Methicillin-induced AIN was thus considered the prototype for this disease, and AIN was viewed as having a relatively monomorphic presentation. Multiple etiologies have since been recognized with quite variable clinical features (Table 11.2). The combination of AKI, urinary symptoms (e.g. flank pain, macroscopic hematuria, or oliguria), and symptoms of hypersensitivity (e.g. rash, fever, or arthralgias) should alert the clinician to the possibility of AIN. However, signs and symptoms of hypersensitivity may not be present in up to 45% of patients with AIN (especially in cases attributable to NSAIDs), and in one series they were present in 19% of patients with drug-induced, biopsy-proven acute tubular necrosis (ATN) [17]. The temporal relationship between the initiation of a new drug and the development of renal injury may also aid in making the diagnosis. Disease manifestations develop within 3 weeks of initiation of the inciting drug in about 80% of patients, with an average latency of onset of 10 days (range, 1 day to >1 year) [2]. The duration of onset may be longer with NSAIDs, with a mean latent period of 2–3 months [9, 10]. In

Table 11.1 Causes of AIN.

<u>**Drugs**[a]</u>

Antimicrobial agents

Penicillins[b] (especially penicillin, ampicillin, and methicillin), cephalosporins, ciprofloxacin,[b] indinavir, rifampin,[b] and sulfonamides[b] (including cotrimoxazole[b])

NSAIDs, COX-2 inhibitors, salicylates

fenoprofen,[b] ibuprofen,[b] indomethacin,[b] naproxen, phenylbutazone, piroxicam,[b] tolmentin, zomepirac

Anticonvulsants

Phenytoin[b]

Diuretics

Furosemide,[b] thiazides

Gastric antisecretory drugs

Cimetidine,[b] omeprazole

Other drugs

Allopurinol,[b] phenindione[b]

<u>**Infections**</u>

Bacteria

Brucella spp.,[b] *Campylobacter jejuni, Corynebacterium diphtheriae, Chlamydia* spp., *Escherichia coli, Legionella* spp., *L. interrogans, Mycobacterium tuberculosis,*[b] *Mycoplasma pneumoniae, Rickettsia* spp., *Salmonella* spp.,[b] *Staphylococcus* spp., *Streptococcus* spp., *Yersinia pseudotuberculosis*

Viruses

Cytomegalovirus, Epstein-Barr virus,[b] hantaviruses, hepatitis B virus, human immunodefficiency virus, herpes simplex virus, measles virus, polyomaviruses

Parasites

Leishmania donovani, Toxoplasma gondii [b]

Systemic diseases

Light chain gammopathy, sarcoidosis,[b] Sjogren's syndrome,[b] systemic lupus erythematosus, tubulointerstitial nephritis and uveitis sydrome,[b] Wegener's and other vasculitides

<u>**Other causes**</u>

Wasp sting, Chinese herbs, idiopathic[b]

Source: Johnson & Feehally [5].

[a] Due to the fact that a very large number of drugs have been associated with AIN, only drug classes and the most common individual offending medicines are listed here.
[b] Agent that may be associated with granulomatous interstitial nephritis

AIN related to infection or systemic diseases, the clinical features of the inciting disease usually predominate.

Laboratory findings

Hematuria and/or sterile pyuria are often present but are non-specific findings. The presence of white blood cell (WBC) casts is more specific, although they can also be seen in pyelonephritis and certain proliferative glomerulonephritides. Eosinophiluria (urine eosinophils numbering >1% of the urine WBC count) can be seen, usually detected more reliably with Hansel's stain than with Wright's stain [18,19]. However, by combining the data from three series, the presence of eosinophiluria using Hansel's stain has a positive predictive value of only 62% and sensitivity of 62%, even when considering only cases with AKI [18,19,20]. Though the negative predictive value is high (92%), this is not much greater than the combined prevalence of the other non-AIN causes of AKI in these studies (82%). The diagnostic value of eosinophiluria might be improved if other causes of eosinophiluria, such as urinary tract infection (28% prevalence of eosinophiluria) and atheroembolic disease (up to 88% prevalence), are excluded [2,21].

Other laboratory abnormalities that may be present in AIN include renal tubular acidosis, a concentrating defect, or elements of a Fanconi's syndrome. Mild proteinuria is common, but sometimes it may be in the nephrotic range. Though heavy proteinuria has been reported with AIN from various drugs, it is classically associated with NSAIDs. Minimal change glomerulopathy with nephrotic syndrome is present in approximately 38% of AIN cases from NSAIDs [9]. Signs of multiorgan dysfunction, such as elevated transaminases and hemolysis, are occasionally seen. Lymphocyte stimulation testing can confirm hypersensitivity to the culprit medication if several drug exposures, each with a potential for causing AIN, have occurred [22]. Renal imaging often reveals normal to large kidneys with increased echogenicity.

Renal biopsy is the gold standard for the definitive diagnosis of AIN. A cellular infiltrate consisting mostly of T cells and macrophages with edema increases the separation of tubules from

Table 11.2 Causes of AIN and characteristic clinical and laboratory features.

Inciting agent [reference(s)]	Clinical features	Laboratory findings	Clinical course
All drugs other than methicillin [2,5,9]	• Fever (45%) • Rash (42%) • Arthralgia (12%) • Flank pain (45%) • Oliguria (40%) • Macroscopic hematuria (17%) • New or worsened hypertension (20%)	• Hematuria (53%) • Pyuria (50%) • Mild proteinuria (58%) • Eosinophilia (40%)	• Mean 10-day exposure prior to onset • Temporary dialysis required in 32–50% • CKD remains in 36–40%

Methicillin [2,5]	• **Hypersensitivity symptoms common:**
	  • **Fever** (85%)
	  • Rash (25%)
	  • Arthralgias (10%)
	• Oliguria (25%)
	• **Macroscopic hematuria** (80%)
		• Hematuria (90%)
		• Pyuria (95%, often w/ WBC casts)
		• Mild proteinuria (80%)
		• **Eosinophilia** (80%)
		• **Eosinophiluria** (almost all patients)
			• Mean duration of impaired renal function, 1.5 mos
			• Temporary dialysis required in 17%
			• **CKD remains in only 10%**

NSAIDs [2,5,9,10]	• **Hypersensitivity symptoms uncommon:** • Fever, rash, or arthralgias (10%) • Macroscopic hematuria (7%) • New or worsened hypertension (17%)	• **Nephrotic-range proteinuria** (38%) • Hematuria (38%) • Pyuria (40%) • Eosinophilia (40%) • Renal biopsy may also show **minimal change disease**	• **Mean exposure 2–3 mos before presentation** • Temporary dialysis required in 20–38% • **CKD remains in 56%**
Allopurinol [11]	• **Hypersensitivity symptoms very common & robust** • Signs of vasculitis possible • **Often occurs in setting of renal insufficiency** from accumulation of the inciting metabolite, oxypurinol	• **Eosinophilia** fairly common • **Hepatitis** common • Renal biopsy may reveal **immune complex deposition at TBM**	• **Mortality may be as high as 25%** • Rate of renal recovery unknown

Rifampin [12]	• **Hypersensitivity symptoms common & robust:**
	  • Fever (45%)
	  • **Nausea or vomiting** (72%)
	  • **Abdominal pain** (40%)
	  • Rash uncommon
	• Flank pain (17%)
	• **Oligoanuria** (96%)
		• Eosinophilia (7%)
		• Coombs-positive **hemolysis** (25%)
		• **Thrombocytopenia** (50%)
		• **Hemoglobinuria** (17%)
		• Hepatitis (25%)
		• **Antirifampin antibodies** (almost all patients)
		• Renal biopsy rarely shows immune complex deposition at TBM
			• **Usually occurs 24 h after dose** with current intermittent dosing or after previous continuous exposure (up to 1 yr prior)
			• Dialysis required in almost all cases
			• **CKD remains in only 3%**

Leptospiral nephropathy [13]	• Preceding **exposure to animal excrement** • Fever (93%) • **Jaundice** (93%) • Hepatomegaly (76%) • Gingival/GI **bleeding**, purpura (79%) • Macroscopic hematuria (26%) • **Conjunctival suffusion** (12%) • Altered mental status (50%) • Hypotension (62%) • **Oligoanuria** (95%) • Rhabdomyolysis (62%)	• **Cholestatic hepatitis** (93%) • **Hemolytic anemia** (72%) • **Thrombocytopenia** (81%) • **Hypokalemia** (renal wasting) (38%) • **Hyponatremia** (79%) • Rhabdomyolysis (62%) • **Positive blood/urine cultures or serology** • Renal biopsy reveals inflammation predominating at proximal tubules early; interstitial hemorrhage possible	• Nephropathy occurs in 40% of cases of leptospirosis • **Mortality of 26%** • Temporary dialysis required in 74% • **Persistent tubular transport defects may remain in 29%** • CKD remains in only 10.3%

Table 11.2 (*cont.*)

Inciting agent [reference(s)]	Clinical features	Laboratory findings	Clinical course
BK nephropathy [14]	• Usually occurs in renal allografts 1 yr after transplant in setting of **aggressive immunosuppression** • May occur in other immunosuppressed states also (e.g. HIV) • Fever uncommon • Macroscopic hematuria rare	• **"Decoy cells"** (tubular cells with enlarged nucleus, intranuclear inclusions) in urine sediment, 100% sensitivity/71% specificity • **Viremia by PCR** 100% sensitive/88% specific • Renal biopsy reveals **SV40 stain positive intranuclear inclusion bodies**	• Acute or gradual deterioration in renal function • Decreases 5-year renal allograft survival from 76 to 46% • Often **resolves with decrease in immunosuppression**
Sarcoidosis [15]	• Extrarenal symptoms of sarcoidosis predominate with **pulmonary, ocular, and skin symptoms** most common • Renal limited disease is very rare • Most often occurs in young adults • Higher incidence in black population	• Eosinophilia (25%) • **Hypercalcemia** or normocalcemia despite advanced kidney failure • **Chest radiography with hilar adenopathy** and/or infiltrates (90%) • Elevated ACE level not reliable with renal involvement • Renal biopsy reveals **noncaseating granulomas** and giant cells	• Often a remitting/relapsing course responsive to pulse increase in steroids • **CKD remains in 90%**
TINU [16]	• 3:1 female predominance • **Median age of onset, 15 yrs** • **Eye pain or redness** (32%) • Fever (53%) • Weight loss (47%) • Abdominal or flank pain (28%) • Arthralgias or myalgias (17%) • Rash (1%)	• Eosinophilia (17%) • **Elevated serum IgG** (83%) • Renal biopsy shows granulomas in 13%; unlike sarcoidosis, uveitis is not granulomatous	• Uveitis precedes renal disease in 21%, is concurrent in 15%, and follows it in 65% • **Complete renal recovery often occurs spontaneously within 1 yr** • Uveitis recurs in 54%, but recurrence of AIN is rare • CKD is rare

Abbreviations: GI, gastrointestinal; TBM, tubular basement membrane; SV40, simian virus 40; IgG, immunoglobulin G; CKD, chronic kidney disease.

Note: Particularly distinctive features are noted in bold. The percentages are estimates of the prevalence of the associated finding for each etiology.

one another, and there may be tubulitis or frank tubular necrosis in severe AIN (Figure 11.1). Neutrophils, eosinophils, and plasma cells can often also be found. Occasionally there is granulomatous inflammation, which might provide clues as to the offending agent, since this is associated with a limited list of causes (Table 11.1). Immunofluorescence and electron microscopy usually reveal no immune complexes, but tubular basement membrane deposition can rarely be seen. Glomeruli are usually normal, but electron microscopy may reveal foot process effacement in NSAID-associated AIN. A summary of the relevant laboratory findings is given in Table 11.2.

Course and treatment

Given the polymorphic nature of the disease and the multiple potential causative agents, AIN does not have a uniform course or response to treatment. In the prototype, methicillin-induced AIN, the prognosis was excellent, with complete recovery of renal function noted in 90% of patients after a mean period of 1.5 months after cessation of the drug exposure [2]. In nonmethicillin, drug-induced AIN, chronic kidney disease (CKD) is an expected

sequela in 36–40% of cases [2,9]. The prevalence of CKD is even higher (56%) with NSAID-induced AIN [9]. In one series consisting of seven cases of infection-associated AIN, all had complete renal recovery. However, in this case series the inciting infections were readily treatable or self-limited [9]. Indeed, the prognosis for AIN may depend on the promptness of elimination of the inciting agent, with those etiologies associated with milder symptoms and therefore delayed diagnosis (e.g. NSAIDs, chronic infections, sarcoidosis) having worse prognosis than those with more acute and dramatic presentations (e.g. methicillin, rifampin, acute bacterial or viral infections) (Table 11.2).

The heterogeneity of AIN and the lack of randomized, controlled trials have made it difficult to formulate evidence-based therapeutic strategies. Clearly, the most important therapeutic maneuver is prompt removal of the inciting agent. Although it is tempting to combat the hypersensitivity response with adjunctive corticosteroids, the usefulness of this intervention remains uncertain. Retrospective studies, including a series of 100 cases pooled from seven reports [5] and a recent series of 42 cases [1], suggest no reduction in the incidence of CKD with corticosteroids. However, it can
Figure 11.1 AIN, drug induced, with hematoxylin and eosin stain. Note the presence of interstitial edema and predominantly mononuclear inflammatory cells separating the normally adjacent tubules (A). A few eosinophils (arrows) and a plasma cell (arrowhead) can be seen on higher power (B). (Courtesy of Dr. Rosa Davila, Washington University School of Medicine.)

be argued that a beneficial effect is less evident because patients with more severe disease are more likely to receive corticosteroids. Indeed, in the two large negative analyses just mentioned, the patients who received corticosteroids had a tendency toward a higher peak creatinine (Cr) than the untreated group (mean peak Cr, 9.3 vs. 6.5 mg/dL [reference 5] and 8.0 vs. 6.2 mg/dL [reference 1]). Although peak serum creatinine has not been shown to correlate with prognosis [9,23,24], it is still possible that other markers of worse disease bias clinicians towards corticosteroid treatment.

The best data supporting the use of corticosteroids come from a series of 14 patients, all with methicillin-induced AIN. Corticosteroids were associated with complete renal recovery in six of eight treated patients, compared to only two of six untreated patients, and the treated group recovered more quickly (9.3 vs. 54 days) [25]. Positive observational data with corticosteroids in AIN from other etiologies exist but are limited to small case series [25,27,28]. In many reports, the most apparent effect of corticosteroids was

an association with a more rapid recovery of renal function. As for the use of other immunosuppressants, the literature is limited to rare case reports, mostly involving the more unusual causes of AIN. One recent retrospective series described the use of mycophenolate mofetil in eight cases of steroid-dependent AIN (renal function worsened with attempts at steroid withdrawal, and all patients received at least 6 months of corticosteroids). Only two of the eight cases were thought to be drug induced, with the remaining cases being idiopathic or associated with systemic diseases such as sarcoidosis or collagen vascular disease. Treatment with mycophenolate mofetil resulted in a stabilization or slight improvement in renal function (mean creatinine decreased from 2.3 to 1.6 mg/dL); however, an average of 2 years of therapy were required [29].

Given these data, a reasonable treatment strategy would be to reserve corticosteroids for patients with idiopathic AIN, systemic diseases for which corticosteroids have a proven role (e.g. sarcoidosis, Sjogren's, vasculitides), or cases with characteristics associated with worse renal prognosis. The latter includes delayed onset of renal recovery after removal of the inciting agent (>1 week), prolonged exposure to the offending agent (>2–3 weeks), preexisting CKD, and histology with intense and diffuse interstitial infiltrate, granuloma formation, or significant fibrosis and tubular atrophy [9,23,24]. A frequently used regimen is oral prednisone, 1 mg/kg, for a duration of therapy guided by the improvement in renal function, usually 3 weeks. The presence of conditions that can be exacerbated by corticosteroid therapy (e.g. slow-healing wounds, brittle diabetes, or active infection) should dissuade the clinician from this option. Furthermore, studies have suggested that corticosteroids do not alter the course of NSAID-induced AIN [1,30], but if poor prognostic factors are present, treatment can still be considered. Other immunosuppressants should be reserved for cases that are not responsive to withdrawal of the inciting agent alone when corticosteroid resistance or dependence occurs.

AKI associated with multiple myeloma

Definitions and etiology
Multiple myeloma (MM) is a malignancy of plasma cells, with an incidence of about 2–4/100,000 people. AKI has been reported as the presenting feature in 12–20% of patients with MM [31,32]. The major causes of AKI associated with MM or plasma cell dyscrasias include prerenal AKI secondary to hypercalcemia and volume depletion, AKI from glomerular disease (light chain deposition disease and amyloidosis), cast nephropathy (myeloma kidney), and drug-induced AKI (e.g. intravenous bisphosphonates). Only the latter two will be discussed in this chapter.

Cast nephropathy
Clinical features and laboratory findings
The diagnosis of cast nephropathy is suspected when patients present with rapidly declining renal function associated with the presence of free light chains detected by plasma or urine electrophoresis. There is a paucity of data regarding characteristic
Figure 11.2 Myeloma cast nephropathy, with hematoxylin and eosin stain. Note the characteristic eosinophilic, "corrugated paper" appearance of this cast that is adherent to the wall of the tubule. There is resulting tubular cell toxicity and inflammation, with an interstitial infiltrate and cells engulfing the cast at its point of adherence (arrow). (Courtesy of Dr. Helen Liapis, Washington University School of Medicine.)

diagnostic studies, such as the fractional excretion of sodium, urinalysis, and proteinuria that distinguish cast nephropathy from other causes of AKI in patients with myeloma. The definitive diagnosis is made by kidney biopsy, but this is not routinely performed unless there are confounding factors that make the diagnosis uncertain or if the treating physician feels that it is necessary to guide therapy. On light microscopy, cast nephropathy is manifested by the presence of large lamellated eosinophilic casts in the distal convoluted and collecting tubules. Leakage of tubular contents into the interstitium can elicit an inflammatory response similar in appearance to interstitial nephritis [33] (Figure 11.2). The casts are comprised primarily of monoclonal light chains but also contain albumin, Tamm-Horsfall protein, fibrin, and polyclonal light chains.

Course and treatment

Treatment of cast nephropathy should include hydration, correction of hypercalcemia, and discontinuation of nephrotoxic medications, such as NSAIDs and angiotensin converting enzyme inhibitors (ACEi). A retrospective study revealed that patients with MM and AKI have decreased survival compared to MM patients without renal impairment (median survival of 22 vs. 47 months) [34]. However, there was no difference in survival between those with AKI requiring dialysis versus those with AKI that did not require dialysis. Thus, there are no data to suggest that dialysis should be withheld from patients with MM. Three prospective controlled trials have evaluated the role of therapeutic plasma exchange (TPE) in the treatment of cast nephropathy. The first study evaluated 29 patients with Bence-Jones proteinuria in the setting of MM and AKI [35]. All patients received corticosteroids and cytotoxic therapy, with 15 patients undergoing TPE with hemodialysis as required (group 1) and the other 14 patients all undergoing peritoneal dialysis regardless of need (group 2). Renal recovery

was noted in 13 patients in group 1, compared to only 2 patients in group 2. One-year survival was also significantly higher in group 1 (66% vs. 28%; $P < 0.01$).

The second study reported no difference in patient survival or in renal recovery in those assigned to chemotherapy plus TPE versus chemotherapy alone [36]. The third and largest study evaluated 104 patients with AKI and MM and randomized them to conventional therapy plus TPE versus conventional therapy alone [32]. There was no difference in the primary composite end point of death, dialysis, or GFR of <30 ml/min. There was a 52% reduction in dialysis dependency among survivors at 6 months in the TPE arm, but this was not statistically significant. Given the conflicting data, TPE cannot be generally recommended in the treatment of cast nephropathy, but it can be considered in patients with cast nephropathy and rapidly deteriorating renal function in order to improve renal function and decrease the risk of dialysis dependency.

AKI secondary to bisphosphonate therapy

Intravenous bisphosphonates are widely used in the treatment of hypercalcemia of malignancy. Several case reports have documented AKI and severe symptomatic hypocalcemia associated with intravenous bisphosphonate (zoledronate and pamidronate) use in MM. In a series of six patients with AKI associated with zolendronate, kidney biopsy revealed evidence of tubular injury with luminal ectasia, cytoplasmic vacuolization, hypereosinophilia, loss of brush border, and apoptosis along with interstitial inflammation and fibrosis [37]. The 2003 MM Guidelines recommend that serum creatinine should be measured prior to administration of intravenous bisphosphonates [38]. An elevation of serum creatinine by 0.5 mg/dL from baseline should trigger either a dose or schedule adjustment in the administration of bisphosphonates. Zoledronate is not recommended if serum creatinine is greater than 3 mg/dL. A recent case report also suggests that evaluation for and correction of vitamin D deficiency should be done before administration of bisphosphonates, to reduce the risk for life-threatening hypocalcemia [39].

Crystalline nephropathies

Definition, etiology, and pathogenesis

Crystalline nephropathies describe the AKI that results from the intratubular precipitation of substances. The most common cause of crystalline nephropathy is tumor lysis syndrome (TLS), which consists of acute uric acid nephropathy and acute phosphate nephropathy. Less common causes of crystalline nephropathy include calcium oxalate, acyclovir, sulfonamides, methotrexate, indinavir, and triamterene. There are also case reports associated with ciprofloxacin, foscarnet, ampicillin, and plasma cell dyscrasias.

Intratubular crystal formation and deposition of a substance is promoted by three mechanisms: high concentrations in the tubular fluid, prolonged intratubular transit time, and decreased solubility [40]. The first two mechanisms occur in the setting of decreased

effective circulating volume, which is a major risk factor for all of the crystalline nephropathies. Decreased effective circulating volume results in increased proximal tubular sodium and fluid reabsorption, resulting in both a high concentration of the offending compound in the distal tubule and decreased distal flow rates. This allows the substance a longer time to precipitate out of the saturated tubular fluid and to accumulate. Underlying CKD is also a major risk factor for the crystalline nephropathies, because a larger amount of the compound is excreted per functioning nephron and drug overdosing for the level of renal function is frequent. The third mechanism, decreased solubility, is often dependent on the distal tubular fluid pH. Compounds with a pKa <7, such as uric acid, calcium oxalate, sulfonamides, methotrexate, and triamterene, tend to precipitate in acidic urine, whereas compounds with a pKa >7, such as indinavir and calcium phosphate, tend to precipitate in alkaline urine. The clinical contexts in which the more common crystalline nephropathies occur are summarized in Table 11.3. Crystalline AKI from TLS and ethylene glycol intoxication are discussed separately due to their unique pathogenic mechanisms and treatment strategies.

Clinical features

Extensive crystal deposition results in pain from distention of the renal capsule and is similar in nature to the pain due to nephrolithiasis. In certain cases (especially with indinavir and sulfonamides), macroscopic lithiasis and its characteristic presenting symptoms can exist alone or concomitantly with intratubular crystal nephropathy [47,48]. Hypocalcemia due to coprecipitation of calcium in acute phosphate nephropathy and oxalate nephropathy may result in paresthesias, lethargy, or tetany. High levels of acyclovir seen in AKI can lead to hallucinations, delirium, and myoclonus. Methotrexate can cause stroke-like symptoms (not dose related) as well as nausea, rash, and mucositis (usually dose related).

Laboratory findings

Urine sediment findings are nonspecific and will often reveal hematuria, pyuria, and mild proteinuria. Although the offending substances have unique crystal morphologies on urine microscopy, examining the sediment is not independently diagnostic. Obstructed tubules may not empty urine into the collecting system, and therefore the absence of crystals dose not exclude crystalline nephropathy. The presence of crystals does not prove their pathogenic role, because calcium oxalate, calcium phosphate, and uric acid crystalluria can very often be seen in normal individuals. Furthermore, crystalluria has been found in patients without AKI in frequencies varying from 100% of healthy individuals receiving a single 100-mg dose of triamterene and ascorbic acid (for urinary acidification) to 17% of all patients taking indinavir [47,52].

Renal ultrasound may reveal bilaterally enlarged and echogenic kidneys and can identify concomitant macroscopic lithiasis. Renal biopsy is required to make a definitive diagnosis. Light microscopy can reveal crystalline deposits (usually in the distal tubules), with a surrounding interstitial infiltrate that may contain giant cells as part of a foreign body reaction. Evidence of ATN can also be present, as many of the inciting agents display direct tubular cell toxicity. Polarized microscopy may demonstrate birefringence, depending on the offending agent (Figure 11.3). A summary of the characteristic laboratory findings is outlined in Table 3.

Course and management

In most cases of crystalline nephropathy, the renal prognosis is excellent if further exposure to the precipitating substance can be avoided. In drug-related crystalline nephropathies, recovery of renal function is expected to occur within days to weeks after cessation or even just dose reduction of the drug. An exception is the underrecognized phosphate nephropathy that may occur after the use of phosphate-containing laxatives prior to colonoscopy. Although there was likely selection bias for more severe cases, the largest series characterizing this disease found that none of 21 affected patients returned to their previous level of renal function and 4 progressed to require chronic dialysis [41].

The mainstay of prevention is avoidance of the two most frequent predisposing factors: volume depletion and drug overdosing by failing to adjust for renal dysfunction. Establishing a brisk urine output (e.g.100–150 mL/h or greater) in high-risk patients is extremely important. For substances with pKa <7 (e.g. uric acid, calcium oxalate, sulfonamides, methotrexate, triamterene) urinary alkalinization by administering intravenous isotonic bicarbonate solutions or oral citrate can be considered. Urine pH should be periodically followed to ensure an appropriate level of alkalinization. Acetazolamide may be added if a metabolic alkalosis ensues. Attempting to acidify the urine to increase the solubility of weakly basic compounds is dangerous and not recommended. These preventive strategies are based on underlying pathophysiologic mechanisms, and evidence proving reduced renal complications with these measures is lacking, except perhaps with high-dose methotrexate administration.

Treatment of established AKI consists of discontinuing the culprit agent and, if nonoliguric and not volume overloaded, applying many of the same principles used in prevention: forced diuresis (aggressive volume expansion with judicious use of diuretics) and, for weak acids, urinary alkalinization. In the setting of AKI, moderate to large doses of diuretics may be required to establish adequate urine flow, and care must be taken with bicarbonate loading to avoid profound alkalosis. Additionally, early initiation of renal replacement therapy (RRT) can rapidly decrease the concentration of some inciting agents (e.g. phosphate, oxalate, and methotrexate). Again, evidence for improvement in renal outcome with these maneuvers is lacking. See Table 11.3 for details on specific management strategies.

Tumor lysis syndrome
Pathophysiology

TLS results from the sudden release of several intracellular constituents to the extracellular space from massive tumor cell death.

Table 11.3 Causes of crystalline nephropathy, their distinctive clinical and laboratory features, and strategies for prevention and treatment.

Inciting agent [reference]	Clinical context	Laboratory findings	Prevention and treatment	Disease course
Phosphate [41]	• TLS, especially posttreatment form • Phosphasoda bowel prep with risk increased by ACEi/diuretic use, advanced age, CKD, and/or female gender • Rhabdomyolysis (rare) • Severe hemolysis (rare)	• Crystalluria with weakly birefringent, long prisms, often in rosettes • Hyperphosphatemia (peaking 1–2 days after initiation of treatment in TLS) out of proportion to renal insufficiency • Hypocalcemia • Hyperkalemia out of proportion to renal insufficiency • High LDH in TLS, rhabdomyolysis, & hemolysis • Renal biopsy: von Kossa-positive crystals	*Prevention* • Forced diuresis[b] • Non-calcium-based phosphate binders *Treatment* • Forced diuresis[b] • Non-calcium-based phosphate binders • Avoid treatment of hypocalcemia unless symptomatic or ECG changes present • Consider early initiation of RRT, especially CRRT	Incidence of CKD higher in cases caused by phosphasoda
Uric acid [42,43]	• TLS, especially spontaneous form • Rhabdomyolysis (rare) • HGPRT deficiency (rare)	• Crystalluria with brownish, strongly birefringent, rhomboid plates, rosettes, or needles • UA >15 mg/dL (peaking 2–3 days after initiation of treatment in TLS) • Urine UA/urine Cr >1 (<0.75 suggests alternative diagnosis) • Hyperkalemia out of proportion to renal insufficiency • Elevated LDH in TLS & rhabdomyolysis	*Prevention* • Forced diuresis[b] • Allopurinol or rasburicase *Treatment* • Rasburicase • RRT (if rasburicase not available)	Full renal recovery expected in the absence of other insults; higher mortality in spontaneous TLS
Oxalate [44]	• EG poisoning (9/19 in largest series developed AKI) • High-dose i.v. ascorbic acid–xylitol–sorbitol infusions (rare) • Primary hyperoxaluria (rare)	• Crystalluria with birefringent monohydrate needles or dihydrate envelope shapes appearing >4 h after EG ingestion • Hypocalcemia • In EG poisoning, osmolal gap >10 mOsm/L & detectable serum and urine EG early with subsequent development of severe anion gap acidosis • Renal biopsy: silver nitrate/rubeanic acid stain-positive crystals	*Prevention* • Forced diuresis[b] • Consider urine alkalinization • Fomepizole for high-risk EG ingestion[a] (ethanol is 2nd line) • i.v. thiamine, magnesium, and pyridoxine in alcoholic patients *Treatment* • Forced diuresis[b] • Consider urine alkalinization • Avoid treatment of hypocalcemia unless symptomatic or ECG changes present • Fomepizole (ethanol is 2nd line) if EG level >20 mg/dL • Early initiation of RRT, esp. if EG >50 mg/dL and renal insufficiency or acidosis present	• Full renal recovery occurred in 6/9 patients; dration & severity of AKI is predicted by severity of acidosis at presentation
Acyclovir [46]	• 11% develop AKI with high-dose rapid i.v. bolus • Very rare with oral acyclovir or valacyclovir	• Crystalluria with birefringent needles with occasional engulfment by WBC	*Prevention* • Forced diuresis[b] • Increase time of i.v. infusion to 1 h *Treatment* • Forced diuresis[b] • Decreasing the dose is sufficient in 40–50% of patients	Full renal recovery expected

Table 11.3 (*cont*).

Inciting agent [reference]	Clinical context	Laboratory findings	Prevention and treatment	Disease course
Indinavir [47]	• 18.6% develop AKI, especially with longer treatment, smaller body size, & concurrent TMP-SMX	• Crystalluria with birefringent plates, fans, or starbursts • Isosthenuria common • CT with i.v. contrast shows wedge-shaped perfusion defects in up to 50%	*Treatment* • Forced diuresis[b] • Urologic consultation if concomitant macroscopic obstruction present (not uncommon)	AKI is easily reversible as opposed to the slowly progressive injury seen in indinavir-induced AIN
Methotrexate [48,49]	• 2–4% develop AKI with high-dose i.v. therapy; increased risk in older patients and with concomitant use of NSAID or other highly protein-bound drugs which increase free methotrexate levels	• Crystalluria with amorphous yellow casts • High serum methotrexate level • Anemia, leukopenia, or thrombocytopenia possible	*Prevention* • Forced diuresis[b] • Urinary alkalinization to pH $\geq$8 *Treatment* • Forced diuresis[b] • Urinary alkalinization to pH $\geq$8 • Leucovorin rescue $\pm$ thymidine for extrarenal toxicity until methotrexate level <0.05 μmol/L • Consider carboxypeptidase G2 (>98% fall in levels by 15 min) vs. daily 6-h high-flux hemodialysis (clears drug in 5.5 days)	Median time to renal recovery to 2–3 wks
Sulfonamides [50]	• Usually with high-dose therapy • More common with sulfadiazine (1.9–7.5% incidence in AIDS patients) • Low serum albumin may increase risk from higher free drug levels	• Crystalluria with variable shapes from shocks of wheat to spheres • Positive lignin test (orange urine upon mixing with 10% hydrochloric acid) • Densities in parenchyma and in collection system on ultrasound are common	*Treatment* • Forced diuresis[b] • Urine alkalinization to pH >7.1 • Dose reduction usually sufficient • Urologic consultation if macroscopic obstruction present (not uncommon)	Full renal recovery is prompt, sometimes within hours, but median 6 days
Triamterene [40]	• Rare; must distinguish from the much more common AIN, or AKI with concomitant NSAID use	• Crystalluria with birefringent orange casts & spheres • Hyperkalemia out of proportion to renal insufficiency	*Treatment* • Forced diuresis[b] • Urine alkalinization to pH >7.5 • May require urologic consultation for the more common triamterene stone if obstructed	Full renal recovery is expected

Abbreviations: HGPRT, hypoxanthine-guanine phosphoribosyl transferase; EG, ethylene glycol; i.v., intravenous; TMP-SMX, trimethoprim-sulfamethoxazole; LDH, lactate dehydrogenase; UA, uric acid; CT, computerized tomography; ECG, electrocardiogram; CRRT, continuous renal replacement therapy; TLS, tumor lysis syndrome.

[a] Patients at high risk for organ dysfunction in EG poisoning are those with serum EG of >20 mg/dL, or with known recent ingestion of EG with osmolal gap >10mOsm/L, OR strong suspicion of recent ingestion and 2 of the following: pH <7.3, HCO3 <20mEq/L, osmolal gap >10mOsm/L, and urinary oxalate crystals [45].

[b] Forced diuresis refers to aggressive hydration with judicious use of diuretics to achieve and maintain brisk urine flow rate.

The main risk factor is the presence of a large tumor burden with a rapid doubling time and thus exquisite response to cytolytic therapy. Most cancers associated with TLS are high-grade lymphoproliferative malignancies, with up to 6% of these patients developing this complication [51]. It has also been reported with several aggressive solid tumors, including lung and breast carcinoma. Although the disease usually arises in the setting of traditional potent chemotherapy directed against nucleic acid processing, it has also been observed with interferon therapy, endocrine therapies such as corticosteroids or tamoxifen, and radiation therapy. Furthermore, spontaneous TLS can occur when aggressive cancers rapidly outstrip their nutrient supply.

The AKI due to TLS has historically been thought of as an acute uric acid nephropathy. Purine nucleosides are released by dying cells and are metabolized to hypoxanthine and xanthine. Xanthine oxidase converts both intermediates to uric acid. At normal
Figure 11.3 Oxalate nephropathy, shown with hematoxylin and eosin stain. This patient developed kidney failure in the setting of primary hyperoxaluria. (A) Note the distortion of the tubular architecture associated with intratubular deposits of calcium oxalate (arrowheads). There is an interstitial infiltrate along with interstitial fibrosis consistent with disease chronicity. (B) Under polarized light the deposits exhibit birefringence (black arrows). (Courtesy of Dr. Rosa Davila, Washington University School of Medicine.)

plasma pH, 98% of uric acid exists as the more-soluble ionized salt, urate (pKa 5.5). In the normally acidic tubular fluid, it exists primarily as the less-soluble, nonionized uric acid and may precipitate. Recently, it has become apparent that acute phosphate nephropathy is also an important cause of AKI in TLS, now that hypouricemic therapy is commonly employed for prophylaxis in patients at risk for TLS [51]. Significant amounts of phosphate complexed with adenosine exist in the intracellular compartment, especially in metabolically active cancer cells. Once released by cell death, phosphate precipitates in the renal tubules and other tissues as calcium phosphate. In spontaneous TLS, severe hyperphosphatemia is less likely, since the surviving tumor cells, with their high metabolic rate, rapidly recycle released phosphate.

Management

Patients at high risk for TLS, such as those with high-grade lymphoproliferative malignancies and large tumor burdens about to receive aggressive cytoreductive chemotherapy, or those with high pretreatment lactate dehydrogenase, WBC count and serum uric acid values or patients with urine uric acid/urine creatinine ratio of >1, preexisting renal insufficiency or leukemic kidney infiltration [42] should receive preventive therapy. Patients with "laboratory TLS" (modest perturbations in serum electrolytes but no symptoms or evidence of organ dysfunction) should also receive preventive measures. Volume expansion to achieve brisk urine flow and hypouricemic therapy should be initiated 2 days prior to the start of chemotherapy. Urine alkalinization is *not* recommended given the potential risk of calcium phosphate precipitation in alkaline urine. Alkalemia can also worsen hypocalcemia by increasing protein binding of free calcium. Furthermore, data from animal studies revealed no reduction in the occurrence of uric acid nephropathy with urine alkalinization [53].

Two options for hypouricemic therapy exist: allopurinol and rasburicase. Allopurinol (400–800 mg, total daily dose) competitively inhibits xanthine oxidase, thus preventing the *further* production of uric acid. Uric acid levels decrease over the subsequent 2 days with continued excretion of preformed uric acid. Rasburicase is a recombinant uricase enzyme and can convert *existing* uric acid to allantoin, which is 5–10 times more soluble in urine than uric acid. After intravenous administration (0.05–0.20 mg/kg over 30 min), uric acid levels decrease by 86% at 4 h compared to the 12% reduction with allopurinol [54]. However, comparative data between allopurinol and rasburicase regarding meaningful clinical end points, such as reductions in AKI, dialysis requirement, or death do not exist. Therefore, the extremely high cost of rasburicase deters its use in prevention unless an allopurinol allergy is present. Nevertheless, one analysis, albeit with serious limitations, estimated that the prophylactic use of rasburicase over allopurinol might be cost-effective in children with high-grade lymphoproliferative malignancies [55].

Patients with evidence of organ system dysfunction have "clinical TLS" and require therapeutic rather than preventive interventions. Most patients with resulting AKI will not require dialysis and will recover to their previous renal function, although patient and renal prognosis may be worse with spontaneous TLS. Similar to preventive methods, maintaining adequate urine flow and suppressing further rises in the serum concentration of uric acid and phosphate is essential. Previously, hemodialysis was sometimes initiated early in order to rapidly reduce uric acid levels, with a 50% reduction occurring after 6 h of hemodialysis (clearance of 70–145 mL/min) [56]. Rasburicase results in more prompt reduction of uric acid and eliminates this indication for RRT. However, when significant hyperphosphatemia is present, early RRT may still be required along with non-calcium-based phosphate binders to prevent further phosphate precipitation and/or hypocalcemia. Indeed, hypocalcemia should not be treated with intravenous calcium without first lowering the phosphorus, unless the patient is symptomatic or there is evidence of electrocardiographic changes. With intermittent hemodialysis, phosphorus clearance is fairly inefficient (50–90 mL/min) and daily or twice-daily treatments are needed to achieve negative phosphorus balance. Continuous RRT

(up to 40-mL/min clearance) may be more effective at reducing phosphorus levels [57].

Ethylene glycol poisoning

Ethylene glycol is metabolized by hepatic alcohol dehydrogenase to four toxic organic compounds: glycoaldehyde, glycolic acid, glyoxylic acid, and oxalic acid. Accumulation of organic anions (glycolate, glyoxylate, and oxalate) leads to severe anion gap metabolic acidosis. These compounds, especially glycolic acid, are direct cell toxins and cause multiorgan dysfunction leading to cardiotoxicity, ATN, and nervous system depression. Oxalate precipitates with calcium in several tissues, including the renal tubules, causing crystalline nephropathy.

The clinical manifestations of ethylene glycol intoxication evolve over time as the alcohol is metabolized. During the first 30 min to 12 h, ethylene glycol causes inebriation, with progression to seizures or coma. Twelve to 36 h postingestion, peak concentrations of organic acid intermediates lead to profound acidosis, with Kussmaul's respirations and cardiopulmonary failure. Twenty-four to 72 h postingestion, the oxalate end product accumulates in tissues, resulting in AKI. This time course is prolonged in cases of ethanol co-ingestion, due to its competitive inhibition of alcohol dehydrogenase.

Treatment of ethylene glycol toxicity should be focused on decreasing the concentration of toxic metabolites. This can be achieved by 1) reducing organic acid formation through the use of competitive alcohol dehydrogenase inhibitors, such as fomepizole or ethanol, 2) increasing metabolite clearance through early initiation of RRT, and 3) conversion to less toxic metabolites by cofactor supplementation (Table 11.3).

Atheroembolic renal disease

Definition, prevalence, and pathogenesis

Atheroembolic renal disease refers to the progressive AKI that arises from occlusion of the renal microvasculature by lipid debris and subsequent inflammation. It is an underrecognized cause of renal insufficiency in the older patient population, with 4.2% of renal biopsies from patients over 65 years revealing this significant finding [58]. Clinically significant renal atheroemboli occur in <0.2% of cardiac catheterizations [59] but are more common with aortography and aortic surgeries. With the progress of invasive endovascular procedures, the incidence is likely to increase.

Most patients who develop atheroembolic renal disease have significant aortic atherosclerosis, with more severe vascular disease correlating with a higher incidence of cholesterol embolism [60]. There is usually an inciting event leading to plaque destabilization and distal showering of lipid debris, although spontaneous atheroemboli may occur in up to 21% of cases. Plaque destabilization may occur either from vascular wall trauma from vascular surgery or percutaneous endovascular procedures (which accounts for 65% of cases with an inciting event) or from anticoagulation (21% of provoked cases) [61]. Anticoagulation is thought to cause hemorrhage into plaques or prevent protective thrombus formation over ulcerated plaques. The administration of thrombolytics also can cause lipid release. The cholesterol lodges in the small arterioles and incites thrombus formation, causing distal ischemia and infarction. Within 5 days there may be recannalization of the thrombus, but an inflammatory foreign body arteritis ensues. Because the cholesterol is not soluble and it is never successfully cleared by phagocytes, inflammation persists and leads to progressive fibrosis and later obliteration of the lumen of the small vessel. With involvement of multiple arterioles, the result is persistent, patchy ischemia of several nephrons, instigating progressive renal insufficiency.

Clinical features and laboratory findings

Atheroembolic renal disease is a disease of the elderly (mean age, 66–70 years) with a male (4:1) and Caucasian (30:1 vs. African Americans) predominance. Because a significant embolic shower can occur after an unpredictable period following plaque disturbance, the time of disease onset can be quite variable: from 3 days up to 3 months after the initiating event. Other organ systems, such as the skin, gastrointestinal tract, and central nervous system, are commonly involved as well (Table 11.4). In fact, the reliance on characteristic skin findings for diagnosis (reported in 80% of cases) may contribute to the underrepresentation of this disease among the dark-skinned African American population [65]. The multisystem involvement along with the frequent occurrence of eosinophilia (48% of cases) and an elevated erythrocyte sedimentation rate mimics vasculitis. Depressed complement levels can also be seen, with reported rates varying from <15% to 66% [69,71].

Renal biopsy reveals empty clefts in arcuate and interlobular arteries and, less commonly, afferent arterioles. These result from the dissolution of lipid from these sites by the fixation process. Depending on the age of the lesion, varying degrees of arteritis and intimal fibrosis can be seen (Figure 4). In severe, acute cases there may be signs of ATN. Late in evolution, patchy glomerular sclerosis and tubular atrophy may be visualized in areas supplied by the affected vessels. Similar arteriolar inflammation or fibrosis can be found in other tissues, especially the muscle, gastrointestinal tract, and skin. Biopsy of skin lesions may have the most diagnostic yield, with a reported sensitivity of 92% [66].

Course and management

Three patterns of disease evolution are apparent in atheroembolic renal disease [61]. An acute course (35% of cases) resulting from a massive embolic load is characterized by an abrupt deterioration in renal function and multiorgan involvement 3–7 days after the inciting event. The more common, subacute course (56%) occurs after repeated smaller embolic showers or through progression

Table 11.4 Clinical findings in patients with renal atheroembolic disease and frequency of occurrence.

Clinical finding	Frequency of occurrence (%)
Signs and symptoms	
New-onset, accelerated, or labile hypertension	78
Skin findings (cyanotic or ulcerated digits or scrotum, livedo reticularis on back or lower extremities, nodules, less commonly purpura)	80
GI symptoms (nausea, abdominal pain, GI bleeding)	24
CNS symptoms (focal neurologic deficits, progressive dementia)	11
Retinal emboli (Hollenhorst plaque on fundoscopy)	19
Fevers	Uncommon
Laboratory findings [reference]	
Microscopic hematuria [62,63]	53
Mild proteinuria (rarely nephrotic associated with a secondary collapsing FSGS or accelerated hypertension) [63,64]	63
Eosinophiluria (by Hansel's stain) [21]	88
Peripheral blood eosinophilia [69]	48–88%
Hypocomplementemia [69,71]	<15–66
Various markers of ischemic organ injury (elevated creatinine kinase, amylase/lipase, transaminases)	Not uncommon
Elevated erythrocyte sedimentation rate and/or C-reactive protein	Very common
Renal artery stenosis by Doppler or angiography [61,62]	44

Abbreviations: GI, gastrointestinal; CNS, central nervous system; FSGS, focal and segmental glomerulosclerosis.

Unless otherwise indicated, frequency data come from combining 3 case series of *clinically significant* renal disease totaling 171 patients [61, 62, 63]. CK, creatine kinase; CNS, central nervous system; FSGS, focal segmental glomerular sclerosis; GI, gastrointestinal.

of the obliterative arteritis in previously involved vessels. There is a stepwise deterioration in renal function, with stabilization by 3–8 weeks. The least common chronic course (9% of cases) manifests as a slowly progressive renal insufficiency that is hard to discriminate from worsening hypertensive nephrosclerosis or ischemic renovascular disease.

Progression to dialysis dependence occurs in one-third of the patients who survive the initial insult. Preexisting CKD and a history of significant claudication confers greater risk for this outcome [62,67]. Some mild improvement in renal function can occur with time, from progressive hyperfiltration by the remaining nephrons. As a result, 21–32% of patients on chronic dialysis from atheroembolic renal disease can recover enough renal function to stop dialysis [62,68,69].

Early studies revealed a grim outcome for patients with acute, multivisceral atheroembolic disease, with 1-year survival rates of 13–36% [63,70]. Death usually occurs from cardiac ischemia, heart failure, stroke, or gastrointestinal ischemia with malnutrition [61,63,68]. An aggressive supportive regimen specifically targeting these mechanisms of mortality was prospectively evaluated in a population with acute multivisceral atheroembolic disease [62]. Principles of therapy included the following: 1) a proscription against further anticoagulation or intravascular manipulations, even in the setting of recurrent cardiac ischemia or vascular

Figure 11.4 Renal atheroembolic disease, H and E stain. Cholesterol clefts remaining in an intralobular artery where lipid had been prior to the fixation process are indicated by arrows. The early inflammatory arteritis composed of eosinophils, neutrophils, and macrophages is later replaced by a giant cell foreign body reaction (arrow head), intimal proliferation, and fibrosis. (Courtesy of Dr. Helen Liapis, Washington University School of Medicine)
stents (if dialysis was required, it was performed without anticoagulation); 2) aggressive management of heart failure and blood pressure reduction to <140/80 mmHg with the stepwise use of vasodilators (preferentially ACEi), diuretics, and then ultrafiltration; 3) aggressive nutritional support, parenterally if needed. This intensive support strategy resulted in a 1-year survival of 77%, a vast improvement from previous series. Interestingly, the aggressive use of ACEi in the setting of AKI was not associated with an increase in the need for dialysis and allowed eventual dialysis cessation in several patients. A similar result (1-year survival of 69%) was noted in a second uncontrolled study employing the same basic principles, although there was no mention of preferential ACEi therapy [61]. Although limited, these studies represent the best data regarding treatment, and these principles should be incorporated in the management of this disease. If the relative contraindication for anticoagulation makes hemodialysis difficult, peritoneal dialysis should be considered.

Several adjunctive therapies to improve renal outcome have been attempted in cases of atheroembolic renal disease. Corticosteroids have not been proven to affect renal outcome, but low doses (0.3 mg of prednisone/kg) might improve anorexia and abdominal pain from mesenteric involvement [62]. Statins have theoretical benefits in decreasing inflammation and stabilizing atherosclerotic plaques, thus potentially reducing risks of further embolic events. An observational analysis found a lower rate of statin therapy among those patients who eventually progressed to end-stage renal disease (4.3 vs. 30.6% in those not requiring chronic dialysis) [67]. Given the cardiovascular risk factors in this population, it is prudent to include statin therapy in the treatment regimen. A few case reports have shown encouraging results with vasodilatory prostaglandins (iloprost); however, larger studies are required [72]. Regarding prevention, one study evaluated the brachial artery approach during cardiac catheterization in those with extensive aortic atherosclerotic disease. Although this did not reveal a lower incidence of cholesterol emboli, the incidence of atheroembolic disease in this analysis was likely too small to detect an effect [73]. This approach is a reasonable consideration in high-risk patients undergoing cardiac catheterization.

Renal artery and vein thromboses

Renal artery thrombosis

Acute renal artery thrombosis (RAT) is extremely rare, with only about 300 cases reported in the literature. Most of the cases are unilateral, and only a few cases of bilateral RAT leading to AKI have been described. The leading causes of acute RAT are blunt abdominal trauma (acceleration–deceleration injury) and the antiphospholipid antibody syndrome [74,75]. Other hypercoagulable diseases, such as nephrotic syndrome (NS), have also been associated with RAT. Computerized tomography with intravenous contrast of the abdomen is the diagnostic modality of choice. Treatment of traumatic RAT is dependent on the duration of ischemia. In one case series, surgical revascularization had a success rate (de-

fined as independence from dialysis) of 56% if the ischemia time was less than 12 h. The median ischemic time in the unsuccessful revascularizations was 48 h, and the mortality in these patients was 29% [76]. At present, there are insufficient data to recommend an evidence-based treatment plan for RAT.

Renal vein thrombosis

Renal vein thrombosis (RVT), either unilateral or bilateral, is also a rare cause of AKI. The common etiologies are NS and other hypercoagulable states, such as anti-phospholipid antibody syndrome. Of all the causes of NS, patients with membranous glomerulonephritis have the highest prevalence of RVT (37%) [77]. Selective renal venogram is considered the gold standard for diagnosis, but it is not routinely performed due to a high risk for contrast-induced AKI as well as vascular complications. In one series, computerized tomography had a sensitivity of 92% and specificity of 100%. A series investigating Doppler ultrasonography revealed a sensitivity of 85% and specificity of 56%, but this modality is heavily operator dependent [77]. Magnetic resonance imaging can also be used, although adequate studies have not evaluated this modality.

Treatment of RVT involves conventional anticoagulation with intravenous heparin and warfarin sodium. Use of thrombolytics in RVT has been reported, but given the risk for bleeding, their use should be considered only in patients with severe bilateral RVT with rapidly declining renal function [78]. There are insufficient data to support the use of primary prophylactic anticoagulation in patients with NS. At this time, the decision to use prophylactic anticoagulation should be made on a case-by-case basis, keeping in mind that membranous glomerulonephritis and patients with profound hypoalbuminemia (albumin less than 2 mg/dL) probably have the highest risk of thromboembolism. However, once a patient has developed a thrombotic event, anticoagulation should be continued until the resolution of the NS, since the risk of recurrence is extremely high [79]. Given these data, it would be prudent to restart anticoagulation in this select group of patients if the NS recurs.

12 Renal Replacement Therapy in Acute Kidney Injury

Steven D. Weisbord & Paul M. Palevsky

Renal Section, VA Pittsburgh Healthcare System, and Renal-Electrolyte Division, Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, USA.

Introduction

Acute kidney injury (AKI) is a common condition in hospitalized patients and is an independent risk factor for mortality [1–6]. Interventions to prevent the development of AKI are limited to a small number of clinical settings, including pre-renal azotemia, radiocontrast nephropathy, and pigment-induced AKI. In addition, there are no effective pharmacologic interventions for the treatment of most forms of intrinsic AKI. As a result, renal replacement therapy (RRT) is the cornerstone of care in patients with severe AKI. Over the past 2 decades there has been a proliferation of modalities of RRT available for the management of AKI. Whereas the options for therapy were previously limited to intermittent hemodialysis (IHD) and peritoneal dialysis (PD), the current armamentarium also includes various modalities of continuous RRT (CRRT) and newer "hybrid" therapies, such as extended duration dialysis and sustained low-efficiency dialysis (SLED). Despite the increasing technological sophistication of RRT, key management issues, such as the optimal timing of initiation, selection of modality, and dosing of RRT, remain controversial. The clinical complexity of patients with severe AKI has made clinical trials addressing these questions particularly challenging.

This chapter focuses on the role of RRT in the treatment of AKI and summarizes the current evidence basis for the optimal timing of initiation of treatment and effects of selection of modality and dose of therapy on patient outcomes. We also address several management issues related to the delivery of specific modalities of RRT for patients with AKI.

Prescription and delivery of RRT

Timing of initiation of RRT

In patients with AKI complicated by intractable hyperkalemia, severe metabolic acidosis, volume overload, or overt uremic symp-

toms, the decision to initiate RRT is straightforward. However, in the absence of these overt manifestations, there is uncertainty regarding the optimal time to initiate renal support. Whether the initiation of RRT before the development of absolute indications, including overt uremia, volume overload, or metabolic complications, improves patient outcome has been a matter of some debate. Those who favor early initiation argue that RRT should be instituted as soon as a significant and persistent reduction in the glomerular filtration rate develops, prior to the development of potentially deleterious metabolic abnormalities or volume overload. The counterargument is that early initiation of RRT will expose some patients to risks of treatment, such as the insertion and prolonged placement of intravenous catheters, the need for anticoagulation, and the potential for hypotension and other treatment-related complications; these patients, if managed conservatively, might recover renal function without ever developing an "absolute" indication for RRT.

Nearly 50 years ago, the prophylactic benefits of dialysis were initially proposed by Teschan and colleagues and by Easterling and Forland in uncontrolled case series [7,8]. Several subsequent retrospective studies aimed to substantiate this hypothesis [9–11] (Table 12.1). The first prospective study evaluating timing of initiation of RRT was published in 1975 by Conger [12]. In that study, 18 consecutive patients were assigned in an alternating fashion to early (intensive) or late (nonintensive) IHD [12]. Patients receiving the intensive regimen exhibited lower mortality (20% vs. 64%; $P < 0.01$) and less frequent infectious and gastrointestinal complications. In the only subsequent prospective study on the timing of initiation of IHD, Gillum *et al.* randomized 34 patients to initiate dialysis with even smaller elevations of blood urea nitrogen (BUN) and serum creatinine, and they found lower mortality (47% vs. 59%) but more frequent hemorrhagic and septic complications with the nonintensive management strategy [13]. These differences, however, failed to reach statistical significance. Collectively, these early studies formed the basis for conventional teaching that dialytic support should be initiated when the BUN approaches 100 mg/dL and that there is no added benefit from earlier initiation in the absence of other specific indications. The

inherent methodological limitations of these studies, including the retrospective design of the earlier studies and the small number of subjects in the two prospective studies, as well as the differences in technology between the eras when these studies were performed and current practice, must be taken into consideration in interpreting these results.

More recent studies have focused on the timing of initiation of CRRT. Gettings and colleagues retrospectively assessed outcomes among 100 consecutive adults with posttraumatic AKI treated with continuous venovenous hemofiltration (CVVH), stratifying timing of initiation based on the pretreatment BUN [14]. The early group (BUN < 60 mg/dL) started CRRT an average of 9 days sooner than the late group (BUN ≥ 60 mg/dL) (10 ± 15 days vs. 19 ± 27 days; $P < 0.0001$) and had substantially lower preinitiation BUN (43 ± 13 mg/dL vs. 94 ± 28 mg/dL; $P < 0.0001$). Survival was found to be nearly twofold greater in the early group (39% vs. 20%; $P = 0.041$). Although acuity of illness was comparable in the two groups, the retrospective study design precluded a comprehensive assessment of whether the outcomes were related to unrecognized differences in the clinical characteristics of the two groups. Similarly, two retrospective analyses in post-cardiac surgery patients

revealed lower mortality rates in patients in whom CVVH was initiated based on a urine output of less than 100 mL/8 h, independent of metabolic parameters, compared to patients in whom CVVH was not begun until overt metabolic thresholds were met [15,16]. The only prospective randomized study evaluating the timing of initiation of CRRT to date, reported by Bouman and colleagues, failed to observe superior outcomes with early initiation of renal support, although the sample size was small and the overall patient survival of 70–75% suggested a lower acuity of illness than most studies of critically ill patients with AKI [17].

Recently, Liu and colleagues analyzed prospectively collected data from the Program to Improve Care in Acute Renal Disease, a multicenter observational study of AKI, and assessed risk of death in patients requiring RRT as a function of BUN prior to initiation of therapy [18]. Patients were stratified based on the median BUN, 76 mg/dL. Crude survival rates were slightly lower for the patients who started RRT at higher BUN concentrations, despite a lower burden of organ system failure. After adjustment for covariates, stratification by study site and by initial modality of RRT, and utilization of a propensity score model, the relative risk for death associated with initiation of renal support at a higher BUN was 2.0

[e] Patients received PD, not IHD.

(95% confidence interval, 1.2–3.2). Thus, although there are data suggesting that "early" initiation of renal support in AKI is associated with improved survival, the evidence base is not sufficiently robust to draw firm conclusions. Resolution of this question will require adequately powered, prospective, randomized trials.

Modality of RRT

Although previously limited to IHD or PD, the current armamentarium of available RRT modalities includes the multiple forms of CRRT and the recently introduced hybrid treatments (e.g. SLED and extended duration dialysis). Unfortunately, objective and sound data to guide the selection of modality remain limited (Table 12.2).

Although clinical practices suggest that it is commonly believed that CRRT is superior to IHD in hemodynamically unstable patients, clinical trials have failed to demonstrate that this is the case. However, the propensity for seriously ill and more hemodynamically tenuous patients to receive CRRT rather than IHD, along with the inherent limitations of retrospective and nonrandomized study designs, confounded many of the early studies that compared continuous and intermittent therapies. Several studies have applied multivariable analyses to adjust for these issues. In a single-center retrospective study, Swarz and colleagues compared patients treated with either CVVH or IHD and found an unadjusted twofold-greater mortality in patients treated with CVVH [19]. After adjusting for the greater severity of illness in the CVVH group, no differences in mortality were observed. Similarly, in a prospective, multicenter, observational study published by Guérin and colleagues, mortality was 79% in patients managed with CRRT compared to 59% in patients who received IHD [20]. However, after adjustment for comorbidities, modality of RRT was not independently associated with outcome.

Four randomized controlled trials comparing CRRT and IHD have been published in peer-reviewed journals. In a small randomized controlled trial designed to compare the effects of CVVH and IHD on systemic hemodynamics and splanchnic perfusion in patients with septic shock, mortality was 70% in 20 patients randomized to CVVH and in 10 patients who received IHD [21]. In a multicenter randomized controlled trial of 166 patients with AKI, Mehta and colleagues observed intensive care unit and hospital mortality rates of 59.5% and 65.5%, respectively, in patients randomized to CRRT, compared to 41.5% and 47.6%, respectively, in patients randomized to IHD ($P < 0.02$) [22]. However, imbalanced randomization resulted in patients in the CRRT arm having greater severity of illness as measured by APACHE III score and a higher rate of liver failure, both of which were independently associated with increased mortality. After covariate adjustment, the investigators found no difference in mortality attributable to modality of RRT. In addition to the issues related to imbalanced randomization, interpretation of this study is also confounded by a very high rate of crossover between treatment modalities in both study arms. In a single-center randomized trial involving 80 patients, Augustine and colleagues reported more effective fluid removal and greater hemodynamic stability associated with continuous venovenous hemodialysis (CVVHD) compared to IHD but observed no difference in survival [23]. Similarly, in another single-center randomized controlled trial from Switzerland, Uehlinger and colleagues observed no difference in survival in 70 patients randomized to continuous venovenous hemodiafiltration (CVVHDF) compared to 55 patients assigned to IHD [25]. Most recently, the Hemodiafe study, a multicenter randomized controlled trial conducted in 21 intensive care units in France, demonstrated no difference in mortality in 184 patients randomized to IHD compared to 175 patients randomized to (CVVHDF) [24]. This study is particularly notable for the fact that IHD was delivered to patients despite marked hemodynamic instability, with very little crossover between treatment groups.

Multiple meta-analyses comparing outcomes between these modalities of RRT have been published [26–30]. The first two of these meta-analyses were published prior to the most recent randomized controlled trials [26,27]. One included both randomized and nonrandomized studies and concluded that weaknesses in the quality of the studies significantly limited meaningful comparisons between modalities [26]. However, based on weighting of the studies using an *a priori* assessment of study quality and comparability of severity of illness between treatment arms, the authors suggested that CRRT might be associated with a lower relative mortality risk. The second of these early meta-analyses was limited to six randomized trials, of which only one, the trial reported by Mehta and colleagues, was designed to evaluate mortality as an outcome and had been published in a peer-reviewed journal [27]. The authors found no differences in survival associated with modality of RRT. The three subsequent meta-analyses [28–30], which included the more recent randomized controlled trials of Uehlinger *et al.* [24] and the Hemodiafe study [25], differed in their criteria for including studies, resulting in minor differences

in their calculated odds ratios (ORs) for mortality, but all three found no differences in mortality associated with use of IHD or CRRT.

The propensity for hemodynamic instability and intradialytic hypotension during IHD has led to the suggestion that CRRT may be associated with an increased likelihood for recovery of renal function [22,31,32]. Although this benefit has been observed in surviving patients, to conclude that this is attributable to the modality would fail to account for the competing risk of mortality. Reanalyzing the data from these studies using the combined end point of death or nonrecovery of renal function, no difference in outcome between modalities is observed [33]. In addition, no differences in recovery of renal function were observed in either the single-center randomized controlled trial published by Augustine *et al.* or by Uehlinger *et al.*, or in the Hemodiafe study [23–25].

The initial modalities of CRRT utilized an arteriovenous circuit. Blood flow through the extracorporeal circuit was driven by the gradient between mean arterial pressure and central venous pressure. Although these modalities required little technology, they have been largely supplanted by pump-driven venovenous therapies. Several factors favor the use of venovenous therapies. The intrinsic resistance of the extracorporeal circuit coupled with the limited arteriovenous pressure gradient limits blood flow and ultimately the maximal achievable solute clearance with arteriovenous therapies. In addition, the arteriovenous circuit is associated with a significantly greater risk of vascular-related complications [34]. For this reason, the arteriovenous therapies should generally be restricted to situations where equipment for venovenous therapy is not available.

Solute removal during RRT may occur by diffusion (HD), convection (hemofiltration), or a combination of both (hemodiafiltration). Theoretically, convective clearance provides greater removal of middle- and higher-molecular-weight solutes. It has been postulated that this may be clinically relevant, particularly in patients with sepsis-associated AKI, because proinflammatory cytokines are in this molecular size range. In one study, lower tumor necrosis factor alpha levels were demonstrated using CVVH compared to continuous venovenous HD; however, no clinical outcome benefit was reported [35]. No studies comparing the relative benefits of convective and diffusive therapies on mortality have been reported.

Studies comparing other forms of RRT have been limited. One randomized controlled trial found that CVVH was superior to PD in infection-associated AKI, although the predominance of malaria as the cause of AKI limited the study's generalizability for Western populations [36]. No studies have directly compared "hybrid" treatments to either IHD or CRRT, although hybrid therapies have been shown to provide similar hemodynamic stability and solute control compared to CRRT [37].

In summary, methodological limitations in the observational studies to date and negative results of randomized trials preclude the development of evidence-based guidelines for the selection of RRT modality for the treatment of AKI. Choice of modality

should therefore be guided by the individual patient's clinical status, provider expertise, and the availability of equipment and personnel.

Dose of RRT

Although there are extensive data guiding the dosing of dialysis for patients with end-stage renal disease, the body of evidence informing prescription of RRT dose in AKI is much more limited. When evaluating the dosing of IHD, both the dose per treatment and the treatment frequency need to be considered.

There is a paucity of data regarding the "adequate" per-treatment dose of IHD in AKI. Paganini and colleagues retrospectively evaluated survival as a function of the delivered dose of dialysis in critically ill patients with AKI [38]. Among patients at either the low or high extremes of severity of illness, dialysis dose had no impact on patient outcome. However, in patients with an intermediate severity of illness, the delivery of dialysis dose in excess of the 50th percentile (Kt/V, ~1) was associated with lower mortality risk than the delivery of lower doses of dialysis. It should be noted that this median delivered dialysis dose was substantially lower than what would be deemed appropriate in the setting of end-stage renal disease. No prospective studies addressing this issue have been published. As a result, given the lack of specific data for AKI, a consensus panel convened by the multinational Acute Dialysis Quality Initiative recommended that patients with AKI receive at least the minimum dose that is considered appropriate for patients with end-stage renal disease [39]. It is important to note that several studies have established that there is a significant discrepancy between prescribed and delivered dose for IHD; however, routine monitoring of the delivered dose of dialysis is not common [40–42].

Only one study has evaluated the effects of treatment frequency of IHD on outcomes among patients with AKI. Schiffl and colleagues assigned 160 critically ill patients with acute tubular necrosis to daily or alternate-day dialysis on an alternating basis and found that patients who received daily dialysis had both lower mortality 14 days after discontinuation of RRT (28% vs. 46%; $P = 0.01$) and shorter duration of AKI (9 ± 2 vs. 16 ± 6 days; $P = 0.001$) [40]. However, it is important to note that the dose of dialysis delivered to the alternate-day treatment group was exceptionally low (mean delivered Kt/V, 0.94 ± 0.11). This resulted in a markedly elevated time-averaged BUN concentration, which may have been the reason that this treatment group had a high incidence of complications, including gastrointestinal bleeding, mental status alterations, and infections, complications that may have resulted from inadequate dialysis [40]. Therefore, although this study demonstrates that increasing the delivered dose of dialysis from a very low level by increasing the frequency of treatment improves survival, it is not possible to conclude that increasing the frequency of "adequate" alternate-day or a thrice-weekly schedule versus daily therapy would improve outcome.

There are more data regarding the appropriate dosing of CRRT. Ronco and colleagues randomized 435 patients to one of three CVVH doses, defined by ultrafiltration rates of 20, 35, and 45 mL/kg/h [6]. Mortality was markedly lower in the intermediate- and high-dose arms (43% and 42%, respectively) compared to the low-dose arm (59%; $P < 0.001$). The absence of a survival benefit of high-dose therapy compared to the intermediate dose argued against a linear relationship between dose and outcome. Similarly, Saudan and colleagues reported overall improved mortality when dialysate flow (CVVHDF) was added to a fixed dose of CVVH [43]. A total of 102 patients were randomized to receive CVVH with a mean ultrafiltration rate of 25 ± 5 mL/kg/h, and 104 patients were randomized to CVVHDF with a mean ultrafiltration rate of 24 ± 6 mL/kg h and a mean dialysate flow rate of 18 ± 5 mL/kg/h. The addition of diffusive clearance was associated with an increase in 28-day survival from 39% to 59% ($P = 0.03$) and increased 90-day survival from 34% to 59% ($P = 0.0005$). In contrast, Bouman and colleagues did not observe this advantage with higher doses of CRRT [17]. However, the overall study mortality of less than 30% suggests that the enrolled patients were poorly representative of most critically ill patients with AKI. More recently, Tolwani and colleagues reported no difference in outcomes in 200 patients randomized to CVVHDF at either 20 to 35 mL/kg/h [44]. Survival to ICU discharge or 30 days, whichever was earlier, was 49% in the patients randomized to the higher dose group, compared to 56% of patients randomized to the lower dose of therapy.

The largest study evaluating intensity of RRT in AKI, the VA/NIH Acute Renal Failure Trial Network (ATN) study, utilized a strategy that included both IHD in hemodynamically stable patients and either CVVHDF or SLED in hemodynamically unstable patients [45]. In the intensive management strategy, IHD and SLED were provided daily (except Sunday), and CVVHDF was provided with an effluent flow of 35 mL/kg/h; in the less-intensive strategy, IHD and SLED were provided every other day (except Sunday), and CVVHDF was dosed at 20 mL/kg/h. In both treatment arms the target delivered single-pool Kt/V$_{urea}$ for IHD and SLED was 1.2–1.4/treatment, with an actual delivered dose during IHD of 1.32 ± 0.36. Sixty-day all-cause mortality was 53.6% in the 563 patients randomized to intensive therapy, compared to 51.5% in the 561 patients randomized to the less-intensive therapy (OR, 1.09; 95% CI, 0.86–1.40; $P = 0.47$). There was also no difference in the duration of RRT, recovery of kidney function, or course of nonrenal organ system failure.

Thus, although several smaller single-center studies have suggested that increased intensity of RRT is associated with improved outcomes, this approach is not supported across studies. Differences between study results most likely reflect differences among study designs and populations. For example, the delivered dose of IHD in the ATN study [45] was substantially higher than in the earlier study of Schifl and colleagues [40]. Similarly, only 12% of the patients in the study of Ronco and colleagues had sepsis [6], compared to 63% in the ATN study [45].

In summary, current evidence suggests that in the absence of specific medical indications (e.g. control of hyperkalemia) in patients with AKI, there is no additional benefit to providing IHD more frequently than every other day, with a delivered single-pool Kt/V$_{urea}$ of at least 1.2/treatment. Similarly, current evidence

suggests that there is no additional benefit associated with provision of CRRT at an effluent flow rate of more than 20 mL/kg/h.

Mechanistic considerations in RRT

There are multiple technical considerations that need to be considered when prescribing RRT. We present data on the choice of hemodialyzer and hemofilter, use and type of anticoagulation, and selection of dialysate buffer.

Choice of hemodialyzer and hemofilter

As the result of animal studies suggesting that the activation of cellular and humoral processes by exposure of blood to bioincompatible dialysis membranes delays recovery from experimental AKI, a series of studies evaluated the effects of membrane biocompatibility on outcomes in patients with AKI (Table 12.3). More than a decade ago, Shiffl and colleagues randomized 76 patients with AKI to receive RRT with either cuprophane or polyacrylonitrile membranes [46]. Among patients dialyzed with cuprophane, there was a higher overall mortality (66% vs. 37%) and increased death from sepsis (55% vs. 16%). A subsequent single-center trial by Hakim et al., which was later extended to include additional study sites, demonstrated improved survival and recovery of renal function with the use of polymethylmethacrylate or polysulfone membranes compared to cellulosic membranes [47,48]. The benefit in this study was more substantial in nonoliguric than oliguric patients. However, a subsequent trial by Jorres et al. did not replicate these results [49]. Subsequent studies have compared various unsubstituted and substituted cellulosic membranes to more biocompatible synthetic dialyzers and have reported conflicting results as to the benefit of biocompatible membranes on survival and renal recovery [48,50–52].

Three meta-analyses have been conducted to help resolve these conflicting data. Jaber and colleagues examined seven studies, including both randomized and nonrandomized trials, encompassing a total of 722 patients [53]. Overall mortality rates were similar in those dialyzed with bioincompatible versus biocompatible membranes (46% vs. 45%). A subsequent meta-analysis broadened the study sample by including an additional observational study by Neveu et al. [54,55]. Overall survival was greater with synthetic membranes than cellulose-based membranes (62% vs. 55%; OR, 1.37; $P = 0.03$), although there were no differences in recovery of renal function. Using sensitivity analyses, the authors also found a survival benefit when synthetic membranes were compared to cuprophane membranes (OR, 1.64; $P = 0.013$), yet no overall survival advantage could be demonstrated with the use of synthetic membranes (OR, 1.2; not statistically significant). A more recent Cochrane analysis included nine studies with a total of 1062 patients and concluded that there is no demonstrable clinical advantage to the use of biocompatible membranes [56].

Thus, the current body of knowledge suggests that synthetic membranes provide a survival advantage(s) over cuprophane membranes for patients with AKI. Data comparing synthetic and substituted cellulose dialysis membranes are conflicting, and no firm conclusions can be drawn on the impact of membrane composition on recovery of renal function. Since the major advantage of cellulosic membranes compared to synthetic membranes is their low cost, these issues may have become moot with the recent reductions in the costs of synthetic membranes.

Use of anticoagulation

The most widely used anticoagulant for RRT in patients with AKI is unfractionated heparin [57]. Although an effective anticoagulant, heparin is associated with a risk of bleeding and with the

development of heparin-induced thrombocytopenia (HIT). Regional heparinization protocols, with reversal of heparin by infusion of protamine into the return line, have been developed to prevent systemic anticoagulation and minimize bleeding risk. Unfortunately, these protocols are cumbersome, may be associated with paradoxical increased risk of bleeding if excess protamine is infused, and do not alter the risk of HIT. Other anticoagulants that are safe in patients with a history of HIT include prostacylin (prostaglandin I_2), hirudin, and argatroban.

Regional citrate anticoagulation has also emerged as a viable alternative to standard approaches to anticoagulant therapy, particularly for patients managed with CRRT. Citrate is infused into the prefilter line and exerts its effect in the extracorporeal circuit by chelating calcium, which is an essential component in the coagulation cascade. A normal systemic ionized calcium concentration is maintained through the concomitant infusion of calcium into the return line or a peripheral vein. Multiple protocols for regional citrate anticoagulation have been developed, but until recently there were few direct comparisons with standard heparin therapy. In a study of patients with AKI receiving CVVH, Monchi and colleagues randomized patients to heparin or regional citrate anticoagulation [58]. Patients who required the use of more than one dialysis filter were administered the alternate anticoagulant for subsequent circuits. Median filter patency was greater (70 h vs. 40 h; $P = 0.0007$), and transfusion requirements were lower with citrate anticoagulation, whereas adverse events were comparable between study arms. In a trial of 30 critically ill patients receiving CRRT that was published by Kutsogiannis and colleagues, hemofilter survival was nearly three times longer with citrate therapy than heparin (124.5 h vs. 38.3 h; $P < 0.001$), whereas risk of hemorrhage was lower in patients anticoagulated with citrate (relative risk, 0.14; $P = 0.05$) [59]. Although unfractionated heparin remains the most commonly employed strategy for anticoagulation in patients with AKI who require RRT, these emerging data support the safety and potential superiority of regional citrate anticoagulation.

Choice of dialysate buffer for CRRT

Historically, lactate and acetate have been the primary buffers used in replacement fluid and dialysate for CRRT. Both are rapidly metabolized by the liver and skeletal muscle to bicarbonate, providing their basis for use as effective buffers. Elevations in blood lactate levels can occur during lactate-buffered CRRT, particularly among patients with underlying lactic acidosis and/or impaired hepatic function, potentially contributing to increased protein catabolism and impaired myocardial contractility. Until relatively recently, commercially available bicarbonate-based fluids for CRRT were unavailable due to the instability of bicarbonate solutions stored in gas-permeable containers. The recent introduction of commercially available bicarbonate-buffered fluids for CRRT coupled with the findings of studies over the past decade that have compared the effects of lactate-buffered and bicarbonate-buffered fluids forms the basis for recommendations for the use of bicarbonate-buffered fluids for CRRT (Table 12.4).

In 1995, Kierdorf and colleagues randomized 20 patients treated with CVVH to receive lactate-buffered or bicarbonate-buffered replacement fluids using a crossover study design [60]. No substantive differences in metabolic parameters, pH, control of azotemia, or hemodynamic status were seen between the two groups. Subsequently, Thomas et al. randomized 40 patients receiving hemofiltration to receive replacement fluids with either bicarbonate or lactate as the primary buffer and found no differences in correction of acidosis, hemodynamic parameters, or oxygen transport variables [61].

More recently, Barenbrock and colleagues demonstrated that bicarbonate-buffered replacement fluid was associated with fewer hypotensive episodes (0.26 ± 0.9 episodes/24 h vs. 0.60 ± 0.31 episodes/24 h; $P < 0.05$) and a lower rate of cardiovascular events (15% vs. 38%; $P < 0.01$) than lactate-buffered replacement fluid [62]. Although overall mortality rates and rates of death in patients with sepsis were comparable, there was a trend toward decreased mortality with the use of bicarbonate among those with cardiac

failure (29% vs. 57%; $P = 0.058$). A crossover cohort study by McLean *et al.* revealed more rapid control of systemic acidosis with bicarbonate-buffered fluids than with lactate-buffered fluids in patients treated with continuous venovenous hemodiafiltration [63]. Mean arterial pressure rose by 5.76 mmHg with bicarbonate-buffered fluids and fell by 2.66 mmHg during the use of lactate-containing fluids.

Thus, despite the paucity of data demonstrating a survival benefit with bicarbonate-buffered dialysate and/or replacement fluid, the preponderance of evidence to date suggests a benefit on hemodynamic and cardiovascular parameters.

Summary

1) RRT remains the mainstay of supportive care for patients with established AKI. Unfortunately, there is insufficient evidence to make firm recommendations on the optimal timing of initiation of RRT.

2) Current data do not suggest superiority of any specific modality of renal support in patients with AKI, although outcomes with PD may be inferior. Clinical characteristics of patients, provider expertise, and locally available technology may all need to be considered when addressing these issues.

3) In the absence of specific medical indications (e.g. control of hyperkalemia), there is no additional benefit to providing IHD more frequently than every other day, so long as the delivered single-pool Kt/V_{urea} is at least 1.2/treatment. Although some studies have observed improved survival with higher doses of CRRT, current data suggest that there is no additional benefit associated with effluent flow rates exceeding 20 mL/kg/h.

4) The benefit associated with biocompatible dialysis membranes is uncertain, although there may be survival advantages relative to cuprophane membranes. The importance of resolving this issue, however, may be moot, given the marked reductions in costs for synthetic membranes over the past decade.

5) Heparin continues to be the primary means of anticoagulation, yet citrate may offer certain advantages and should be considered an effective alternative.

6) Bicarbonate-buffered fluids for CRRT are now commercially available. Although it remains unclear whether bicarbonate-buffered fluids are associated with a survival advantage over lactate- or acetate-buffered fluids, cardiovascular events may be less pronounced and hemodynamic stability improved with the use of bicarbonate-buffered fluid.

Ongoing studies should help resolve many of these unanswered questions related to the delivery of RRT and the overall goal of improving outcomes among patients with AKI.

3 Primary Glomerulonephritis

13 Management of Idiopathic Nephrotic Syndrome in Adults: Minimal Change Disease and Focal Segmental Glomerulosclerosis

Alain Meyrier

Hôpital Georges Pompidou and Faculté de Médecine René Descartes, Paris, France.

In 1999, evidence-based recommendations for treating adult idiopathic nephrotic syndrome (INS) were published in *Kidney International* [1,2]. One could assume that little has changed regarding minimal change disease (MCD) and focal segmental glomerulonephritis (FSGS) since then, but a review of the literature shows that new treatment-related concepts have been developed. First, not all recommendations presented in the 1999 compendium meet the second millennium nephrologist's experience. Second, some patients with genetic mutations affecting podocin, ACTN-4, or CD2AP, may develop their first episode of nephrosis as an adult when it does not respond to immunosuppressive treatment [3–12]. In a series of 139 cases Ghiggheri *et al.* [13] excluded 18 patients with mutations, 11% of the entire group. This indicates that some patients with mutations and who fail immunosuppression may explain some of the variability in observed treatment effects in trials. In addition, a number of publications suggest that cases of FSGS might stem from viral or toxic factors that were not considered in 1999 but could lead to a response to immunosuppressive therapy different from that of cases with an immunologic background [14–17].

Other research has led to the notion that MCD and FSGS might be distinct entities rather than two subsets of INS [18–24]. Finally, a number of new immunosuppressive agents, marketed in the field of organ transplantation, have now been tried in the treatment of INS, and the evidence supporting their use merits discussion.

Definitions

MCD

The definition of MCD has not changed. It presents as nephrotic syndrome of sudden onset. In adults proteinuria is less selective than in children. Hypertension may be present. A functional impaired glomerular filtration rate is common at onset and normalizes with remission. Light microscopy and immunofluorescence show normal glomeruli. Electron microscopy discloses foot process flattening and no immune deposits.

FSGS

In contrast with MCD, our current clinical and histologic knowledge of FSGS has evolved. The onset of nephrotic syndrome can be more insidious than in MCD, except in the so-called glomerular tip lesion, a variant whose response to treatment is comparable to that of MCD [26–28]. In other forms, an explosive onset also seems to entail a response to treatment closer to MCD than in more progressive forms, although considerable overlap exists [29]. Hypertension and renal insufficiency are not unusual from the onset. Proteinuria is not selective. A detailed discussion of the histopathology of FSGS is beyond the scope of this chapter but is available elsewhere [30–34]; it is not covered further here because there are no implications for specific treatment [33,34].

Remission

Complete remission

There is general agreement regarding the definition of complete remission (CR): 24-h proteinuria of $\leq$0.3 g and serum albumin of $\geq$3.5 g/dL, persisting for at least 1 month.

Partial remission

Partial remission (PR) has been variably defined among publications. An acceptable definition is 24-h proteinuria of $>$0.3 g and $<$3 g, along with a rise of serum albumin of $\geq$3 g/dL and stable renal function. A 50% reduction from peak proteinuria has prognostic relevance and has recently been suggested as an added component to the definition.

Relapse

The definition of relapse also varies among publications. In fact, clinicians' experiences suggest that some patients in whom treatment has achieved remission may occasionally experience short spells of minimal and spontaneously decreasing proteinuria without hypoalbuminemia or clinical manifestations justifying
Figure 13.1 Time to remission in children (ISKDC) and in adults treated with corticosteroids for minimal change disease. (Adapted from ref 38).

treatment. From this experience, 24-h proteinuria of ≥3 g/day for more than 3 days with incipient decline in serum albumin levels appears to be an acceptable definition of relapse.

Steroid dependency

Two relapses occurring during steroid therapy or within 14 days of completing steroid therapy can be accepted as defining steroid dependency. More than 3 relapses/year may be considered to meet the definition of "multiple relapses."

Spontaneous remission

Spontaneous remission may occur in 10–20% of MCD [38]. It is considered rare in FSGS (3/81 [reference 46] or 1/42 [reference 47]). Yet, it is worth noting that in the most severe variant of FSGS, that is, collapsing glomerulopathy, Valeri *et al.* [48] observed three cases of spontaneous remission.

Renal function: progression to chronic kidney disease

Aside from functional renal insufficiency, which is not rare in case of severe proteinuria [49], renal function remains normal in MCD and tends to decline in FSGS, especially in cases with proteinuria of >14 g/day and in steroid-resistant patients, in whom end-stage renal disease (ESRD) is reached within an average time course of 5.5 years [50]. The risk of persistent renal insufficiency in MCD is extremely low, the only exceptions being concurrent acute tubular necrosis, seen in the elderly and in people with preexisting severe hypertension and compromised cortical blood flow [1]. Conversely, the risk for adult patients with nephrotic FSGS who

progress to ESRD following a CR is very low (2/119; 1.7%), somewhat higher following a PR (9/67; 13%), and occurs in over half of the steroid-resistant group (94/175; 54%) [33]. On a whole, decline in renal function is the rule in FSGS resistant to treatment. A partial remission portends a significantly better prognosis than in the treatment-resistant nephrotic patient [29].

MCD

Natural history

MCD presenting in adulthood

In contrast with about 95% of cases of INS, which occur in children and are due to MCD, this histologic variant makes up less than 50% of such cases in adults [49]. Although most patients experience a single attack, a multirelapsing course may occur, especially if the onset is before 30 years of age.

MCD presenting in the elderly

More than 20% of adult MCD cases affect persons older than 70 years [49]. The precise pathologic diagnosis can be ambiguous, as some glomerular lesions of focal sclerosis may be secondary to aging. Elderly nephrotic patients are prone to present with functional renal insufficiency and in some cases acute tubular necrosis.

A first attack of MCD-related NS in adults is usually corticosteroid sensitive. Relapses are distinctly less frequent in adults than in children. Corticosteroid response is slower in adults than in children [38,52–54] (Figure 13.1), and 4 months of continuous steroid treatment is required before one can conclude steroid resistance. Because of the risks of long-term steroid use, including diabetes and osteonecrosis, 6 months of full-dose corticosteroid treatment

before considering alternate therapy, as suggested by the earlier literature [1], does not seem the proper balance between risk and benefit today.

Management

Recommendations

Recommendation 1: corticosteroids

Corticosteroids remain the mainstay of first-line treatment of MCD in adults. The drug of choice is prednisone. Prednisolone is commonly prescribed, but the pharmacokinetics of this form of steroid may vary with its intestinal absorption. This is true, for instance, in patients taking aluminum gels. Prednisone should be used instead of prednisolone (opinion), with a recommended dose of 1 mg/kg/day, not exceeding 80 mg. In the elderly some clinicians use a dosage of 2 mg/kg given on an alternate-day basis, although no specific study has addressed the issue of similar efficacy and better tolerability. The issue of steroid toxicity is well-recognized, but although weight gain, diabetes, and osteonecrosis are constantly cited regarding prolonged treatment with steroids in adult MCD, very few published studies have provided specific long-term data on the rates of these complications. In adults there are no randomized controlled trials (RCTs) that provide evidence on the dose of corticosteroids that should be given or the frequency or duration.

Only one paper has addressed the option of cyclosporine A (CsA) as first-line treatment in high-risk patients with adult MCD [41]. In that study, high-risk patients were those with a history of psychosis, a history of bleeding duodenal ulcer, or morbid obesity.

Recommendation 2: alkylating agents

Alkylating agents (cyclophosphamide or chlorambucil) are indicated in multirelapsing cases more than for steroid-resistant forms (opinion), although true steroid resistance is rare in true MCD, that is, cases in which a repeat renal biopsy carried out after 4 months of unsuccessful corticosteroid therapy still shows MCD. In most cases the second histopathologic examination discloses lesions of FSGS that had been overlooked or not sampled on the first biopsy, or had not yet appeared at the onset of the nephrotic syndrome, which explains the initial failure of steroids [38,51–54].

Despite the lack of studies specifically related to adult multirelapsers, it is likely that cytotoxic agents result in prolonged remissions, as shown in RCTs in children. Cyclophosphamide, at 2–3 mg/kg/day, is more commonly used than chlorambucil, without clear evidence of the superiority of one over the other. It should be administered orally and not in the form of intravenous pulses, and presumably, considering the experience acquired with childhood onset cases, for 8 weeks. Alkylating agents entail known hazards of hematologic, infectious, and oncologic side effects, but quantifying these risks is not possible given the available data. In men and women the risk of sterility is significant if the course is prolonged, and the risk increases with increasing age at the time of onset of the therapy.

Recommendation 3: CsA

CsA has been used in adults with MCD since 1986 [1]. Its side effects include hypertension, tremor, gingival hyperplasia, and hypertrichosis. Conversely, CsA has the advantage of not being cytotoxic, does not induce sterility, and entails fewer metabolic disturbances. These reasons may justify its use as first-line treatment in patients at risk of diabetes, osteonecrosis, or infertility.

One of the main safety concerns of CsA therapy in INS is the potential for nephrotoxicity. This is a class effect common to all calcineurin inhibitors, including tacrolimus [55,56]. Previous studies indicated that the dosage and type of primary renal disease are two elements to keep in mind when interpreting a decline in renal function [45].

A problem that has appeared since 1999 is that of formulation. Most publications mention "cyclosporine" and do not specify whether they are discussing Sandimmune or Neoral or a generic form of the drug, which may be important because it is known that the better pharmacokinetic profile of Neoral may lead to better efficacy and hence a distinct reduction of dosage [55,56] below the maximum of 5 mg/kg/day recommended for Sandimmune [45].

Evidence

Aside from clinical scenarios in which steroids are contraindicated [41], CsA first-line monotherapy has been used in many case series (level IV studies) with very low dosages [57]. One such study [41] included 86 adult patients with MCD and nephrotic syndrome that were resistant to conventional therapy or were steroid dependent or multirelapsers. They were treated with the Sandimmune formulation at a dose of 5.18 ± 0.94 mg/kg/day. Superior efficacy was reported in steroid-dependent patients (CR in 73% of cases and PR in 14%) compared to those who were steroid resistant (30% and 26%, respectively). Serum creatinine levels remained stable during CsA treatment. These patients were not all CsA dependent, as ∼20–25% were progressively tapered off after 2 years without relapsing [45].

Recommendation 4: mycophenolate mofetil

Studies of mycophenolate mofetil (MMF) in the treatment of MCD in adults are few and are limited to case series and reports [58–60]. Considering the encouraging results obtained in childhood nephrosis (see chapter 66–68), MMF may have a place in the treatment of adult MCD, but so far evidence either supporting or refuting its use is absent.

Summary

MCD is not uncommon in adults and may assume a multirelapsing course. The majority of patients respond to corticosteroids with complete remission, although this may require 4 months of treatment, compared with 6–8 weeks in children, with the attendant hazards of steroid toxicity. Steroid resistance may be due to an initially missed diagnosis of FSGS, and resistance should be considered an indication to verify the diagnosis by a repeat kidney biopsy. The frequency of relapses diminishes with age: after 30 years of age a single attack of NS is the most common variant

Table 13.1 Treatment of adult MCD[a].

Study author [reference]	Study design	No. of patients	Treatment outcomes	Comments and recommendations
Nakayama [38]	Retrospective study Prednisolone 60–80 mg/day in 57 pts + Cyc for 6 + CsA for 2	57 (originally 62, −5 with spontaneous remissions)	CR: 53/57 (38 within 8 wks, 15 later) PR: 3/57 F: 1/57 Age of Early relapsers: 24.4 ± 3.2 yrs Late relapsers: 42.5 ± 4.4 yrs Nonrelapsers: 41.9 ± 4.1 yrs	The study suggests that remission requires 4 mos of treatment before pronouncing failure
Meyrier [41]	Open collaborative prospective multicenter study (1986–1996) of CsA (Sandimmune) ∼ 5mg/kg/day	82	CR: 60 (74%) PR: 11 (13%) F: 11 (13%)	High predictive value of previous response to steroids No decline in renal function
Tse [39]	Retrospective study based on age at onset	50 (35 18–50 yrs old, 15 >50 yrs)	18–50 yrs, CR at wks 2, 4, 6, and 8: 15.6, 62.5, 87.5, and 93.75% >50 yrs, CR: 9, 45.5, 91, and 100%	The response to steroids is similar, irrrespective of age The study confirms that remission requires 4 mos of treatment before admitting failure
Matsumoto [57]	CsA monotherapy, 2–3 mg/kg/day, after pulse MP or oral prednisone	36 (26 first attack, 10 relapses)	CR: 75% CsA alone, 100% CsA + MP, 92% prednisone alone	Too few patients to determine the superiority of CsA over steroids

Abbreviations: Cyc, cyclophosphamide; F, failure; Rx, treatment; MP, methylprednisolone.
[a] All studies are case series, level IV.

of MCD. In selected cases, low-dose CsA can be considered an alternative to steroids, with very little nephrotoxicity. The place of MMF in the treatment of adult MCD remains to be determined. The strength of evidence supporting these statements is very low, being largely based on case series (Table 13.1).

FSGS

Natural history
The incidence and the prevalence of nephrotic FSGS are steadily rising [61,62]. Patients of black African ancestry are twice as likely to develop FSGS than patients of white European origin [50]. This is true of most histological variants, especially the cellular variants [33,47]. The exception is the glomerular tip lesion [26–28]. The response to corticosteroid treatment in black people is distinctly worse than in white people [63], although the overall outcome of the disease in each race follows the same trend.

Management
All forms of FSGS require treatment, irrespective of the histopathologic variant [27,28,33,34]. The goal of therapy is to reduce, if not eliminate, proteinuria. Inducing even a partial remission reduces the rate of deterioration in renal function [29]. Corticosteroids remain the first-line treatment. Response to steroids is also the best indicator of a better long-term prognosis. In case of failure, a panoply of immunosuppressive drugs have been tried, including

new immunosuppressive agents used in solid organ transplantation. Unfortunately, the majority of these studies have included few patients and are case series (level IV studies). A few recent publications on rituximab (reviewed in reference 64) indicate that the anti-CD20 monoclonal antibody may inconstantly obtain a remission in cases of FSGS, especially when the NS relapses after renal transplantation.

Recommendations
Recommendation 1: corticosteroids
The initial response to treatment in adults with FSGS was analyzed by Korbet *et al.* [33,66,67]. The trend before 1980 was to treat for a short time and with low doses of steroids. The highest CR rates, >30%, were observed in cases treated for >5 months, and the lowest, ≤20%, were seen in patients treated for ≤2 months. Thus, corticosteroid treatment must be sufficiently long. Full-dose (1 mg/kg/day) prednisone is given for 8–12 weeks, followed in case of remission, even partial, by slow tapering over months to avoid a "rebound" relapse [68]. CR portends a favorable outcome, comparable to that of steroid-responsive MCD [50]. In fact, a minority of patients with nephrotic FSGS achieve stable remission after tapering steroids to complete withdrawal. Most cases are steroid dependent, usually to a high threshold dose. This poses a serious problem, as pursuing indefinite treatment with a high-maintenance dose leads to steroid side effects. Steroid dependency or resistance leads to the need to consider other treatment options, with the aim of

reducing proteinuria. In the case of steroid dependency, this may mean trading steroid toxicity for other complications.

In steroid-responsive cases, the rates of CR, PR, and failure are, respectively, on the order of 50%, 25%, and 25% of cases [33]. The response to steroids is significantly lower in black patients. Crook *et al.* analyzed the response to steroids in a retrospective case series comprised of 65 African Americans [63] and concluded that in this group of patients, steroids were in general ineffective and that the rate of complications was high.

Evidence

Few studies have addressed specifically the effect of steroids on nephrotic FSGS, with the exception of Crook *et al.* [63]. A single case series [64] included a surprisingly high proportion of patients doing well without treatment. Four case series [36,37,47,69] included 151 patients and showed that steroids were credited with about a 30% complete or partial remission. Troyanov *et al.* [29] estimated by multivariate analysis the significance of PR in nephrotic FSGS. They showed that even PR portends a significantly better prognosis than steroid resistance. A special case is that of glomerular tip lesion, classified by the Columbia group as a variant of FSGS. A majority of this subset responds to steroids as in MCD, as shown by Stokes *et al.* [28] and by Chun *et al.* [34].

In summary, in the absence of any RCT data, current consensus remains that corticosteroids are the first line of therapy. Full doses must be applied for an extended period of time before determining failure. CR portends a very favorable outcome. PR is also a goal pursued with steroid therapy. A minority of patients with nephrotic FSGS achieve stable remission after tapering steroids to a stop. Most cases are steroid dependent. Steroid dependency or resistance leads to the need to consider other treatment options aimed at reducing proteinuria, but which trade steroid toxicity for other complications.

Recommendation 2: alkylating agents

The best indication for use of an alkylating agent is the case of a steroid-dependent or multirelapsing patient, which is rare in nephrotic FSGS. Some studies included patients treated with a combination of cyclophosphamide or chlorambucil and steroids.

Evidence

The best study was a randomized trial in 57 patients by Heering *et al.* [70], which included 23 patients treated for 6 months with steroids and chlorambucil. They achieved 17% CR and 48% PR. Five of 23 progressed to ESRD. The contributions of other studies to treatment recommendations about alkylating agents are uncertain, such as Martinelli *et al.*'s case series [71]. In short, there is no strong evidence to recommend alkylating agents in the treatment of FSGS.

Recommendation 3: CsA

CsA has been used for 2 decades in the treatment of FSGS. It has been shown that its efficacy is greatly increased by a combination with low-dose steroids [41]. A comparison was made in 226 patients treated for steroid-resistant nephrotic syndrome (the majority were FSGS with some cases of MCD), with 127 receiving CsA alone and 103 receiving CsA plus steroids. The proportions of patients with CR, PR, and failure were, respectively, 14% versus 24%, 12% versus 24%, and 74% versus 52%. CsA combined with low-dose steroids can therefore be considered both an immunosuppressive drug and a steroid-sparing agent to treat resistant forms of FSGS.

Evidence

In Cattran's study [35], patients were randomized to a 26-week regimen of low-dose CsA (3.5 mg/kg/day) or placebo in 49 patients with steroid-resistant FSGS. CsA was tapered over the next 4 weeks and then stopped. Both groups also received low-dose prednisone (0.15 mg/kg/day), which was then tapered over the subsequent 8 weeks. Patients were followed up for an average of 200 weeks. CR was rare. By week 26, CR or PR had occurred in 70% of the treatment group versus only 4% of the placebo group ($P < 0.001$). Relapse off of CsA occurred in 40% of patients achieving remission by 52 weeks and in a further 20% by week 78, with the remainder continuing in remission to the end of the observation period. Long-term renal function was significantly better preserved in the CsA group. This trial was the first to demonstrate that low-dose CsA-induced partial remission reduces the rate of progression of nephrotic FSGS patients to renal insufficiency.

Another case series [41] was based on 68 patients treated with 5.18 ± 0.94 mg/kg/day of cyclosporine (Sandimmune formulation). The results on nephrotic syndrome were 14 CR (21%), 19 PR (28%), and 35 failures (51%). Other case series have comprised patients treated with CsA (among other immunosuppressants) and support the beneficial effect of CsA for inducing at least PR in nephrotic FSGS.

Recommendation 4: tacrolimus (FK-506)

Tacrolimus, like CsA, is a calcineurin inhibitor that inhibits T-cell-driven elaboration of cytokines [18,41]. The results with this medication are roughly comparable to those obtained with CsA in clinical practice, but there are no RCTs for this indication. So far, the experience acquired is too scarce to lead to specific recommendations regarding its use in FSGS.

Recommendation 5: sirolimus

Sirolimus (Rapamycin) inhibits the response to cytokines. The current experience with this drug is controversial and inadequate to allow recommendations on its use in FSGS [74,75].

Recommendation 6: MMF

The current experience regarding MMF in the treatment of FSGS seems more or less encouraging [76–78], but the lack of RCTs precludes firm recommendations regarding this new immunosuppressive drug.

Table 13.2 Treatment of FSGS.

Study author [reference]	Study design	*n*	Treatment outcomes	Comments and recommendations
Cattran [35]	RCT, 26 weeks CsA (3.5 mg/kg/day) + low-dose prednisone	49 (26 CsA, 23 placebo)	70% of treated group CR or PR by 26 wks, vs 4% in placebo group Relapse: 60% by wk 78; remainder remained in remission; renal function decline was less in treatment group than in placebo group	This RCT showed the efficacy for inducing CR + PR in nephrotic FSGS without affecting renal function
Ponticelli [36]	Retrospective multicenter study; included pts with serum creatinine up to 3 mg/dL Various regimens applied (steroids, combination or succession of steroids, and alkylating agents or CsA)	80 (initially 53 steroids, 27 immunosuppressive drugs)	<u>First treatment</u> Steroids (*n* = 53) Cytotoxic drugs (*n* = 27) CR: 21 CR: 8 PR: 10 PR: 3 F: 22 F: 16 <u>Second treatment</u> Steroids (*n* = 6) Cytotoxic Rx CsA CR: 1 CR: 1 CR: 0 PR: 1 PR: 5 PR: 7	1) Major side effects in 11 2) 70% of patients may maintain stable renal function with prolonged Rx 3) Inclusion of pts with renal insufficiency and variability of treatment courses make analysis of data and recommendations difficult
Alexopoulos [37]	17 nephrotic pts with FSGS, 6 not treated and 11 treated w/ prednisolone 4 PR and 4 F treated with add-on Cyc (*n* = 2) ⟶ or CsA (*n* = 6), 2–3 mg/kg/day for 6–12 mos ⟶	11 treated	CR 3 (28 %) PR 4 (36 %) F 4 (36 %) PR: 1 PR: 1	Renal survival at 5 yrs: 86% in treated, 65% untreated pts (*P* < 0.03) Nephrotic FSGS responding to treatment had better renal survival than in case of F. Age and serum creatinine at biopsy independent risk factors leading to ESRD Analysis of data quite difficult
Ghiggheri [13]	Retrospective open nonrandomized study, children and adults; 84 not treated and 55 treated	139 (18 [11%] who had mutations were excluded)	20 pts (36%) responsive to CsA	No signs of renal toxicity on repeat biopsy Note significant percentage of genetic mutations
Chun 2004 [34]	Retrospective study based on histology Prednisone at 1 mg/kg/day for 3–4 mos (up to 80 mg/day) tapered progressively Elderly pts: alternate-day Rx 4–5 mos	51	<u>Classic FSGS</u> <u>Cell FSGS</u> <u>Tip lesion</u> 17 25 9 CR 6 16 7 PR 3 10 2 NB: Pts in this series could be the same as those described in Schwartz 1999 (same numbers except for tip lesion type)	The authors consider cellular FSGS and collapsing glomerulopathy the same entity Results of steroid Rx are the same irrespective of histology Pts with FSGS benefit from prolonged steroid Rx irrespective of histology
Stirling [69]	Retrospective record review in 5 UK renal units (1975–1999)	136 (76 on steroids; 45 alone, 31 with additional immunosuppression: 26 Cyc, 26 CsA, 20 Aza)	CR + PR: 67% Remission with 5-yr survival off dialysis in 94%; F with 5-yr survival off dialysis in 53%	Pts treated with steroids are more likely to enter remission than those left untreated Remission rate of up to 80% can be achieved with prolonged treatment Pts who do not achieve remission have a poor prognosis
Crook [63]	Retrospective review of charts, selection of majority of African Americans with nephrotic FSGS	72 (65 African Americans, 43 treated with steroids) Follow-up: 48.3 mos	17/43 reached ESRD 26/43 doubled their initial serum creatinine conc 1/3 treated with steroids developed complications	A beneficial effect of steroids was not observed in this series of predominantly African American adults with nephrotic FSGS
Deegens [65]	Retrospective study of initially untreated patients with normal renal function and negative family history; median follow-up 9.4 yrs (2.1–18.6)	20	13 pts in remission without any treatment Renal function deterioration in 7, among which 4 were treated 10-year renal survival, 89%	This series has an unusual percentage of patients with spontaneous remission
Segarra [72]	Prospective open study; switch to FK-506 + full-dose steroids for 25 patients who did not attain remission with CsA + full-dose steroids	25	At 6 mos, 10 CR + 2 PR + 5 with "diminution of proteinuria" Time to remission: 112 ± 24 days Reversible nephrotoxicity in 40% FK-506 dependency in 76%	Preliminary results might indicate some superiority of FK-506 + steroids over CsA + steroids in treatment of FSGS
Voehringer [74]	Prospective open trial of sirolimus in FSGS (5 primary) following failure of CsA–FK-506, prednisone + MMF, and in 3 on Cyc	7	No effect at 6 mos	Sirolimus did not prove to a beneficial effect on nephrotic syndrome or renal function
Segarra [78]	Prospective open trial of MMF in FSGS resistant to other treatment options	22	Slow remission (150 ± 68 days), CR in 2, PR in 10, F in 10	MMF Rx causes a moderate decrease in proteinuria in 50% of pts who do not have other treatment options; the response to therapy is largely influenced by preserved renal function and requires sustained MMF treatment

Abbreviations: FSGS: focal segmental glomerulosclerosis. RCT: randomized controlled trial. CR: complete remission. PR: partial remission. F: failure (no remission). ESRD: end-stage renal disease. Rx: treatment. CsA: cyclosporine Cyc: cyclophosphamide. Aza: azathioprine MMF: mycophénolate mofetil Pts: patients.

Summary

Nephrotic FSGS, irrespective of its histopathologic variant, is always an indication for a course of full-dose steroids, preferably prednisone (opinion) and for a minimum of 4 months prior to labeling the patient steroid resistant (opinion). CR portends an excellent prognosis. PR is beneficial, both clinically and in terms of preservation of renal function. In the case of steroid resistance, the use of a combination of CsA and low-dose steroids obtains partial or, more rarely, complete remission in about 50–70% of patients, with a definite advantage regarding long-term preservation of renal function. Among the various other immunosuppressants tried in the treatment of FSGS, MMF has the advantage of no nephrotoxicity, but the studies to date, although positive, have been small and pilot in nature (Table 13.2).

Plasmapheresis

The rationale for treating nephrotic FSGS with plasma exchange is based on the concept of a glomerular permeability factor, postulated by Shalhoub in 1974 [79], and despite this factor being the subject of numerous publications, much remains uncertain about this factor [18]. There is no evidence that plasma exchange modifies the course of FSGS, outside of the particular case of relapse of nephrotic syndrome in a kidney transplant recipient [33]. Based on the concept of a "circulating factor," plasmapheresis has been advocated to remove it, reduce proteinuria, and avoid the progression to renal insufficiency, but there is little evidence for or against its use [80–86]. In 2001 Bosch and Wendler [87] concluded, in a review of extracorporeal plasma treatment in primary and recurrent FSGS, that there was only poor evidence to support its use, and no significant additional data have been added since that time.

Similarly, plasma protein adsorption on columns coated with staphylococcal protein A [88] does not seem to remove specifically the elusive circulating factor responsible for the proteinuria, as this experimental protocol also reduces proteinuria in other glomerulopathies [89].

Pregnancy

INS occurring during pregnancy poses a unique situation. The majority of the data relative to the effects of immunosuppressive treatment in pregnancy are based on post-kidney transplantation reports. High-dose corticosteroids entail a risk to the fetus [90]. Alkylating agents are contraindicated. In the CsA era, case reports, center reports, and registry data have supported the concept that successful pregnancy outcomes are possible for mother and newborn in the presence of stable graft function and well-controlled maternal comorbidities, such as hypertension. While the risks of prematurity and low birth weight are greater than those seen in the general population, there has been no increase in the malformation rate of newborns. Successful pregnancy outcomes have been reported in non-renal CsA recipients as well [91–93]. The available experience with MMF has been limited to organ transplantation [91–93]. Two newborns with malformations were noted in a limited case series with MMF exposure, but other factors may have also been at play. The use of MMF during pregnancy continues to be an unresolved issue. In summary, CsA seems to be the less toxic agent to treat a case of INS during pregnancy, but the data are weak.

14 Membranous Nephropathy

Fernando C. Fervenza[1] & Daniel C. Cattran[2]

[1]Division of Nephrology and Hypertension, Mayo Clinic College of Medicine, Rochester, USA
[2]Department of Medicine, University of Toronto, Toronto, Ontario, Canada

Introduction

Idiopathic membranous nephropathy (MN) is a relatively common immune-mediated glomerular disease and remains the leading cause of nephrotic syndrome (NS) in Caucasian adults. Its incidence rate has remained constant over the past 3 decades, in contrast to other primary glomerular diseases, such as immunoglobulin A (IgA) nephropathy and focal segmental glomerulosclerosis [1,2]. In the majority of cases, the etiological agent is unknown, and the disorder is termed idiopathic. Secondary MN forms may account for up to one-third of cases and are associated with autoimmune diseases (e.g. systemic lupus erythematosus [SLE]), infections (e.g. hepatitis B and C), medications (e.g. nonsteroidal anti-inflammatory drugs [NSAIDs], D-penicillamine, gold), and neoplasias (e.g. carcinomas) [3]. The association with malignancy increases with age of the patient, reaching up to 20% in patients over the age of 60. Because idiopathic and secondary forms have similar clinical presentations, the designation of idiopathic is made only after ruling out secondary causes by a careful history, physical examination, and laboratory evaluation of the patient. It is crucial to rule out secondary causes of MN, because the management of these cases is directed towards removing or correcting the underlying cause. The disease is rare in children, and when it does occur, it is commonly associated with an immunologically mediated disorder such as SLE.

Natural history

MN is a chronic disease, with spontaneous remission and relapses. There is great variability in the rate of disease progression, and the natural course is difficult to assess in part due to the different criteria the nephrologist uses to select patients for biopsy, as well as geographic variability and genetic characteristics of the subjects

that have been presented in the different studies [4–6]. Much of the data comes from studies that included patients with both idiopathic MN and secondary MN as well as treated and untreated patients [7]. In addition, the majority of studies were conducted prior to the availability of agents that could potentially modify the natural course of the disease, such as angiotensin converting enzyme inhibitors (ACEi). Spontaneous remissions are said to occur in up to 30% of cases, usually in the first 2 years after presentation, but this may happen at any time over the course of the illness. The proportion of patients going into spontaneous remission is much lower when patients are selected who have higher grades of proteinuria at presentation, for example, proteinuria of >8 g/24 h. The remaining two-thirds of patients who do not undergo spontaneous remission generally divide equally into either those with persistent proteinuria who will maintain renal function long term or those patients who will progress to kidney failure. In Caucasian patients with NS, 10-year kidney survival of <70% has been reported [4,8–11]. Because of its high incidence rate, MN remains the second or third leading cause of end-stage renal disease (ESRD) among the primary glomerulonephritis types [12]. Even patients who do not progress but remain nephrotic are at an increased risk for life-threatening thromboembolic and cardiovascular events. A rapid change in either the degree of proteinuria or in the rate of loss of renal function, especially in a previously stable patient, should raise the possibility of a superimposed condition, for example, interstitial nephritis, anti-glomerular basement membrane disease, or renal vein thrombosis.

Clinical manifestations

The disease affects patients of all ages and races, but it is more common in men than women by a 2:1 to 3:1 ratio. Idiopathic MN is most often diagnosed in middle-aged patients, with the peak incidence during the fourth and fifth decades of life, and is relatively uncommon in patients under 20 years. At presentation, 60–70% of patients will have NS. The remaining 30–40% of cases present with proteinuria of <3.5 g/24 h and are most commonly found at

the time of a routine examination in an otherwise-asymptomatic patient. The presence of microscopic hematuria is common (30–40%), but macroscopic hematuria and red cell casts are rare and suggest a different histopathology. In patients with idiopathic MN, serum C3 and C4 complement levels are always normal. At presentation, the great majority of patients are normotensive, with only 10–20% having hypertension, and only a small fraction of patients (<10%) having significant renal insufficiency. Patients with MN have significant abnormalities in their lipid profile and are at increased risk for thromboembolic events.

Predicting factors

Evaluating the prognosis is critical in making decisions regarding when and what to use in terms of treatment, for example, conservative versus immunosuppressive treatment in patients with MN [13–15]. An accurate predictor of outcome of patients with idiopathic MN would allow separation of those patients who are likely to have a long-term renal survival without treatment from those who are likely to progress. This would allow us to target immunosuppressive treatment to patients at high risk of renal disease progression. However, finding useful markers that predict this last group has been difficult. Many individual factors, such as advanced age, male gender, and selected biopsy findings (e.g. degree of interstitial fibrosis, glomerulosclerosis, vascular damage, or glomeruli with focal segmental glomerulosclerosis) have all been found to be predictors of prognosis and/or response to immunosuppressive therapy in patients with MN [16]. In addition, the degree of proteinuria may also predict those who are most likely to progress. Pei *et al.* observed a 47% risk for progression in patients with proteinuria of >4 g/24 h for longer than 18 months and a 66% risk in patients with proteinuria of >8 g/24 h for more than 6 months [17]. Urinary excretion ratios of α_1-microglobulin, β_2-microglobulin, IgM, and IgG have also been found to be strong predictors of outcome in MN [18–21]. Determining these ratios has been helpful in assessing the severity of overall renal injury and to predict those who are most likely to respond to immunosuppressive therapy [22]. Unfortunately, methods for quantification of urinary α_1-microglobulin, β_2-microglobulin, IgM, and IgG are not widely available and this limits their clinical use. There is also concern with the establishment of cutoff values for these ratios because they may reflect activity only at certain times during the course of the disease and under certain conditions, which may vary widely over time and be independent of the activity of the primary disease. The degree of renal impairment at presentation has also been found to correlate with long-term renal survival. However, renal function at presentation is widely variable and may be independent of disease severity. A recent study by Hladunewich *et al.* that used glomerular filtration rate (GFR) determinations based on inulin clearance indicated that, among patients with MN, for those with nephrotic-range proteinuria the presenting GFR may be artificially low [23]. Estimating renal function by using a serum creatinine value is also problematic in these patients because in NS

there is an increase in the tubular secretion of creatinine which may result in a marked overestimation of the GFR [24]. Thus, the use of immunosuppressive treatment limited only to those patients who exhibit deterioration in renal function, based on reaching a determined serum creatinine threshold, e.g. ≥1.5 mg/dL, may result in delaying treatment beyond the point at which the kidney damage may still be reversible.

Thus far, the best model for the identification of patients at risk was developed with data derived from the Toronto Glomerulonephritis Registry [17,25]. This model takes into consideration the initial creatinine clearance (CrCl), the slope of the CrCl curve, and the lowest level of proteinuria during a 6-month observation period. This risk score assessment has good performance characteristics and to date is the only one that has been validated in two geographically diverse MN populations, one from Italy and the other from Finland [25]. Based on data using this model, patients who present with a normal CrCl, proteinuria of ≤4 g/24 h, and stable renal function over a 6-month observation period have an excellent long-term prognosis. Patients whose CrCl remains unchanged during 6 months of observation but who continue to have proteinuria of >4 g but <8 g/24 h have a 55% probability of developing chronic renal insufficiency, and patients with persistent proteinuria of >8 g/24 h, independent of the degree of renal dysfunction, have a 66–80% probability of progression to chronic kidney failure within 10 years. On the other hand, patients with MN who were never nephrotic have an excellent long-term renal survival. A review of this algorithm has recently been published [12].

Response measurements

The best-accepted responses are improved renal survival and complete remission (CR) of proteinuria. About 30% of MN cases will relapse subsequent to a CR [26]. The great majority who do, however, will relapse to sub-nephrotic-range proteinuria and will have stable long-term function. More recently, partial remission (PR) has been also recognized as a positive outcome. A recent review of 350 nephrotic patients with MN found that the 10-year renal survival was 100% in the CR group, 90% in the PR group, and 45% in the no-remission group [27]. Patients with CR or PR have a similar rate of decline: −1.5 mL/min/year in the CR group and −2 mL/min/year in the PR group. In contrast, the no-remission group lost GFR at a rate of −10 mL/min/year. Thus, both CR and PR appear to be excellent predictors of long-term renal survival. In the two largest studies of patients with MN who achieved CR, only a few developed mild renal insufficiency, over a long observation period, and none progressed to ESRD.

Treatment

Using the algorithm for predicting outcome described above, we can rationally assign patients to conservative, nonimmunosuppressive therapy or to immunosuppressive therapy according to their risk for renal disease progression.

Conservative therapy

Conservative therapy is based on controlling edema, dietary protein intake, blood pressure, and hyperlipidemia. Dietary protein intake should be restricted to 0.8 g of high-quality protein/kg ideal body weight/day, as protein restriction may reduce proteinuria (15–25%) and slow renal disease progression. Blood pressure control is important both as protection against cardiovascular events and to reduce proteinuria and slow the progression of the renal disease. In the Modification of Diet in Renal Disease study, patients with proteinuria of >1 g/day had a significantly better outcome if their blood pressure was reduced to 125/75 mmHg [28]. Thus, in patients with proteinuric renal disease, including MN, the current target for blood pressure is ≤125/75 mmHg. ACEi and/or angiotensin receptor blockers (ARBs) are effective antihypertensive agents that can reduce proteinuria and slow progression of renal disease in both diabetic and nondiabetic chronic nephropathy patients, and for these reasons they are the preferred agents to treat hypertension in proteinuric renal diseases. However, the following issues need to be considered when using an ACEi and/or an ARB in patients with MN: 1) The degree of renal protection is related to the degree of proteinuria reduction, and if proteinuria is not lowered, the benefit is substantially attenuated. 2) In patients with MN, the antiproteinuric effect is modest (<30% decrease) and is more significant in patients with lower levels of proteinuria [29–31]. 3) In contrast to other proteinuric renal diseases, for example, diabetes mellitus, ACEi may not offer the same degree of renal protection to patients with MN [31]. In studies by du Buf-Vereijken *et al.* [11] and in a review by Troyanov *et al.* [26], the use of ACEi or ARBs when subjected to multivariate analysis did not have independent value in determining the prognosis for patients with MN. Furthermore, Praga *et al.* showed that in patients with NS, the majority of which had MN, ACEi were ineffective in reducing proteinuria, and this poor antiproteinuric response in MN patients was associated with a poor renal function outcome [33,34]. In those patients with a significant antiproteinuric response, the effect is usually seen within 2 months of initiation of therapy [29]. Thus, for patients with lower levels of proteinuria (<4 g/24 h), treatment with and ACEi and/or an ARB may be enough to reduce proteinuria to subnephrotic levels with little chance of significant adverse effect. However, in patients with higher degrees of proteinuria, the use of these medications alone is unlikely to result in a substantial reduction in proteinuria or preservation of renal function. Patients need to be instructed to follow a low-salt diet, because high salt intake (e.g. 200 mg Na or 4.6 g sodium/day) can significantly impair the beneficial effects of angiotensin II blockade.

Lipid abnormalities associated with proteinuria are likely important players in the high cardiovascular risk seen in these patients and provide an important target for treatment. Statins may have a synergistic antiproteinuric effect when combined with ACEi, but this effect is small and mainly observed in patients with proteinuria of <3 g/24 h. When used in combination with high-dose cyclosporine (CsA), statins may increase the risk of rhabdomyolysis.

Patients with severe NS are at increased risk for thromboembolic complications. Mahmoodi *et al.* recently reported on the incidence of thromboembolism in a cohort of 298 patients with NS [35]. During a mean follow-up of 10 years, 29 patients had at least one episode of venous thromboembolism (VTE) and 43 had at least one episode of arterial thromboembolism (ATE). The resulting annual incidence rates for VTE and ATE were 1.02% and 1.48%, respectively. However, the incidence of VTE and ATE was considerably higher in the first 6 months following the diagnosis of NS (9.85% and 5.52% for VTE and ATE, respectively) [35]. Prophylactic anticoagulation has been shown in retrospective reviews to be beneficial in reducing fatal thromboembolic episodes in nephrotic patients with MN without a concomitant increase in the risk of bleeding [36]. In general, MN patients who are severely nephrotic (proteinuria of >10 g/day and serum albumin of <2.5 g/day) are candidates for anticoagulation.

In severe untreatable NS, NSAIDs can reduce proteinuria by 30–50%, are additive to the effects of ACEi, and can provide symptomatic relief [37,38]. The combined use of NSAIDs and ACEi or ARBs should be conducted under careful monitoring, especially in elderly patients and in those with hypertension and renal insufficiency, because acute and nonreversible renal failure may ensue.

Immunosuppressive therapy

Several treatment strategies, including a variety of immunosuppressive agents, have been shown to be at least partially successful in reducing proteinuria in MN [39]. The available evidence is presented according to the risk group (e.g. low, medium, and high) that the patients in the studies most closely represent.

Treatment of low-risk patients

Patients in the low-risk group are categorized by a <5% risk for progression over 5 years of observation. They are defined by normal renal function and proteinuria of ≤4 g/24 h over a 6-month observation period. Evidence to support this approach comes from published validation studies and from recent data on the clinical relevance of PR [25,27]. Treatment should be conservative only, given the excellent prognosis of this group of patients when untreated.

Treatment of medium-risk patients

Patients in the medium-risk group are defined by normal renal function and persistent proteinuria between 4 and 8 g/24 h over 6 months of observation despite the institution of maximum conservative therapy.

Corticosteroids

The early US collaborative study of adult idiopathic NS reported that a 2- to 3-month course of high-dose alternate-day prednisone resulted in a significant reduction, compared to placebo, in progression to renal failure, although there was no effect on the degree of proteinuria [40]. Subsequently, the Toronto Glomerulonephritis Study Group conducted a prospective randomized study in which patients were assigned to receive either a 6-month course of prednisone given on alternate days ($n = 81$) or no specific

Table 14.1 Corticosteroids treatment in idiopathic membranous nephropathy

Author	Year	Level of Evidence	Risk group	N	Treatment regimens	Follow-up (months)	Outcomes/comments
CSAINS [40]	1979	1	Medium	72	Prednisone 100–150 mg p.o. on alternate days × 8–12 weeks vs. placebo	23	10 of 38 controls, but only 1 of 34 given prednisone had SCr > 5mg/dl or died. Rapid decline of renal function in controls considered unexpected.
Cattran [41]	1989	1	Medium	158	Prednisone 125–150 mg p.o. on alternate days × 6 mos vs. placebo	48	Proportion of patients with CR similar in the 2 groups. No differences in annual change in CrCl between the 2 groups. No sustained difference in proteinuria
Cameron [42]	1990	1	High	107	Prednisolone 45 mg/m^2 on alternate days × 8 weeks vs placebo	52	No difference in remission rates for NS in either short (6 and 12 months) or long (48 months) term. No differences in rates of renal function decline
Short [43]	1987	5	High	15	MTP 1g I.v. × 5 days followed by prednisolone 100 mg, 75 mg 50 mg, then 25 mg on alternate days for 4 weeks; then dose decreasing by a further 5 mg each month	32	Serum creatinine fell by a mean of 46%. In 10 patients the beneficial effect was sustained, but in 3 it had reversed by six months. In the other 2 patients the progressive decline of renal function was not influenced

Abbreviations are: p.o., oral; NS, nephrotic syndrome; MTP, methylprednisolone; SCr, serum creatinine; CrCl, creatinine clearance

treatment ($n = 77$) [41]. Patients in the prednisone group entered the study with a median CrCl of 72 mL/min/1.73 m^2 (range, 15–156) and a median rate of urinary protein excretion of 6.8 g/24 h (range, 0.3–26). The study showed no significant benefit of corticosteroid treatment alone in either induction of remission or preservation of renal function, even after the data were adjusted to include only patients with proteinuria at entry of >3.5 g/24 h [41]. Whether greater and more prolonged courses of prednisone, as in patients with idiopathic focal segmental glomerulosclerosis, may prove more effective in MN is unknown, but this approach is likely to be associated with significant steroid toxicity. These studies are summarized in Table 14.1 [40–43].

Cytotoxic agents combined with corticosteroids

In patients with a moderate risk of progression, a number of randomized trials have suggested that monthly cycling of steroids and cytotoxic agents is four to five times more likely to induce CR of NS, and halt disease progression, compared to no therapy or corticosteroids alone. The largest studies and with the longest follow-up were conducted by Ponticelli's group. The first study compared the effects of 6-month cycles of methylprednisolone (MTP) administered intravenously and oral steroids alternating monthly with chlorambucil, compared to conservative treatment [44]. CR was achieved in 50%, and PR was found in 31% of the cases. Among the controls, CR was achieved in 7% and PR in 24% of the patients. After up to 10 years of follow-up, patients treated with combination therapy had a 92% probability of renal survival compared with 60% in the control group, and only 8% of treated patients versus 40% of untreated ones had reached ESRD [45]. Women and patients with mild glomerular lesions (stages 1 and 2) were more likely to enter remission after therapy in this study. A second study

compared 6 months of alternating monthly pulses of MTP plus oral steroids and chlorambucil cycled as described above versus MTP pulses plus steroids alone, and the investigators found at 3 years that 66% of the patients given steroids and chlorambucil versus 42% of patients given steroids alone were in remission; this differences was significant [46]. At 4 years this difference was no longer statistically significant, although a seemingly large 20% difference favoring the combined treatment persisted. In a third study from the same investigators, patients were enrolled in a 6-month study comparing MTP pulses on months 1, 3, and 5 followed by oral prednisone alternating monthly with either chlorambucil (same doses as in prior studies) or oral cyclophosphamide [47]. The study showed that 82% of patients assigned to MTP and chlorambucil versus 93% of patients assigned to MTP and cyclophosphamide entered a complete or partial remission of the NS ($P = 0.116$, not significant). The use of cyclophosphamide was associated with fewer side effects, but renal function was equally preserved in both groups for up to 3 years.

These observations have been recently confirmed by Jha *et al.*, who reported the 10-year follow-up of a randomized controlled trial on 93 patients allocated to either conservative therapy or to receive a 6-month course of alternating predisolone [48]. Proteinuria was 5.9 ± 2.2 and 6.1 ± 2.5 g/24 h in the conservative and immunosuppressive therapy groups, respectively. Renal function was well-preserved, with estimated GFRs above 80 mL/min in both groups. Of the 47 patients treated with immunosuppressive therapy, 34 achieved remission (15 CR and 19 PR), compared with 16 (5 CR and 11 PR) of 46 in the control group ($P < 0.0001$). The 10-year dialysis-free survival was 89 and 65% ($P = 0.016$), and the likelihood of survival without death, dialysis, or doubling of serum creatinine was 79% in the treated group versus 44% in the control

group ($P = 0.0006$). The incidence of infections was similar in the two groups [48].

Thus, in a number of studies, both cyclophosphamide and chlorambucil in combination with corticosteroids appear to be effective in the treatment of patients with idiopathic MN and preserved renal function, with benefits maintained well beyond the 1-year treatment period, although relapse rates approached 35% at 2 years. The long-term adverse effects of these cytotoxic agents, in particular, effects on fertility and also malignancy are the major drawbacks to the universal application of this form of therapy. A recent publication suggests that the risk of malignancy is not increased for patients treated with cumulative cyclophosphamide doses of ≤ 36 g but increases significantly in patients with cumulative cyclophosphamide doses of ≥ 36 g [49]. These studies are summarized in Table 14.2 [45–48,50–61].

Cyclosporine A

Early uncontrolled studies of CsA suggested an initial benefit but a high relapse rate [31,62]. In the first single-blind randomized controlled study, 51 patients with steroid-resistant MN were treated with low-dose prednisone plus CsA and compared to patients treated with placebo plus prednisone [63]. At the end of 26 weeks of treatment, 75% of patients (21 of 28) in the CsA group versus only 22% of patients (5 of 23) in the controls had achieved a PR or CR ($P < 0.001$) (CR in two patients in the CsA group versus one in the placebo group). CsA was well-tolerated, and no subjects had to discontinue treatment because of adverse effects. Relapses occurred in about 40% of patients within 1 year of discontinuation of CsA treatment; this is a very similar relapse rate to that seen with combined cytotoxic agent–corticosteroid regimens. Relapses should not be considered failure of therapy, because reintroduction of CsA or its alternative, that is, the cytotoxic agent–corticosteroid regimen, are usually capable of inducing another remission. Data from the German Cyclosporine in NS Study Group suggest that prolonging CsA treatment (>1 year) results in a higher (34% CR at 1 year) and more sustained rate of remission [64]. Taken together, these data suggest that CsA can induce a remission (CR or PR) of NS in 50–60% of patients. Prolonged low-dose CsA (~1.5 mg/kg/day) could be considered for long-term maintenance of patients who achieve CR or PR, especially in patients at high risk for relapse [65]. It is important to emphasize that although reduction of proteinuria usually occurs within a few weeks, the majority of CR occurred after more than 6 months of treatment. On the other hand, if after 3–4 months of CsA therapy at adequate doses proteinuria is not significantly reduced, it is unlikely that the therapy will be effective. Significant adverse effects, including hypertension and nephrotoxicity, can accompany prolonged CsA treatment. The latter is dose and duration dependent as well as age dependent. These studies are summarized in Table 14.3 [31,66–69].

Tacrolimus

An alternative to CsA was reported in a recent study by Praga *et al*. which evaluated tacrolimus (TAC) monotherapy in idiopathic MN [70]. In this study, 25 patients with normal renal function (mean proteinuria, ~8 g/24 h) received TAC (0.05 mg/kg day) over 12 months with a 6-month taper, whereas 23 patients served as controls. After 18 months, the probability of remission was 94% in the TAC group but only 35% in the control group. Six patients in the control group and only one in the TAC group reached the secondary end point of a 50% increase in serum creatinine [70]. Unfortunately, almost half of the patients relapsed after TAC was withdrawn, and similar to patients treated with CsA, maintenance of remission may require prolonged use of TAC at a low dose.

Treatment of high-risk patients

Patients in the high-risk group are characterized by progressive loss of renal function and/or by persistent high-grade proteinuria of ≥ 8 g/24 h during the 6 months of observation.

Corticosteroids

The UK Medical Research Council study, a randomized, prospective, double-blind, controlled trial, assessed the medium-term effect of an 8-week course of high-dose prednisolone in this patient population [42]. A total of 103 patients with preserved renal function (average CrCl, 88 ± 30 mL/min) were randomized to the treatment group ($n = 52$) or to the control group ($n = 51$). Entry 24-h urinary protein excretion was 10.8 ± 6 in the treated group versus 10.4 ± 5 in the control group. At 36 months, there was no significant difference regarding the degree of proteinuria between the control and the treatment group. Similarly, there were no differences with regard to loss of renal function between the treatment and control groups (Table 14.1) [40–43]. Renal function did deteriorate equally in both groups, confirming that this study population was indeed high risk.

Cytotoxic agents combined with corticosteroids

There has not been a randomized, controlled trial of cytotoxic agents plus corticosteroids in this high-risk group. A summary of the studies conducted in this group of patients is presented in Table 14.2 [45–47,50–61].

Cyclosporine

There has been only one controlled trial with CsA in patients with high-grade proteinuria and progressive renal failure. In this study, 17 patients of the initial 64 MN patients who had a loss in CrCl of ≥ 8 mL/min during the 12-month observation period were randomly assigned to either CsA treatment (9 patients) or placebo (8 patients) for 12 months (phase 2) [69]. At the time of initiation of treatment, the average CrCl of these patients was in the mid-50s, and they had an average proteinuria of 11 g/day. After 12 months, there was a significant reduction in proteinuria, and the rate of loss (slope) of renal function in the CsA group was reduced from -2.4 to -0.7 mL/min/month, whereas in the placebo group the change was insignificant, -2.2 to -2.1 mL/min/month ($P < 0.02$). This improvement was sustained in ~50% of the patients for up to 2 years after CsA was stopped (Table 14.3) [33,66–69].

Table 14.2 Cytotoxic treatment in idiopathic membranous nephropathy

Author	Year	Level of Evidence	Risk group	N	Treatment regimens	Mean Follow-up (months)	Outcomes/comments
Ponticelli [51]	1984	1	Medium	67	MTP 1g i.v. × 3 days followed by MTP 0.4 mg/kg p.o. × 27 days, on months 1, 3 and 5 and CHL (0.2 mg/kg/d) on months 2, 4 and 6, vs. symptomatic therapy.	31	At the end of follow-up 23 of 32 treated patients (72%) were in CR or PR, as compared with 9 out of 30 controls (30%).
Ponticelli [46]	1992	1	Medium	92	MTP 1g, i.v. × 3 days; followed by MTP 0.4 mg/kg p.o. × 27 days, on months 1, 3 and 5 and CHL (0.2 mg/kg/d) on months 2, 4 and 6, vs MTP alone	48	At 3 years, 66% remission in MTP/CHL group vs 40% in MTP group. At 4 years, the difference was no longer statistically significant.
Ponticelli [45]	1995	1	Medium	67	MTP 1g i.v. × 3 days followed by prednisone 0.5 mg/kg/d × 27 days on months 1, 3 and 5 and CHL (0.2 mg/kg/d) on months 2, 4 and 6, vs symptomatic therapy	120	92% probability of renal survival in treated compared with 60% in the control group. 8% of treated patients vs. 40% of the untreated group reached ESRD.
Ponticelli [47]	1998	1	Medium	87	MTP 1g i.v. × 3 days followed by MTP 0.4 mg/kg/d p.o. × 27 days on months 1, 3 and 5 alternating with either CHL 0.2 mg/kg/d or CYC 2.5 mg/kg/d on months 2, 4 and 6	36	CR/PR in 82% of patients on MTP/CHL vs 93% on MTP/CYC ($P = $ NS). Side effects lower in the MTP/CYC group
Jha [48]	2007	1	Medium	93	MTP 1 g i.v. × 3 days followed by prednisolone 0.5 mg/kg/d p.o. × 27 days on months 1, 3 and 5 and CYC 2 mg/kg/d on months 2, 4, and 6, vs. conservative therapy	120	CR/PR in 72% of patients on MTP/CYC vs 35% in control group
Murphy [52]	1992	2	Medium	40	CYC 1.5 mg/kg × 6 months + DIP/W24 X 2 years vs symptomatic therapy		Treatment group had less proteinuria. No differences in renal function at 2 years
Donadio [50]	1974	2	Medium	22	CYC 1.5 to 2.5 mg/kg p.o. × 1 year vs. symptomatic therapy	12	No benefit of CYC on proteinuria, renal function, or histology
Falk [56]	1992	2	High	26	Prednisone 2 mg/kg on alternate days × 8 weeks, tapered over 4 weeks, vs. CYC 0.5–1 g/m^2 i.v. monthly × 6 months, + MTP (7 mg/kg) × 3 followed by prednisone (2 mg/kg/alternate days) for 8 weeks, then tapered over next 4 weeks.	29	No impact of CYC on renal function, level of proteinuria, or progression to ESRD
West [53]	1987	4	High	26	CYC 2 mg/kg × 20 ± 4 months ± prednisone vs. prednisone or symptomatic therapy	49	CYC associated with an increased rate of remission of NS and better preservation of renal function. Adverse effects were significant.
Jindal [57]	1992	4	High	9	CYC (1–2 mg/kg/d) for a mean of 23. ± 4 months (8 to 54) ± prednisone (6/9 patients; dose 33 ± 9 mg/d) compared to 17 controls receiving prednisone, max. dose 50–125 mg alternate days in 9/17 and 40–80 mg in 6/17, for a mean of 20 ± 4 months.	64–83	CR in 4/9 and PR in 5/9 in CYC group. One patient in the CYC group and 10 patients in control group reached ESRD. Four relapses in 3 treated patients, and 3 of 4 responded to repeat therapy. Of the 7 controls who did not reach ESRD, only 2 had persistent NS.
Torres [60]	2002	4	High	19	Prednisone (1 mg/kg/d month 1 0.5 mg/kg/d month 2, 0.5 mg/kg/d months 3 to 6) together with CHL 0.15 mg/kg/d for the first 14 weeks, vs. historic control group on symptomatic therapy	48	At the end of follow-up, 65% of patients in the control group had reached ESRD, 10% had advanced renal failure, and 25% had died. Majority of treated patients showed stabilization or improvement of renal function.

(continued)

Table 14.2 (cont.)

Author	Year	Level of Evidence	Risk group	N	Treatment regimens	Mean Follow-up (months)	Outcomes/comments
Bruns [55]	1991	5	High	11	CYC, 100 mg/d in all patients + prednisone (60–100 mg alternate days) in 10/11 patients, for 1 year	24–25	Serum creatinine decreased in 10 patients on combined therapy by 6 months and remained stable in 7/8 followed long-term. Proteinuria decreased from 11.9 to 2.3 g/d. Similar course observed in the 1 patient on CYC alone.
Warwick [58]	1994	5	High	21	Prednisolone 125 mg alternate days on months 1, 3 and 5 and CHL 10 mg/d on months 2, 4 and 6. Later patients received MTP 1g i.v. × 3 at the start first cycle of treatment. Four patients were retreated.	39	Renal function stable or improved in 11/21 patients (52%). Of these 11, PR in 4 and CR in 2. Serum creatinine >5.7 mg/dl or ESRD in 6 patients (29%). 3 patients died. Side effects + significant complications related to therapy in >50% of patients.
Branten [59]	1998	5	High	32	MTP 1g i.v. × 3 days, followed by prednisone (0.5 mg/kg/d months 1, 3 and 5), and CHL (0.15 mg/kg/d months 2, 4 and 6); or CYC (1.5–2 mg/kg/d for 1 year) + steroids in a comparable dose.	26–38	Renal function improved in both groups but the improvement was short-lived in the CHL group. Remissions of proteinuria more frequent after CYC treatment (15/17 vs. 5/15). CHL associated with more side effects.
Du Buf-Vereijken [61]	2004	5	High	65	MTP 1g i.v. × 3 days at months 1, 3 and 5, and prednisone 0.5 mg/kg/48h for 6 months + CYC (1.5–2 mg/kg/d) × 12 months	51	Renal function improved or stabilized in all patients. At the end of follow-up, CR in 16, PR in 31, 4 progressed to ESRD, and 5 patients had died. Overall survival 86% after 5 years.
Mathieson [54]	1988	6	High	8	MTP 1g i.v. × 3 days; 0.5 mg/kg/d p.o. × 27 days, then CHL 0.15–0.2 mg/kg × 28 days × 3 cycles	8	Renal function improved in 6, stabilized in 1, and deteriorated in 1 patient. Proteinuria fell from 15 to 2 g/d. Side effects were severe.

Abbreviations are: MTP, methylprednisolone; CYC, cyclophosphamide; CHL, chlorambucil; DIP/W, dipyridamole/warfarin; CR, complete remission; PR, partial remission.

New therapies

A number of uncontrolled studies have evaluated the effects of new immunosuppressive agents in the treatment of patients with MN.

Mycophenolate mofetil

There has been a paucity of studies using mycophenolate mofetil (MMF) for MN. In a pilot study, Miller *et al.* treated 16 patients with 1.5–2 g/day of MMF for a mean of 8 months [71]. These patients would be categorized as either medium or high risk for progression given the severity of their proteinuria and the fact that they had previously failed a variety of other immunosuppressive drugs. The results were modest: six patients had a ≥50% reduction in their proteinuria, two had a minor reduction in proteinuria, four had no change, three were withdrawn because of significant adverse effects, and one stopped treatment on his own. There were no significant changes in mean serum creatinine, or serum albumin levels, over the course of the study. In patients who responded, the lowest degree of proteinuria was reached within 6 months, suggesting that patients who are likely to respond would do so in this time frame. This was a pilot study and is somewhat difficult to interpret as negative or positive, given the setting of resistance to all other agents. Similar results were reported in a retrospective analysis of 17 patients with MN who were treated by Choi *et al.*

(15 patients had nephrotic-range proteinuria and 6 had renal insufficiency) [72]. Patients were either steroid dependent, steroid resistant, or steroid intolerant, with or without CsA, or they had been resistant or had a suboptimal response to CsA, or they had signs of progressive renal failure. Overall, treatment with MMF (0.5–1.0 g twice daily for a mean of 12 months) combined with steroids in most patients resulted in a 61% reduction of proteinuria (7.8 to 2.3 g/24 h; $P = 0.001$), with eight patients having PR and two patients CR. Renal function improved in three of six patients with kidney failure.

More recently, Branten *et al.* reported on 32 patients with MN and renal insufficiency (serum creatinine of >1.5 mg/dL) treated with MMF (1 g, twice daily) for 12 months and compared the results with those obtained for 32 patients from a historic control group treated for the same period of time with oral cyclophosphamide (1.5 mg/kg/day) [73]. Both groups received high-dose steroid treatment (methylpredisone, intravenously, 1 g three times at months 1, 3, and 5, followed by oral predisone at 0.5 mg/kg every other day for 6 months, with subsequent tapering). Overall, 21 MMF-treated patients developed PR of proteinuria, in 6 patients proteinuria decreased by at least 50%, and no response was observed in 5 patients. Cumulative incidences of remission of proteinuria at 12 months were 66% in the MMF group versus 72% in the cyclophosphamide group ($P = 0.3$). Side effects occurred

Table 14.3 Cyclosporin A treatment in idiopathic membranous nephropathy

Author	Year	Level of Evidence	Risk group	N	Treatment regimens	Follow-up (months)	Outcomes/comments
Cattran [63]	2001	1	Medium	51	Prednisone (0.15 mg/kg/d) plus CsA (3–4 mg/kg/d) vs. placebo plus prednisone × 26 weeks.	19.5	75% of patients in CsA group vs. 22% in control group achieved PR or CR. Relapse rate 43% in CsA group vs. 40% in placebo by week 52.
Cattran [69]	1995	2	High	17	CsA 3.5 mg/kg/d × 12 months vs. placebo	21	CsA associated with slower rate of decline in renal function. Sustained remission of proteinuria in 6/8 CsA patients.
Alexopoulos [65]	2006	3	Medium	51	CsA 2–3 mg/kg/day and prednisone vs CsA (same dose) alone for 12 mo. responders were placed on long-term low dose CsA 1–1.5 mg/kg/d and prednisone vs CsA alone	26	After 12 months of treatment, 26 patients in the combination group and 17 patients in the CsA alone group had a CR or PR of proteinuria. Daily CsA dose was higher in non-relapsers in both groups while relapsers in both groups had lower CsA trough levels
Ambalavanan [31]	1996	5	Medium	41	CsA 4–5 mg/kg/d for 3–6 months. Lupus serology (+) in 12 patients Retreatment in 20 of 31 patients who relapsed after stopping CsA	18	CsA lowered median proteinuria by 56%, from 7.3 to 3.2 g/24h. In 6 patients with declining GFR during prolonged CsA therapy, a repeat biopsy showed more prominent immune deposits and thicker GBM.
Rostoker [68]	1993	5	High	15	CsA 4–5 mg/kg × 12–30 months Prednisone 1–2 mg/kg/d × 2 months	40	CR or PR in 11/15 (73%) patients. Relapse in 3/9 on CsA withdrawal, but the relapse remain sensitive to CsA. All patients had received corticosteroids (1 mg/kg/d × 2 months) prior to enrollment.
DeSanto [66]	1987	6	Medium-Low	5	CsA 7 mg/kg/d for 6 months plus MTP 1–0.3 mg/kg/d for one month, reduced to 0.3–0.15 mg/kg on the second month, and then down to 0.15 mg/kg for 4 months	8	All had failed prior cytotoxic therapy. Prompt remission of proteinuria in 4/5 patients. No renal failure.

Abbreviations are: MTP, methylprednisolone; CsA, cyclosporin A; CR, complete remission; PR, partial remission; GBM, glomerular basement membrane

at a similar rate between the two groups, but relapses were much more common in the MMF-treated group [73].

Rituximab

Evidence from both experimental and human studies has indicated that MN is mediated by the deposition of IgG antibodies in the subepithelial aspect of the glomerular basement membrane. Thus, it is reasonable to postulate that suppression of antibody production by depleting B cells and/or plasma cells may improve or even resolve the glomerular pathology in MN. Rituximab is a genetically engineered, chimeric, murine/human IgG1κ monoclonal antibody against the CD20 antigen that is found on the surface of normal and malignant pre-B and mature B cells but is not expressed on hematopoietic stem cells, normal plasma cells, or other normal tissues. In a pilot study of rituximab in idiopathic MN, Ruggenenti *et al.* prospectively treated eight nephrotic patients with MN with four weekly courses of rituxan (375 mg/m^2) and followed them for 1 year [74,75]. All patients had complete depletion of circulating B cells lasting up to 1 year. Proteinuria significantly decreased from a mean (±standard deviation [SD]) of 8.6 ± 4.2 g at baseline to 3.0 ± 2.5 g at 12 months; −66%; *P* <0.005). This included two patients with <0.5 g /24 h and <3.5

g/24 h in three other patients. Proteinuria decreased in the three remaining patients by 74, 44, and 41%. Renal function remained stable in all patients. Adverse effects were reported as mild and included chills and fever in one patient and an anaphylactic reaction in another patient. A recent publication from these investigators suggests that rituximab is likely to be most effective in patients with a minimal degree of tubulo-interstitial injury [76].

We recently conducted a prospective open-label pilot trial in 15 newly biopsied patients (<3 years) with idiopathic MN and proteinuria of >4 g/24 h despite ACEi or ARB use for >3 months and systolic BP of <130 mmHg [71]. Thirteen men and 2 women, median age 47 years (range, 33–63) and with a mean serum creatinine of 1.4 ± 0.5 mg/dL, were treated with rituximab (1 g) on days 1 and 15. At 6 months, patients who still had proteinuria of >3 g/24 h and in whom the total CD19$^+$ B-cell count was >15 cells/μl received a second identical course of rituximab. All patients tolerated rituximab well and achieved swift B-lymphocyte depletion by day 28. Baseline proteinuria of 13.0 ± 5.7 g/24 h (range, 8.4–23.5) decreased to 9.1 ± 7.4, 9.3 ± 7.9, 7.2 ± 6.2, and 6.0 ± 7.0 g/24 h (range, 0.2–20) at 3, 6, 9, and 12 months, respectively (means ± SD). Fourteen patients completed a 12-month follow-up: CR (proteinuria <0.3 g/24 h) was achieved in two patients, PR (<3 g/24 h)

MN Treatment Algorithm

Mild proteinuria (<4 g/day) + normal renal function	Moderate proteinuria (≥4 <8 g/day) + Normal renal function	Heavy proteinuria (≥8 g/day) ± ↓renal function
Conservative treatment* Continue to monitor	Conservative treatment* Monitor for 6 months	Conservative treatment* Monitor ≤ 6 months**
	Persistent proteinuria (≥ 4 g/day)	Persistent proteinuria ≥8 g/day ± ↓renal function
	Cytotoxic/steroids Mycophenolate mofetil***	Cyclosporine Mycophenolate mofetil***
	Cyclosporine/Tacrolimus Rituximab***	Cytotoxic/steroids Rituximab***

MAYO CLINIC

CP1123327 -16

Figure 14.1 *Conservative treatment involves the use of ACEi ± ARB blocker to maintain BP<125/75 mmHg, lipid control with HMG-CoA reductase inhibitor, dietary protein restriction (0.6–0.8g/kg ideal body weight/day), dietary NaCl intake (goal is 2 to 3 g Na) to optimize antiproteinuric effects of ACEi and ARBs, smoking cessation, and attempt to reduce obesity, if present.
**Decreasing function or complication: start treatment early
***Data from non randomized control studies.

was achieved in six patients, and five patients did not respond. Two patients progressed to ESRD. The mean drop in proteinuria from baseline to 12 months was 6.2 ± 5.1 g and was statistically significant ($P = 0.002$, paired t test). Rituximab was well-tolerated and was effective in reducing proteinuria in patients with idiopathic MN. However, the responses varied widely among patients, and further research is needed in order to identify *a priori* which of the patients would be likely to benefit from rituximab treatment. These pilot studies, although encouraging, need to be confirmed by larger randomized controlled studies before recommendations can be made regarding rituximab.

Eculizumab

Eculizumab is a new, humanized anti-C5 monoclonal antibody designed to prevent the cleavage of C5 into its proinflammatory by-products. In a recent randomized controlled trial (currently reported in abstract form only), 200 patients with MN were treated every 2 weeks with two different intravenous dose regimens and compared to a placebo group, over a total of 16 weeks [78]. Neither of the active drug regimens of eculizumab showed any significant effect on proteinuria or renal function compared to placebo. It was later determined that adequate inhibition of C5 was seen in only a small proportion of patients, suggesting that the doses given were inadequate. More encouraging results were seen in a continuation of the original study, in which eculizumab was used for up to 1 year, with a significant reduction in proteinuria in some patients (including two patients who went into CR). Whether complement inhibition with higher doses of eculizumab will prove to be more effective, as well as safe, in the treatment of MN remains a question.

Adrenocorticotropic hormone

In a study by Berg and colleagues, synthetic adrenocorticotropic hormone (ACTH) administered for 1 year decreased proteinuria in patients with idiopathic MN [79,80]. More recently, Ponticelli

et al. conducted a randomized pilot study comparing methylprednisolone plus a cytotoxic agent versus synthetic ACTH in 32 patients with idiopathic MN [81]. Of these, 16 were randomly assigned to receive methylprednisolone plus chlorambucil or cyclophosphamide (group A), and 16 were assigned to receive ACTH (group B). ACTH was administered by one intramuscular injection (1 mg) every other week, with the frequency increased to two injections per week for a total treatment period of 1 year. Data were reported according to intention-to-treat analysis. CR or PR as a first event was attained by 93% of patients in group A (5 CR and 10 PR) and 87% in group B (10 CR and 4 PR), and the difference between the two groups was not significant. Side effects associated with the use of ACTH included dizziness, glucose intolerance, diarrhea, and the development of bronze-colored skin, which resolved after the end of therapy. Whereas these studies suggest that prolonged synthetic ACTH therapy may represent an effective therapy in patients with idiopathic MN, more extensive randomized studies with longer follow-up are needed before therapeutic recommendations can be made. At the present time, the synthetic formulation of ACTH used in the above studies is not available in the USA.

Disease and treatment summary

In conclusion, control of NS, specifically with CR or PR, is clearly associated with prolonged renal survival and a slower rate of renal disease progression. There are no standard or universal first-line specific therapeutic options for idiopathic MN. Supportive or conservative care should be given in all cases and should include the use of potentially renal protective agents such as ACEi and ARBs and lipid-lowering agents. In patients who are at low risk of progression, conservative therapy should suffice, given their excellent prognosis, although long-term follow-up is needed to ensure that there is no disease progression or worsening of proteinuria. Patients at medium or high risk are candidates for immunosuppressive therapy. Patients with persistent nephrotic-range proteinuria are at increased risk for cardiovascular and thromboembolic complications. Proteinuria is an inducer of kidney injury and plays a major role in the development of progressive tubular injury, interstitial fibrosis, and subsequent loss in GFR. The higher the sustained level of proteinuria, the more likely the development of ESRD. Therefore, even if the main benefit of immunosuppressive therapy is to accelerate the induction of a remission, it may still have value in the long term. A treatment algorithm that combines the predictive factors and best evidence for immunosuppressive therapy is presented in Figure 14.1. In following this algorithm, physicians must also take into account the individual patient and their wishes in order to make the best decision regarding which therapy should be initiated. These routines are not mutually exclusive and may follow one after the other (with a drug holiday) if the first one chosen does not succeed in reducing the proteinuria to the desired range and/or adverse side effects make completion of a course of therapy untenable. Patients who do not respond well or relapse after a first course of immunosuppression therapy may benefit from a second course of immunosuppression [82].

Preliminary evidence on the use of anti-CD20 antibodies suggests this is another agent that may be as effective, and safer, than our current regimens, but it needs further assessment before being widely recommended. Patients with severe renal insufficiency (serum creatinine of ≥3 mg/dL) are less likely to benefit from immunosuppression therapy, and the risk of treatment is significantly higher, and so these patients should be considered for conservative therapy only and with plans made for transplantation in the future.

15 IgA Nephropathy in Adults and Children

Jonathan Barratt,[1] John Feehally,[1] & Ronald Hogg[2]

[1]The John Walls Renal Unit, Leicester General Hospital, and Department of Infection, Immunity & Inflammation, University of Leicester, Leicester, United Kingdom
[2]Division of Pediatric Nephrology, Children's Health Center, St. Joseph's Hospital and Medical Center, Phoenix, USA

Introduction

Immunoglobulin A nephropathy (IgAN) is the most common pattern of glomerulonephritis in all countries where renal biopsy is widely practiced and is an important cause of end-stage renal disease (ESRD) at all ages [1]. IgAN is a mesangial proliferative glomerulonephritis characterized by the predominant deposition of IgA in the glomerular mesangium. The degree of histopathologic injury is extremely variable, and this is reflected in the varied tempo and severity of clinical presentation seen in this disease [2]. Closely associated with IgAN is Henoch-Schönlein purpura (HSP), a small vessel systemic vasculitis characterized by small blood vessel deposition of IgA predominantly affecting the skin, joints, gut, and kidney. The nephritis of HSP is also characterized by mesangial IgA deposition and may be histologically indistinguishable from IgAN [3].

No clinical presentation is pathognomonic of IgAN, not even the archetypal young male with episodic macroscopic hematuria following an upper respiratory tract infection. Also, although a number of abnormalities in circulating IgA and its production have been reported in IgAN patients, cohorts are heterogeneous with respect to these abnormalities, making their diagnostic utility poor [4]. Therefore, a diagnosis of IgAN currently requires a renal biopsy.

Recurrence of IgAN after transplantation, and also the rare cases of resolution of IgA deposits in transplanted kidneys from donors with IgAN, supports the hypothesis that mesangial IgA is derived from a pathogenic IgA fraction within the circulating pool of serum IgA [4–6]. What defines this pathogenic IgA fraction is incompletely understood, but there is evidence for the importance of low-affinity, undergalactosylated polymeric IgA1 molecules forming circulating IgA immune complexes with a propensity for both mesangial deposition and mesangial cell activation [7]. The lack of a complete understanding of the pathogenesis of IgAN has re-

sulted in there still being no treatment known to modify mesangial deposition of IgA. Available treatment options are mostly directed at downstream immune and inflammatory events in the glomerulus and the tubulo-interstitium that may lead to renal scarring. It is therefore likely that these are generic treatments with potential benefit in other chronic glomerular diseases.

In this chapter, we summarize the published studies according to their level of evidence and provide recommendations for the common clinical situations that confront the nephrologist treating patients with idiopathic IgAN (Figure 15.1). In each section, we will describe the results of therapeutic approaches to these clinical situations in adults with IgA nephropathy, followed by a pediatric perspective for which we review the results of similar therapeutic trials in children and adolescents. Some of these reports have been reviewed previously [8]. Whenever possible, the pediatric experience with each treatment will be compared with evidence-based conclusions drawn from adult studies. In this way, we will attempt to facilitate comparison between pediatric and adult recommendations for the management of patients with IgAN. Discussions of the treatment of HSP or secondary forms of IgAN are not included in this chapter.

Natural history

Adult IgAN

The natural history of IgAN has now been well-defined in a number of large series with prolonged follow-up [9]. Fewer than 10% of all patients with IgAN have complete resolution of urinary abnormalities [10] and episodes of macroscopic hematuria become less frequent with time after diagnosis, although the majority of patients will still have persistent microscopic hematuria. All patients have the potential for slowly progressive chronic kidney disease leading eventually to ESRD. Approximately 25–30% of any cohort will require renal replacement therapy within 20–25 years of presentation. From the first renal symptom, on average, 1.5% of patients with IgAN have been calculated to reach ESRD per year [11], but the observed risk varies with the diagnostic approach. Centers

Biopsy proven IgA nephropathy

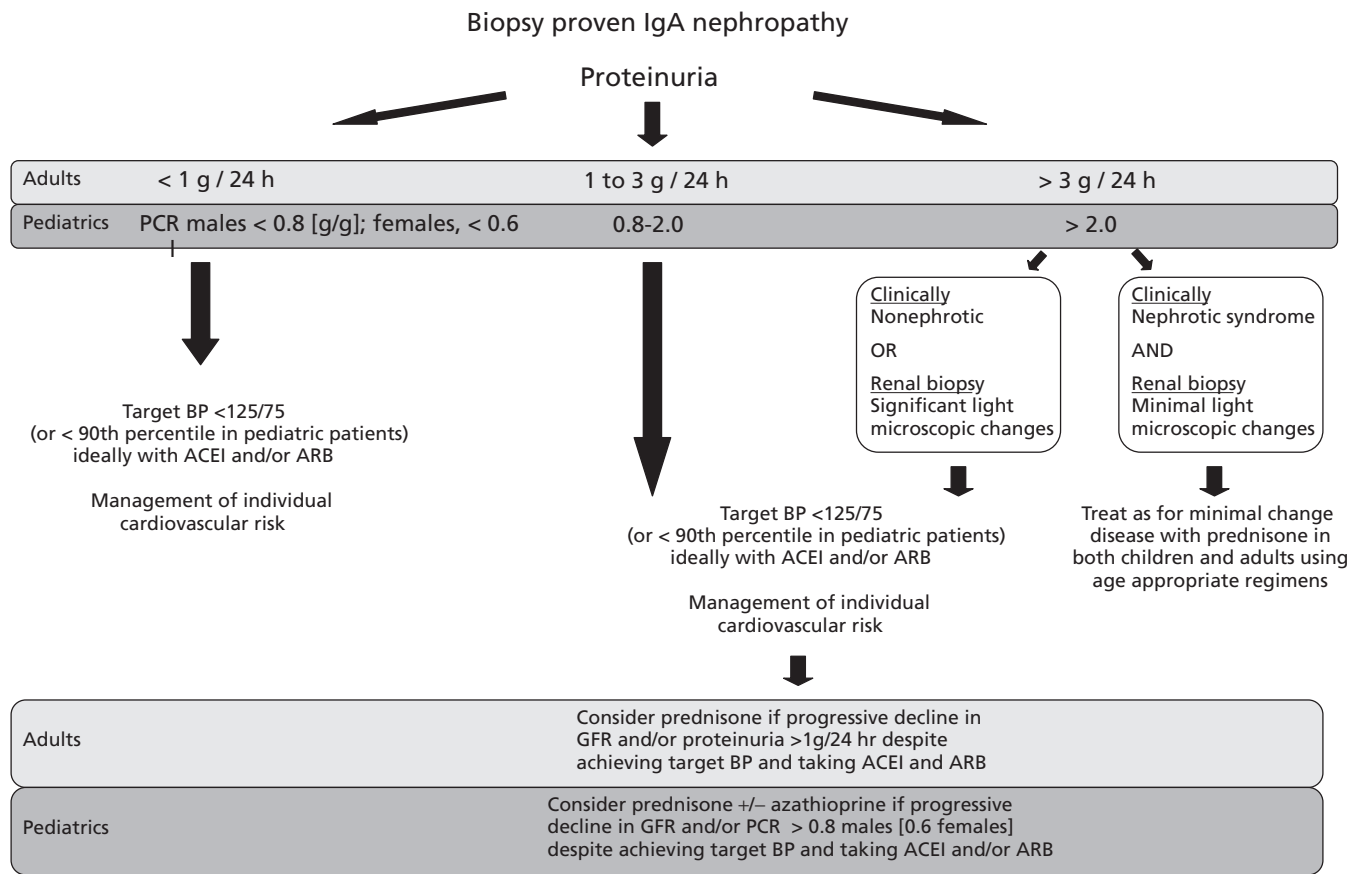
Proteinuria


Figure 15.1 Flowchart for the management of IgA Nephropathy.

with a low threshold for renal biopsy for patients with mild urine abnormalities, particularly those in countries where urine screening programs are established, will likely diagnose IgAN in a larger number of patients with mild disease and good prognosis (length bias) and at an earlier stage in their disease (lead-time bias), thus favorably influencing the overall outcome of the cohort.

Rarely, acute kidney injury can complicate preexisting IgAN, and evaluation should include a further renal biopsy unless renal function improves rapidly with supportive measures. Acute kidney injury develops by two distinct mechanisms (Figure 15.2). There may be acute, severe immune and inflammatory injury producing crescent formation, or crescentic IgA nephropathy, which may be amenable to intensive immunosuppression. Alternatively, acute kidney injury can occasionally occur with mild glomerular injury when heavy glomerular hematuria leads to tubular occlusion and/or damage by red blood cells. This is a reversible phenomenon, and recovery of renal function occurs with supportive measures.

Pediatric IgAN

Children with progressive forms of IgAN will often not develop ESRD until they are adults [12,13]. Thus, most pediatric trials must rely on surrogate measures, as discussed in the next sec-

tion. Some reports of childhood IgAN have concluded that the risk of progressive renal failure is very low [14–16], whereas others have shown that a significant number of pediatric patients with IgAN will progress to ESRD [12,13,17]. It has been estimated that as many as 30% will progress to ESRD in the USA [13], but for Japanese children only 11–20% are expected to progress to ESRD [12,16,17]. However, similar to many adult studies, predictions are based on different selection criteria for renal biopsy candidates [16,18]. In addition, when progressive disease occurs, it is often insidious, resulting in considerable difficulty in assessing outcomes over the short term. This also presents a significant obstacle when designing clinical trials to evaluate the effect of therapeutic interventions within a feasible time period (i.e. 3–5 years).

Prognostic factors

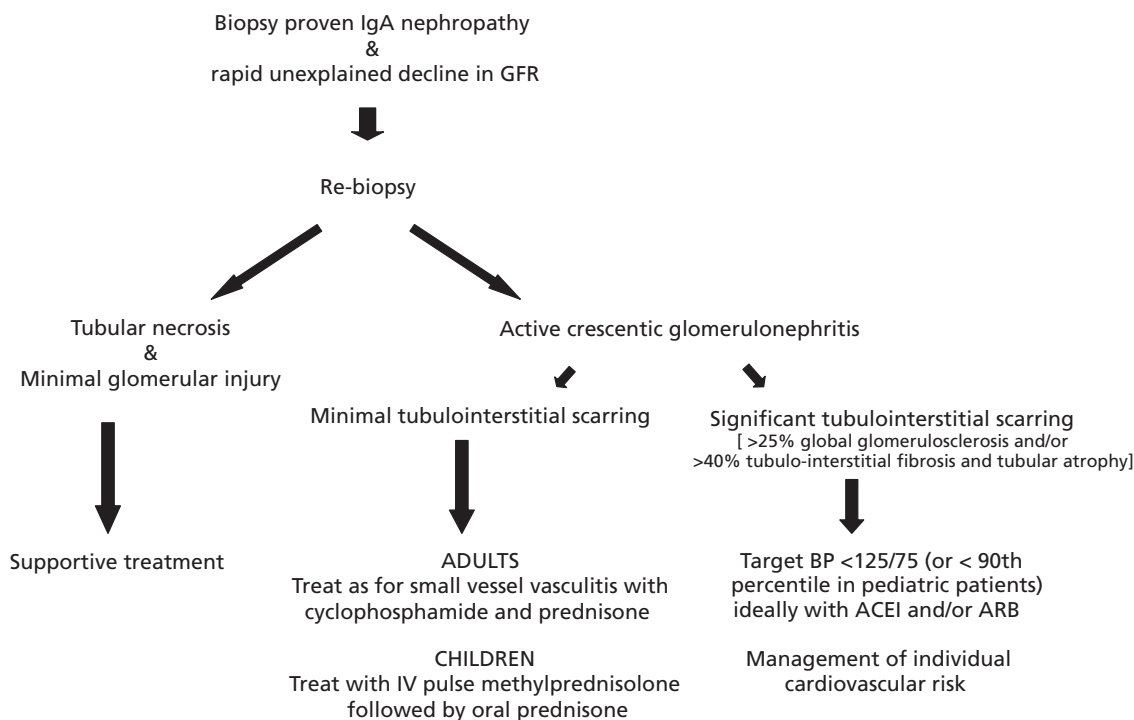
Many studies have identified features at presentation that mark a poor prognosis (Table 15.1) [9]: proteinuria more than 1 g/24 h, raised serum creatinine, and hypertension. The severity of proteinuria has been shown to correlate with extent of glomerular lesions [19]. In one study 98% of patients presenting with proteinuria of <1 g/24 h had at least a 15-year renal survival [20].


Figure 15.2 Flowchart for the evaluation and management of patients with previously diagnosed IgA Nephropathy who present with a rapid unexplained decline in renal function.

Another analysis identified those with proteinuria of more than 1 g/24 h and serum creatinine more than 1.7 mg/dL. The 7-year renal survival was 99% if both values were below this threshold, 87% if either one was above the cutoff, and 21% if both were above the cutoff [21]. More recently, serum uric acid levels have been found to correlate with a poor prognosis (and severity of tubulo-interstitial injury) [22]. Episodic macroscopic hematuria does not entail a poor prognosis. It is likely that this observation reflects the variation in time between clinical presentation and diagnosis, which can hinder the accurate interpretation of the natural history. Histopathologic features marking a poor prognosis include glomerulosclerosis, tubular atrophy, and interstitial fibrosis. Clearly, none of these features is specific to IgAN, and they would all mark a poor prognosis in any chronic glomerular disease. Capillary wall IgA deposits are the only histologic feature specific to IgAN which has prognostic significance [11].

The various prognostic factors described may be informative for groups of patients but do not have sufficient accuracy to predict the prognosis of an individual patient with complete confidence. More refined methods of assessing disease activity are required to define those patients in whom IgA deposition will lead to substantial and sustained glomerular injury. An approach incorporating sequential information on blood pressure (BP) and proteinuria can further refine the prediction of risk of progression [23–25], although this will still only account for 30% of overall risk. In milder disease, one study suggested that proteinuria may in fact be a less powerful predictive factor than expected [26]. Although prognostic formulae using simple clinical and laboratory data have been proposed [24,26], there is not yet sufficient consensus to recommend their use in clinical practice for the prediction of individual progression risk.

Methods

We have reviewed the English literature published on the treatment of IgAN since 1976. Despite the prevalence of IgAN, published randomized controlled trials (RCTs) are few in number, and even recent RCTs are not always sufficiently powered to provide definitive information on tested interventions. In part, this is because IgAN is a slowly progressive disease, making it necessary to study large numbers of patients for prolonged periods of time to determine the efficacy of any therapeutic intervention. Another consequence of the slowly progressive nature of IgAN is that for many of the trials now published, patient recruitment occurred at a time when the management of progressive glomerular disease was less clearly defined than it is now. These caveats are even more relevant for reports dealing with therapeutic interventions in children with IgAN. Although the most important outcome indicator for all patients with IgAN is based on deterioration of the glomerular filtration rate (GFR), the period from diagnosis to ESRD in patients with onset in childhood may be decades. Thus, most studies of therapy for pediatric IgAN have relied on surrogate markers, such as deterioration in renal biopsy findings [27,28] and/or decline in the amount of proteinuria or hematuria [28–30]. Significant deterioration in renal function (i.e. 40–50% reduction of GFR or

doubling of serum creatinine concentration) is the surrogate end point most associated with progression to ESRD, although this occurs infrequently in patients participating in pediatric trials of IgAN [31].

Recommendations

All patients with IgAN
Recommendations for adults
All adult patients with IgAN should have a BP of <125/75 to 130/80 mmHg (level I recommendation). The antihypertensive agents of choice should be angiotensin converting enzyme inhibitors (ACEi) and angiotensin II receptor blockers (ARB) (level I recommendation). Combination therapy with an ACEi and ARB may provide additional benefit compared to either single agent alone (level II recommendation). Furthermore, all patients should have an individual assessment of their cardiovascular risk, particularly those with progressive chronic kidney disease, hypertension, and dyslipidemia, and treated accordingly (reviewed in Chapter 6).

Recommendations for children
It is also important to maintain pediatric patients with IgAN in a normotensive range, utilizing age-, gender-, and height-appropriate norms for BP [32] (grade I recommendation). ACEi and ARB are the first choice for treatment of hypertension and/or proteinuria (grade I recommendation).

Evidence in adults
In common with virtually all kidney diseases, hypertension is a risk factor for progression in IgAN and should be treated early in the course of the disease [9,33]. There is, however, limited RCT evidence devoted specifically to IgAN concerning a target BP required to preserve renal function. In one 3-year RCT of 49 patients with IgAN, the achieved mean BP of 129/70 mmHg stabilized GFR over 3 years, whereas patients with an achieved mean BP of 136/76 mmHg showed an average decline in GFR of 13 mL/min over 3 years [34]. As with other proteinuric glomerular diseases, the antiproteinuric effect of antihypertensive treatment appears to predict renoprotection, and so therapy should be titrated not only to target BP values but also to maximize reduction of proteinuria. There is increasing evidence that the antihypertensive strategy of choice should be maximal renin–angiotensin system (RAS) blockade, to both achieve a target BP of <125/75 to 130/80 mmHg and to minimize proteinuria [35] (Table 15.2). Retrospective data from the Toronto GN registry have shown that patients with IgAN treated with an ACEi to control BP had a lower rate of annual loss of renal function than similar patients treated with alternative antihypertensives [36]. This is supported by an RCT of 44 patients that demonstrated an additional benefit of an ACEi (enalapril) on progressive kidney disease in IgAN despite equivalent BP control [37]. This benefit was believed to have arisen from the additional reduction in proteinuria seen in the ACEi-treated group. Similarly, a more recent and larger RCT of 109 Asian patients showed benefit with an ARB (valsartan) both in proteinuria reduction and in retarding the rate of renal deterioration, although the investigators were unable to demonstrate a significant improvement in their

[b] Of the 336 patients in the COOPERATE study, 131 had IgAN.

primary end points of doubling of serum creatinine or ESRD at 2 years [38].

A number of studies have demonstrated the potential for additive renoprotection when an ACEi is given in combination with an ARB in IgAN, but no studies have long-term outcome data [39,40]. The COOPERATE study, in which 131 of 301 patients had IgAN, demonstrated superior renoprotection with an ACEi (trandolapril)–ARB (losartan) combination than an ACEi or ARB alone, with no further lowering of BP in nonnephrotic proteinuric renal diseases [41]. No formal subgroup analysis of those with IgAN in this study has been reported, however.

Evidence in children

A recent placebo-controlled RCT conducted in 23 centers in five European countries that evaluated benazepril (0.2 mg/kg/day) in 66 children and young adults <35 years of age provided evidence to support the use of ACEi in pediatric patients [42]. The patient cohort included 29 patients ≤18 years of age. Seventy-four percent of the patients had their initial renal abnormalities when they were ≤18 years old. The overall allocation of patients was 32 in the benazepril arm and 34 in the placebo arm. There was a significant benefit with benazepril in preventing progression of renal disease in these patients (defined as a reduction in GFR by 30% versus baseline, or worsening of proteinuria to ≤3.5 g/L/1.73 m²/day). Such progression was seen in 9/34 (26%) of the placebo group but only 1/32 (3%) of the benazepril group. Furthermore, at the end of the trial, the number of patients with proteinuria of <0.5 g/L/1.73 m²/day in the benazepril group was significantly higher than the number in the placebo group (13/32 [40%] vs. 3/34 [9%]; $P = 0.0002$). This was evident in both the groups of children (6/10 [60%] vs. 2/19 [10%]) and adults (7/12 [58%] vs. 1/15 [7%]) in this trial.

Patients with recurrent macroscopic hematuria
Recommendation for adults and children
Patients with recurrent macroscopic hematuria require no specific additional intervention (level II recommendation).

Evidence in adults
Episodes of macroscopic hematuria are self-limiting and can be provoked by a range of mucosal, most commonly respiratory, infections. There is no evidence supporting prophylactic use of antibiotics, even in the minority of patients in whom recurrent episodes are provoked by bacterial tonsillitis. Tonsillectomy is still favored as therapy in some regions of the world, notably Japan. Although several retrospective studies of the effectiveness of tonsillectomy have been published, most contain small numbers of patients, are nonrandomized, uncontrolled trials, and have generated conflicting data. In one Japanese study tonsillectomy was shown to be an independent factor in predicting remission in 329 patients followed for a minimum of 3 years [43]. A second retrospective study from Japan looked at the outcome in 118 patients followed over 20 years, of which 48 underwent tonsillectomy [44]. Benefit from the tonsillectomy only became apparent 10 years after initial diagnosis. The concomitant use of other treatment modalities and changing therapeutic goals during the follow-up period make these data difficult to interpret. A retrospective study from Germany of 55 patients in whom 16 had had a tonsillectomy suggested no benefit of tonsillectomy at 10 years [45]. A retrospective study of 112 Chinese patients, of whom 54 underwent tonsillectomy, similarly showed no difference in renal survival at 130 months [46]. Preliminary data from a prospective Japanese RCT of tonsillectomy combined with steroids versus steroids alone reported improvement in hematuria and proteinuria in the tonsillectomy group but no difference in the proportion of patients doubling their serum creatinine at 24 months [47].

Evidence in children

As for adults, there are no prospective clinical trials evaluating the role of tonsillectomy in children with IgAN. In 1985, Lozano *et al.* reported on eight Spanish patients of mean age 18.7 years with a history of frequent episodes of gross hematuria following upper respiratory tract infections and who had had a tonsillectomy. These patients, over the subsequent 2 years, had significantly fewer episodes of gross hematuria, and the percentage of their blood lymphocytes producing polymeric IgA also fell [48]. In 1996, Tomioka *et al.* reported that 13 of 15 children with IgAN who underwent tonsillectomy had improved urinalyses, with 6 of them going into remission [49]. More recently, changes in the levels of hematuria and proteinuria were assessed by Sanai *et al.* in eight children treated with "medication" combined with tonsillectomy compared to 7 "control" children treated with "medication" [50]. These patients were a small subset of a larger patient cohort (ages 3–13 years) that included five children with HSP nephritis and eight with "other" types of glomerulonephritis. No details were given regarding the "medication" that was employed. The authors reported that both proteinuria and hematuria improved in five of eight patients in the tonsillectomy group compared to only one of the seven children with IgAN who received "medication only." However, it is of interest that significant improvement also followed tonsillectomy in five of the eight children with "other glomerulonephritis."

These limited data on the effect of tonsillectomy in children with IgAN are similar to the reports in adults. Most of the studies that have been reported in both groups are retrospective in nature, are based on unvalidated surrogate markers for outcome, and are confounded by co-interventions. There is no convincing evidence that tonsillectomy will prevent progressive renal disease in children or adults, and so this procedure should not be done (level II recommendation).

Patients with isolated microscopic hematuria and proteinuria of <1 g/24 h
Recommendation for adults and children

Adult patients with isolated microscopic hematuria and proteinuria of <1 g/24 h require no specific additional intervention (level II recommendation). There are insufficient data to establish a specific evidence-based recommendation for children in this category, but we suggest that such patients require no additional therapy if their urinary protein (grams)/creatinine (grams) ratio is <0.6 (boys) or <0.8 (girls) (grade II recommendation).

Evidence

Available data suggest that most patients presenting with proteinuria of <1 g/24 h have at least a 15-year renal survival [20]. It is generally accepted that these patients require no additional treatment, although they should receive regular follow-up. It is, however, important to note that while a threshold for proteinuria of 1 g/24 h is commonly used to identify those at increased risk of progression (and therefore warranting treatment), this is an arbitrary value, and the risk attributable to proteinuria is almost certainly

a continuum. Interventions that may lower proteinuria further, and are therefore likely renoprotective, for example RAS blockade, have not been tested in this setting in either adults or children.

Patients with rapidly declining GFR
Recommendations for adults

Unexplained acute kidney injury complicating preexistent IgAN requires evaluation with a kidney biopsy (Figure 15.2). Crescentic IgAN associated with active glomerular inflammation and deteriorating renal function in the absence of significant chronic damage should be treated with induction therapy comprising cyclophosphamide and corticosteroids followed by maintenance therapy of azathioprine and corticosteroids at doses similar to those used for the treatment of ANCA-positive small vessel vasculitis (level II recommendation).

Recommendation for children

Although there are no controlled trials of treatment regimens for children with crescentic IgAN, we recommend that pediatric patients with rapidly progressive disease and crescents in ≥50% of their glomeruli be treated with a 2-week course of intravenous (i.v.) methylprednisone pulses (six doses of 1 g/1.73 m^2 every other day), followed by 1 month of daily prednisone (1 mg/kg/day) and then alternate-day prednisone for 2–3 months (level II recommendation). Additional therapy with cyclophosphamide should be considered in patients who fail to respond to the pulse therapy (level II recommendation).

Evidence in adults

Acute kidney injury may occur as the first presentation of IgAN with little preceding renal insult or, alternatively, may be superimposed on a background of preexistent disease with variable degrees of chronic glomerular and tubulo-interstitial scarring. Even if the diagnosis of IgAN has previously been established, evaluation should include renal biopsy to distinguish between acute kidney injury due to acute tubular necrosis, which should be self-limiting with supportive treatment, and crescentic IgAN, which may be amenable to intensive immunosuppression.

Crescentic IgAN has a less favorable prognosis, even with immunosuppressive therapy, than other forms of crescentic glomerulonephritis, such as ANCA-associated small vessel vasculitis; cumulative published cases suggest that renal survival in crescentic IgAN is only 50% at 1 year and 20% at 5 years [9,51]. Evidence of chronic glomerular and tubulo-interstitial injury with scarring usually predicts a poor response to intensive immunosuppression. There is no published systematic definition of the degree of chronicity that predicts poor response to immunosuppressive treatment, but we do not recommend such an approach if a representative renal biopsy shows >40% tubulo-interstitial fibrosis and/or >25% global glomerulosclerosis.

A number of case series have recently been published that indicate good preservation of renal function when using treatment regimens similar to those recommended for renal vasculitis, usually with high-dose corticosteroids and cyclophosphamide, and

[a] Overall quality very low: inconsistent effects, nonrandomized, very small studies, surrogate outcomes.

in some cases plasma exchange (Table 15.3). However, all of these series are small nonrandomized studies, most using historical controls. There has still been no RCT of these treatments in crescentic IgAN, and response to treatment is not uniform. In addition, comparisons across studies are difficult because published reports use varying definitions of crescentic IgAN. Some include cases where crescents are seen, but others include acute injury where the glomerular tuft is not intense and renal function is not deteriorating. One report indicated that there is a subset of crescentic IgAN with circulating ANCA antibodies which respond well to immunosuppression [52].

Evidence in children

As in adults, the prognosis for children with crescentic IgAN is also poor according to most reports [53]. However, in the largest pediatric experience reported to date, Niaudet *et al.* described a very aggressive and successful approach to 12 children aged 8–14 years with crescentic IgAN, 10 of whom had crescents in ≥50% of their glomeruli [54]. The patients received i.v. methylprednisone in a dose of 1 gm/1.73 m^2 every other day, followed by 1 month of daily prednisone (1 mg/kg/day) and then alternate-day prednisone for 2–3 months. Three of the patients received a second course of pulse methylprednisone, whereas three others received cyclophosphamide. Although uncontrolled, the authors described very good results after a follow-up period of 1–9 years, because none of the children progressed to ESRD, nine had improved histology on repeat biopsy, and six had recovered clinically, although one patient was still hypertensive.

Patients with nephrotic syndrome
Recommendation for adults and children

In patients presenting with nephrotic syndrome, preserved renal function, and minimal glomerular injury evident on light microscopy, a trial of high-dose corticosteroids using a regimen appropriate for minimal change disease in IgAN should be considered (level I recommendation). However, there is no evidence to support prolonged exposure to corticosteroids if there is not a prompt

response, nor for their use in nephrotic syndrome in the presence of structural glomerular damage.

Evidence in adults

In many patients with IgAN, nephrotic syndrome-range proteinuria is a manifestation of significant structural glomerular damage and progressive renal dysfunction. However, a small minority of both adults and children have nephrosis with minimal glomerular change on renal biopsy, although there are also IgA deposits, and proteinuria remits promptly in response to corticosteroids. In these patients, two common glomerular diseases may coincide: minimal change nephrotic syndrome and IgAN [55,56]. The only RCT of corticosteroids in nephrotic IgAN confirmed this approach, since there was remission of proteinuria only in patients with minimal glomerular change on light microscopy [57]. More recent RCTs of corticosteroids in IgAN have excluded those with nephrotic-range proteinuria, so there is little evidence to inform treatment choices for nephrotic IgAN with significant histologic glomerular injury.

Evidence in children

A number of reports have also described the association of mesangial IgA deposition in association with steroid-responsive nephrotic syndrome in children [58–60]. In at least two of the patients described in the SPNSG report, there was a temporal dissociation between the onset and course of nephrotic syndrome and the later development of clinical features of IgAN [58].

Patients with slowly progressive renal impairment
Recommendations for adults

Tight BP control to a target of <125/75 mmHg and evaluation of individual cardiovascular risk are essential in this group of patients. In patients with persistent proteinuria (>1 g/24 h) despite tight BP control (<125/75 mmHg) and maximal RAS blockade, a 6-month treatment course of corticosteroids may reduce proteinuria (level II recommendation) and stabilize kidney function (level II recommendation). Available evidence does not support

a role for mycophenolate mofetil (MMF) (level I recommendation), although additional evidence from appropriately designed studies may soon be available. We cannot recommend the use of cyclophosphamide (grade I recommendation), fish oil (level I recommendation), and other agents at the present time.

Recommendations for children

Based upon the limited evidence currently available, we are unable to make a specific recommendation regarding the use of fish oil supplements for treatment of IgAN in the pediatric patient, although preliminary data from the North American IgA Nephropathy Trials indicate that such therapy may be efficacious in reducing proteinuria in such patients (77). We recommend that a trial of alternate-day prednisone be considered in pediatric patients who have deterioration of GFR or persistent proteinuria (level II recommendation). If prednisone alone is unhelpful, we recommend therapy combining corticosteroids with azathioprine (level II recommendation)

Evidence in adults and children

Patients at risk of progressive renal dysfunction are typically those with hypertension, proteinuria of >1 g/24 h, or reduced GFR at the time of diagnosis. Specific treatment strategies in this group of patients remain contentious. Progression is usually slow, and therefore large studies with prolonged follow-up are necessary to evaluate new treatment strategies in these patients. Recently reported RCTs have tested interventions intended to slow immune and inflammatory events implicated in progressive IgAN, including corticosteroids, cyclophosphamide, and MMF. Because of the long duration required to identify with confidence the benefit of interventions, it is inevitable that recruitment into a number of these studies goes back 10 years or more, to a time when the generic approach to progressive glomerular disease was less well defined, so that BP targets and the use of RAS blockade are variable in these studies.

Immunosuppressive treatments

Corticosteroids in adults

The recent review of immunosuppressive treatments for IgAN by the Cochrane Renal Group identified six RCTs of sufficient quality to be included in their meta-analysis of corticosteroid treatment in IgAN (Table 15.4) [61]. This analysis suggests that corticosteroid therapy may be effective in reducing proteinuria (six trials, 263 patients) and reducing risk of ESRD (six trials, 341 patients), although the meta-analysis was unable to evaluate the influence of RAS blockade or achieved BP in the analysis. Follow-up in a large Italian study of corticosteroid treatment has now reached 10 years. and the investigators report impressive benefit of treatment in reducing proteinuria and preventing ESRD [62]. However, the high-dose corticosteroid regimen, with pulse methylprednisone (1 g daily for 3 days at induction and beginning of months 2 and 4) and alternate-day oral prednisone (0.5 mg/kg) for 6 months, is regarded by many physicians as likely to carry considerable toxicity, even though none was reported by the investigators. Notably, RAS blockade was only used in a minority of patients in this study, although equally distributed among the participants, and achieved BP was not in line with current recommendations. Another recent RCT of corticosteroids (20-mg/day induction and 5-mg/day maintenance) from Japan in which BP control was tight even though RAS blockade was not used showed only a modest reduction in proteinuria with no protection of GFR [63]. It is unclear whether this lack of renoprotection was due to the lower dose of corticosteroid or a genuine lack of effect in patients managed to current BP targets.

Corticosteroids in children

The short-term effects of prednisone on proteinuria and hematuria were examined by Welch *et al.* in a group of children with IgAN. Twenty patients were randomized to either placebo or prednisone (2 mg/kg/day, maximum 80 mg) for 2 weeks, followed by the same dose on alternate days for 10 weeks [30]. After a 12-week washout period, the treatments were reversed in each subject. No difference in the severity of hematuria was reported after treatment with prednisone compared to placebo. However, most of the subjects had only mild histologic changes, and the subjects in this study would not be expected to have progressive disease.

Waldo and Wyatt *et al.* compared the outcomes of 13 children with IgAN in Alabama followed for 4–10 years after they received alternate-day prednisone for 2 years with 15 children in Tennessee who received no steroid therapy [29]. All of the patients had either proteinuria of >1 g/m^2/day or renal biopsies showing more than a minimal degree of interstitial fibrosis, tubular atrophy, or glomerular sclerosis. None of the 13 treated patients progressed to ESRD, compared to 5 of 15 of the untreated patients ($P = 0.04$). At last follow-up, 12 of 13 treated patients had no hematuria and normal protein excretion ($P < 0.001$ compared with nontreated historic control patients).

Cyclophosphamide with/without azathioprine in adults

The use of cyclophosphamide in patients at very high risk of progression (ESRD predicted in all cases within 5 years) is supported by a single study. Patients received cyclophosphamide (1.5 mg/kg/day for 3 months) followed by azathioprine (1.5 mg/kg/day) in conjunction with high-dose prednisone (40-mg/day induction, 10-mg/day maintenance) and were followed for at least 2 years [64]. Notably, BP control and use of RAS blockade in this trial fell outside current recommendations. Previous RCTs of cyclophosphamide in less severe, slowly progressive IgAN have shown no consistent benefit (reviewed by Feehally [65]), and this is supported by the Cochrane Renal Group meta-analysis, which failed to show any significant renal survival benefit from those RCTs incorporating cyclophosphamide, cyclosporine, or other cytotoxic agents, although there was a significant reduction in daily proteinuria [61]. These studies were, however, insufficiently powered to exclude any effect on progression with certainty.

Table 15.4 RCTs included in the Cochrane Renal Group meta-analysis evaluating the benefit of corticosteroids in IgAN.[a]

Author [reference]	N	Treatment	Follow-up (mos)	Results

[a] Overall quality low: inconsistent effects, variable quality of RCT design and reporting, small studies, surrogate outcomes.

Cyclophosphamide with/without azathioprine in children

The efficacy of a 1-year course of prednisone and azathioprine in combination was evaluated in 10 children with IgAN by Andreoli *et al.* [66]. Outcome measures included proteinuria and changes in acute and chronic scores on pre- and posttreatment renal biopsies. Prednisone at 60 mg/m^2 (maximum, 60 mg) once daily for 8 weeks was followed by the same dose every other day for 10 months. Azathioprine at 2–3 mg/kg/day was given for 12 months. Proteinuria fell from 4.1 to 1.6 g/day after treatment ($P < 0.01$). Serial renal biopsies showed that the activity score improved ($P > 0.01$), but the chronicity score was unchanged. The level of microscopic hematuria (red blood cells per high-power field) also improved in each of the 10 patients.

In 1994, Murakami *et al.*, in a retrospective study, evaluated the efficacy of a 6-month course of prednisolone at 10–15 mg on alternate days, cyclophosphamide at 1 mg/kg once daily, and dipyridamole at 5 mg/kg once daily in 17 pediatric patients (age 10.4 ± 3.4 years) who had proteinuria of >1 g/m^2/day plus histologic risk factors for progressive disease, and they compared the results to 21 patients (age 10.1 ± 3.0 years) with similar features who received the same regimen plus warfarin for 3 months in a dose that was adjusted to maintain the thrombotest in the anticoagulant range (as stated by the authors) [67]. The dipyridamole therapy was subsequently continued in all patients until the patient had ≤1 proteinuria. The patients were then followed for 2–10 years (mean, 4.8 years). The authors reported that both groups of patients showed significant improvement in proteinuria but noted that chronic histology indices on posttherapy biopsies (performed in 14 patients) were similar to those reported by Andreoli *et al.* [66], in that they showed persistent signs of chronic disease. Subsequent follow-up studies showed rebound deterioration of proteinuria 5–6 years after the therapy was given. These authors speculated

that their protocol was effective in delaying the progression of renal disease in their patients and that more sustained benefit might be achieved with longer courses of therapy, and with agents having less risk of toxicity.

In 1999, Yoshikawa *et al.* reported an RCT evaluating 2 years of therapy in two groups of children: group 1 received prednisone, azathioprine, heparin, warfarin, and dipyridamole; group 2 received heparin, warfarin, and didyridamole [28]. The prednisone dose was 2 mg/kg/day (maximum, 80 mg) for 4 weeks, followed by 2 mg/kg every other day for 4 weeks, 1.5 mg/kg every other day for 4 weeks, and 1 mg/kg every other day for 21 months. The azathioprine dose was 2 mg/kg/day. Although there was no significant change in GFR in either group, group 1 patients had a significant reduction of proteinuria following therapy (1.35 to 0.22 g/day), whereas group 2 patients did not (0.98 to 0.88 g/day). There was also a significant decrease in glomerular IgA staining in follow-up biopsies in group 1 patients but not in group 2. These follow-up biopsies showed progression of glomerular sclerosis in control patients but not in those receiving prednisone and azathioprine.

In a more recent report in 2006, Yoshikawa *et al.* described the results of a second RCT that compared the effects of combination therapy using prednisone, azathioprine, warfarin, and dipyridanole in 40 children versus prednisone alone in 40 children [68]. Both regimens were given for 24 months. The authors did not incorporate any clinical or laboratory entry requirements in their study design, but all patients were required to have diffuse mesangial hypercellularity on initial renal biopsy. Both treatment regimens were associated with remarkable improvement: proteinuria was less than 100 mg/m^2/day at the end of therapy in 92% of the combination therapy group and in 74% of the prednisone group ($P = 0.007$). In addition, whereas the percentage of glomeruli showing sclerotic changes was unchanged from baseline

Table 15.5 Evidence for the use of MMF in IgAN.[a]

Author [reference]	Design	N	MMR treatment	Follow-up (mos)	Results
Maes [69]	RCT	34	2 g/day for 36/12	36	No effect on GFR decline, no effect on proteinuria
Chen [71]	RCT	93	1–1.5g/day for 6/12 1 g/day for 6/12 0.75 g/day for 6/12	18	No effect on GFR decline, ↓ proteinuria
Tang [72]	RCT	40	2 g/day for 6/12	18	No effect on GFR decline, ↓ proteinuria
Frisch [70]	RCT	32	2 g/day for 12/12	24	No effect on GFR decline, no effect on proteinuria

[a] Overall quality low: inconsistent effects, variable quality of RCT design and reporting, small studies, surrogate outcomes.

in the patients receiving combination therapy (5.0% at baseline and 4.6% at follow-up), it was significantly higher at follow-up in those receiving only prednisone (3.1% and 14.6%, respectively; $P = 0.0003$). However, it should be noted the use of ACEi and ARB was prohibited in all of the patients in this trial; hence, it is not clear whether such aggressive immunosuppressive therapy would be the first choice of therapy in clinical practice for patients with laboratory and biopsy features comparable to those of the patients described.

MMF and mizoribine in adults and children

MMF has been used in four major trials for IgAN (Table 15.5). Two studies reported no benefit from MMF (2 g/day) in patients either at risk of progression (hypertensive and/or proteinuria of >1 g /24 h and/or reduced GFR within 5 years of diagnosis) [69] or with more advanced disease (mean serum creatinine at entry, 2.6 mg/dL) [70]. Both of these studies achieved rigorous BP control with use of an ACEi. In two separate studies on patients with less advanced renal impairment, MMF (1–2 g/day) did reduce proteinuria over an 18-month follow-up period, but neither study demonstrated a change in rate of renal decline [71,72]. Again, both studies achieved tight BP control with ACE inhibition.

A recent retrospective study in Japan showed that mizoribine, which blocks purine synthesis in a manner similar to MMF, resulted in a significant reduction in proteinuria when given to 20 pediatric patients in combination with prednisone, warfarin, and

dipyridamole [73]. This was significantly better than the reduction in proteinuria seen in 21 historic control patients who were given only prednisone, warfarin, and dipyridamole, or in 20 historic control patients who also received i.v. pulses of methylprednisone. Follow-up renal biopsies in the mizoribine-treated patients showed no progression of chronic lesions, whereas the other two sets of patients had a significant increase in the chronicity index. A recent pilot study using mizoribine, again in combination with prednisone, warfarin, and dipyridamole, confirmed the efficacy and safety of this regimen in treating children with IgAN [74].

The relatively small size and short duration of the studies to date justify further evaluation of MMF and related compounds, and other studies are in progress [75].

Fish oil in adults

A number of studies have evaluated the role of fish oils (eicosapentanoic acid and docosahexanoic acid in IgAN (Table 15.6). An RCT of 106 patients with proteinuria of >1 g/24 h and impaired renal function at enrollment (60% also hypertensive) found those treated with fish oil had a slower rate of decline in GFR at both 2 and 5 years [76,77]. This effect appeared independent of the dose used [78]. These results have not been replicated in other RCTs studying similar patient cohorts [79–81]. A recent meta-analysis (three trials, 175 patients [76,79,81]) failed to detect a benefit of fish oils on renal outcome in IgAN [82]. Furthermore, a recent RCT showed no benefit following 2 years of treatment with fish oil

Table 15.6 Evidence for the use of fish oil in IgAN.[a]

Author [reference]	Design	N	EPA + DHA daily doses (g)	Follow-up (mos)	Results
Bennett [79]	RCT	37	1.8 + 1.2	24	No effect on GFR decline
Pettersson [81]	RCT	32	3.3 + 1.8	6	↓ GFR, no effect on proteinuria
Donadio [76, 77]	RCT	106	1.8 + 1.2	24 and 60	Slower ↓ GFR
Donadio [78]	RCT	73	3.8 + 2.9 1.9 + 1.5	24	No difference between high- and low-dose EPA–DHA
Hogg [80]	RCT	96	1.88 + 1.48	24	No effect on GFR decline, ↓ proteinuria

Abbreviations: EPA, eicosapentanoic acid; DHA, docosahexanoic acid.
[a] Overall quality low: inconsistent effects, variable quality of RCT design and reporting, small studies, surrogate outcomes.

compared to placebo [80], although a subsequent post hoc analysis of the data in the study revealed a dose-dependent decrease in proteinuria in the fish oil group [77].

Other therapies

Warfarin, urokinase, antiplatelet agents, phenytoin, sodium cromoglycate, dietary gluten restriction, and a low-antigen content diet have all been assessed for the treatment of IgAN and have not been shown to affect renal outcomes [65].

The use of newer immunosuppressive agents, such as leflunomide, rituximab, and sirolimus, while of potential interest for this group of patients, should be considered experimental therapies at this point.

Introduction

The term membranoproliferative glomerulonephritis (MPGN) has been used for many decades to describe a group of glomerular diseases that have in common (by light microscopic examination) a pathologic increase in the cellularity of the mesangium, accompanied by an increase in mesangial matrix, and in which the peripheral capillary walls are thickened and distorted. This capillary wall alteration is the consequence of a disturbance of the glomerular basement membrane structure and/or a layering effect of the capillary wall (double contour) caused by interposition of mesangial cells or trapping of circulating cells between old and newly synthesized layers of basement membrane [1,2]. These abnormalities are most often diffuse and generalized and lead to a simplification of the architecture of the glomeruli and an accentuation of the lobulation of the glomerular capillaries. Extracapillary crescent formation can complicate the pathological picture. The terms mesangiocapillary glomerulonephritis and lobular glomerulonephritis have also been used to describe this group of entities. The strong association of MPGN with hypocomplementemia, discovered by West and coworkers in 1965, also led to the use of "hypocomplementemic persistent (chronic) glomerulonephritis" as an early term for this group of disorders [3].

The light microscopic lesions of MPGN are extremely heterogeneous with respect to underlying immunopathology, ultrastructure, presumed etiology, and pathogenesis. This extraordinary diversity complicates attempts to evaluate the therapeutic responsiveness of the lesions of MPGN. It is not the intent of this chapter to review the origins of this diversity in detail but to provide a brief analysis is in order to help make some sense of the confusing literature on treatment of MPGN.

Classification

The ultrastructural appearance of the light microscopic pattern of MPGN gives rise to several subtypes [1,2]. The most common subtype, accounting for about 60–80% of cases of MPGN, is MPGN type I, which is characterized by subendothelial electron-dense deposits (often presumed to be immune complexes) and regularly contains immunoglobulin G (IgG) and/or C3. The intensity of the C3 deposits tend to predominate over the intensity of the IgG deposits. These deposits may acquire an organized substructure when associated with cryoglobulinemia (such as that associated with chronic hepatitis C viral infection) [4] or a nonamyloid monoclonal immunoglobulin deposition disease (MIDD). A form of type I MPGN due to disturbances in complement dysregulation in which only C3 is deposited in glomeruli has also recently been defined [5,6]. The nephritis associated with systemic lupus erythematosus (SLE) also commonly presents with a membranoproliferative pattern by light microscopy. Chronic thrombotic microangiopathies (such as thrombotic thrombocytopenic purpura [TTP] and hemolytic uremia syndrome [HUS]) can also lead to a pattern superficially resembling MPGN type I by light microscopy but usually without any subendothelial dense deposits by electron microscopy. Amorphous, non-electron-dense, flocculent subendothelial deposits may be seen in this circumstance. Fibrillary or immunotactoid glomerulonephritis can also evoke a pattern of MPGN.

The form of MPGN type I in which deposits of both IgG and C3 are common has been traced to a chronic infection with hepatitis C virus in many cases (80% in Europe, 50–70% in the USA, and rarely in parts of Africa and some developing developing countries) [4,7–9]. Systemic hypocomplementemia (lowered levels of C3 and or C4) are found in 50–70% of patients with MPGN type I. Low C4 and normal or low C3 levels are characteristic of hepatitis C virus-associated MPGN [4,7], especially when mixed IgG/IgM cryoglobulinemia (type II cryoglobulinemia) is concomitantly present [4]. Numerous other chronic infections may also produce a

pattern of MPGN type I, but some cases remain to be explained by an unknown underlying disease (idiopathic MPGN type I). The infection-related glomerulopathies are covered in chapter 23 of this textbook.

In recent years the idiopathic forms of MPGN type I have become increasingly uncommon in developed countries, but they remain a frequent cause of glomerular disease in developing nations [8,9]. Although unproven, it seems likely that many cases of so-called idiopathic MPGN type I, unassociated with any regulatory abnormality of complement metabolism, thrombotic microangiopathy, MIDD, fibrillary glomerulonephritis, or SLE, are in fact examples of chronic infections with as-yet-unidentified organisms (possibly lentiviruses). The disparity in the frequency of MPGN type I in developed compared to developing nations has given rise to the "Hygiene Hypothesis" of Johnson and coworkers [10]. This hypothesis suggests that the high prevalence of MPGN observed in developing countries and its steady decline in prevalence in developed countries is due to poor hygienic conditions in the developing countries and an imbalance of the Th1/Th2 functional subsets of lymphocytes, favoring vigorous humoral and cellular responses to infectious organisms.

The MPGN type II pattern is very distinctive by electron microscopic analysis, accounts for about 10–20% of all cases of MPGN [1,2,11], and is seen more often in children and young adults. In this form of MPGN the glomerular basement membrane is transformed into a thickened layer due to the presence of an electron-dense material in what was previously recognized as the lamina densa. The findings gave rise to the name dense deposit disease as a synonym for MPGN type II [11]. Subepithelial deposits can also be seen, particularly early in the course of the disease or during acute exacerbations associated with hypocomplementemia. Subendothelial deposits are typically absent, in contradistinction to MPGN type I. Variable degrees of mesangial and extraglomerular capillary hypercellularity, including crescents, are also present, and the capillary wall may be thickened due to the presence of the dense intramembranous deposits. MPGN type II is also characterized by extensive deposits of C3 (usually C3c fragment) in the mesangium and in the capillary wall (and can include subepithelial deposits) [12]. IgG and IgM deposits are usually absent or scanty. Similar deposits can be found in extrarenal tissue, including the spleen and Bruch's membrane of the eye, leading to "drusen" in the retina, suggesting that they arise from the circulation [11].

Abnormalities in complement metabolism are very common in MPGN type II, and 80% or more of patients will exhibit a decrease in serum C3 (but not C4) concentration [11]. Acquired and genetic forms of factor H deficiency (a complement regulatory protein) are also particularly common in MPGN type II. An IgG autoantibody to the C3 convertase (C3 nephritic factor, or C3Nef) of the alternative pathway of complement activation is commonly found in hypocomplementemic subjects. MPGN type II is also associated with partial lipodystrophy (Dunnigan-Koeberling syndrome)

[11]. Thus, MPGN type II is very different from MPGN type I in regard to appearance and underlying pathogenesis. Rarely, MPGN type II can evolve as a sequela of postinfectious GN, but most cases are idiopathic. The morphology and pathogenesis of MPGN type II are distinctly different from MPGN type I, and some believe that MPGN type II should not be classified as a form of MPGN at all [13,14]. The light microscopic findings in MPGN type II are quite varied, with only about 25% showing the typical membranoproliferative pattern [13,14].

MPGN type III is very heterogeneous, and some studies have divided this group even further into types IIIA and IIIB, depending on the appearance of the glomerular basement membrane and the deposits [1,2]. MPGN type IIIA, also known as the Strife and Anders variant, is characterized by electron-dense deposits and a disruption of the glomerular basement membrane with fragmentation and multilayering [1,2]. MPGN type IIIB, also known as the Burkholder variant, is characterized by subendothelial, intramembranous, and subepithelial electron-dense deposits, often resembling class IV and class V lupus nephritis [1,2]. Together, MPGN types IIIA and IIIB account for less than 10% of all cases of MPGN. Complement abnormalities, including persistently reduced levels of C3, are very common, occurring in 50–80% of cases.

All three major forms of MPGN can recur in the transplanted kidney, and the frequency of recurrence is more related to the severity of the disease than to the underlying subtype [15]. Because MPGN type II is more commonly associated with crescents and a more progressive course, it is more frequently associated with a recurrence in the allografted kidney. Such recurrence rates for MPGN type II have approached 100% in some series, with at least 50% leading to graft failure [11].

A light microscopic pattern resembling MPGN can also be observed in MIDD (kappa light chain nephropathy), complement regulatory protein deficiencies (factor H and I deficiency), fibrillary glomerulonephritis, lupus nephritis (class IV and class V), chronic thrombotic microangiopathy (TTP and HUS), chronic allograft nephropathy, some cases of diabetic nephropathy (nodular diabetic glomerulosclerosis), and in idiopathic lobular glomerulopathy. These disorders can generally be distinguished from MPGN secondary to hepatitis C virus infection or idiopathic forms by careful immunohistological and electron microscopic analysis [1,2,4] supplemented by serological analysis. Genetic analysis may be required in some cases of complement regulatory disturbances [11].

In summary, the light microscopic lesions of MPGN encompass an extremely diverse group of disorders. It is not surprising that the results of treatment have been so varied, since each therapeutic study may have examined a collection of subjects with different underlying pathogenetic alterations. Failure to recognize important etiologic factors, particularly concomitant hepatitis C viral infection (4), but also monoclonal immunoglobulin deposition diseases, thrombotic microangiopathies, or complement regulatory abnormalities, may have also contributed to the varying results

of treatments as reported in the literature, particularly those appearing before 1990.

Clinical features and natural history

Despite the morphologic and pathogenetic heterogeneity of the subtypes, the clinical presentation of MPGN is rather uniform and quite independent of subtype [1,2]. Proteinuria, commonly evoking the nephrotic syndrome, hematuria (gross and microscopic), hypertension, and impaired glomerular filtration rate (GFR) are frequent presenting findings. The discovery of hypocomplementemia (reduced levels of C3 and/or C4 or lowered C/H50) is the feature which distinguishes MPGN from the other forms of primary idiopathic glomerular disease (minimal change disease, focal and segmental glomerulosclerosis, membranous nephropathy, and IgA nephropathy seldom, if ever, display hypocomplementemia). Once a renal biopsy diagnosis of MPGN is made,

additional studies are always indicated to properly assign the patient to an etio-pathogenetic category, if possible (Figure 16.1).

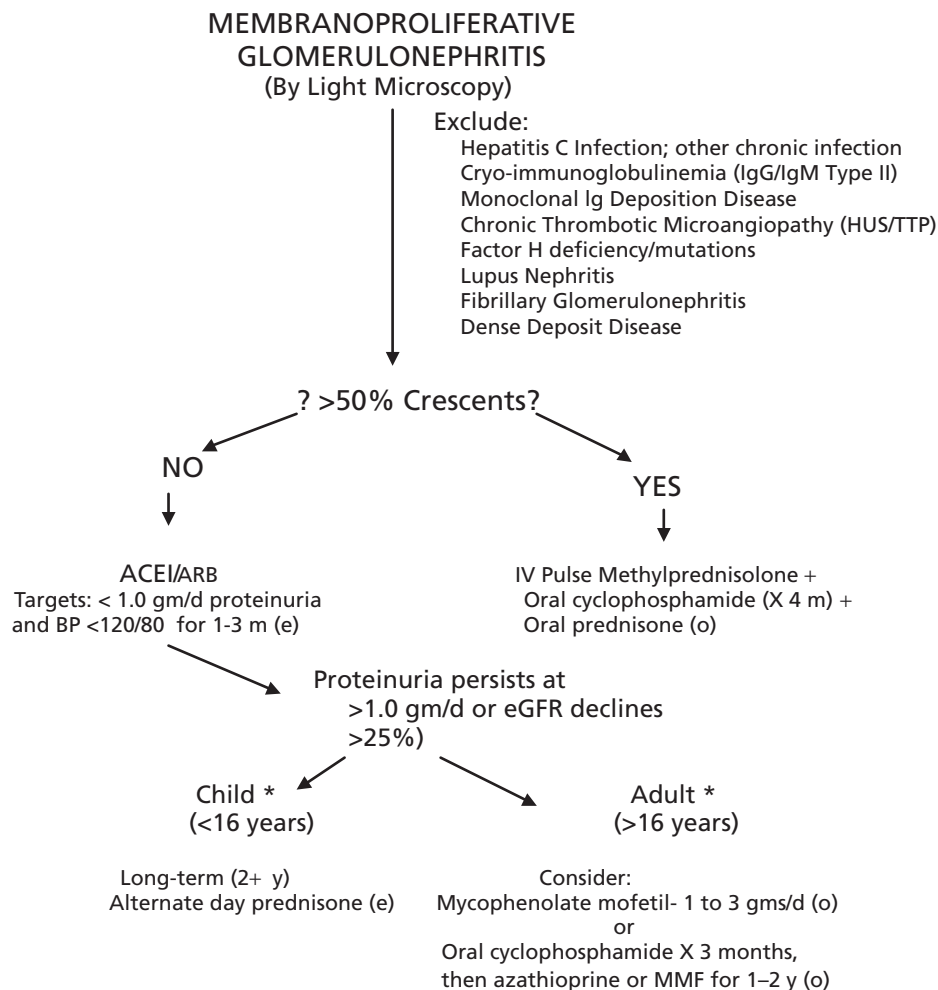
If MPGN type I is found, then a search for an underlying infection (particularly hepatitis C viral infection), a monoclonal immunoglobulin deposition disease, an autoimmune disease (such as SLE), a complement regulatory abnormality, or another systemic disease should be sought. If MPGN type II is found, then a complement regulatory abnormality (particularly factor H deficiency and mutations in the *CFH* gene) should be investigated and a search made for extrarenal deposits (in the eye with an ophthalmologic search for retinal drusen) as well as an examination for lipodystrophy [11,16]. If MPGN type IIIA or IIIB is found, then a search for autoimmune disease (particularly SLE) or a chronic infection is in order. If an "organized" substructure of the electron-dense deposits is observed by electron microscopy, then an evaluation for cryoglobulinemia or an MIDD is in order. Only after all of these searches prove negative can one reasonably assign the label "idiopathic" to a case of MPGN identified by light microscopy of a renal biopsy.


Figure 16.1 Suggested algorithm for evaluation and treatment of MPGN. (e), evidence based; (o), opinion based; *, MPGN type I only.

A contemporary analysis of the natural history of MPGN (unmodified by any specific therapy), and all of its varieties, is extraordinarily difficult. The reasons for this are multiple. Older studies did not take into account the possible influence of concomitant infection with hepatitis C virus or the presence of complement regulatory protein abnormalities [4,16]. Many observational studies included patients treated with various regimens; direct comparisons of outcomes among such studies are not possible. Many studies did not take into account the impact of length and lead-time bias when cases were identified through screening efforts [17]. Changes in conservative therapy, particularly the more extensive use of antihypertensive agents (including angiotensin II inhibitors) may have changed outcomes in those subjects with more severe levels of proteinuria and/or hypertension.

Despite these limitations, general statements can be made regarding factors that appear to be associated with a progressive course leading to end-stage renal disease (ESRD) and factors which are associated with a more benign outcome, even including spontaneous clinical remission. Broad agreement exists that persistence of nephrotic-range proteinuria (>3.0 g/g of creatinine in a spot urine sample in an adult or >40 mg/h/m^2 in a child) is associated with a poor prognosis. Elevation of serum creatinine into the abnormal range at the time of discovery and the presence of hypertension (blood pressure >140/90 mmHg) are also signs portending an unfavorable outcome [1,2]. By contrast, the presence of hematuria and its severity have variable effects on outcome. Marked hematuria (>500,000 erythrocytes/mL of uncentrifuged urine) is strongly associated with the presence of crescents, which usually confers a less favorable prognosis. The presence and magnitude of hypocomplementemia in MPGN is generally of little consequence from the standpoint of prognosis. Concomitant infection with hepatitis C virus often confers a worse prognosis, although this may be altered by successful eradication of the infection (see below) [4]. Patients with MPGN who have normal renal function at discovery and have persistent nonnephrotic proteinuria seldom progress to ESRD [18].

Pathological features of the renal biopsy at the time of diagnosis also impact on determination of likely outcomes. Extensive crescentic disease (>50% involvement of glomeruli) is associated with a highly unfavorable course (in the absence of treatment) [1,2]. Extensive glomerulosclerosis, tubulo-interstitial fibrosis, and tubular atrophy signify an established chronic process and indicate a future likelihood of further progression. Such findings often are strongly associated with an elevation of serum creatinine levels. Whether the subvarieties of MPGN (types I, II, and III) really have differing prognoses, independent of the severity of the disease (e.g. presence of nephrotic syndrome, superimposed crescentic disease, glomerulosclerosis, interstitial fibrosis) remains uncertain [15,19–24]. Claims have been made that MPGN type III has a more benign evolution than either MPGN type I or type II [23,24]. Whatever the true state of affairs may be, it is reasonable to assume that the majority of patients with MPGN and persistence of nephrotic syndrome will show progression toward ESRD, but at variable rates. Overall renal survival (free of the need for

renal replacement therapy) is in the vicinity of 60–80% at 10 years from the time of diagnosis, with a mean renal survival of about 8 years for those patients with MPGN who have persisting nephrotic syndrome [1,19].

Characterization of the overall long-term renal survival (5 and 10 years after diagnosis) for untreated idiopathic MPGN can be in part reconstructed from reports in the literature. Some factors that limit the accuracy of these predictions have been mentioned previously and include the following: 1) lead-time bias for patients discovered during screening; 2) lack of stratification of patients into hepatitis C virus-positive and -negative cases; 3) inclusion of treated patients in observational studies of prognosis; 4) lack of information regarding the degree of blood pressure control and the use of agents affecting angiotensin II action; 5) lack of detailed information regarding concomitant renal lesions affecting outcome (e.g. crescentic involvement); 6) failure to stratify patients according to the presence and persistence of complement regulatory dysfunction, thrombotic microangiopathy, or monoclonal immunoglobulin deposition disease.

Despite these caveats, approximate values for the anticipated renal survival in groups (but not individuals) not receiving any specific therapy for MPGN can be gleaned from the placebo or untreated arms of the reported randomized controlled trials of specific therapies (see also below).

For example, in the open-label, randomized controlled trial of therapy for MPGN in children and adults reported by Cattran *et al.* in 1985, the control group (*n*= 32) who received no specific therapy displayed a 2-year renal survival of 85% in MPGN type I and 90% in MPGN type II [25]. All of these patients had an initial creatinine clearance of <80 mL/min/1.73 m^2 and proteinuria of >2.0 g/day at entry. It is also noteworthy that in this study 8 of 32 control patients achieved a spontaneous clinical remission. In the randomized, placebo-controlled trial of treatment of MPGN reported by Tarshish *et al.* in 1992 (completed in 1980), the actuarial renal survival (stable renal function) in the placebo group (*n*= 40) was only 12% at 130 months, and a progressive decline of renal function was noted in about 60% of the placebo group [26]. In this study 52% had MPGN type I, 17% had MPGN type II, and 30% had MPGN type III or other types of MPGN. The hepatitis C virus status of these patients was not known.

In the randomized, double-blind placebo-controlled trial of therapy for MPGN type I (hepatitis C status unknown) reported by Donadio *et al.* in 1984, the average decline in GFR was 19.6 mL/min/year/1.73 m^2 in the placebo group [27]. A total of 9 of 19 patients in the placebo group developed ESRD after 33 months. However, a later reappraisal of this study suggested that the poor prognosis observed in the placebo group could be accounted for by the long duration of disease prior to entry into the randomized trial [17].

Observational studies involving untreated patients can also give some insight into the natural history of MPGN, but these studies are also confounded by lack of information concerning control of blood pressure, use of angiotensin II inhibition, and stratification of underlying disease (e.g. hepatitis C viral infection). In

2004, Cansick *et al.* studied the long-term outcome of 53 children with MPGN (58% type I, 26% type II, and 16% type III and others) [19]. The median follow-up was 3.5 years (range, 0–17 years). Twenty-nine of the 53 children were treated with steroids in an uncontrolled manner. Overall renal survival (including the treated patients and patients without nephrotic syndrome) was 92% at 5 years and 83% at 10 years. In the group of patients with nephrotic syndrome at discovery, the mean renal survival was 8.9 years compared to 13.6 years when nephrotic syndrome was absent. In the study by Chan *et al.* in 1989, 27 of 46 (59%) patients with MPGN (including 20% with hepatitis B virus infection) developed or died of ESRD within a follow-up period averaging 60 months, with no differences in outcome between a treated group (*n* = 19) and an untreated group (*n* = 27) [21]. In a recent report by Fujita *et al.*, the prognosis for untreated "atypical" (unclassifiable) forms of MPGN has been quite favorable (five of six underwent a spontaneous clinical remission after a 10-year follow-up) [28].

In summary, it is a challenging task to reconstruct a consistent pattern of long-term outcome for untreated MPGN from an inspection of the contemporary literature. Very clearly, the presence of nephrotic syndrome connotes an unfavorable prognosis, with a 50% actuarial renal survival being reached at somewhere between 5 and 9 years after discovery. Impaired renal function in addition to nephrotic syndrome would likely indicate an even more unfavorable prognosis, but the outcome would also depend on the severity of hypertension and its treatment with angiotensin II inhibition. Spontaneous clinical recovery appears to be more likely when patients are discovered during screening surveys in childhood and perhaps in those with atypical forms of MPGN. Concomitant hepatitis C virus infection likely confers a worse prognosis, but this has not been well-studied [4]. Overall renal survival of MPGN type I patients among treated and untreated adults and

children averages about 60% at 10 years (range, 50–80%), with children having a somewhat more favorable outcome than adults [21,24].

Evidence base for treatment decisions

Randomized controlled trials

Given the extraordinary diversity of the group of disorders covered under the generic heading of MPGN, it is not surprising that the evaluation of the evidence for treatment of MPGN leads down a controversial and generally confusing path. Unfortunately, much of the evidence bearing on the question of treatment is observational and uncontrolled, and even the limited number of controlled trials that have been conducted thus far have had serious flaws (in design or execution) or limitations in light of contemporary knowledge regarding MPGN. Only six randomized, controlled trials (involving fewer than 270 patients with MPGN) have been conducted, completed, and reported for MPGN to date (Table 16.1).

One study by Cattran and colleagues [25] evaluated the effects of combinations of cyclophosphamide, dipyridamole, and anticoagulants. This study failed to show any difference between control and treated groups but may have been underpowered to show a difference even if one existed. Two studies of alternate-day glucocorticoids alone (Tarshish *et al.* [26] and Mota-Hernandez [24]) and two studies of dipyridamole and aspirin (Donadio *et al.* [27] and Zauner *et al.* [30]) have been conducted. One of the two dipyridamole–aspirin trials failed to show any difference between treatment and control groups upon reappraisal (Donadio *et al.* [17]). One additional nonrandomized crossover trial of warfarin and dipyridamole was reported in 1983 by Zimmerman *et al.* [31]. A randomized trial of cyclophosphamide, anticoagulants,

Table 16.1 Key characteristics of randomized and controlled or cross-over trials of therapy in MPGN (in order of year of publication)

Study	No. of patients	MPGN type	Design	Results
Tiller *et al.*(1981)	39 (A)	I/II	Open-label, CP/Wa/S vs. no therapy	Inconclusive; underpowered
Mota-Hernandez *et al.* (1982)	18 (C)	I	Placebo vs. alt-day steroids	Reduced ESRD
Zimmerman *et al.* (1983)	18 (A)	I	Cross-over, open label Wa/DiP vs. no therapy	Better renal function in unpaired analysis but not with paired analysis
Donadio *et al.* (1984)	40 (A)	I	Double-blind, placebo vs. aspirin/DiP	Better GFR (not confirmed in later analysis)
Cattran *et al.* (1985)	59 (A/C)	I/II	Open-label, CP/Wa/DiP vs. no therapy	No benefit for renal function or proteinuria (25% remission in control)
Tarshish *et al.* (1992)	80 (C)	I/II/III	Double-blind, placebo vs. alt-day steroids	Nonsignificant ($P = 0.07$) trend for better renal function
Zauner *et al.* (1994)	18 (A)	I/II	Open-label, nonplacebo vs. aspirin/DiP	Reduced proteinuria, no GFR change
Giri *et al.* (2002)	30 (A)	I	ACEi vs. non-ACEi	Improved renal function and proteinuria in ACEi group

Abbreviations: A, adults; c, children; S, steroids; CP, cyclophosphamide; Wa, warfarin; DiP, dipyridamole; ACEi, angiotensin converting enzyme inhibitor.

and steroids was interrupted after randomization of 39 subjects due to difficulty in recruiting subjects [32]. No differences in the outcomes for treated and control groups were observed in this study, but the power to detect differences in outcomes was very low. An additional study of angiotensin II inhibition has also been reported (Giri *et al.* [33]). Due to the paucity of trials and the heterogeneity of the studies, no meta-analyses specifically directed to MPGN have been conducted to date; however, Schena has conducted a meta-analysis of immunosuppressive therapy of nephrotic syndrome due to primary glomerulonephritis in adults, which included an analysis of MPGN [34]. Schena concluded that no benefits of immunosuppression in MPGN could be determined because of the substantial imprecision around the point estimates of effect due to sparse data (wide confidence limits). It is important to point out that the entire randomized trial evidence base for treatment of MPGN comes from trials conducted 12–26 years ago. One might legitimately ask how relevant these studies are for the "modern" approach to management of MPGN. Nevertheless, it is appropriate to describe these studies in some detail, especially to point out their strengths and weaknesses.

The study by Cattran *et al.* was an open-label, nonblinded, randomized prospective trial (untreated patients served as controls) [25]. A total of 59 patients (adults and children) with MPGN were randomized to receive cyclophosphamide, warfarin, and dipyridamole for 18 months or no specific therapy. At entry, all patients had an endogenous creatinine clearance of <80 mL/min and >2.0 g of protein in the urine/day. Both MPGN type I and type II were included. The actuarial renal survival rate was not different between the treated and nontreated groups at 2 years, and there was no difference in the outcome of MPGN type I and type II. No differences in protein excretion rates were noted in either group at any time. There was no influence of the initial level of renal function on the subsequent rate of decline in creatinine clearance, as assessed by the slope of 1/serum creatinine. This negative study was underpowered to show a difference even if it existed, and too few patients with MPGN type II were randomized to make any statement regarding efficacy of therapy in this variant of MPGN.

The study by Tarshish*et al.* was actually completed 12 years earlier than it was published, and it was conducted as part of the International Study of Kidney Disease in Children (26). This study was a randomized, double-blind, placebo-controlled study of long-term alternate-day prednisone therapy (40 mg/m^2 every other day) in MPGN. A total of 80 patients (all children) were randomized, including 42 with type I, 14 with type II, 17 with type III, and 7 with nonclassified MPGN. Only patients with nephrotic syndrome and an initial GFR of >70mL/min/1.73 m^2 were included. The mean duration of therapy was 41 months. Treatment failure was the main prespecified end point of the study, and it was defined as achieving an increase in serum creatinine from baseline of 30% or more or an absolute rise of serum creatinine of >35 μmol/L from baseline. It is noteworthy that the mean duration of disease prior to randomization was only 8.9 months in the prednisone-treated group

and 18.1 months in the placebo-treated group ($P < 0.05$). This baseline difference is likely to have biased the results of the study. Actuarial renal survival showed a nonsignificant ($P = 0.07$) trend to better survival in the treated group (61% in treated vs. 12% in the placebo group at 130 months of follow-up). Overall treatment failure occurred in 40% of the prednisone-treated group versus 55% in the placebo-treated group (not significant). In a secondary analysis which excluded MPGN type II and the unclassified forms of MPGN, the prednisone-treated group had only 33% treatment failures while the placebo-treated group had 58% treatment failures. These differences in outcome were not noted until after 90 months of observation, when only 11 prednisone-treated and 7 placebo-treated patients were still under observation. The power of the study to detect differences was small (0.35). In general, treatment was well-tolerated except for a tendency of prednisone to aggravate hypertension (which could have biased the study in favor of the placebo treatment). Overall, one would have to regard this study as negative (or at best, inconclusive) and underpowered, despite the presence of trends favoring treatments. The differences in the time between discovery and randomization between the treated and placebo groups and the differences in blood pressure between the groups could easily have confounded the results.

Mota-Hernandez *et al.* conducted a placebo-controlled study in children with MPGN [29]. In this study 18 patients were randomized to receive prednisone or a placebo and were followed for up to 5 years. One of nine patients in the prednisone group developed ESRD compared to four of nine patients in the placebo group. Repeat kidney biopsies at 3 and 5 years showed improvement in mesangial hypercellularity and resolution of deposits. Tubulointerstitial lesions did not improve, except in those whose proteinuria remitted. The small number of patients enrolled in this study precludes any definite conclusions, but the trend toward improvement was noticeable. Thus, the evidence for efficacy of alternate-day prednisone treatment of MPGN must remain suggestive but inconclusive.

Two studies have examined the efficacy of combined aspirin and dipyridamole therapy in MPGN. Donadio *et al.* conducted a randomized, double-blind, placebo-controlled trial of dipyridamole (225 mg/day) and aspirin (975 mg/day) for 1 year in 40 adult patients with MPGN type I [27]. Abnormal platelet survival at baseline was corrected by this treatment. Three of 21 patients receiving active therapy developed ESRD after 62 months of follow-up, compared to 9 of 19 after 33 months of follow-up in the placebo group. The main end point of the study was the change in measured GFR over time. The analysis was not by intention-to-treat. The GFR declined by 1.3 mL/min/1.73 m^2/year in the active drug-treated group and declined by 19.6 mL/min/1.73 m^2/year in the placebo group ($P < 0.01$). Mild bleeding complications, requiring discontinuance of treatment (but no transfusions), were noted in about 15% of patients. The initial interpretation of this study was that dipyridamole and aspirin therapy slows progression of renal disease in MPGN type I. However, 5 years later the same authors

reanalyzed the data from this trial [17]. When the results were examined in a fashion enabling comparisons of the two groups from the time of onset of therapy (from randomization) rather than from the time of onset of disease, no differences in patient survival or survival free of renal failure were demonstrated. The previously suggested benefits of dipyridamole and aspirin were an artifact of differential lengths of observation from clinical onset of disease. Similar biases are likely to be present in observational studies utilizing historical controls for comparison purposes (see below).

Zauner *et al.* and the German Collaborative Glomerulonephritis Study Group conducted a further randomized, open-label, non-placebo-controlled trial of dipyridamole (75 mg/day) and aspirin (500 mg/day) for 36 months in 18 adult patients with MPGN (type I in 15 and type II in 3) [30]. All patients had impaired renal function and heavy proteinuria at randomization. Proteinuria declined significantly in both groups, but to a greater extent in the active drug-treated group ($P < 0.05$). A total of 7 of 10 patients reached a partial remission in the treated group, while only 2 of 8 reached a similar level of remission in the control group ($P < 0.05$). There was no difference in serum creatinine values in either group postrandomization, but the observation period was probably too short to show any difference in progression of renal disease between the two groups. The decline in proteinuria also might have been due to better blood pressure control in the treated group.

Thus, there is no consistent evidence of efficacy for a combination of dipyridamole and aspirin in slowing the rate of progression of renal disease in MPGN, but all studies so far reported have been underpowered to show such an effect even if it were present. No controlled studies of this form of therapy have been conducted in children.

A prospective, open-label trial with a crossover design utilizing warfarin and dipyridamole was reported by Zimmerman *et al.* in 1983 [31]. Eighteen patients with MPGN, primarily type I, completed either a control or an active treatment year, whereas 13 patients completed both a control and an active treatment year. The analysis involved both unpaired (10 patients in an initial control year compared to 8 patients receiving treatment first) and paired comparisons (13 patients). In the unpaired comparisons, renal function (as assessed by the slope of 1/serum creatinine) was preserved in the treated group but deteriorated in the control group ($P < 0.025$). Proteinuria also fell in the treated group. Doubling of the serum creatinine occurred in 40% of the control group but in 0% of the treated group. Paired analysis of the crossover patients tended to support the findings in the unpaired analysis, but the overall differences were insignificant. Bleeding complications were frequent (cerebral, gastrointestinal, menorrhagia, and hematuria) and were the primary cause for dropping out from the study. Although this small study was encouraging, the findings have never been confirmed in a separate randomized controlled study analyzed using intention-to-treat principles, and the side effects of anticoagulation were sufficient to dampen enthusiasm for this approach to treat MPGN, despite the well-known involvement

of coagulation and platelet aggregation in the disorder. There is good reason to suggest that this study needs to be repeated in a randomized, double-blind, placebo-controlled fashion using modern anticoagulant drugs that have a more favorable profile of bleeding complications in order to evaluate its status as an approach to treatment of MPGN.

Finally, inhibition of angiotensin II action has been clearly demonstrated in randomized, controlled clinical trials to have beneficial effects on the course of many forms of proteinuric renal disease [35]. The effects are mediated both by better control of blood pressure and by a reduction in proteinuria. Many of these trials have included small numbers of patients with MPGN, with too few to justify a specific independent evaluation of angiotensin II inhibition on MPGN. Only one randomized controlled trial examined the specific effects of angiotensin II inhibition in MPGN. Giri *et al.* conducted a small, randomized, controlled trial of angiotensin II inhibition in patients with MPGN and mild to moderate renal insufficiency (serum creatinine of >1.4 mg/dL) [33]. All patients were controlled to the same level of blood pressure (<140/90 mmHg). Three groups were studied: group I, a control group with BP controlled to <140/90 mmHg with non-angiotensin II inhibition or calcium channel blockers; group II, a group treated with nifedipine at 30 mg/day; and group III, a group treated with nifedipine at 30 mg/day and enalapril at 10 mg/day. Each group consisted of only 10 patients. After 9 months of observation, serum creatinine and albuminuria increased in the control group, whereas serum creatinine and albuminuria decreased in the enalapril-treated group. There was no change in serum creatinine in the nifedipine-treated group, but albuminuria did increase. All patients had adequate blood pressure control during the observation period. Even though they are of a short-term nature, these findings are quite consistent with those of other larger and longer-term studies of other forms of glomerular disease and proteinuria. They add to the evidence base, which suggests that all patients with MPGN (regardless of type) and abnormal blood pressure or proteinuria should be treated with angiotensin II inhibitors with a goal of blood pressure control (to values of <130 mmHg systolic) and reduction of proteinuria to values of <500 mg/day.

In summary, the evidence base concerning efficacy of treatment strategies from randomized controlled trials in MPGN is weak and inconsistent (a very low to low level). Moderate evidence of efficacy for long-term alternate steroids is available for children only. Combinations of dipyridamole and aspirin do not appear to be consistently effective over long-term periods of observation in adults with MPGN, even though they are remarkably safe and may produce a reduction in proteinuria over the short term. Multidrug immunosuppressive–anticoagulant–antithrombotic therapy using cyclophosphamide, warfarin, and dipyridamole did not appear to be effective in MPGN, but studies were underpowered to show such an effect and the entry criteria for the studies may have diminished the likelihood of observing any benefit. Combinations of anticoagulants and antithrombotics (warfarin

and dipyridamole) may be effective in MPGN but have an undesirable profile of side effects (bleeding). The best-studied and probably most effective measure is to employ inhibitors of angiotensin II in patients with proteinuria with the goal of reducing blood pressure and proteinuria.

Observational, uncontrolled studies

The majority of published data on the natural history and treatment of MPGN are in the form of observational, uncontrolled studies. The weaknesses of such studies are readily apparent and have been emphasized by Donadio and Offord [17]. At best they are hypothesis-generating rather than proof of efficacy. They are also subject to publication bias (positive studies are selected for reporting), so that compilation of the results of multiple studies cannot be relied upon to give a true reflection of overall efficacy. Despite these caveats, observational studies can give clues to the existence of therapies that might have beneficial effects. Due to the uncommon occurrence of MPGN (at least in developed countries), such reports may be the only data which can be generated, as randomized trials with adequate power are extraordinarily difficult to execute for MPGN.

The use of long-term (6–8 years), high-dose, alternate-day glucocorticoid (prednisone) therapy of MPGN has attracted the most attention in observational studies. Beginning with the pioneering efforts of the Cincinnati group (West, McEnery, McAdams, Strife, and Braun), benefits of long-term, alternate-day steroids have been suggested to modify the course of MPGN in children [36–38]. Renal survival was improved in treated patients compared to historical controls (particularly when diffuse mesangial cell proliferation was seen on initial renal biopsy). Cumulative renal survival of 82% at 10 years and 56% at 20 years has been reported. These renal survival values are superior to those reported in untreated patients, but direct comparison is hazardous because of differences in baseline conditions in the different groups (e.g. presence of impaired renal function at baseline, nephrotic syndrome, etc.). Serial biopsies in treated patients have shown improvements in histopathology [36–40]. A return of urinalysis values to normal has been observed in about 30% of treated patients [41], whereas spontaneous remissions are thought to be uncommon in MPGN. Hematuria, proteinuria, and hypoalbuminemia also improve with steroid therapy. Stable or normal renal function is seen in about 75% of patients, while 25% deteriorate under treatment. These findings have been supported by other independent observational studies. Differences in "responsiveness" to treatment among the various subtypes have also been reported. Braun *et al.* found that MPGN type I was most responsive to alternate-day steroid therapy, whereas MPGN type III was unresponsive, progressive, and showed a tendency for more relapses [38]. Hypocomplementemia was also more persistent in MPGN type III than in MPGN type I.

Early therapy with steroids, before renal function is impaired, may be more effective than delayed therapy, but this has not been well-established [42]. Limited courses of steroids may also be effective, at least over the short term [40–44]. Patients with MPGN who do not have nephrotic syndrome tend to have a more favorable

course, and the purported benefits of steroids seen in nephrotic children have not been replicated in nonnephrotic children with MPGN [18]. Rarely, clinical remission may occur after steroid therapy is discontinued [45].

Pulses of high-dose methylprednisolone followed by short-term daily oral prednisone have been studied in small observational trials [40,43,44,46]. Bahat *et al.* recently reported on a small, uncontrolled observational trial of intravenous pulse steroid therapy ($n = 11$) compared to oral steroid therapy ($n = 8$) in children with MPGN. After a follow-up period of about 6 years, 1 of 11 in the pulse steroid therapy group and 4 of 8 in the oral steroid therapy group had developed ESRD [47]. About 60% of patients "improved," but follow-up was short (averaging 27 months) in most studies, so long-term benefits of this approach to therapy are unknown, although the observational studies are encouraging. The combination of pulse methyl prednisolone, short-term oral steroids, and dipyridamole may allow for earlier discontinuance of steroid therapy without sacrificing putative benefits. No comparison of this regimen and the high-dose alternate-day regimen has been reported, so it cannot be claimed that one is better than the other. The benefits of steroids in MPGN type II are much less well understood. No evidence of efficacy has been noted in very limited analyses. Other, atypical (nonclassifiable) forms of MPGN may have a more favorable course, even without therapy [28].

Thus, observational and uncontrolled studies have rather consistently demonstrated beneficial effects of steroid therapy (using a variety of regimens) in children with MPGN type I. Publication bias may have been involved in these studies, however. Side effects are important considerations, since long-term steroids can produce growth retardation, osteopenia, cataracts, diabetes, psychiatric abnormalities, and obesity. Hypertension may be aggravated by this therapeutic approach and requires very careful observation and aggressive therapy. Observational studies of steroid therapy alone, either alternate day, daily, or pulse, in adults with MPGN are very limited and inconclusive.

Observational studies of aspirin and dipyridamole combinations for MPGN are very limited. In general, reduction in proteinuria and stabilization of renal function have been seen [46,48], especially when combined with steroid therapy [46].

Combinations of cyclophosphamide, warfarin, and dipyridamole were among the first therapies examined for MPGN. Very impressive and favorable results were reported by Kincaid-Smith as early as 1972 [49]. Many patients treated in this manner also had "malignant hypertension," and some of the benefits observed may have been due to better control of blood pressure rather than a specific effect of the combination therapy. Patients with an initial creatinine clearance of <31 mL/min nearly always deteriorated, whereas six of eight patients with creatinine clearances of >31 mL/min improved with this therapy. The overall 3-year survival was 85% in the treated group ($n = 16$) versus 0% 3-year survival in a historical control group of 13 untreated patients [49]. Similar results were reported 8 years later by Chapman *et al.*, who employed a regimen of azathioprine, warfarin, dipyridamole, and steroids in a small group of 10 patients with MPGN, including

4 with MPGN type II [50]. In 1994, Faedda and coworkers reported an uncontrolled trial of pulse methylprednisolone, oral prednisone, and cyclophosphamide in 19 patients with MPGN (4 of whom had MPGN type II) [51]. After 10 months, 15 of 19 entered remission, 3 of 19 improved, and 1 of 19 progressed. Relapses occurred in 6 of the 15 patients who remitted, and those who were retreated for a relapse all improved. As a whole group, serum creatinine changed from 165 μmol/L (1.9 mg/dL) before treatment to 156 μmol/L (1.8 mg/dL) during therapy and to 224 μmol/L (2.5 mg/dL) at the end of follow-up. Urine protein excretion declined. No data were given on blood pressure control. These very impressive results of combined steroid and cyclophosphamide therapy of MPGN have not yet been replicated in a controlled, randomized trial.

Thus, combinations of immunosuppressive agents and steroids (orally or as intravenous pulses) or anticoagulants or antithrombotics have shown beneficial effects in observational, uncontrolled studies. The lack of controls and the possibility that other concomitant measures (such as better blood pressure control) contributed to the positive findings must be mentioned as mitigating factors. Obviously, a controlled randomized trial is needed to confirm these very suggestive observations.

Other agents have also been used to treat MPGN. Published studies are generally small, are of short duration, and lack controls. The use of nonsteroidal anti-inflammatory drugs (NSAIDs) was advocated based on longitudinal, uncontrolled studies conducted in the 1970s and 1980s [52–54]. Results equivalent to those claimed by advocates of the alternate-day steroid regimens were observed. This form of therapy fell into disuse as the potential renal-damaging and gastrointestinal effects of NSAIDs became recognized. No controlled studies were ever performed. Cyclosporine or tacrolimus have also been suggested as effective agents for MPGN, but the basis for these claims are a few case reports, and publication bias needs to be considered [55–58]. Buckley's syndrome (hyper-IgE syndrome) associated with MPGN apparently responds to cyclosporine [57].

Mycophenolate mofetil (MMF) has emerged as a promising new agent for the treatment of MPGN [59–63]. Approximately a dozen patients have been treated with MMF combined with steroids in various dosages (usually 2.0 g/day or less of MMF for 6 months to 1 year) with substantial decline in proteinuria and stabilization or improvement in renal function in the majority of reports. Side effects have been mild, usually consisting of leukopenia and/or diarrhea at higher doses. These adverse effects are self-limited and improve with reductions in dose. Improvement in renal function and/or proteinuria is not seen in all cases, and the follow-up has been very short in most reports. A randomized controlled trial is needed to evaluate the significance of these anecdotal reports and to separate the effects of the concomitant use of steroids from the effects of MMF. A single case report of MPGN arising in a patient with X-linked agammaglobulinemia during intravenous immunoglobulin therapy reported that the patient responded with a complete remission following pulse methylprednisolone therapy alone [64].

Plasma replacement and/or plasma exchange could theoretically be of benefit in patients with MPGN types I or II due to deficiencies in factor H or I, but this has not yet been rigorously tested (see below).

MPGN can frequently recur in a transplanted kidney, especially when the disease is severe and progressive or associated with crescentic involvement [15, 65]. All types of MPGN can recur, but this event is most common in MPGN type II, largely due to the greater severity of this variant and its more common association with crescentic disease [15,65,66]. Recurrent MPGN often leads to loss of graft function. Treatment of recurrent disease is quite uncertain, but recent studies suggest a possible role for intensive plasma exchange, cyclophosphamide, or high-dose MMF (3.0 g/day) [66–68].

The therapy of hepatitis C virus infection-associated MPGN type I [4] is discussed in chapter 25 and will not be reviewed here. It is likely that some of the studies quoted and analyzed in prior sections of this report included patients with unrecognized hepatitis C virus infections [1,4,7]. Many of these patients also have mixed essential cryoglobulinemia (type II cryoglobulinemia), and they may also have overt chronic liver disease. All patients presenting with MPGN type I are now routinely tested for antibodies to hepatitis C virus and often are also examined for circulating hepatitis C virions by reverse polymerase chain reaction. Thus, it should not be difficult to separate MPGN type I due to hepatitis C from the idiopathic forms of MPGN type I. The former predominate in Western cultures, but the latter are seen more frequently in developing countries, such as in Africa [7–9].

The management of MPGN type II (dense deposit disease) requires special consideration, as detailed in a recent special communication based on the Hixton Retreat of the Dense Deposit Disease Focus Group [16]. According to an analysis from the Hixton Retreat group, if MPGN type II is diagnosed by renal biopsy and ultrastructural examination, serologic assays for C3 nephritic factor (C3Nef) and factor H gene (*CFH*) mutations should be performed. If assays for C3Nef are positive (expected in about 75% of cases), then a trial of plasma exchange–plasma infusion and/or rituximab should be attempted. No prospective trials have been conducted to evaluate the safety or efficacy of this approach. If a *CFH* mutation is found (expected in about 15–25% of cases and presumably associated with a functional deficiency of the complement regulator factor H), then therapy with plasma infusion is indicated. Anecdotal and experimental evidence is available to support such a recommendation [16,69]. If neither C3Nef nor a *CFH* mutation is found, then empirical therapy with eculizumab (Soliris; Alexion Pharmaceuticals, Inc., Cheshire, CT), a monoclonal antibody directed to the C5 component of the complement cascade that inhibits complement-mediated cell injury, could be initiated. Eculizumab is approved by the US Food and Drug Administration for treatment of paroxysmal nocturnal hemoglobinuria but has not yet been studied for MPGN type II. Sulodexide, a proprietary mixture of sulfated glycoso-aminoglycans, has also been suggested for therapy, but no trials have been conducted as yet [16]. It is apparent that steroids administered in conventional

dosages are ineffective for MPGN type II, and immunosuppressive agents would not likely be effective either [16]. High-dose pulse steroid therapy combined with cyclophosphamide and plasma exchange may be tried for MPGN type II associated with extensive crescents and rapidly progressive glomerulonephritis, but there is no clear evidence for efficacy and safety for this approach. Very rarely, steroid therapy may be effective in acute nonproliferative glomerulonephritis, which can be confused with MPGN type II in children [70]. The role of mutations in the factor H gene in the production of both MPGN types I and II and glomerulonephritis with isolated C3 deposition [5,6] and HUS is gradually becoming better understood, especially because of the availability of animal models of disease [71–74].

Treatment of the underlying plasma cell dyscrasia in MPGN type I associated with MIDD is nearly always indicated.

Management of thrombotic microangiopathy (TTP and HUS) in those patients with concomitant MPGN is difficult, but if a deficiency of ADAMTS-13 or factor H (or I) can be documented, plasma infusions and/or plasma exchange may be indicated [16,69,74]. The treatment of lupus nephritis and a lesion of MPGN and fibrillary glomerulonephritis is also covered elsewhere (see chapters 22).

Summary and recommendations

It should be abundantly clear that the evidence base for treatment decisions in MPGN is weak and inconsistent, with a paucity of rigorously designed and executed controlled trials that would conform to modern-day standards of excellence (see references 1 and 75 for reviews). Thus, treatment decisions in MPGN are often made on the basis of less-convincing evidence from observational studies, many of which were short term and used only historical controls. A summary of an evidence- and opinion-based approach to evaluation and therapeutic decision making in MPGN is given in Figure 16.1. MPGN presenting with persistent nephrotic-range proteinuria is a progressive disease which can and frequently does lead to loss of renal function and ESRD. All patients with the lesion of MPGN type I should be thoroughly and systematically evaluated for secondary causes, particularly hepatitis C viral infection, with or without concomitant cryoglobulinemia, monoclonal immunoglobulin deposition diseases, chronic thrombotic microangiopathy, fibrillary or immunotactoid glomerulonephritis, autoimmune diseases (such as atypical SLE), and complement regulatory dysfunction (e.g. factor H deficiency) before commencing a trial of therapy. MPGN type II is equally heterogeneous, with some cases reflecting an abnormality in regulation of complement metabolism (factor H deficiency), which would not be expected to respond simply to steroids or immunosuppressive agents but might respond to plasma infusions or plasma exchange [16,69]. MPGN type III is relatively uncommon but may have a greater resistance to any form of therapy. Other atypical, nonclassifiable forms of MPGN may have a more benign outcome, even if left untreated. Recurrences of MPGN in allografts are common and

often result in graft loss. Treatment of recurrent disease is difficult and problematical.

At the present time the cumulative evidence from controlled and randomized trials and observational data suggests that a trial of high-dose alternate-day steroid therapy *may* be indicated in children with otherwise-idiopathic MPGN type I (low evidence; level II recommendation). Long-term therapy may be required with the attendant risks of steroid toxicity. Children with MPGN types II and III respond less favorably to this regimen, and there is no evidence of efficacy of steroids in any form or dosage in these subvariants of MPGN. Initiation of steroid therapy with high-dose intravenous pulses of methylprednisolone and shorter-term therapy with daily steroids may achieve equivalent effects, but no head-to-head comparisons of the two steroid-based regimens are available. Exacerbations of hypertension can develop with steroid treatment and must be aggressively managed. There are no data to support this steroid-based approach in adults with idiopathic MPGN type I.

Combinations of dipyridamole and aspirin may result in short-term beneficial effects (reduced proteinuria), but there is no evidence to support any long-term benefits or prevention of ESRD in adults with MPGN types I, II, or III. Insufficient data for the efficacy of these regimens in children are available to make any recommendations. Use of this combination of agents in adults is optional (very low evidence; level II recommendation).

Combinations of cyclophosphamide, warfarin, and dipyridamole (without concomitant steroids) are probably not effective in MPGN of any type (low evidence; level I recommendation). Whether combinations of cyclophosphamide, intravenous methylprednisolone pulses, and oral steroids are beneficial needs to be evaluated in a randomized controlled trial, but observational data suggest benefits, at least over the short term, in a subset of patients treated before irreversible renal disease has developed (e.g. estimated GFR of >30 mL/min/1.73 m^2). Such an approach might be especially helpful in patients with extensive crescentic glomerular disease and rapidly progressive glomerulonephritis (low evidence; level II recommendation). Before embarking on this unproven and potentially risky regimen, the presence of an occult infection with hepatitis C or hepatitis B virus, a complement regulatory abnormality (e.g. factor H deficiency), chronic thrombotic microangiopathy, or MIDD should be rigorously excluded (see figure 16.1). The benefits of an anticoagulant or antithrombotic approach (using warfarin and dipyridamole without steroids or immunosuppressive agents) has been validated in a limited crossover trial, but bleeding complications are worrisome and no confirmation of the putative benefits has appeared in the several decades since a trial with this combination was first reported. Little enthusiasm can be generated for use of this regimen (very low evidence; level I recommendation).

The most widely used and evidence-based regimen is strict control of blood pressure (to values below 130/80 mmHg), preferably with the use of inhibitors of angiotensin II action (angiotensin converting enzyme inhibitors alone or in combination with angiotensin II receptor antagonists), often in combination with a

low-salt diet and diuretics (high evidence; level I recommendation). This approach is strongly supported from multiple randomized controlled trials, though not specifically for MPGN. The goal of this therapy should be to reduce proteinuria to the lowest possible value consistent with side effects and symptoms as well as to lower blood pressure. This regimen is indicated in all patients with MPGN (regardless of type) who have proteinuria (>500 mg/day) and/or hypertension (blood pressure of >130 mmHg systolic). Patients with MPGN who have stable renal function and who have nonnephrotic levels of proteinuria probably do not need any therapy other than maintenance of normal blood pressure through use of angiotensin II inhibition (moderate evidence; level I recommendation).

The roles of other agents in therapy remain uncertain, largely due to the lack of controlled randomized trials. Cyclosporine or tacrolimus are generally ineffective but may reduce proteinura in the short term (low evidence; level II recommendation). NSAIDs may reduce proteinuria but have no proven benefit for the long-term course and may be associated with side effects (gastrointestinal), aggravate hypertension, and may be potentially nephrotoxic (very low evidence; level I recommendation). MMF is a promising new agent with preliminary favorable effects reported in very limited observational studies. A controlled trial is needed before this agent can be routinely recommended for MPGN type I. Its use should be limited to patients with an adverse prognosis until more information regarding effectiveness is available (low evidence; level I recommendation).

Patients with very severe MPGN associated with extensive crescents may benefit from aggressive use of cyclophosphamide, pulse methylprednisolone, and plasma exchange, but no controlled trials are available and none are unlikely to be conducted due to the rarity of this complication of MPGN (low evidence; level I recommendation).

Patients with MPGN type II require an approach tailored to the underlying abnormality. If a *CFH* mutation can be identified, then therapy with plasma infusions are probably indicated (moderate evidence, level II recommendation). The therapy for patients with MPGN type II not associated with a *CFH* mutation is very uncertain. Rituximab, eculizumab, or plasma exchange or plasma infusion could be tried, but no data are available to evaluate the safety or efficacy of this highly experimental approach.

Patients with recurrent MPGN in a renal allograft would possibly best be managed by a trial of plasma exchange or plasma infusion (possibly for MPGN type II only), oral cyclophosphamide, or high-dose MMF plus prednisone (MPGN type I only; very low evidence; level I recommendation).

4 Secondary Diseases of the Kidney

Hypertensive Renal Disease

17 Hypertension: Classification and Diagnosis

Bernardo Rodriguez-Iturbe & Crispín Marin Villalobos

Nephrology Section, Hospital Universitario, and Universidad del Zulia, School of Medicine, Maracaibo, Venezuela

Introduction

A high level of arterial blood pressure, or hypertension, is a mortality and morbidity risk factor for cardiovascular and kidney disease and is responsible for 7.1 million deaths and 64 million disease adjusted life-years lost worldwide [1]. It is estimated that 25–35% of the world's population older than 18 years and more than 60% of individuals older than 70 years have blood pressure levels of ≥140/90 mmHg [2].

Because blood pressure levels are on a continuum, separation of normal and high values is somewhat arbitrary, with excess cardiovascular risk found with blood pressure values higher than 115 mmHg systolic and 75 mmHg diastolic blood pressure [3]. Guidelines from the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure* [4] (Table 17.1) define hypertension in adults as a systolic blood pressure of ≥140 mmHg or diastolic blood pressure of ≥90 mmHg (average of two or more blood pressure determinations at two or more clinic visits). The category of prehypertension (systolic blood pressure of 120–139 mmHg or diastolic blood pressure of 80–89 mmHg) is also included, as this group of patients usually develop hypertension, and prehypertension is present in about 25% of the general population. Target levels for antihypertensive treatment have recently been lowered in patients with diabetes or kidney disease who are at increased risk for cardiovascular disease. In growing children, the blood pressure increases at about 1.5 mmHg systolic and 0.7 mmHg diastolic per year, and hypertension is defined as blood pressure levels equal to or greater than the 95th percentile of the distribution for age, sex, and height. Blood pressure levels between the 90th and 95th percentiles are considered high-normal [5].

A similar classification was essentially agreed upon by the World Health Organization, International Society of Hypertension, European Society of Hypertension, and the European Society of Cardiology (Table 17.1) [6].

Isolated systolic hypertension, isolated diastolic hypertension, "white coat" hypertension, isolated ambulatory hypertension, pseudohypertension, and orthostatic hypotension are defined in Table 17.2.

Auscultatory determination of Korotkoff sounds by trained personnel using a mercury sphygmomanometer is the traditionally accepted reference standard for blood pressure measurement. The systolic blood pressure corresponds to the beginning (phase I) and diastolic blood pressure to the cessation (phase V) of Korotkoff sounds. In older individuals with a wide pulse pressure there may be an auscultatory gap, when the sound disappears between systolic and diastolic pressure and reappears as cuff deflation continues. This can be avoided if the arm is elevated for 30 s before inflating the cuff.

Determination of blood pressure in different settings

Blood pressure in a clinic

Determination of blood pressure in a clinic is assumed to be a surrogate marker for the average blood pressure over time in a given patient, but it should be recognized that errors may result from misclassification of individuals as hypertensive when they are not (false positives) as well as from failure to recognize hypertension in some patients who have normal clinic readings (false negatives). Furthermore, clinic blood pressure does not disclose patients whose blood pressure remains high at night ("nondippers") and who have higher cardiovascular morbidity [7]. The mercury sphygmomanometer is the reference equipment for blood pressure determination but, like all technical items, regular maintenance is essential. It should be routinely checked for leaks and other problems, which affect as many as 25% of the devices currently in use [8]. Recently, aneroid and oscillometric automated devices have been used more commonly and, while generally accurate [9,10], they should be calibrated periodically with a mercury manometer

Table 17.1 Classification and definition of hypertension.

Classification system and hypertension category	Systolic BP (mmHg)	Diastolic BP (mmHg)
JNC-7		
Normal	<120	<80
Prehypertensive	120–139	80–89
Stage 1 hypertension	140–159	90–99
Stage 2 hypertension	≥160	≥100
WHO/ISH/ESH/ESC		
Optimal	<120	<80
Normal	120–129	80–84
High-normal	130–139	85–89
Stage 1 hypertension	140–159	90–99
Stage 2 hypertension	160–179	100–109
Stage 3 hypertension	≥180	≥110

Abbreviations: JNC-7, Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure, 7th report (National Heart, Lung, and Blood Institute); WHO/ISH/ESH/ESC, a joint committee of the World Health Organization, International Society of Hypertension, European Society of Hypertension, and European Society of Cardiology.

[11]. In small children and neonates, Doppler ultrasound (systolic blood pressure) and oscillometric equipment (systolic, diastolic, and mean blood pressure) are commonly used.

There are several details that need to be considered when measuring blood pressure in the clinic. The patient should be seated with back support, without crossing the legs, and relaxed for more

Table 17.2 Hypertension definitions, from the AHA scientific statement.

Category	Definition
Isolated systolic hypertension	SBP ≥140, DBP <90
Isolated diastolic hypertension	SBP <140, DBP ≥90
White coat hypertension	Clinic BP >140/90 Ambulatory BP (avg) <135/85
Isolated ambulatory hypertension	Clinic BP <135/85 Ambulatory BP (avg) >140/90
Ambulatory hypertension	24-h avg >135/85
Ambulatory daytime hypertension	Avg daytime values >140/90
Ambulatory nighttime hypertension	Avg nighttime values >125/75
Pseudohypertension	Advanced or calcified arteries require high cuff pressure to compress them
Accelerated or malignant hypertension	DBP usually >120 in association with grade III (arteriolar narrowing and "nicking," flame-shaped hemorrhages, and exudates) or grade IV retinopathy (papilledema); treat as medical emergency

Source: American Heart Association [11].
Abbreviations: SBP, systolic blood pressure; DBP, diastolic blood pressure (all BP values are in mmHg).

than 5 min before measurements are taken. The cuff should have a length and width that are about 80% and 40%, respectively, of the arm circumference and should be placed on the upper arm at about the level of the right atrium. These conditions are important because, if not followed, they could result in an overestimation by as much as 20–25 mmHg (5 mmHg higher for undercuffing large arms, 8 mmHg higher in the supine position, 5 mmHg for crossing the legs, 5 mmHg for having the arm 2–3 in. above the right atrium) [12–14]. Ideally, three readings should be taken to reduce measurement error, and additional readings are required when differences between readings exceed 5 mmHg [11].

Specific problems may be present in elderly individuals (frequency of orthostatic hypotension), children (inappropriately small cuff size, anxiety), patients with arrhythmias (variability), and pulseless syndromes (Takayasu's arteritis, occlusive arterial disease, atherosclerosis) that may result in interarm blood pressure differences of greater than 10 mmHg [15].

Home monitoring of blood pressure

Home monitoring is convenient, cheap, and probably a better predictor of cardiovascular morbidity than clinic measurements [16]. Also, home monitoring of blood pressure is associated with increased compliance with recommended treatment [17]. Home blood pressure is usually determined by electronic oscillometric equipment rather than aneroid sphygmomanometers. A list of validated equipment for this purpose is available elsewhere (http://www.dableducational.org). The preferred devices measure blood pressure in the arm. It is recommended that these devices have annual checks for accuracy. Devices that give printed records are recommended, to avoid erroneous verbal reports to the physician [18]. In addition it is recommended that the patient follow the same guidelines discussed earlier and take three readings, usually in the morning and at night. The accepted upper limit of normal for ambulatory blood pressure is 135/85 mmHg [19].

Ambulatory blood pressure

Ambulatory blood pressure is measured with automated noninvasive equipment that takes blood pressure readings every 30 min over a 24-h period and, after computerized analysis, reports summary data of specific determinations, average 24-h values, and average day and night values. Although ambulatory blood pressure probably provides the most valid prognostic information [20], it is cumbersome, costly, uncomfortable, and not universally available. Ambulatory blood pressure measurement is usually done to identify individuals with "white coat" hypertension and those who do not have a nighttime reduction (nondippers). It may also prove useful in evaluating patients in whom episodes of hypertension or hypotension are suspected, in patients whose blood pressure is found intermittently to be above 140/90 mmHg (borderline hypertension), and in patients whose blood pressure varies widely during clinic visits.

Abnormally high ambulatory blood pressure is defined by 24-h average values of >135/85 mmHg, average daytime values of

Table 17.3 Frequencies of hypertension conditions.

Clinical condition[a] and etiology	Frequency
Essential hypertension Unknown cause	90–95%
Isolated systolic hypertension Reduced aortic compliance	>60% of hypertension after age 65 yrs
Increased systolic load (aortic insufficiency, patent ductus arteriosus, arteriovenous fistula, thyrotoxicosis, anemia, Paget's bone disease	<1%
Renal parenchymal diseases Glomerulonephritis (acute or chronic), pyelonephritis, polycystic disease, tubulo-interstitial disease, diabetic nephropathy, obstructive uropathy	4–6%
Pregnancy Eclampsia, preeclampsia	5% of all pregnancies
Renal vascular disorders Renal artery stenosis (atherosclerosis, fibromuscular hyperplasia)	1–4%
Endocrine diseases Primary aldosteronism, Cushing's disease, congenital adrenogenital syndromes (17α- or 11β-hydroxylase deficiency), pheochromocytoma, hypo- or hyperthyroidism, hyperparathyroidism (hypercalcemia), acromegaly	1%
Medications or toxic exposure Glucorticoids, mineralocorticoids, sympatho-mimetics, oral contraceptives, cyclosporine, nonsteroidal anti-infammatory drugs, erythropoietin, cocaine, amphetamines	1%
Coarctation of aorta	0.1–1%
Increased vascular volume or viscosity Polycythemia (vera, high altitude, or overtransfusion)	
Neurogenic disorders Familiar dysautonomia, acute spinal cord section, increased intracranial pressure	
Miscellaneous Acute porphyria, acute withdrawal from clonidine	

[a] Conditions are listed in order of decreasing frequency.

>140/90 mmHg, and average nighttime values of >125/75 mmHg (Table 17.2) [11].

Other settings

Determination of blood pressure in public places with automated devices does not meet accuracy requirements [21], and their usefulness rests primarily in increasing public awareness of the need for evaluation and treatment of hypertension.

Classification of hypertension

The etiologic classification of hypertension is traditionally made by separating the known (secondary) causes of increased blood pressure from the vast majority of cases without a discernible cause, which are designated as primary, idiopathic, or more commonly, essential hypertension (Table 17.3). The pathogenic mechanisms responsible for essential hypertension are discussed in chapter 18.

As indicated in Table 17.3, the vast majority of patients have essential hypertension, and the most common cause of secondary hypertension is parenchymal renal disease.

In children the prevalence of hypertension is about 1% [22]. The prevalence of persistent secondary hypertension is less than 0.1%, and 70–80% of these patients have parenchymal renal disease (acute glomerulonephritis, Henoch-Schönlein nephritis, hemolytic uremic syndrome, reflux nephropathy, etc.) and 5–10% have renovascular disease (fibromuscular dysplasia or arteritis). Coarctation of the aorta is reported in 0–29% of pediatric patients [23,24], and endocrine causes of hypertension (pheochromocytoma, congenital adrenal hyperplasia, apparent mineralocorticoid excess, and glucocorticoid remediable aldosteronism) are found in 1–8%. Renal tumors (Wilms' tumor, hamartoma, and hemangiopericytoma) rarely cause hypertension. Hypertension occurs in 60–90% of children who have received transplants, which is a higher percentage than in adults with functioning renal grafts [25].

Hypertension as a cause and consequence of kidney disease

For many years, malignant hypertension has been known to cause end-stage renal disease, but it was debated for some time whether

Does hypertension require immediate treatment (≥180/110)?

Yes
Treat hypertension emergency

No

Initial Evaluation

Complete History, including life style characteristics (sedentary, excercise, smoking, alcohol, diet), medications, family history
Physical Exam (including evaluation of BMI, waist:hip ratio, carotid and abdominal bruits, ophtalmoscopic evaluation)
Blood tests: Hematology, Lipid profile, Fasting blood sugar, creatinine, Na, K, Cl, bicarbonate.
Urine: routine, sediment, protein/creatinine ratio
Other: Electrocardiogram, Chest X ray

Secondary Hypertension
appropriate diagnostic tests

Essential Hypertension
Evaluation of risk factors
Target organ damage
Identify initial treatment strategies

Figure 17.1 Initial evaluation of the patient with hypertension.

uncomplicated hypertension was the cause of nephrosclerosis [26]. This question was answered by the Multiple Risk Factor Intervention Trial, which demonstrated that both systolic and diastolic hypertension were strong independent risk factors of end-stage renal disease [27], and other studies have shown that reducing blood pressure with angiotensin converting enzyme inhibitors reduces the risk of end-stage renal disease or death by as much as 55% in 3–5 years if the systolic blood pressure is controlled to levels of 139 mmHg or lower [28,29]. There is considerable variation in reports of the incidence of hypertension as a cause of end-stage renal disease, ranging from 27% in the USA [30] to 13% in Europe and 6% in Japan [31]. In Latin America there is considerable variation between countries and within countries, but the reported mean value is 28% [32].

Hypertension is also a consequence of renal disease. Reduction in nephron number of any cause, intrarenal inflammation, and increased intrarenal angiotensin II and oxidative stress result in a tendency to sodium retention, leading to hypertension [33]. Diabetic nephropathy occurs in about 40% of type 2 diabetics and is the most common cause of end-stage renal disease worldwide, and hypertension is present in almost all patients with type 2 diabetes.

Unilateral renal disease is also a cause of hypertension. Unilateral segmental renal hypoplasia (associated with vesicourethral reflux), unilateral renal agenesis, hydronephrosis, and renal trauma may occasionally result in hypertension. Hypertension associated with perirenal hematoma has been considered to be renin-induced due to parenchymal compression, in a manner similar to the hypertension resulting from the perinephritic hull resulting from cellophane wrapping of the kidney (Page kidney). Recently, evidence has been advanced indicating that in the Page kidney model, hypertension is caused by interstitial inflammation and increased intrarenal (rather than plasma) angiotensin II activity [34], and it is likely that similar mechanisms may be operating in subcapsular renal hematoma because nephrectomy, but not the relief of the compression, is frequently associated with normalization of blood pressure [35].

Evaluation of the hypertensive patient

When a patient with hypertension is initially evaluated, the severity of the hypertension may warrant immediate treatment. A cost-effective initial evaluation of the patient is shown in Figure 17.1, and this evaluation should be directed to 1) examine the possibility of secondary causes of hypertension, 2) determine the existence of risk factors and target organ damage, and 3) define initial treatment strategies. If secondary causes of hypertension are suspected (Table 17.3), specific diagnostic tests are indicated (Table 17.4).

In the patient history, information on diet, habits, ingestion of medications such as oral contraceptives and nonsteroidal anti-inflammatory agents, family history of hypertension or kidney disease, and past history of edema, proteinuria, or hematuria, among other factors, is important. Recent onset of hypertension before the age of 20 years or after the age of 60 years should raise suspicion of renal artery stenosis in addition to the findings listed in Table 17.4.

Physical examination may disclose palpable kidneys (polycystic kidney disease), abdominal murmurs (renal artery stenosis),

Table 17.4 Diagnostic evaluation of the most common causes of secondary hypertension.

Condition	Clinical finding(s)	Abnormal laboratory tests	Sensitivity/specificity (%)[a]	Reference(s)
Renal parenchymal disease	History of renal disease, edema, flank pain, urinary symptoms, hematuria	Serum creatinine, proteinuria, blood glucose, urine sediment		
Renal artery stenosis	Recent development or sudden worsening of hypertension, abdominal bruit, azotemia induced by ACE inhibitor, flash pulmonary edema, hypokalemia, azotemia with normal urine sediment	Captopril-enhanced Doppler ultrasound scan	60–65/NR	[38,39]
		MRA	62–94/85 (for transplant artery stenosis, 100/75) 64/92	[40,41,42]
		Gadolinium-enhanced MRA	88–100/71–100	[40]
		Angio-CT		
		Digital subtraction renal artery angiography	Gold standard	[41]
Hyperaldosteronism	Hypokalemia	Serum aldosterone/plasma renin ratio	89 /96	[43]
		CT scan	62/77	[44]
		MRI	100/64	[44]
Pheochromocytoma	Episodes of headache, palpitation, and sweating	Urinary metanephrines	100/NR	[45]
		Plasma cathecholamines	85/NR	[45]
		Urinary VMA	89/NR	[45]
		CT scan (localization)	85–95	[45,46]
		MRI (localization)	>95	[45,46]

Abbreviations: MRI, magnetic resonance imaging; MRA, magnetic resonance angiography; CT, computer tomography (CAT scan); ACE, angiotensin converting enzyme; NR, not reported; VMA, vanillyl madelic acid.

deafness (Alport's disease), neurofibromatosis (pheochromocy- toma), or adenoma sebaceum (tuberous sclerosis).

Laboratory investigations should always include urine sediment analysis and, if proteinuria is detected, 24-h urinary protein excre- tion or a spot creatinine/protein concentration ratio should be de- termined. A test for albuminuria (micral test or albumin/creatinine ratio in spot morning urine, followed by quantified excretion in timed urine samples if the data are in the microalbuminuric range) may help detect kidney damage before the appearance of clinical proteinuria. In addition, for all patients the levels of plasma cre- atinine (used to calculate the glomerular filtration rate by stan- dard formulas), electrolytes (hypokalemia would suggest diuretic therapy, renal artery stenosis, or hyperaldosteronism), and fast- ing glucose (if abnormal, evaluate for diabetes), lipid profile, and body mass index (to determine risk factors) should be determined. An electrocardiogram and echocardiogram are indicated to detect and monitor left ventricular hypertrophy.

Radiological and image analyses are not routinely indicated. De- pending on the suspected diagnosis, renal ultrasonography (for obstruction, stone disease, and polycystic kidneys), intravenous urography (for obstruction, stone disease, and to determine whether macroscopic hematuria is present), computerized tomog- raphy, magnetic resonance angiography, and renal angiography (as the reference standard for renal artery stenosis, prior to correc- tion) may all be useful. Renography with isotopes that are elimi-

nated by glomerular filtration (e.g. ^{99}Tc-diethylenetriaminepenta acetic acid) are markers of renal blood flow, and evaluation with [^{123}I]iodohippurate may occasionally also be useful. Magnetic res- onance angiography is useful in the study of renal artery stenosis (Table 17.4) but only when the stenosis is in the main renal artery.

In children, hypertension is usually asymptomatic or presents with nonspecific symptoms: failure to thrive, irritability, and con- vulsions in infants, and headache, visual disturbances, vomit- ing, epistaxis, growth retardation, and facial palsy in older chil- dren [36]. If hypertension is severe, the initial evaluation in chil- dren should include not only hematology, blood chemistries, and urinary sediment but also abdominal ultrasound studies and ^{99}mTc-dimercaptosuccinic acid scans (for detecting segmental scars resulting from pyelonephritis) and determinations of end- organ damage (echocardiography, electrocardiography) [37]. In- travenous urography and voiding cystourethrography are only in- dicated if vesicoureteral reflux or obstruction is suspected.

Evidence for hypertensive renal damage

Historically, renal failure in patients with hypertension occurred mainly as the result of malignant hypertension [1]. However, with the introduction of potent antihypertensive drugs, malignant hypertension and kidney failure caused by malignant hypertension have become rare [2]. Because virtually no renal end points were observed in individuals with primary hypertension in relatively short-term studies, it had been widely assumed that primary hypertension caused few, if any, renal sequelae in individuals without primary kidney disease. More recent observational data over longer periods of time suggested that this view needed modification. The failure to observe renal sequelae may be explained primarily by the insufficient duration of trials designed to observe cardiovascular end points. Today, evidence from long-term observational studies has shown that, in individuals without primary chronic kidney disease (CKD), a relationship exists between the level of blood pressure (BP) and impaired renal function. These studies also show that the evolution of kidney failure in patients with nonmalignant hypertension usually takes decades [3–7]. The true frequency of this is unknown, because no series have been reported where the diagnosis of "renal failure from hypertensive nephropathy" was confirmed by renal biopsy. Registry data are unreliable, as shown by large differences in end-stage renal disease incidence data due to hypertension reported from different countries. The most convincing evidence comes from small series where the diagnosis has been established by renal biopsy [8]. These findings support the view that the term "benign nephrosclerosis" (which goes back to Volhard and Fahr [9]) is a misnomer and underestimates the role of primary hypertension in the initiation and progression of CKD. Even more common, the mild impairment of renal function seen in many elderly patients with primary hypertension, although infrequently causing dialysis-dependent

kidney failure, is not benign because of the high cardiovascular risk conferred by even minor renal dysfunction, as reflected by diminished estimated glomerular filtration rate (GFR) [10–12] or albuminuria or proteinuria [13–15].

The evidence that essential hypertension may (relatively infrequently) lead even to end-stage renal disease is based on experimental as well as human studies. In animal models of primary hypertension that may result in CKD, for example, Dahl salt-sensitive rats and some strains of spontaneously hypertensive rats, a clear-cut relationship exists between the BP increase and development of kidney failure [16,17], particularly when sensitizing maneuvers such as unilateral nephrectomy are performed [18,19] that are known to cause dilatation of the afferent (preglomerular) artery, thus triggering glomerular hypertension [20–22]. Moreover, in these animals lowering BP retards progression of renal injury [23–25]. The hypothesis of "nephron underdosing," proposed by Brenner [26], potentially provides a link between the genesis of hypertension and the evolution of CKD in these experimental settings and in humans [27–30]. According to this theory, a reduced number of nephrons causes hypertension, which in turn may further accelerate the development of abnormalities in renal structure and function.

What is the evidence in humans? Evidence for an important role of high BP in the development of CKD and progressive loss of renal function has been provided by historical observations of untreated hypertensive patients [31], although these observations are confounded by the occurrence of malignant hypertension. In the tradition of the classical anatomical descriptions of Gull and Suton [32] and Volhard and Fahr [9], additional information has come from the scarce biopsy studies in hypertensive patients with presumed "hypertensive nephropathy" and no evidence of primary kidney disease or diabetes mellitus [8,33–36], autopsy studies [37,38], and long-term observational studies in patients with presumed primary hypertension who have been followed for more than a decade [3–6]. Registry information of patients on hypertensive nephropathy as a cause for renal replacement therapy, for instance, in the US Renal Data System [39], is unreliable because of the absence of biopsy confirmation. Striking differences in the

reported frequencies between countries [40] may, in part, be due to varying susceptibilities of some ethnicities, particularly black people, to hypertensive kidney damage [36]. In the general US population, approximately 0.2% developed terminal kidney failure during an average observational period of 16 years, and this risk was clearly related to BP [5]. In patients with primary hypertension this proportion was considerably higher and increased in parallel with the severity of hypertension. In patients with severe hypertension, more than 3% developed end-stage renal disease, that is, their relative risk for the development of kidney failure was 12.4 compared to subjects with "optimal" BP. Progression to kidney failure was a function of the BP value in several studies, systolic BP being more tightly correlated than diastolic BP, with the elderly and Black people having a worse prognosis [3,4]. In individuals without evidence of kidney disease at baseline, as reflected by an absence of proteinuria, a graded increase of the risk to develop end-stage renal disease with time was found even for BP values within the "normal" range according to past WHO definitions [6]. Hypertension may also cause renal failure indirectly, by promoting atherosclerosis of the abdominal aorta with ischemic nephropathy resulting from renal artery stenosis, cholesterol embolism, or arteriolosclerosis, or a combination of these conditions [38].

One interesting observation is the finding that BP goes with the transplanted kidney in humans [42] as it does in experimental animals [43], suggesting that in humans a functional defect in the kidneys plays a causal role in the development of primary hypertension. It has been argued that the kidney is the culprit as well as the victim of high BP [44]. This argument is not invalidated by the evidence, from cross-kidney transplantation experiments in AT_1 receptor knockout animals, that extrarenal vascular territories make nonredundant contributions to BP regulation [45].

Diagnosis of hypertensive renal damage

Classically, it has been postulated that the typical finding in primary hypertension is ischemic kidney disease leading to the constellation of small kidneys with impaired renal function but without significant proteinuria. This assumption was disproved by findings in biopsy studies showing that even nephrotic proteinuria may be found in patients with ischemic kidney disease [34].

Measurement of GFR

The GFR can be measured using different methods. The gold standard for the measurement of true GFR is still inulin clearance, but iohexol, Cr-EDTA, or iothalamate clearances are valuable alternatives. However, these clearance measurements are cumbersome and too expensive for routine clinical use or use in epidemiological studies. Thus, estimates of GFR based on the measurement of serum creatinine, such as with the MDRD [46] and Cockcroft-Gault equation [47], are widely accepted, but these estimates are not very accurate, particularly in the near-normal range [46]. Also, they have not been validated in specific populations and

ethnicities, such as the very old, patients with a renal allograft, African Americans, or Asians. The newer MDRD formula, which was derived from data of the Modification of Diet in Renal Disease trial, is more accurate for advanced rather than early-stage CKD [46]. A major problem with the MDRD equation is that it depends on the accuracy of serum creatinine measurement, which may vary considerably between different laboratories. In addition, interethnic differences may result in different estimates. Newer tests for GFR, such as serum cystatin C, are becoming available that are not confounded by muscle mass or tubular transport of creatinine [46,48].

Quantification of urinary albumin and protein excretion

Albuminuria is usually categorized into micro- and macroalbuminuria, but the method by which urine should be collected is still unresolved: spot urine (with or without creatinine correction), morning urine, or 24-h urine. It is also unclear how urinary albumin should be measured: immune detection or high-performance liquid chromatography [49,50]. Albuminuria also varies physiologically and is reversibly elevated by physical exercise, fever, and heart failure.

Despite these unresolved methodological problems, an increased urinary albumin (and protein) excretion rate has been clearly documented in patients with essential hypertension, although recent epidemiologic studies have shown that the prevalence of albuminuria is rather modest [51–55]. Nevertheless, this parameter is of considerable interest, because it identifies hypertensive individuals at particularly high risk of cardiovascular complications and death [13,56] (see Table 30.3 in chapter 30 for more information on risk factors in CKD progression). In the Göteborg study the proteinuria was even more predictive than total cholesterol for adverse cardiovascular outcomes [56]. The reasons why urinary albumin excretion is predictive of cardiovascular death have not been clarified, but it has been hypothesized that elevated urinary albumin excretion, as a result of glomerular injury, may reflect generalized endothelial dysfunction in nonrenal vascular beds as well [57]. In line with this assumption, an increased transcapillary escape rate of albumin as a potential marker of generalized endothelial dysfunction has been found in patients with essential hypertension [58]. It is also not clear whether albuminuria reflects a functional disturbance of the glomerulus, structural renal damage, or both, and whether albuminuria is fully explained by glomerular leakage or whether abnormalities of tubular albumin reabsorption contribute. Further information from biopsy studies with ultrastructural and gene expression analyses would be highly desirable. It is also uncertain whether in patients with essential hypertension (micro)albuminuria is associated with the long-term risk of progressive renal injury [59] as it is in diabetes mellitus [60]. Despite such gaps in our knowledge, measurement of urinary albumin provides information important for patient management because of the tight relation between urinary albumin excretion (even in the high-normal range) and the risk of cardiovascular complications.

Prevention and treatment

Strategies of prevention and treatment of hypertension-induced CKD are all based on observational studies, because large controlled prospective trials on this issue are completely lacking with the exception of the African American Study of Kidney Disease and Hypertension (AASK) study in the specific population of African American patients. The few relevant observational studies that are available suffer from drawbacks such as insufficient duration and/or inclusion of mostly young individuals in whom renal risk is considerably lower, absence of information on albuminuria and/or proteinuria as a renal risk modifier, and selecting (and validating) cardiovascular events, assuming that factors affecting cardiovascular end points also affect renal outcome (what is good for the heart is good for the kidney). Also, in the studies that did measure a renal end point, this was frequently confounded by comorbidities such as (undetected) chronic heart failure, diabetes, and prediabetes. In the studies where medication has been used which reduces renin–angiotensin–aldosterone system (RAAS) activity it is difficult to evaluate whether, for example, changes in GFR are the result of natural history, RAAS blockade, or BP lowering.

These shortcomings mean there is some uncertainty inherent in the following recommendations concerning BP and the choice of specific antihypertensive drugs.

Target BP

Relatively small studies have suggested that antihypertensive treatment reduces renal damage caused by hypertension [61,62]. This was not confirmed in a meta-analysis of the available literature by Hsu, in which no significant overall effect could be shown [63], with the exception of the AASK study in African Americans.

It is uncertain which BP parameter is the most important treatment target for renoprotection in hypertensive CKD: systolic BP, diastolic BP, or pulse pressure. It is also unclear which measurement is most relevant: clinic BP, home BP, 24-h ambulatory BP monitoring, nighttime BP, monitoring of early morning surge, or BP variability.

In patients with CKD due to diabetes mellitus, observational studies and post hoc analyses of intervention trials have shown that systolic BP is more predictive of renal function loss than diastolic BP or pulse pressure [64]. Further, observational data indicate that high nocturnal BP is associated with a more rapid loss of renal function in nondiabetic patients [65], but such information is lacking for patients with hypertensive renal damage. The authors concluded that general recommendations based on clinic BP do not do justice to the complexity of BP control. Published guidelines define a target BP of below 140/90 mmHg in the absence of renal disease, below 130/85 mmHg for patients with CKD and diabetes, and even values below this threshold in patients with gross proteinuria [66–68].

The only currently available solid evidence to support these recommendations in patients with CKD as a result of hypertension-induced kidney failure is the AASK study [69]. In that study, comprising a total of 1094 African Americans with hypertensive kidney disease (GFR between 20 and 65 mL/min/1.73 m^2), the effects of two levels of BP control and three antihypertensive drug classes on change in GFR (i.e. GFR slope) during a follow-up period of 3–6.4 years were examined. Participants were randomly assigned to either usual BP control, that is, mean arterial BP between 102 and 107 mmHg ($n = 554$), or lower BP, that is, mean arterial BP of $\leq$92 mmHg ($n = 540$). The initial treatment was either the β-receptor blocker metoprolol ($n = 441$), the angiotensin converting enzyme inhibitor (ACEI) ramipril ($n = 436$), or the dihydropyridine calcium channel blocker amlodipine ($n = 217$). Open-label agents were added if necessary to achieve the assigned BP goals. The GFR slope was determined separately during the first 3 months following randomization (acute slope) and after 3 months (chronic slope), because the acute effects of the interventions on GFR may have differed from their long-term effects on disease progression. They achieved BP on average 128/78 mmHg in the lower BP group and 141/85 mmHg in the usual BP group, but the mean GFR slope from baseline through 4 years did not differ significantly between either intervention (lower BP group, −2.21 mL/min, vs. usual BP group, −1.95 mL/min/1.73 m^2/year) (Figure 18.1) [69]. Moreover, the lower BP goal did not significantly reduce the rate of the clinical composite outcome, including occurrence of end-stage renal failure. None of the drug group comparisons showed consistent significant differences in the GFR slope. However, compared with the metoprolol and amlodipine groups, the ramipril group had a reduced relative risk of 22% ($P = 0.04$) and 38% ($P = 0.004$), respectively. The authors concluded that lower BP control has no additional benefit of slowing progression of hypertensive nephrosclerosis and that an ACEI appears to be more effective than a β-receptor blocker or dihydropyridine calcium channel blockers in slowing GFR decline. However, the increase in proteinuria over time during the observation period was significantly less ($P < 0.001$) with lower target BP (Figure 18.2), and the same was true for the ACEI and β-receptor blocker treatment arms, compared to the amlodipine group ($P < 0.001$). Given the important role of proteinuria as a progression promoter in primary kidney disease and diabetic nephropathy, this finding corroborates the importance of insufficient trial duration for the proper assessment of progression in patients with hypertensive nephrosclerosis. Another limitation of the AASK trial is that the results are restricted to African Americans, so that they must be confirmed for other ethnicities. It should be stressed that to achieve the assigned BP goals in the AASK trial, most patients required more than monotherapy. The average number of antihypertensive drugs was 2.7 in the usual BP group and 3.5 in the lower BP group [69].

All classes of antihypertensive drugs are effective in lowering BP in patients with renal malfunction. However, adverse effects should be considered, particularly for aggressive BP lowering in the elderly with comorbidities, which may increase cardiac events and/or mortality, as recently shown in intervention trials [70,71]. When the systolic BP was reduced below 120 mmHg, all-cause mortality was higher by a factor of 3, a finding that is reminiscent
Figure 18.1 Effects of BP goal and selection of antihypertensive agent on GFR (AASK trial [69]). Mean changes in GFR by randomized group are shown. Data are the estimated mean changes (with standard errors of the means) in GFR (in mL/min/1.73 m^2) from baseline through follow-up with the two BP goal interventions (A) and with the three drug interventions (B). The plot is based on a multislope generalization of the two-slope mixed-effects model, in which different mean slopes are estimated within each treatment group for each interval between scheduled GFR measurements. Numbers of patients with GFR data at years 0, 1, 2, 3, 4, and 5 in all treatment groups combined were 1094, 953, 837, 731, 469, and 262, respectively.

of the J-curve phenomenon, that is, a paradoxical increase in mortality. As a consequence, in patients with known coronary heart disease, systolic BP should not be reduced below 120 mmHg and diastolic BP should not be reduced below approximately 70 mmHg (in order to avoid coronary under perfusion). The sensitivity to low diastolic BP is explained by the fact that coronary perfusion occurs during diastole only. Some caution with aggressive BP lowering is also appropriate in patients with disseminated atherosclerosis, particularly of the arteries supplying the central nervous system

(cerebral ischemia) or the kidneys, that is, bilateral or dominant kidney renal artery stenosis (ischemic nephropathy). This is especially true in disease states such as diabetes, when autoregulation is disturbed, exposing the patient to the risk of organ ischemia (e.g. cerebral micro-infarction) when BP is lowered excessively.

Specific benefit of RAAS blockade

Generally, no preference for a specific antihypertensive agent is justified on the basis of currently available data, although results
Figure 18.2 Effect of BP goal and selection of antihypertensive agent on proteinuria (AASK trial [69]). Percent changes in proteinuria by randomized group are shown. Data are the estimated percent changes in the urine protein/creatinine ratio from baseline through follow-up by BP goal and drug regimen. Based on the two-slope linear spline model for the log(urinary protein/creatinine) ratio, the percent change in geometric mean proteinuria to 4 years was significantly lower for the lower BP goal than the usual BP goal (P < 0.001) and was significantly higher in the amlodipine group than the other two drug groups (P < 0.001).

of some studies in patients with primary hypertension show better reduction of albuminuria and perhaps also better renal outcome [72,73] with RAAS blockade. Nevertheless, a specific renoprotective effect has been proven only in primary CKD and patients with diabetic nephropathy. The relevance of these findings for managing patients with primary hypertension and renal dysfunction remains questionable in the absence of prospective controlled data.

19 Management of Hypertension in Chronic Kidney Disease

Aimun Ahmed, Fairol H. Ibrahim, & Meguid El Nahas

Sheffield Kidney Institute, Sheffield, UK.

Hypertension and risk of developing chronic kidney disease

A large number of community-based studies have identified a number of markers and factors known to be associated with increased risk of developing chronic kidney disease (CKD), foremost among them, systemic hypertension and diabetes mellitus, but also dyslipidemia, obesity, and smoking. These markers are identical to those associated with increased risk of cardiovascular disease (CVD), highlighting the close association between CKD and CVD. Of these, systemic hypertension is the single most important factor predicting the onset of CKD; a number of large community-based studies have linked raised blood pressure (BP) levels to the increased incidence of CKD.

In the USA, the Multiple Risk Factor Intervention Trial screened 332,544 men aged 35–57 years between 1973 and 1975 and followed them for an average of 16 years [1]. Of these, 814 subjects either died of end-stage renal disease (ESRD) or were treated for that condition (15.6 cases/100,000 person-years of observation) [1]. A strong, graded relation between both systolic and diastolic BP and ESRD was identified independent of associations with age, race, income, use of medication for diabetes mellitus, history of myocardial infarction, serum cholesterol concentration, and cigarette smoking. Compared with men with an optimal level of BP (<120/80 mmHg), the relative risk of ESRD for those with stage 4 hypertension (systolic pressure of ≥210 mmHg or diastolic pressure of ≥120 mmHg) was 22.1 [1].

Also in the USA, the Washington County, Maryland study [2] showed that the association between hypertension and smoking on the future risk of CKD in 23,534 men and women was proportional to the baseline levels of BP. The adjusted hazard ratio of developing

CKD among women was 2.5 for normal BP, 3.0 for high-normal BP, 3.8 for stage 1 hypertension, 6.3 for stage 2 hypertension, and 8.8 for stage 3 or 4 hypertension compared with individuals with optimal BP. In men, the relationship was similar but somewhat weaker. A large proportion of the attributable risk of CKD in this population was associated with stage 1 hypertension (23%) and cigarette smoking (31%) (Table 19.1) [2].

Data from Kaiser Permanente in northern California that were based on a total of 316,675 US adults showed that the adjusted rate for developing CKD was 1.62 for a BP of 120–129/80–85 mmHg, 1.98 for BP of 130–139/85–89 mmHg, 2.59 for BP of 140–159/90–99 mmHg, and up to 3.86 for BP of 160–179/100–109 mmHg [3].

It could be concluded from these studies that increased risk of incident CKD is observed with BP levels considered in the high-normal or the prehypertensive range (120–139/80–89 mmHg).

Similarly, data from Japan's Okinawa island survey of over 110,000 individuals followed for over 17 years also linked the development of proteinuria and CKD to high baseline levels of BP [4].

Hypertension and risk of progression of CKD

As with the development of CKD, its progression has been associated with a number of factors. They consist of modifiable and nonmodifiable factors. Among the modifiable risk factors, both systemic hypertension and proteinuria are the most significant [5]. They are associated with a faster rate of progression of established disease. A faster rate of progression of CKD has been associated with both high systolic as well as high diastolic BP levels. Some have also linked faster progression with raised pulse pressure [6]. Correlations have also been made between an overall high BP level detected by 24-h ambulatory BP monitoring and a faster rate of decline of glomerular filtration rate (GFR) [7].

Of the 49 studies examining the relationship between raised BP and faster progression of CKD published by the Kidney Disease Outcomes Quality Initiative (K/DOQI) in 2002, 29 studies showed

Table 19.1 Classification of hypertension.[a]

BP classification	Systolic BP (mmHg)	Diastolic BP (mmHg)
Optimal	<120	*and* <80
Prehypertension		
Normal	120–129	80–84
High-normal	130–139	85–89
Stage 1 (mild) hypertension	140–159	*or* 90–99
Stage 2 (moderate) hypertension	160–179	100–109
Stages 3 and 4 (severe) hypertension	≥180	≥110
Isolated systolic (grade 1) hypertension	140–159	<90
Isolated systolic (grade2) hypertension	≥160	<90

[a]This classification is based on that of the British Hypertension Society, ESH, JNC-7, and that of WHO/ISH. If systolic BP and diastolic BP fall into different categories, the higher value should be used for classification purposes.

an association by univariate analysis and 20 remained significant by multivariate analysis evaluation [8].

Mechanisms of hypertension in CKD

The kidney is the key organ involved in the regulation of systemic BP. It is involved in the pathogenesis of hypertension and is one of the organs most severely affected by raised BP. Conventional teaching has implicated fluid and salt overload and the activation of the renin–angiotensin–aldosterone system (RAAS) in the pathogenesis of hypertension in CKD. However, additional data also suggest other mediators. For instance, there is no doubt that the sympathetic nervous system is activated in CKD [9]. This may be a direct effect of kidney injury and scarring with afferent renal signals stimulating the sympathetic nervous system or indirectly via the activation of the RAAS [10]. Experimental data show that renal denervation results in a fall in systemic BP and an attenuation of CKD [11,12]. Endothelin (ET) has also been shown to be raised in CKD, implicating ET1 and ET3 in the pathogenesis of hypertension [13], which may be mediated by the activation of the ET agonist receptor known to cause vascular constriction. ET antagonists have been shown to reduce systemic hypertension and slow the progression of experimental CKD. Other putative mechanisms of raised BP in CKD include the well-known increased arterial stiffness associated with impaired kidney function and reflected in the increased arterial pulse wave velocity observed early in the course of CKD [14]. Arterial stiffness is associated with systolic hypertension and coronary artery disease. Finally, a significant number of elderly and diabetic patients with

CKD suffer from atherosclerotic renovascular disease and renal ischemia.

Guidelines for management of hypertension

When to treat

Global guidelines for the management of essential hypertension agree on a number of points. These include the threshold of initiation of antihypertensive therapy based on risk stratification. In general, it is acceptable to consider those at increased CVD risk for earlier treatment. High CVD risk is defined as a >20% event risk over 10 years, which is equivalent to a congestive heart disease (CHD) risk of approximately 10% over 10 years [15].

The European Best Practice Guidelines (EBPG) for the management of hypertension stipulate that those with a >20% increased CVD risk over 10 years should be treated based on a lower threshold of BP (<130/80 mmHg) to achieve the maximum reduction in the total cardiovascular risk [16]. The EBPG, like most other guidelines [17], consider patients with CKD at high CVD risk, thus warranting early intervention [8,17,18]. In those patients with CKD and high CVD risk, an integrated therapeutic intervention (statin and antiplatelet therapy) frequently should be considered [16,19].

The EBPG recommend that proteinuria should be lowered in patients with CKD to values as near to normal as possible with either an angiotensin converting enzyme inhibitor (ACEi) or an angiotensin receptor blocker (ARB) (or a combination of both). To achieve the BP goal, combination therapy is usually required, with the addition of a diuretic, a calcium antagonist, and other antihypertensive agents [16]. The EBPG also recommend the treatment of all modifiable risk factors associated with hypertension (hyperglycemia, dyslipidemia, and smoking). Nondiabetic CKD patients with minimal proteinuria, however, have no benefit from treatment with an ACEi [20].

The Seventh Report of the Joint National Committee for the Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC-7) recommended treating systolic BP and diastolic BP to targets of <140/90 mmHg, aiming to decrease cardiovascular and renal morbidity and mortality in healthy subjects. In patients with hypertension and diabetes or CKD, the BP goal is lower, <130/80 mmHg [21].

Similar recommendations have been made by the British Hypertension Society, with a threshold for intervention of ≥140/90 mmHg in individuals with high CVD risk, including patients with CKD [22]. Target BP for those with CKD are <130/80 mmHg, and reducing BP to <125/75 mmHg may produce additional effects in those with proteinuria of >1 g/24 h (urine protein/creatinine ratio of >100 mg/mmol) [22].

In general, it is acceptable that patients with CKD are considered at the highest CVD risk [17,18], thus warranting a low threshold for initiation of antihypertensive treatment and lower target BP levels.

Table 19.2 Life-style modification recommendations for management of hypertension.

Intervention	Recommendation
Weight reduction	Maintain ideal body mass index (20–25 kg/m^2)
DASH eating plan	Consume diet rich in fruit, vegetables, and low-fat dairy products and with reduced content of saturated and total fat
Dietary sodium restriction	Reduce dietary sodium intake to 100 mmol/day (<2.4 g sodium or <6 g sodium chloride)
Physical activity	Engage in regular aerobic physical activity, e.g. brisk walking for at least 30 min most days
Alcohol moderation	Men: ≤21 units/wk; women: ≤14 units/wk

Guidelines for management of hypertensive CKD

How to treat

Nonpharmacological interventions

A range of nonpharmacological interventions have been advocated for the control of mild hypertension. These include life-style modifications, such as weight loss, regular exercise, and reduction in dietary salt and fat as well as increased intake of fruits and vegetables [23,24]. The Dietary Approaches to Stop Hypertension (DASH) studies showed the beneficial effect of a diet rich in fruits and vegetables and low in fat on blood pressure level. In addition, the DASH-Salt studies showed that dietary salt restriction further reduces BP in those already on a standard DASH diet [25]. Cessation of smoking and reduction of alcohol intake [25,26], weight reduction, and increased physical activity have also been shown to reduce BP [24] (Table 19.2).

Pharmacological interventions

In patients with CKD, pharmacological intervention, often with more than one drug, is required to control hypertension. In general, it is acceptable that the control of systemic BP has to be associated with a reduction in proteinuria to effect maximum protection in slowing the rate of decline of GFR [27]. In fact, recent studies have suggested that the control of proteinuria may be as important as, if not more important than, the control of hypertension per se [28].

Target BP levels

The K/DOQI guidelines on the management of hypertension in patients with CKD have recommended target BP levels of <130/80 mmHg [17]. These guidelines also suggested consideration of lower targets in heavy proteinuric [29] as well as diabetic patients [29,30]. These recommendations are based on observational and intervention studies.

Sources of data for these recommendations include the original report of the Modification of Diet in Renal Disease (MDRD) study, which suggested that lower blood pressure levels (<140/90 mmHg) may be needed in patients with moderate to heavy proteinuria (>1 g/24 h) [29]. These recommendations are also based on a systematic review of the literature that suggests that the lower the mean arterial BP (MAP) level, the slower the progression of CKD [31] for both diabetic and nondiabetic nephropathies. For the latter, reduction of MAP to levels below 92 mmHg has led to a normalization of the rate of decline in GFR (−1 mL/min/year), prompting those study authors to talk of regression of diabetic nephropathy [32].

The updated MDRD data suggested that a low target BP (MAP of <92 mmHg, compared to <107 mmHg) delayed the onset of kidney failure and a composite outcome of kidney failure and all-cause mortality [33]. This beneficial effect was observed in participants with various causes of nondiabetic CKD and extended across a wide range of proteinuria levels [34], although this was not the randomized intervention of this study.

In contrast, neither the Ramipril Efficacy in Nephropathy 2 (REIN-2) nor the African-American Study of Kidney Disease (AASK) studies showed additional advantage from further BP reduction [34].

Among the REIN-2 patients with nondiabetic proteinuric nephropathies receiving background ACEi therapy (134/82 mmHg), no additional benefit from further BP reduction by felodipine (130/80 mmHg) was shown [35]. However, this study was conducted over a relatively short period of time (1.6 years) and added a calcium antagonist for patients already controlled on an ACEi and achieving a 4.8-mmHg difference in systolic BP.

The AASK of African Americans with hypertensive CKD (baseline GFR around 46 mL/min, median baseline proteinuria of 0.81 g/24 h, follow-up of 5 years) failed to show an advantage to further BP reduction; patients with a mean BP of 128/78 mmHg experienced renal deterioration at the same rate as those achieving a mean of 141/85 mmHg [36]. However, subgroup analysis of those with proteinuria of >1 g/day showed a trend towards slower progression in the lower BP group. In this study, there was a therapeutic advantage for the ACEi (ramipril) on progression and proteinuria (−20%) compared to those treated with beta blockers (−14% for proteinuria). CKD patients treated with the calcium antagonist amlodipine showed a 58% increase in proteinuria.

In diabetic nephropathy (type 2 diabetes), the ABCD trial compared the effects of moderate BP control (target diastolic pressure, 80–89 mmHg) with those of intensive control (target diastolic pressure, 75 mmHg) on the incidence and progression of diabetic vascular complications. During a 5-year follow-up period, no difference was observed between intensive versus moderate BP control and between those randomized to nisoldipine versus enalapril for the outcome of change in creatinine clearance. After the first year of antihypertensive treatment, creatinine clearance stabilized in both the intensive and moderate BP control groups in those patients with baseline normo- or microalbuminuria. In

Stage 1 and 2 CKD
(GFR >60 ml/min/1.73 m²)
with mild proteinuria
(<1 g/24 h) should be treated

favoured as first choice (65) .

Figure 19.1 Algorithm for management of hypertensive CKD patients. Patients with CKD and hypertension should be managed according to the degree of their hypertension, proteinuria, and the stage of CKD.

contrast, patients starting with overt albuminuria demonstrated a steady decline in creatinine clearance of 5–6 mL/min/1.73 m²/year throughout the follow-up period whether they were on intensive or moderate therapy. There was also no difference between the interventions for the risk of progression from normoalbuminuria to microalbuminuria (25% intensive therapy vs. 18% moderate therapy) or microalbuminuria to overt albuminuria (16% intensive therapy vs. 23% moderate therapy) [37].

Regarding target BP levels, it is important to consider levels that would minimize CKD complications, including CVD morbidity and mortality. Although there are no data available for the target level needed to reduce CVD in CKD, results from other non-kidney-related studies are informative. For example, in the HOT trial, for each 5 mmHg decrease in diastolic BP, there was a significant reduction in cardiovascular events [38]. In diabetics at high CVD risk, every 2-mmHg reduction in systolic BP was associated with a 7% reduction in CHD and a 10% reduction in stroke. In this trial, a diastolic BP value of 85 mmHg appeared to reduce risk of major CV events by 27% with no further improvement at lower diastolic BP levels (80 mmHg) [38,39]. Of note, a recent study in patients with CKD and estimated GFR of

<60 mL/min suggested that low BP levels (systolic, <133 mmHg; diastolic, <65 mmHg) are associated with increased mortality in moderate to severe CKD as in patients on hemodialysis [40]. However, the increased mortality noted in these patients could not be dissociated from the patients' underlying cardiovascular status (i.e. reverse causality). Furthermore, diastolic values of less than 65 mmHg are seldom achieved in patients with CKD and hypertension. Regarding the type of agents used to reduce CVD, reports are available to suggest that every single antihypertensive agent has some advantage; ACEi is favored by some to minimize cardiac remodeling.

Target proteinuria

Albuminuria and proteinuria are well-known markers associated with diabetic and nondiabetic kidney disease [41]. Recent data suggest a high prevalence of albuminuria (microalbuminuria) in the general population [42,43]. It is elevated in a variety of conditions, including old age, obesity, hypertension, diabetes, CVD, and CKD. It is also increased in a number of chronic inflammatory conditions, including arthritis, chronic hepatitis, and inflammatory bowel disease. A growing body of evidence points to the fact

that albuminuria therefore may be more a marker of chronic inflammation and/or endothelial dysfunction rather than progressive CKD. In support of such an assumption is the reversibility of albuminuria with the control of the underlying pathology or predisposing factor. In diabetes, it has been shown that albuminuria does not always progress to proteinuria and is readily reversible with glycemic and hypertension control [44].

In other conditions associated with endothelial dysfunction and/or chronic inflammation, albuminuria reduction often parallels the fall in C-reactive protein (CRP) associated with the control of chronic inflammation. Data from the PREVEND study in the Netherlands highlighted this close association between albuminuria and CRP [45,46] and showed that, for example, weight reduction was associated with a fall in albuminuria and CRP levels [47]. Albuminuria should be considered a marker of endothelial dysfunction and inflammation rather than CKD.

In contrast, proteinuria [29,48], along with hypertension, is a very significant risk marker of progressive CKD. Over the last decade a body of evidence has implicated baseline as well as followup proteinuria levels in the progression of CKD [29,48], and the extent of the reduction of baseline proteinuria over a short period, 1–6 months [49], can predict the long-term renal functional response to an intervention. This was shown initially with dietary protein restriction [50] and more recently with hypertension control as well as ACEi [49] and ARBs [51]. In fact, some studies suggested that the beneficial impact of proteinuria reduction is greater and is independent from that of hypertension [52].

Choice of antihypertensive agents

Based on these data, a number of guidelines have favored the use of ACEi and ARBs in the management of hypertensive CKD, and these apply to diabetic and nondiabetic CKD patients. However, a number of observations suggest that the superiority of ACEi and ARBs in the management of hypertensive CKD in slowing the progression of CKD is greater among patients with a higher level of proteinuria [52]. In fact, the pivotal study of the impact of ACEi on the progression of nondiabetic CKD (REIN) failed to show benefit in those with proteinuria of <3 g/24 h [53]. Furthermore, this study also failed to show a therapeutic advantage of ramipril in those with MAP of <101 mmHg, for whom progression was slow, and both conventional agents, including calcium channel blockers (CCBs) and ACEi, had a comparable impact on CKD progression

Other studies that investigated the management of systemic hypertension (ALLHAT, ASCOT, and others) included some patients with CKD, although the degree of functional impairment was variable and often mild (CKD stages 1–3). The ALLHAT study of 33,357 individuals included 5662 patients with CKD (diabetic and nondiabetic, with an estimated GFR of <60 mL/min/1.73 m^2) who were followed for over 4.9 years. They noted that lisinopril was not more effective than chlorthalidone in slowing the progression of CHD or CKD [54]. Consequently, the therapeutic advantage of ACEi or ARBs is uncertain, particularly in patients with early CKD and in those with nondiabetic nephropathy and proteinuria of <1 g/24 h. It is likely that patients included in these trials, including ALLHAT, with mild to moderate hypertensive CKD may not have had severe proteinuria [54].

A meta-analysis of the impact of ACEi on the progression of diabetic and nondiabetic nephropathies showed some advantage on the progression of CKD in the latter but not in diabetics [55]. The data from this meta-analysis have been criticized for the inclusion of data on primary and secondary CKD, including the ALLHAT data, which showed thiazide diuretics to be superior to ACEi. Also, the primary and secondary end points of some of the studies included in the meta-analysis were not directly focused on the impact of treatment on CKD progression. However, the conclusion of the meta-analysis, that the beneficial effect of RAAS inhibition on progression is primarily dependent on better BP control, agrees with a number of observations made for essential hypertension and for diabetic nephropathy. In fact, data from the Steno Institute have shown over the years, in a number of relatively small studies, that progression of diabetic nephropathy can be halted with good BP control and MAP of <92 mmHg regardless of the antihypertensive agent used [56]. The UKPDS confirmed that lower BP led to slower decline in renal function regardless of whether atenolol or captopril was used [57]. Also, the ABCD trial, in a similar population of type 2 diabetic individuals, failed to show an advantage of enalapril over nisoldipine [37]. These observations in diabetic CKD and the implication of the Casas meta-analysis support a large body of literature on the impact of treatment on hypertensive CVD complications, from which the benefit derives primarily from the degree of BP reduction regardless of the antihypertensive agent used [58].

Finally, the indiscriminate use of ACEi and ARBs in CKD patients is not without risks. It is well known that patients with renovascular disease and ischemic nephropathy may be at risk of further renal dysfunction when using these agents. Distinction is also seldom made in the prescribing of RAAS inhibitors to patients with type 2 diabetes mellitus and CKD between those with genuine diabetic nephropathy and significant proteinuria and those with severe atherosclerosis or hypertensive or ischemic nephropathy. This may explain the high incidence of side effects. Also, a recent long-term analysis of the outcome of patients with diabetic nephropathy treated with ACEi suggested that after an initial stabilization, a higher number of patients progressed to ESRD compared to controls [59].

It is generally accepted that an up to 30% acute increase, within a week, in serum creatinine or a fall in GFR of less than 25% is acceptable, and predictable, upon initiation of ACEi and ARBs in patients with CKD [60]. However, close and prolonged monitoring is warranted, as some patients continue to have a rise in serum creatinine within the first 3 months of ACEi or ARB initiation.

Risk stratification of CKD and CVD risk: the CKD-CVD complex

With the above in mind, what recommendations can be made regarding the management of hypertensive CKD? The choice of

agents in hypertensive CKD may have to take into consideration the presence of other CKD and CVD risk markers.

Proteinuria

Evidence suggests that ACEi and ARBs are more effective than conventional agents in CKD patients with heavy proteinuria and MAP levels of >110 mmHg (BP >140/90 mmHg) [53]. This would justify their use as the initial treatment of choice under these conditions. In such patients, including those with advanced diabetic nephropathy, it has been suggested that dihydropyridine CCBs may not be effective at reducing proteinuria, as they have been shown to increase, rather than decrease, glomerular filtration and intraglomerular capillary pressure in experimental animals. There may be an advantage for using one of the nondihydropyridine CCBs, such as verapamil or diltiazem, which have been shown, in a small number of studies, to be as effective in reducing proteinuria as ACEi in type2 diabetic nephropathy [61,62]. Beta blockers have a modest, if any, intrinsic antiproteinuric effect.

In such patients, it is generally acceptable that the threshold for initiation of antihypertensive treatment should be 130/80 mmHg and the target BP level should be <125/75 mmHg [17,21].

To control proteinuria, ACEi and ARB treatment is often ineffective unless combined with dietary salt restriction (below 100 mmol/day; <2.4 g sodium or <6 g sodium chloride) and diuretic therapy. This may explain the inferiority of these agents in some large studies, such as ALLHAT, where lisinopril was not combined with a diuretic. The beneficial effect of adding a diuretic to RAAS inhibition has been demonstrated with thiazide and loop diuretics as well as aldosterone antagonists, with all showing synergy with ACEi and ARB in reducing proteinuria.

As the initial (1–6 months) proteinuria-reducing effect determines long-term outcome, it is sensible to aim at maximal suppression of proteinuria with values of <1 g/24 h; for that level of suppression, the combination of an ACEi and an ARB may be justifiable. The COOPERATE study showed that ACEi and ARBs have additive antiproteinuric effects independent of their blood pressure-lowering impacts [63]. The combination led to a beneficial effect on the progression of CKD as a function of the reduction of proteinuria and independently of BP levels [63].

While reduction of albuminuria may impact favorably on CVD outcomes [62], there are suggestions that in diabetic nephropathy the reduction of proteinuria also favorably affects CVD complications [63,64]. Albuminuria may prove to be a useful CVD risk stratification marker in CKD patients, thus affecting the choice of antihypertensive agents.

Stage of CKD

There is little doubt that the initial level of GFR at the initiation of treatment affects prognosis, with patients with CKD stages of 3–5 at higher risk. Most data evaluating the impact of antihypertensives on the progression of CKD have focused on those patients with the highest risk of progression, in whom changes in BP levels and proteinuria have detectable impacts on CKD progression over short observation times.

Patients with CKD stages 3 and 4 and heavy proteinuria would benefit from ACEi and ARBs, as discussed above, with a target BP of <125/75 mmHg. It has also been argued that even those with CKD stage 5 would benefit from such treatment(s) [65,66]; this awaits confirmation and warrants caution, as these agents could easily precipitate irreversible ESRD.

In patients with CKD stages 1 and 2 with mild proteinuria (<1 g/24 h), progression is often slow and there is little evidence that progression is affected by the type of antihypertensive agent used. There is also a paucity of data on their CVD risk in the absence of decreased GFR (<60 mL/min) and/or anemia. In these patients it would therefore be reasonable to apply the risk stratification recommendations drawn for the treatment of essential hypertension:
1 High risk for CVD: 20% chance of an event over a 10-year period: Those aged >55 years, male, smokers, and hyperlipidemic and/or with a family history of CVD should be treated early (BP 140/90 mmHg), and BP levels should be reduced to <130/80 mmHg [16,17,21].
2 Low risk for CVD: target BP levels of 140/90 mmHg would be acceptable, bearing in mind their low CKD and CVD risk.

Recent guidelines issued by the National Institute of Health and Clinical Excellence suggest that the initiation of antihypertensive therapy with a thiazide diuretic and/or a calcium antagonist would be a reasonable and cost-effective first choice in those over the age of 55 years and for Black patients of any age [67]. These agents seem to provide better CVD risk reduction than beta blockers, in particular against stroke, and are marginally more cost-effective than ACEi and ARBs [67]. This choice is based on a meta-analysis of major hypertension clinical trials as well as a formal economic evaluation [67]. They recommend ACEi as first-line treatment in hypertensive patients younger than 55 years. If more than two agents need to be used to control BP, they recommend a combination of a diuretic, calcium antagonist, and ACEi or ARB [67].

At a recent UK CKD consensus meeting, it was suggested that for most patients with early CKD (stages 1–3) without significant proteinuria (<1 g/24 h or urinary protein/creatinine ratio of <100 mg/mmol), the primary objective of treatment should be to reduce the risk of stroke and heart disease with the choice of antihypertensive agents according to national guidelines; for the UK, initial therapy in those <55 years with an ACEi and in those older than 55 years with a calcium antagonist and/or a diuretic [68]. These recommendations agree with those of the National Institute of Health and Clinical Excellence and the British Hypertension Society and take into consideration the absence of evidence of an additional renoprotective effect of angiotensin inhibitors in nonproteinuric CKD.

Type of CKD

Patients with diabetic nephropathy should preferentially be treated by initial inhibition of the RAAS; there is no evidence of difference in efficacy between ACEi and ARBs in these patients. In nondiabetic CKD patients, the stage of CKD and proteinuria should be the major determinants in selecting an antihypertensive agent, rather than the nature of the underlying nephropathy. In a number of

chronic glomerulonephritis patients, including those with membranous and immunoglobulin A nephropathy, ACEi have been shown to be effective at reducing proteinuria and slowing the progression of renal insufficiency. In patients with polycystic kidney disease it has been argued that ACEi are both beneficial and detrimental; this may reflect the stage of CKD, with early intervention having a more beneficial effect.

An increasing number of patients are recognized as having renovascular disease. These also include a proportion of type 2 diabetic patients with CKD. It is imperative to have a high index of suspicion of such patients in the face of a disproportionately high systolic BP and a wide pulse pressure in patients with a history of atherosclerotic vascular disease. ACEi and ARBs should be avoided in these patients, as they can precipitate further deterioration in renal function as the ischemic kidney depends to a large extent on angiotensin II-mediated efferent arteriolar vasoconstriction to maintain the capillary pressure and filtration of its hypoperfused glomeruli.

Race and ethnicity

It is generally accepted that black people of African or African-Caribbean origin have higher rates of hypertension and higher BP levels than white individuals. This is associated with higher CKD and CVD risks, with the exception of CHD, which is lower than in white people. Hypertension in the black population is often volume dependent and salt sensitive, reflecting a low renin status, favoring dietary salt restriction and diuretic therapy. Among black patients in the ALLHAT study, ACE inhibition led to a significantly higher rate of CVD events: strokes and CHF [69]. However, the AASK trial of African American patients with CKD showed ramipril to be superior to amlodipine; the amlodipine arm had to be stopped prematurely because of apparent worsening of CKD. The decision was controversial, because it implied that CCB may not be suitable for black individuals with CKD. In general, it is advisable to treat black patients with CKD along similar lines to their white counterparts, including the inhibition of the RAAS along with dietary salt restriction and vigorous diuretic therapy.

In the USA and UK, individuals of Asian origin have a higher prevalence of diabetes mellitus and hypertension as well as renal and cardiovascular complications. British Asians may also have a faster rate of progression of diabetic nephropathy [70]. There is no evidence that these individuals respond differently to antihypertensive agents compared to Caucasians. However, their high susceptibility to glucose intolerance and diabetes, obesity, and dyslipidemia may affect the choice of antihypertensive agents. With that in mind, agents modifying the RAAS may have therapeutic advantages, as they decrease the incidence of diabetes and have beneficial effects on components of metabolic syndrome.

Smoking

Patients with CKD who are heavy smokers are at increased risk of progression of diabetic and nondiabetic CKD [71]. It was shown in one study that ACE inhibition considerably reduced the smoking-associated risk of progression to ESRD [72].

Dyslipidemia

It is of relevance that the initiation and progression of CKD has been linked to serum lipid levels [73], which should be considered when prescribing antihypertensive agents because some, such as diuretics and beta blockers, increase serum lipids.

In conclusion, the management of hypertension in CKD depends on the renal and cardiovascular risk profile of the patient. Patients with low renal and cardiovascular risk, namely, those with CKD stages 1 and 2 and no or mild proteinuria (<1 g/24 h), could be treated according to guidelines set by hypertension societies in the EU and USA. On the other hand, those with more advanced renal insufficiency (CKD stages 3–5) and/or those with proteinuria who are at high renal and CVD risk should be treated according to the K/DOQI guidelines for the management of hypertension with lower treatment and target thresholds (i.e. <130/80 mmHg) [54]. The great majority of these patients will require more than one agent to control their BP to recommended target levels of <130/80 mmHg. Compliance is often a problem, and so the conventional stepped-care approach to the management of hypertension may not be optimal to minimize side effects and improve compliance. Combination therapy of two or three drugs at lower doses may be a better initial option [39].

20 Diagnosis and Management of Renovascular Disease

Jörg Radermacher

Department of Nephrology, Klinikum Minden, 32427 Minden, Germany

Introduction

End-stage renal disease requiring renal replacement therapy puts a major economic burden on the health care system. Atherosclerotic renovascular disease has been found in about 12–31% of patients >45 years old with end-stage renal disease [1,2] and constitutes the fastest-growing group of these patients [3]. In unselected patients with hypertension, the prevalence is only about 1–5% [4]. In certain patient populations, such as those with severe hypertension, refractory hypertension, aortic aneurysm [5], or coronary artery disease [6], the prevalence is as high as 20–40% [7].

Patients with renal artery stenosis of >50–70% renal artery diameter are frequently advised to undergo correction of the stenosis. The reason for treatment usually is difficult-to-control hypertension; however, amelioration of kidney failure should also be considered a reason for treatment. Identifying patients whose blood pressure and/or renal function will improve postintervention is difficult. Retrospective studies have shown a lack of improvement in blood pressure and renal function despite correction of the stenosis in 20–46% of patients [8–15]. The term renovascular hypertension is reserved for those patients with improved, or rarely even normalization of, blood pressure after intervention. The term renovascular azotemia is used for those patients who have improved renal function. Frequently, the term ischemic nephropathy is used, but this term does not tell whether a patient is going to be a responder. Renal artery stenosis and renovascular hypertension are frequently used as synonyms in the literature [16]. However, the term renal artery stenosis should be reserved for an anatomical description, whereas renovascular hypertension and renovascular azotemia describe the functional relevance of the stenosis.

Because angioplasty and surgery can lead to complications like cholesterol embolism, persistent acute kidney failure, and even patient death, these procedures should only be performed in patients with a high likelihood of benefit. Possible reasons for a lack of treatment effect are correction of trivial stenoses (<60%), underlying renoparenchymatous disease, technical failure, cholesterol embolism, or radiocontrast toxicity. These aspects will be discussed in this chapter.

Pathophysiology of renal artery stenosis

Renal artery stenosis leads to renal ischemia, causing the release of renin from the juxtaglomerular cells of the kidney and resulting in the conversion of angiotensin I to angiotensin II, subsequent release of aldosterone from the adrenal gland, vasoconstriction, and sodium and water retention. The long-term consequences are the buildup of extracellular matrix and collagen IV via angiotensin II-induced increased expression of transforming growth factor β and interstitial platelet-derived growth factor, resulting in irreversible parenchymal damage [17] also in the nonaffected kidney. The challenge of treatment of atherosclerotic renal artery stenosis is to intervene at a stage before major parenchymal damage has occurred.

Patients who should be screened for renal artery stenosis

Because renal artery stenosis is present in only about 1% of unselected patients with hypertension, general screening is not advisable. The clinical signs suggesting renovascular disease include an abdominal bruit, difficult-to-control hypertension (requiring ≥3 antihypertensive agents), accelerated hypertension or hypertension that was previously well-controlled, worsening of renal function 4–31 days after introduction of angiotensin converting enzyme inhibitor (ACEi) or angiotensin II receptor blocker treatment [18], severe atherosclerosis in other vascular beds, otherwise-unexplained chronic kidney disease, hypertension associated with sudden and repeated left heart failure or pulmonary edema, the onset of hypertension before the age of 30 years (from fibromuscular

renal artery disease) or after the age of 55 years (from atherosclerotic renal artery disease), and differences in the sizes of the two kidneys. It is important to identify these clinical clues, because the prevalence of renal artery stenosis rises up to 39% among these patients [19]. Once renal artery stenosis is suspected, a screening test is used to confirm its presence.

Screening methods for renal artery stenosis

Screening tests should be inexpensive, accurate (i.e. with a low rate of technical failure and high sensitivity and specificity), and noninvasive. This excludes angiography, although angiography is still considered the reference standard for detection and quantification of stenosis. A high interobserver variability for stenosis quantification has been shown (kappa < 0.4) [20]. One study found a pressure gradient of ≥30 mmHg in 13 of 22 renal arteries in which arteriography had shown only minor degrees of stenoses (<50%) [21], a pressure gradient generally associated with a reduction of the glomerular filtration rate (GFR) [22]. Angiography may also cause atheromatous embolization of the kidneys or renal impairment due to radiocontrast nephrotoxicity.

Spiral computed tomography angiography (CTA) and magnetic resonance angiography are noninvasive imaging techniques that have high sensitivity and specificity (>95%) for detecting renal artery stenosis [23–26], although a more recent study did not find the same level of accuracy when these methods were applied in everyday practice [26]. The latter study reported a sensitivity of 64% and a specificity of 92% for CTA and 62% and 84%, respectively, for magnetic resonance angiography. These techniques are also limited by their high costs and, in the case of spiral CT, the use of contrast agents. Magnetic resonance is not suitable for patients with claustrophobia and certain types of metallic implants. Measurement of the concentrations of renin in the renal veins have been used to predict the potential success of surgical revascularization. False-negative and false-positive results are common with this technique, and it is therefore not recommended as a reliable screening test for renal artery stenosis. In theory, the accuracy of renal vein renins are enhanced by using an ACEi (captopril test), which attenuates the vasoconstrictive effect of angiotensin II on the efferent arteriole and reduces filtration on the side of the stenosis [23]. The reported sensitivity and specificity after 25–50 mg of captopril, however, are also low [27].

Captopril scintigraphy (25–50 mg of oral captopril given 12 h before isotope) can detect renal artery stenosis with high sensitivity and acceptable specificity and has also been shown to be of value in identifying patients whose blood pressure will improve after correcting the stenotic lesion [28]. This test, however, has not been shown to predict an improvement in renal function after correction of renal artery stenosis, and it cannot locate the stenosis or determine its severity [23]. Furthermore, the sensitivity of this test is reduced to 80% in patients with renal insufficiency (GFR of <50 mL/min) or in patients with bilateral stenoses or a stenosis in a single functioning kidney [23,29]. It is particularly important to

identify significant stenoses in these patients, because the major rationale for performing surgery or angioplasty is to preserve renal function.

In experienced hands Doppler ultrasonography is highly sensitive and specific for detecting renal artery stenosis, and it is rapid and inexpensive [30]. Two main approaches are used to detect a significant renal artery stenosis of 50–70% [30,31]. The first (direct) approach looks at flow acceleration at the site of the stenosis. This approach has good sensitivity and specificity for detecting stenoses of ≥50%. Obesity, excessive bowel gas, or poor blood flow in the main renal artery can, however, interfere with direct visualization of the renal arteries [30]. The second (indirect) approach looks at poststenotic flow phenomena (tardus and parvus). This approach can be used in nearly all patients but will only detect severe stenoses of >70%. A combination of both approaches is the most suitable technique for accurate detection of renal artery stenosis in almost all patients. In patients with normal or impaired renal function, we reported no technical failure with this combination method and showed high sensitivity (96.7%) and specificity (98.0%) for detecting renal artery stenosis of ≥50% compared with angiography [30,31]. The value of Doppler ultrasonography to reliably detect stenoses of 50% and more has been shown in the majority of more recent studies (Table 20.1).

In summary the best screening test is probably the test performed most frequently at an individual facility. In patients with a GFR of <50 mL/min, CTA (due to radiocontrast toxicity) and captopril scintigraphy (due to low sensitivity) should be avoided.

Quantification of stenosis and estimation of functional relevance

Other than detecting the presence of stenosis, Doppler ultrasonography can also be used to estimate the severity of renal artery stenosis, with reliable estimates for up to 70% diameter reduction. A good correlation compared to intravascular ultrasound has been shown ($R = 0.97$) [44].

There is general agreement [45] that a diameter stenosis of <50% causes neither high blood pressure nor impairment of renal function. For this reason intervention should not be performed for these low-degree stenoses. Stenoses of <60% progress slowly and almost never proceed directly to occlusion [46]. A policy of watchful waiting (e.g. ultrasonographic follow-up of stenoses) is reasonable. Stenoses of >65–80% are considered to be hemodynamically relevant [14,47]. Stenoses in most studies have been graded by angiography. Simon *et al.* found hypersecretion of renin, suggesting functional relevance, in stenoses of >80% diameter reduction [47]. Unfortunately, data on the improvement of blood pressure or renal function after correction of stenosis are lacking. Giroux retrospectively evaluated the degree of stenosis in patients who did or did not have improved blood pressure after correction of renal artery stenosis. They found tighter stenoses in patients that did benefit (79 ± 9% vs. 74 ± 9%; $P < 0.05$), but the differences

Table 20.1 Stenosis criteria and sensitivity and specificity for detection of renal artery stenosis with Doppler ultrasound compared to selective angiography.[a]

Criterion and study [reference]	No. of patients	Criterion	% Technical failure[b]	Degree (%) of stenosis[c]	% Sensitivity/ specificity

Abbreviations: AI, acceleration index; AT, acceleration time; RI, resistance index (Pourcelot index); ESP, early systolic peak; RAR, renal aortic ratio; RRR, renal renal ratio.

[a] Only prospective studies with more than 50 patients and used comparison with intra-arterial angiography as the gold standard were considered.

[b] Technical failure: the renal artery or intrarenal arteries could not be visualized by color Doppler ultrasonography.

[c] The lowest degree of stenosis (% diameter stenosis) detected by the respective ultrasound method. NA, data not available.

were small [14]. Future studies should quantify stenoses using either noninvasive Doppler ultrasound, intravascular ultrasound, or a pressure gradient measured by pressure wire (an expensive method) or catheter.

Exclusion of renoparenchymatous disease

Possibly the main reason for a lack of treatment benefit despite successful correction of renal artery stenosis is preexisting renoparenchymatous disease. The two most frequent diseases coexisting with or even causing renal artery stenosis are long-term hypertension and diabetes leading to hypertensive nephrosclerosis and diabetic glomerulosclerosis [48]. Renal biopsy can predict treatment failure but is usually not indicated in these disease entities [49]. Some readily available clinical and angiographic clues as predictors of treatment success have been suggested [50,51] (Table 20.2). However, none of these parameters is sufficiently sensitive or specific, and contradicting data have been published for many of these. Rapidly deteriorating renal function in the presence of renal artery stenosis has been associated with a favorable response after angioplasty [52]; however, follow-up data on renal function are frequently not available. Some screening methods

have been evaluated regarding prediction of treatment success: measurement of renal vein renin, captopril scintigraphy, magnetic resonance tomography, and Doppler ultrasonography. Because a hemodynamically relevant renal artery stenosis should cause increased renin production, renal vein renin measurements have been considered the reference standard for predicting the functional relevance of stenoses. The diagnostic accuracy of this test is, however, disappointing, and the requirement for invasive venous angiography and radiocontrast agents have made this method almost obsolete. Renal scintigraphy without captopril also has only low diagnostic accuracy, but captopril scintigraphy is an established method to predict a treatment effect. Captopril causes a further fall in GFR in the affected kidney. The positive predictive value for blood pressure improvement of a positive captopril scintigraphy is reported to be 92%; however, sensitivity drops to 80% in patients with impaired renal function [29]. This could be due to dependence of renal filtration on vasoconstriction of the efferent arteriole in patients with advanced renoparenchymatous disease, which is impaired after ACEi treatment. A further drawback of captopril scintigraphy is the requirement for meticulous patient preparation in order to obtain reliable results. Patient preparation includes controlled hydration, controlled sodium diet, and removal of diuretics and ACEi 4–14 days before the investigation

Table 20.2 Predictors of a lack of effect of successful correction of renal artery stenosis related to blood pressure and/or renal function.

Patient characteristic	Studies (reference nos.) that found the parameter to be:	
	Predictive	Not predictive
Advanced age, >65 yrs	13, 15, 54, 55	14, 56, 57
Male gender	54	14, 56, 57
Severe atherosclerosis	14, 15, 56	
Proteinuria >1 g/day	15, 58	
Severely impaired renal function (GFR <40 mL/min)	15, 56	14, 55, 57
No sudden appearance of hypertension, or sudden worsening of previously well-controlled hypertension	13	15
Duration of hypertension >10 yrs	14, 54	55
Diastolic blood pressure <80 mmHg	14, 54, 55	57
Systolic blood pressure <160 mmHg	57	55
Diabetes mellitus	14	15, 56
Nonsmoker	14, 15	
Degree of stenosis <70%	14	13, 57
Resistance index >0.80	15	

[29,53]. van Jaarsveld *et al.* did not find a predictive value of captopril scintigraphy for improvement of blood pressure in their study [13].

Gadolinium-assisted magnetic resonance imaging after ACEi treatment has been used to quantify renal filtration and has provided predictive results comparable to captopril scintigraphy [59]. Prospective studies on this fascinating technique as a predictor for renovascular hypertension or azotemia are lacking at present, however.

In two studies with low patient numbers, an increased intrarenal resistance index value measured by Doppler ultrasonography was associated with a rapid loss of renal function [60] and a lack of blood pressure improvement [61], despite correction of renal artery stenosis. A prospective study found that a resistance index of >0.8 in the interregnal segmental arteries had a sensitivity and specificity of >90% for predicting renal function deterioration and a lack of blood pressure improvement [15] (Figure 20.1).

Correction of renal artery stenosis versus drug treatment

Presently, it is uncertain whether angioplasty or surgery for renal artery stenosis is associated with an improved outcome compared to medical treatment alone. Three randomized controlled trials, with relatively few patients, have been performed and did not show any difference in blood pressure or renal function [13,62,63]. A meta-analysis of these trials found a nonsignificant trend toward blood pressure reduction and lesser requirements for antihypertensive drugs in two of the three trials but no effect on renal function with angioplasty [64]. More studies comparing angioplasty with optimal medical treatment with greater patient numbers are underway (http://www.astral.bham.ac.uk) [65–67]. Until the results of these studies are available, physicians should try to only treat patients for whom there is a high likelihood of a positive response. Drug treatment of renal artery stenosis should include not only antihypertensive drugs but also lipid-lowering drugs, to perhaps prevent progression of renal artery stenosis, and antiplatelet drug treatment to prevent renal artery thrombosis.

Improving short- and long-term results of correction of renal artery stenosis

Ten-year patency rates are still only available for surgically corrected renal artery stenoses, although outcomes may be better after surgery compared to angioplasty [68]. However, angioplasty has become the method of choice because it is less invasive and has a lower mortality rate. Only when an aortic aneurysm or other severe aortic disease requires simultaneous treatment should surgery be the preferred method. Ostial stenoses should always be treated with angioplasty plus stenting; stenoses located >1 cm distally to the aorta or stenoses due to fibromuscular dysplasia can
Figure 20.1 Odds ratios for various factors to predict deterioration of renal function. Squares depict odds ratios; lines depict 95% confidence intervals. RI, resistance index; CHD, coronary heart disease; AOD, atheroocclusive disease of the legs.

be treated with angioplasty alone [69]. A randomized controlled study reported better initial patency rates (88% vs. 57%) and lower restenosis rates (14% vs. 48%) 6 months after stent-assisted angioplasty compared to angioplasty alone in ostial stenoses [70]. However, the same study failed to show superiority of stenting regarding blood pressure or renal function improvement. Newer studies report primary patency rates in the range from 94 to 100% [14,57,71,72], but long-term results are less favorable. Restenosis, *de novo* stenosis, or thrombosis rates in the range of 10% per year have been reported both in stent-treated patients and patients who had angioplasty alone [14,15,52,57,71–74]. Revascularization success should therefore be monitored by ultrasonography at 3 months, 6 months, and yearly intervals thereafter. Newer technologies using sirolimus-coated stents are being evaluated [75].

Cholesterol embolism and radiocontrast toxicity

Cholesterol embolism in the renal arterial bed or the aorta is always a dramatic event. It can lead to progressive loss of renal function despite patency of the renal artery. At present there is no reliable method to detect cholesterol embolism. Renal biopsy is invasive and may miss the site of embolism due to sampling error. Blood eosinophilia or the "blue toe" suggest cholesterol embolism but are not sufficiently sensitive or specific to allow the diagnosis of renal cholesterol embolism. Dejani *et al.* found blood eosinophilia of >5% in 7 of 20 patients older than 55 years with impaired renal function (serum creatinine, >2 mg/dL) treated by renal angioplasty [76]. The feasibility of renal protection devices catching cholesterol crystals and other debris has been shown but has not been tested in randomized controlled trials [77].

A further frequent complication associated with renal angiography and renal arterial stenting is radiocontrast toxicity. Treatment of renal artery stenosis may be of greatest benefit in patients with impaired renal function, and these patients are most sensitive to radiocontrast toxicity. Controlled hydration with NaCl at 1 mL/kg/h for 12 h prior to and after angioplasty is considered standard prophylactic therapy. A randomized controlled trial has shown the superiority of this regimen, compared with additional mannitol or furosemide treatment [78]. Prehydration with sodium bicarbonate (154 mmol plus 900 mL 5% glucose solution) instead of saline alone may further lessen the risk. However, these data have not been confirmed in subsequent studies [79]. Acetylcysteine (600–1,200 mg twice a day) has been shown to have an additive protective effect compared with hydration alone for preservation of renal function and prevention of acute kidney failure in several randomized controlled trials [80,81], but a recent meta-analysis including 19 randomized trials failed to show such a protective effect (see chapter 10) [82].

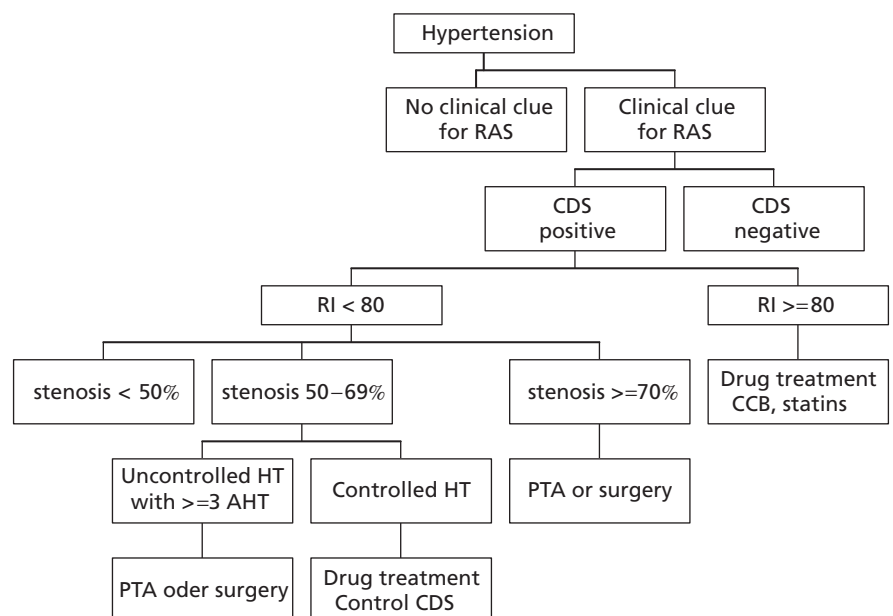
The newer nonionic radiocontrast agents have lessened the risk of toxicity but have not abolished it [83]. Furthermore, the iso-osmolar radiocontrast agent iodixanol has been associated with significantly less contrast nephropathy than the low-osmolar agent iohexol [84]. These results have not been confirmed in other studies. Hemodialysis during or directly after application of radiocontrast agents does not prevent radiocontrast toxicity, but hemofiltration may have a beneficial effect [85]. Here also, confirmatory studies have not been performed, and this method of treatment is invasive and expensive. Calcium channel blockers, ANP [86], dopamine [87], and endothelin receptor antagonist [88] have been proven useless to prevent radiocontrast toxicity. Theophylline may have a protective effect, but its effects are not additive compared to hydration treatment alone [89].


Figure 20.2 Approach to the patient with hypertension and suspected renal artery stenosis.

Conclusions

Patients should only be screened for the presence of renal artery stenosis when the likelihood that they have renal artery stenosis is sufficiently high. Good screening methods are Doppler ultrasonography and captopril scintigraphy, because both of these methods also have some predictive value regarding the likelihood of blood pressure and renal function improvement (RI <80 or positive captopril scintigraphy) following correction of the stenosis. Only patients with a high likelihood for improvement should be treated with angioplasty, because at present the superiority of angioplasty compared to medical treatment alone has not been definitively proven. Future technical improvements regarding prevention of cholesterol embolism and radiocontrast toxicity may increase the proportion of patients who benefit from stenosis correction. Based upon current data, stenoses of >70% should be treated with angioplasty, and stenoses of 50–70% should be treated only if blood pressure cannot be controlled with maximal antihypertensive treatment (opinion). A possible diagnostic and treatment algorithm is shown in Figure 20.2.

21 Diabetes Mellitus

Piero Ruggenenti[1] & Giuseppe Remuzzi[2]

[1]Unit of Nephrology, Azienda Ospedaliera Ospedali Riuniti di Bergamo, 24128 Bergamo, Italy
[2]Clinical Research Center for Rare Diseases "Aldo & Cele Daccò," Mario Negri Institute for Pharmacological Research, 24125 Bergamo, Italy

Introduction

Diabetes mellitus, in particular type 2 diabetes, is a public health concern, and projections for the future are alarming. According to the World Health Organization, diabetes affects over 170 million people worldwide, and this will rise to 300 million people by 2025 [1], about one-third of whom will eventually suffer progressively deteriorating renal function. Ninety to 95% of these patients have type 2 diabetes. The first clinical sign of renal dysfunction in diabetic patients is microalbuminuria (a sign of an endothelial dysfunction not necessarily confined to the kidney), which manifests in 2–5% of patients per year. In 20–40% of cases, microalbuminuria progresses to macroalbuminuria or overt proteinuria, and 10–50% of patients with proteinuria develop chronic kidney disease, which ultimately requires dialysis or transplantation [2]. Of great concern, 40–50% of type 2 diabetic patients with microalbuminuria eventually die of cardiovascular disease. This is threefold more than for diabetic patients without evidence of renal disease [3].

Here we will review the evidence that, in diabetic patients with kidney disease, lowering blood pressure and urinary albumin are effective in reducing the risk of end-stage renal disease (ESRD) as well as of myocardial infarction, heart failure, and stroke and that among antihypertensive medications, angiotensin converting enzyme (ACE) inhibitors or angiotensin II antagonists are the most effective. Although less consistent, data are available that also nondihydropyridine calcium channel blockers (ndCCBs) may lower urinary albumin and slow renal disease progression, and ndCCBs, added to ACE inhibitor therapy, may be more effective. Finally, we will discuss recent evidence that ACE inhibitors can also prevent the onset of microalbuminuria, an early marker of kidney disease, if given to patients with type 2 diabetes and hypertension but normal urinary albumin excretion.

The epidemics of type 2 diabetes and related renal and cardiovascular disease

Diabetes mellitus is the most frequent cause of chronic kidney disease worldwide. Over the past 2 decades, there has been a continuous increase in the incidence of ESRD due to diabetes, predominantly in those with type 2 diabetes [1,2]. In the USA, the proportion of patients with both ESRD and diabetes rose from 27 to 50% between 1982 and 2000, a trend echoed in many developed countries and in non-Caucasian populations (i.e. Afro–Caribbean, Asian, Native American, Australian Aboriginal people, etc.). Until recently, the risk of renal complications was thought to be considerably lower among patients with type 2 diabetes than in those with type 1 diabetes; however, it has now been shown that the risk of nephropathy with progression to ESRD is similar for the two groups [4]. This knowledge has helped to change the perception of type 2 diabetes, and it is now apparent that this disease should be treated with the same seriousness as type 1 diabetes.

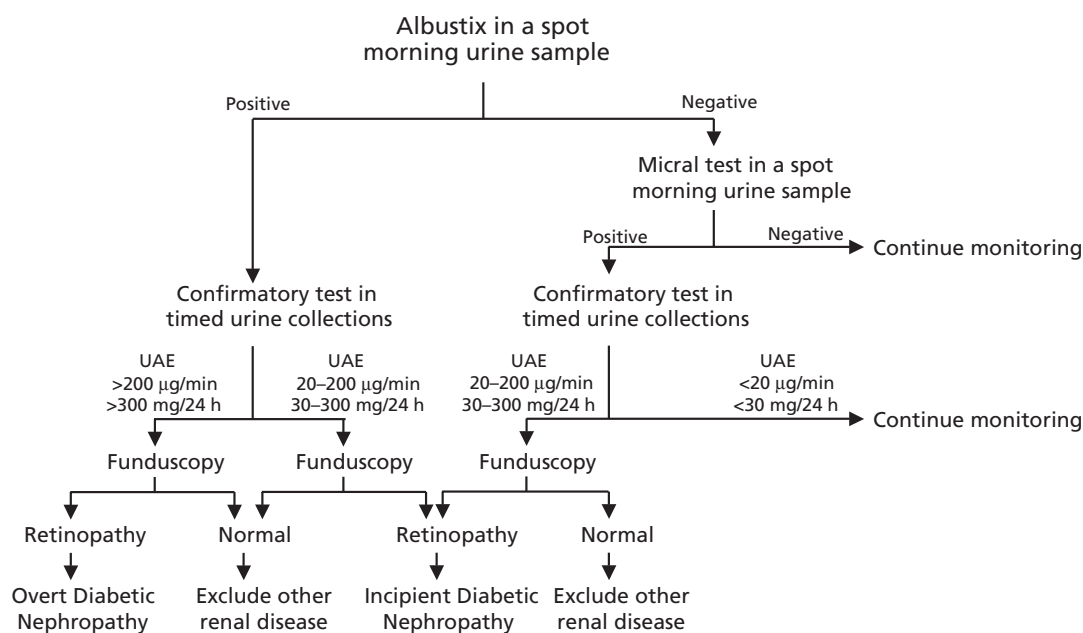
The prevalence of type 2 diabetes, and of related kidney disease, is rapidly increasing due to the progressive ageing of the population and the worldwide epidemic of obesity, especially in developing countries. In parallel, the incidence of ESRD within the type 2 diabetes population has increased dramatically. This may be due partly to improved treatments for hypertension and coronary heart disease, allowing more patients with type 2 diabetes to live long enough for nephropathy and ESRD to develop [5], or it may be because the spectrum of diabetes has become more severe. This phenomenon may also be because patients may be treated less optimally than previously as health care systems struggle with the increased load of diabetic patients. For example, a blood pressure target (i.e. $\leq 130/80$ mmHg) is not being achieved as frequently as is ideal, resulting in increased risk of kidney failure. Also, proteinuria may not be treated as a risk factor. Numerous studies have demonstrated that reducing proteinuria is renoprotective [2]. Targeting treatment to both blood pressure and urinary protein is therefore important to limit or prevent kidney disease in people with diabetes.


Figure 21.1 A possible algorithm to guide diagnosis of diabetic nephropathy.

Albuminuria is associated with cardiovascular disease mortality independent of other cardiovascular risk factors in both type 1 and type 2 diabetes [5,6]. Diabetic subjects with no evidence of kidney disease have cardiovascular morbidity and mortality comparable to those of age-matched controls without diabetes. In those with albuminuria, the risk increases in parallel with the increase in urinary albumin excretion (UAE). Observational analyses of the UKPDS study found that in patients with type 2 diabetes the incidence of cardiovascular events increases by 2- to 4-fold with the appearance of microalbuminuria (UAE, 20–200 μg/min or 30–300 mg/24 h), by 9- to 10-fold with the progression to macroalbuminuria (UAE, >200 μg/min, or 300 mg/24 h), and by more than 20-fold with the development of renal insufficiency and progression to ESRD [3]. Other studies have found that the incidence of coronary heart disease events increases from 16.4% in type 2 diabetic patients with a urinary protein concentration of <150 mg/L to 34.8% in those with a urinary protein concentration of >300 mg/L, and the incidence of stroke increases from 7.2% to 23% [6]. The excessive

cardiovascular risk means that patient survival is dramatically reduced prior to the development of ESRD, and survival levels fall even further on chronic renal replacement therapy [1–5]. The 5-year survival rates after progression to ESRD are currently 5% in Germany and 27% in Australia.

Diabetic renal disease

Definitions and diagnosis

Clinical diagnosis of diabetic nephropathy is established on the basis of persistent albuminuria in diabetic patients with retinopathy and no evidence of nondiabetic renal disease [8]. In those without retinopathy and with another urinary abnormality, a definite diagnosis can be established only on the basis of a histological evaluation of the kidney (Figure 21.1). Historically, five stages are recognized (Table 21.1) [9]. At the onset of diabetes the

Table 21.1 Stages of diabetic nephropathy.

Stage	Years since diabetes onset	GFR/RPF	UAE (μg/min)	Findings	Histology changes[a]
I Hyperperfusion	0	Elevated	>20[b]	Enlarged kidneys	Glomerular hypertrophy
II Clinical Latency	10–15	Normal-elevated	<20	High-normal BP	Thickening of basement membrane
III Incipient Nephropathy	15–20	Normal-elevated	20–200	Hypertension[c]	Widening of mesangium
IV Overt Nephropathy	20–30	Reduced/decreasing	>200	Worsening hypertension[c]	Diffuse/nodular glomerulosclerosis
V Kidney Failure	>30	Severely reduced	>200	Severe hypertension[c]	Scarring

[a] Less specific changes in type 2 diabetes.

[b] Transient increases.

[c] More frequent and more severe and often preceding the diagnosis of nephropathy in type 2 diabetes.
Figure 21.2 Course of diabetic nephropathy according to time-dependent changes in GFR and albuminuria.

glomerular filtration rate (GFR) may be elevated, and there are no evident clinical abnormalities (stage I diabetic nephropathy). Then, with good metabolic control the GFR normalizes (stage II), and over about 10 years microalbuminuria may develop (stage III or incipient nephropathy). Then, albuminuria may increase to the macroalbuminuric range and the GFR starts to decline (stage IV, or overt nephropathy) until kidney failure develops (stage V). More recent evidence, however, suggests that diabetic kidney disease is a continuum. It starts with the appearance of measurable amounts of albumin in the urine and evolves, with a progressive increase in albumin excretion, to a progressive decline in GFR. Not only is this associated with an increased urinary excretion, but also of other plasma components and, without specific treatment, may eventually result in terminal kidney failure (Figure 21.2) [10]. Even with this background, however, here we will use the traditional terminology whenever appropriate to avoid confusion with the earlier literature, in particular, when discussing trials that included patients and evaluated outcomes on the basis of the stages described above.

Thickening of the glomerular basement membrane and diffuse or nodular glomerulosclerosis (diabetic glomerulosclerosis) are the typical features of stage IV diabetic nephropathy, in particular in patients with type 1 diabetes. In those with type 2 diabetes, however, the histology findings may be more heterogeneous, and nonspecific changes related to ageing or nephroangiosclerosis, with or without concomitant nodular glomerulosclerosis, may be observed in 30–60% of cases, according to different published case series [11]. Primary glomerular disease, in particular idiopathic membranous nephropathy, is also relatively frequent in older subjects with type 2 diabetes and should always be suspected in those with overt proteinuria but without severe hypertension, renal insufficiency, or retinopathy [11].

Outcome

In early stages of nephropathy, when structural changes are negligible, UAE may increase secondarily to glomerular hyperfiltration, loss of glomerular barrier negative charges and, possibly, reduced albumin reabsorption at the tubular level [10]. In later stages, however, when the structural changes become prominent, albuminuria is largely sustained by an increased permeability of the glomerular barrier, which allows unrestricted ultrafiltration of plasma macromolecules [12]. These macromolecules, most of which are nephrotoxic, may initiate a self-perpetuating process of progressive glomerulosclerosis, tubulo-interstitial inflammation, and scarring, with progressive renal function loss [13]. Ultrafiltered transferrin-iron complexes pH of proximal release iron, which in turn promotes lipid peroxidative damage, causes insulin-like growth factor 1 to dissociate from binding proteins, and stimulates mitogenesis and synthesis of collagen I and IV in proximal tubular cells, lipoproteins, chemotactic lipid factors. Different complement components may promote tubular injury and interstitial inflammation by generating oxygen free radicals and chemotactic gradients (see reference 13 for more details).

The functional and metabolic changes sustained by renal insufficiency and heavy proteinuria, including worsening hypertension, dyslipidemia, endothelial dysfunction, and insulin resistance, eventually accelerate atherosclerosis and cardiovascular disease, which contributes to the dramatic excess cardiovascular morbidity and mortality associated with overt nephropathy [3]. All together, these data support the hypothesis that the appearance in the urine of plasma proteins different from albumin (which usually occurs in parallel with the increase of UAE from micro- to macroalbuminuria) indicates the transition of the disease from a relatively benign stage of functional and potentially reversible abnormalities to a more severe stage of persistent functional and structural changes that, without treatment, sustain a relentless progression to ESRD (see reference 10 for more details). This highlights the importance of early intervention, when the kidney changes are still potentially reversible and renoprotective therapies might have their greatest beneficial effects.

Predisposing conditions

Studies have identified a number of factors that play a part in the development of diabetic nephropathy [14,15]. These include elevated blood pressure and glycosylated hemoglobin and cholesterol concentrations, smoking, advanced age, high level of insulin resistance, male gender (the risk is lower among women, particularly premenopausal women), and Afro–Caribbean, Asian, or Native American races. A family history of cardiovascular events is also an indicator of renal risk. Actually, genetic factors, including some polymorphisms of the ACE gene, appear to play a part in the development of diabetic nephropathy, as familial clustering of diabetes is found among both type 1 and type 2 diabetic patients. In addition to this, the finding of a family history of cardiovascular events is a powerful indicator of renal risk, with clusters of cardiovascular incidents being seen in first-degree nondiabetic relatives of type 1 and type 2 diabetic patients. There is also an interaction between genetic factors and blood glucose levels for the risk of microalbuminuria in newly diagnosed type 2 diabetic patients. The combination of a positive family history and poor glycemic control greatly increases the risk for development of diabetic nephropathy. Hypertension and family history of hypertension are also independent risk factors for subsequent development of microalbuminuria and nephropathy. A study of Pima Indians showed that the risk of developing nephropathy 5 years after the onset of diabetes was nearly threefold higher for those whose blood pressure was in the upper third (i.e. high-normal category) of blood pressure distribution 1 year prior to the development of diabetes [16].

Hypertension, hyperglycemia, and increased cardiovascular morbidity and mortality are typical components of metabolic syndrome, a syndrome of reduced tissue sensitivity to insulin that is often associated with microalbuminuria. Evidence suggests that insulin resistance precedes and probably contributes to the development of microalbuminuria in type 1 diabetic patients [17], as well as in nondiabetic subjects [18]. Until recently, data for type 2 diabetic patients were less clear, since an association between insulin resistance and microalbuminuria was suggested by some

studies but was not confirmed by others. However, the hypothesis of an association between insulin resistance and microalbuminuria was recently revived by a cross-sectional study showing that in a large cohort of type 2 diabetic patients the homeostasis model assessment index, a surrogate of insulin sensitivity, was significantly associated with the albumin/creatinine ratio measured in spot urine samples [19]. To formally test this possibility, Parvanova *et al.* compared the total body glucose disposal rate, quantified by means of a euglycemic hyperinsulinemic clamp technique, in 50 matched pairs of type 2 diabetic patients with micro- or normoalbuminuria [20]. Data showed that subjects with microalbuminuria were more insulin resistant than those with a normal UAE and that the magnitude of insulin resistance was independently associated with microalbuminuria. Of interest, there was also a clear association between more severe insulin resistance and microalbuminuria in the subgroup of patients with normal blood pressure considered separately from those with arterial hypertension. Altogether, these findings lend support to the possibility that insulin resistance is directly associated with microalbuminuria, regardless of its association with arterial hypertension. Another study showed that insulin sensitivity was similar in patients with macro- or microalbuminuria and was not correlated with the degree of UAE, confirming that increased albuminuria is not per se a primary determinant of insulin resistance.

Thus, increased albuminuria could be taken as an indicator of insulin resistance and of the increased renal and cardiovascular risk (the cardio-renal syndrome) associated with the metabolic syndrome.

The cardio-renal syndrome

Several studies have demonstrated a strong association between albuminuria, kidney disease, and increased cardiovascular risk (the so-called cardio-renal syndrome). The investigators of the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) study [21] examined the data focusing on the relationship between albuminuria and cardiovascular end points or hospitalization for heart failure in 1513 patients with type 2 diabetes and overt nephropathy. Patients with high baseline albuminuria (≥3 g/g of creatinine) had a 1.92-fold higher risk for the cardiovascular end point and a 2.70-fold higher risk for heart failure compared with patients with low albuminuria (<1.5 g/g). Among all available baseline risk markers, albuminuria was the strongest predictor of cardiovascular outcome. The association between albuminuria and cardiovascular outcome was driven by those patients who also had a renal event (doubling of serum creatinine levels or progression to ESRD). It was also shown that albuminuria reduction was the strongest predictor for cardiovascular outcome: there was an 18% reduction in cardiovascular risk for every 50% reduction in albuminuria and a 27% reduction in heart failure risk for every 50% reduction in albuminuria. Thus, albuminuria is an important factor predicting cardiovascular risk in patients with type 2 diabetes and kidney disease. Reducing

albuminuria appears to afford cardiovascular protection in these patients.

With the Irbesartan in Diabetic Nephropathy Trial (IDNT) cohort [22], the investigators examined the baseline characteristics predictive for cardiac events in 1715 individuals with type 2 diabetes, serum creatinine of 1.0–3.0 mg/dL, and UAE rates of $\geq$900 mg/day. A cardiovascular composite end point was used that consisted of cardiovascular death, nonfatal myocardial infarction, hospitalization for heart failure, stroke, amputation, and coronary and peripheral revascularization. Thirty percent of patients had at least one of the cardiovascular composite end points. Older age, male gender, longer duration of diabetes, history of cardiovascular disease, history of congestive heart failure, high urinary albumin/creatinine ratio, and low serum albumin were highly predictive for cardiovascular events; of these, prior history of cardiovascular disease (relative risk [RR], 2.00; 95% confidence interval [CI], 1.63–2.45; $P < 0.0001$) and high urinary albumin/creatinine ratio (RR, 1.29 per natural log unit; 95% CI, 1.13–1.48; $P = 0.0002$) at baseline were the strongest predictors.

Thus, among individuals with diabetes and kidney disease, albuminuria provides prognostic information concerning cardiovascular risk, in addition to that of traditional coronary risk factors. Recent studies, however, have shown that albuminuria has an independent predictive value for cardiovascular events even among subjects without evidence of overt kidney disease and a UAE in normo- or microalbuminuric ranges. Actually, similar to the relationship between blood pressure and risk of cardiovascular events, mounting evidence indicates a continuous relationship between UAE and risk. And like blood pressure, the concept of a threshold level to define normality no longer appears consistent with epidemiological data [23]. Indeed, post hoc analyses of randomized trials in high-risk individuals as well as community-based cohort studies all indicate that incremental increases in albuminuria within the "normal" range carry higher risks of nephropathy or cardiovascular events [24–26]. The Heart Outcome Prevention Evaluation (HOPE) study [24] also showed that the relationship between albuminuria and experiencing a cardiovascular event is not restricted to the microalbuminuric range and extends to as low as 0.5 mg/mmol (albumin/creatinine ratio [A/C]). These observations were confirmed in the Losartan Intervention for End Point Reduction in Hypertension (LIFE) study [25] and several population-based studies [26,27]. In particular, the Framingham Heart Study found that the 6-year risk of cardiovascular disease was threefold higher in nonhypertensive, nondiabetic subjects with urinary A/C ratios above the gender-specific median (3.9 μg/min for men and 7.5 μg/min for women) than in those with urinary A/C ratios below the median [27]. On the basis of the above findings, only negligible amounts of albuminuria below approximately 2 mg/g of urinary creatinine (or an estimated excretion rate of 2 mg/day) should be considered "normal," or as being below a threshold that does not confer excess risk. This corresponds approximately to a urinary concentration of 1–2 μg/ml, that is, below or close to the detection limit of the methods commonly used for the measurement of urinary albumin, such as nephelometry and immunoturbidimetry. Indeed, values above this threshold are significantly associated with risk for overt nephropathy, myocardial infarction, and cardiovascular death. This may have major practical implications, because albuminuria can be ameliorated by decreased insulin sensitivity, weight loss, blood pressure and blood glucose reductions, and renin–angiotensin system (RAS) inhibitor therapy (see reference 10 for more details). In the long-term, these interventions are expected to prevent or delay end-organ damage.

Protecting target organs in people with diabetes and kidney disease

Early studies in type 1 diabetes showed a clear relationship between arterial blood pressure and renal disease progression. This probably reflected the fact that kidneys of subjects with diabetes are more sensitive to the effects of high blood pressure than those of subjects without diabetes, because hyperglycemia may induce a loss of the physiological autoregulation that normally protects the glomerular microcirculation from the variations in systemic blood pressure. In experimental diabetes afferent (preglomerular) vasodilation facilitates the transmission of the aortic pressure to the glomerular vascular bed, thereby increasing glomerular pressure [28]. Thus, intracapillary pressure may be higher than normal, even when the systemic blood pressure is normal, and may further increase when the systemic blood pressure is above "normal." This explains why even small increases in blood pressure (still within the normal range according to the WHO/ISH definition of $\leq$ 130/80 mmHg) can have such a deleterious effect on renal function and why hypertension plays such an important role in the development and progression of diabetic kidney disease.

The first evidence of a beneficial effect of blood pressure reduction was provided by Parving and Mogensen in patients with type 1 diabetes and overt nephropathy [29,30]. They showed that by reducing blood pressure, filtrate loss in diabetic nephropathy could be delayed. Currently, however, it is believed that lowering blood pressure is not enough and that reducing proteinuria is also important [21,22]. Other interventions in addition to lowering blood pressure and proteinuria are important to protect end organs in people with diabetes. Intensified metabolic control reduces the incidence of microalbuminuria and of macrovascular complications in those with no evidence of kidney disease, but there does not seem to be any effect on kidney disease progression in those with established nephropathy. Preliminary evidence suggests that statins, in addition to decreasing cardiovascular events, may reduce proteinuria in diabetic patients with kidney disease. Lifestyle modifications, including weight loss, increased physical activity and, most importantly, smoking cessation, may reduce both micro- and macrovascular complications. Inhibition of the renin–angiotensin–aldosterone system (RAAS) by ACE inhibitors or angiotensin receptor blockers (ARBs) remains, however, the key component of reno- and cardio-protective therapy in people with diabetes [2]. Whether further benefits can be achieved by treatment with nondihydropyridine calcium antagonists or by

Figure 21.3 A possible algorithm to guide antihypertensive and antiproteinuric therapy in people with diabetes. Treatment should be aimed at achieving systolic and diastolic blood pressure < 130/80 mmHg and the maximal reduction in albuminuria, ideally to <20 μg/min. Consider that a diuretic is almost invariably needed to increase the efficacy of RAAS inhibitor therapy and limit hyperkalemia. Abbreviations: ACEi: ACE inhibitor, ARB: angiotensin receptor blocker, CCB calcium channel blocker, RAAS: Renin Angiotensin Aldosterone System.

intensified blood pressure control has not been clearly established (Figure 21.3 and Table 21.2).

Inhibition of the RAAS

ACE inhibitors

Interest in the role of ACE inhibitors in delaying the progression of diabetic nephropathy began in 1986, when an experimental model of kidney damage, comparing the effects of enalapril with a triple combination of the antihypertensives hydralazine, reserpine, and hydrochlorothiazide, demonstrated that enalapril produced an equally good reduction in mean arterial pressure to the triple therapy [31]. In addition to this, enalapril produced a reduction in proteinuria and less-pronounced glomerulosclerosis.

Table 21.2 Targets of multimodal therapy.

Characteristic	Target
Blood pressure	< 130/80 mmHg
Albuminuria	<20 μg/min
LDL	<100 mg/dL
LDL + VLDL	<130 mg/dL
HbA1c	<7.5%

The antiproteinuric and kidney-protecting effects of the ACE inhibitors were originally thought to be attributable to purely hemodynamic effects, relieving the glomerulus by opening the efferent arterioles (postglomerular), thereby reducing glomerular capillary pressure [31]. However, more recently it has become apparent that ACE inhibitors also affect glomerular function by their effects on glomerular size, glomerular permeability, and the increased negative electrical charge of the glomerular membrane [32,33].

In a study by Mathiesen, normotensive and hypertensive diabetic patients with incipient nephropathy, treated with ACE inhibitors, experienced a reduction in UAE [34]. In addition, a study with metoprolol and enalapril demonstrated greater protection of long-term renal function with the ACE inhibitor [35]. A meta-analysis of 12 trials in 698 type 1 diabetic patients with microalbuminuria who were followed for at least 1 year revealed that ACE inhibitors reduced the risk of progression to macroalbuminuria by 62% compared to that of the placebo group. At 2 years, the UAE rate was 50% lower in the patients taking ACE inhibitors than in those receiving placebo [36]. Parving *et al.* showed that the beneficial effect of ACE inhibitors on preventing progression from microalbuminuria to overt nephropathy is long lasting (8 years) and is associated with preservation of normal GFR [37].

Data on ACE inhibitors in type 2 diabetes are relatively sparse. Martinez *et al.* have recently demonstrated that the ACE inhibitor trandolapril can enhance insulin sensitivity (by 17%) and decrease microalbuminuria (by 54%) in hypertensive type 2 diabetic patients [38]. Ravid *et al.* originally described the beneficial effect of ACE inhibition in normotensive, nonobese microalbuminuric patients with type 2 diabetes by demonstrating that only 12% of the patients in the ACE inhibitor group progressed to macroalbuminuria, compared to 42% in the placebo arm [39]. The blood pressure, however, tended to be lower in the ACE inhibitor group, and the study was not powered to assess whether the improved outcome was due to ACE inhibition therapy or rather to more consistent blood pressure reduction.

However, on the basis of the above findings, there is a general consensus that diabetic patients with micro- or macroalbuminuria, even while they are normotensive, should be treated with ACE inhibitors or combinations thereof [40], as per the National Kidney Foundation algorithm [41].

ARBs

A multinational, randomized, double-blind, placebo-controlled study conducted by Parving *et al.* [42] examined the effect of RAAS blockade with the ARB irbesartan at a dose of either 150 mg daily or 300 mg daily, compared to placebo, in 590 hypertensive patients with type 2 diabetes and microalbuminuria followed for 2 years. The primary outcome was the time to onset of macroalbuminuria, taken as a marker of overt diabetic nephropathy. Ten of the 194 patients in the 300-mg group (5.2%) and 19 of the 195 patients in the 150-mg group (9.7%) reached the primary end point, compared with 30 of the 201 patients in the placebo group (14.9%) (hazard ratios, 0.30 [95% CI, 0.14–0.61; $P < 0.001$] and 0.61 [95% CI, 0.34–1.08; $P = 0.08$] for the two irbesartan groups, respectively).

Two studies examined the role of angiotensin receptor blockade on the progression of kidney disease in patients with type 2 diabetes and macroalbuminuria. The RENAAL study [43] showed that, compared with conventional treatment alone (i.e. treatment without ACE inhibitors or ARBs), losartan combined with conventional treatment decreased the level of urinary protein excretion by 35% and reduced the risk of the composite end point (doubled serum creatinine, ESRD, or death) by 22%. This beneficial effect was achieved with comparable blood pressure control in the two treatment arms. In the IDNT study [44] the risk of the combined end point of a doubling of the baseline serum creatinine level, the onset of ESRD, or death from any cause was 20% lower in patients treated with irbesartan than in those treated with conventional therapy and 23% lower than in those treated with amlodipine. These studies also showed a reduction in the rate of heart failure with ARBs but no differences in the overall rate of death or the rate of death from cardiovascular causes.

Angiotensin II blockade was beneficial and well-tolerated regardless of renal function at study entry, a finding that challenges the common belief that RAAS inhibitor therapy should not be offered to individuals who have severe renal insufficiency (i.e. serum creatinine of >3 mg/dL) because of an increased risk of hyperkalemia or acute renal function deterioration, although patients at high risk of adverse effects were ineligible for both trials. In a post hoc, secondary analysis of the RENAAL trial [45], the incidences of ESRD, hospitalizations for heart failure, withdrawals for adverse events, and proteinuria during losartan or conventional treatment were compared within three tertiles of baseline serum creatinine concentrations (highest, 2.1–3.6 mg/dL; middle, 1.6–2.0 mg/dL; lowest, 0.9–1.6 mg/dL). Losartan decreased the risk of ESRD by 24.6, 26.3, and 35.3% in the highest, middle, and lowest tertiles, respectively. For every 100 patients with serum creatinine of >2.0, 1.6–2.0, or <1.6 mg/dL, 4 years of losartan therapy was estimated to save 18.9, 8.4, and 2.9 ESRD events, respectively. Losartan also decreased hospitalizations for heart failure by 50.2 and 45.1 in the highest and middle tertile, respectively. Withdrawals for adverse events other than heart failure were comparable between tertiles and treatment groups. Proteinuria decreased more on losartan than on placebo in all tertiles (highest, 24 vs. −8%; middle, 16 vs. −8%; lowest, 15 vs. −10%).

ACE inhibitors and ARBs: comparative analyses

A meta-analysis of 6167 patients with diabetic kidney disease included in 24 randomized clinical trials of ACE inhibitor or ARB blocker therapy versus placebo or conventional therapy found a similar benefit of both agents on renal outcomes [46]. Indeed, both ACE inhibitors and ARBs slowed progression of kidney disease and promoted regression from micro- to normoalbuminuria. The data, however, showed a reduced all-cause mortality versus conventional therapy or placebo with ACE inhibitors (RR, 0.79, 95% CI, 0.63–0.99), but not with ARBs (RR, 0.99; 95% CI, 0.85–1.17). The relative survival advantage of one class of antihypertensives over the other in this population is, however, still unknown, because only indirect comparisons based on small studies are avail-

able. Indeed, only three trials directly comparing ACE inhibitors with ARBs were included in the meta-analysis. These studies, however, did not report on all-cause mortality, ESRD, or doubling of serum creatinine, which rendered comparative survival analyses impossible. In a more recent study, 250 subjects with type 2 diabetes and early nephropathy were randomly assigned to receive either the ARB telmisartan (80 mg daily, in 120 subjects) or the ACE inhibitor enalapril (20 mg daily, in 130 subjects) [47]. The primary end point was the change in the GFR between the baseline value and the last available value during the 5-year treatment period. After 5 years, the GFR decreased by 17.9 mL/min/1.73 m^2 of body surface area with telmisartan and by 14.9 mL/min/1.73 m^2 with enalapril, with a treatment difference of 3.0 mL/min/1.73 m^2. On the basis of predefined criteria, this difference was not enough to conclude that telmisartan is inferior to enalapril in providing long-term renoprotection in persons with type 2 diabetes. A closer analysis of the data, however, showed that at study end the loss of GFR was 20% more consistent on telmisartan, and that was associated also with a slight excess (22% vs. 16%) of fatal and nonfatal cardiovascular events over enalapril. Thus, altogether, available data suggest a survival benefit and possibly a trend to more-effective renoprotection with ACE inhibitor than with angiotensin II receptor blocker therapy in people with diabetes and kidney disease. Thus, on the basis of available evidence, and also in view of the lower costs, ACE inhibitors should be considered first-line therapy in this population, and ARBs should be considered as second-line or add-on therapy when ACE inhibitors are not tolerated or fail to achieve the target blood pressure.

Combined ACE inhibitor and ARB therapy: preliminary evidence of efficacy

In patients with nondiabetic chronic nephropathies, dual RAS blockade with combined ARB and ACE inhibitor therapy offers greater renoprotective benefits than single-drug RAS blockade with either agent alone. Preliminary evidence indicates that this may apply also to subjects with diabetic kidney disease. The rationale for this approach is based on the consideration that ACE inhibitors and ARBs block the RAS at different levels. Thus, dual RAS blockade may result in a more profound inhibition of the system. Indeed, the Candesartan and Lisinopril Microalbuminuria (CALM) study [48] found that the ACE inhibitor lisinopril and the ARB candesartan achieved similar reductions in blood pressure and albuminuria in 197 patients with type 2 diabetes and incipient nephropathy. A more effective reduction in blood pressure and albuminuria was achieved when the two drugs were used in combination. Several studies have also shown a synergistic antiproteinuric effect in diabetics with overt nephropathy. Whether this translates to more effective renoprotection in the long term is not yet established.

Risks and benefits of antialdosterone therapy

Despite ACE inhibitor or ARB therapy, a substantial proportion of patients with diabetes, in particular type 2, and kidney disease continue to progress or to die prematurely of cardiovascular

events. A possible explanation is that enhanced amounts of aldosterone are produced in these patients despite RAS blockade (aldosterone escape). Sato *et al.* [49] observed aldosterone escape in 40% of patients with type 2 diabetes and early nephropathy despite the use of ACE inhibitors. In these patients, the aldosterone antagonist spironolactone decreased UAE and left ventricular mass index without inducing further reduction in arterial blood pressure. Similar benefits, however, were seen also when aldosterone antagonists were used as first-line therapy. In hypertensive patients with type 2 diabetes and microalbuminuria, eplerenone reduced albuminuria even more effectively than enalapril (62% vs. 45% at 6 months vs. baseline), and albuminuria reduction (74%) was even more consistent when the two drugs were used in combination [50]. Altogether, these data provide preliminary evidence that aldosterone has a pathogenic role in diabetic kidney disease and that aldosterone antagonism may be renoprotective. A major drawback, however, of aldosterone antagonism is the increased risk of hyperkalemia. Thus, caution is recommended when aldosterone antagonists are given in combination with ACE inhibitors or ARBs, and this combined therapy should probably be avoided in poorly compliant patients or in those at highest risk because of poorly controlled hyperglycemia and renal insufficiency.

Role of calcium channel blockade: class effects of dihydropyridine and nondihydropyridine calcium antagonists

The results of studies with CCBs in diabetic patients with kidney disease have been mixed, with an increase in albuminuria actually being observed in some studies in which dCCBs such as nifedipine were used [51]. Clearly, differences exist between different classes of calcium antagonists and their effects on reducing proteinuria, thereby providing nephroprotection.

ndCCBs

The ndCCBs have been shown to reduce proteinuria and retard the progression of diabetic nephropathy [52]. These long-term studies show that ndCCBs, such as verapamil and diltiazem, slow progression of nephropathy significantly better than beta-blockers and that their effect in preserving the kidneys is comparable to that of lisinopril, an ACE inhibitor [52]. A meta-analysis of randomized trials of ndCCBs and dCCBs in hypertensive patients with proteinuric kidney disease found that with comparable blood pressure control, ndCCBs reduced proteinuria by about 30% compared to baseline, whereas dCCBs had no appreciable effects on urinary proteins. These findings were taken to suggest ndCCBs as a possible alternative to diuretics as the preferred agents to lower blood pressure in combination with a RAS inhibitor in patients with chronic proteinuric nephropathies [53].

dCCBs

Dihydropyridine calcium antagonists have been found to be less effective than heart rate-lowering calcium antagonists at reducing

proteinuria [52]. A long-term study of the effects of ramipril and felodipine therapy alone or in combination for nondiabetic kidney disease found that, with 2-year comparable blood pressure control, proteinuria was reduced to a similar extent by ramipril alone or in combination with felodipine, whereas it was significantly increased with felodipine alone [54]. More recently, the Ramipril Efficacy in Nephropathy 2 (REIN-2) study found that intensified blood pressure control by add-on felodipine treatment in 338 patients with nondiabetic chronic nephropathies on background ACE inhibitor therapy failed to reduce proteinuria or limit progression to ESRD [55].

A direct comparison between an ARB and a dCCB was attempted in the MicroAlbuminuria Reduction with Valsartan (MARVAL) study in type 2 diabetic patients with microalbuminuria [56]. Three hundred thirty-two patients with type 2 diabetes and microalbuminuria, with or without hypertension, were randomly assigned to 80 mg/day valsartan or 5 mg/day amlodipine for 24 weeks. A target blood pressure of 135/85 mmHg was aimed for by dose-doubling followed by addition of bendrofluazide and doxazosin whenever needed. The primary end point was the percent change in albuminuria from baseline to 24 weeks. The albuminuria at 24 weeks was 56% of baseline (95% CI, 49.6–63.0) with valsartan and 92% of baseline (95% CI, 81.7–103.7) with amlodipine, a highly significant between-group effect ($P < 0.001$). Valsartan lowered albuminuria similarly in both the hypertensive and normotensive subgroups. More patients reversed to normoalbuminuria with valsartan (29.9% vs. 14.5%; $P = 0.001$). In summary, for the same level of attained blood pressure and the same degree of blood pressure reduction, valsartan lowered albuminuria in patients with type 2 diabetes and microalbuminuria, including the subgroup with baseline normotension, whereas amlodipine had no effect.

A possible explanation for the above findings is that dCCBs induce a preglomerular vasodilation that facilitates the transmission of systemic blood pressure to the capillary network, which may increase intracapillary pressure, an effect that may offset or even overwhelm the benefits of blood pressure reduction, in particular when the blood pressure is reduced a few millimeters of mercury. Thus, dCCBs should be used as second-line therapy, when the blood pressure is above target despite the use of drugs that inhibit the RAAS or that have neutral effects on albuminuria. A possible exception may be more-recent dihydropyridine calcium antagonists, such as manidipine, that, similarly to ACE inhibitors, may reduce postglomerular resistances and therefore may effectively reduce albuminuria also in people with diabetes.

Role of intensified blood pressure control

In type 2 diabetic patients with overt nephropathy enrolled in the RENAAL [57] or IDNT [58] studies, there was a significant relationship between the blood pressure levels achieved during the follow-up period and the incidence of ESRD or cardiovascular events. Although at any level of achieved blood pressure the overall

incidence of events was consistently lower in patients on an ARB than in those on placebo treatment, it was also apparent that the impact of achieved blood pressure on clinical outcomes was independent of patient allocation to ARB or placebo treatment and was consistent within each treatment group [59]. Thus, in type 2 diabetic patients with established nephropathy, both RAS inhibition and blood pressure control have specific and probably additive reno- and cardioprotective effects that may contribute to limit the excess renal and cardiovascular risk via different pathways. Evidence that blood pressure reduction and ACE inhibitor therapy may have an independent and additive protective effect against microalbuminuria is in harmony with current theories on the pathophysiology of diabetic kidney disease [28]. The impact of blood pressure control on the risk of developing microalbuminuria reflects the specific vulnerability of the diabetic kidney to the barotrauma caused by arterial hypertension. Autoregulation of afferent arteriolar tone in response to changes in renal perfusion pressure is defective in diabetes [60], and decreased afferent arteriolar resistance facilitates the transmission of the systemic blood pressure to the glomerular capillary, which increases intracapillary pressure [28,61]. In the long term, these hemodynamic changes may cause endothelial dysfunction, impaired sieving function of the glomerular barrier, increased albumin ultrafiltration, and albuminuria [10]. Thus, reducing systemic blood pressure to normal ranges is crucial to ameliorate glomerular hypertension and prevent glomerular damage. Glomerular hypertension is also ameliorated by drugs, such as ACE inhibitors or ARBs, that dilate the efferent arteriole [61,62]. The incremental benefit of this specific hemodynamic effect would be particularly relevant when arterial hypertension is not effectively controlled [63]. A still-debated issue, however, is whether blood pressure has an independent predictive value also among subjects with blood pressure maintained at usual targets of diastolic pressure of <90 mmHg or mean pressure <107 mmHg and whether further reduction to lower-than-usual targets, according to JCN-7 guidelines [64] of systolic/diastolic pressures of < 130/80 mmHg, may confer additional renoprotection. Whether treatment should target systolic, diastolic, pulse, or mean blood pressure is also far from being established based on controlled studies.

The first evidence that reducing blood pressure to lower-than-usual targets (mean <92 mmHg) may slow the rate of GFR decline in chronic kidney disease was generated by the Modification of Diet in Renal Disease (MDRD) study [65]. As acknowledged by those study authors, however, the proportion of study patients on ACE inhibitor therapy was higher in the low blood pressure group than in the usual blood pressure group. Similarly, the trial by Breyer-Lewis in type 1 diabetic nephropathy patients [66] showed that patients with a lower blood pressure target (mean, <92 mmHg) had an effective reduction in urinary proteins that, by contrast, progressively increased in those with usual target pressure (mean, 100–107 mmHg). Again, however, data were biased by the concomitant treatment with ACE inhibitors that were used at higher doses in patients randomized to the lower-than-usual target group than in those randomized to the usual blood pressure target.

Three other trials comparing the effect of treatment targeted at two different blood pressure levels on similar background RAS inhibitor therapy failed to detect any specific benefit of intensified blood pressure control. The African American Study of Kidney Disease and Hypertension (AASK) found the same rate of GFR decline and the same course of proteinuria in nondiabetic patients in the low (mean, <92 mmHg) or usual (mean, 100–107 mm Hg) blood pressure group [67]. The Appropriate Blood Pressure Control in Diabetes (ABCD) trial showed a similar time-dependent course of creatinine clearance in three large cohorts of type 2 diabetic patients with normo-, micro-, or macroalbuminuria randomized to groups with diastolic blood pressure of <75 mmHg or 80–89 mmHg, respectively [68]. Finally, the REIN-2 study found the same rate of GFR decline, incidence of ESRD, and time-dependent course of proteinuria in two groups of nondiabetic patients with the same ACE inhibitor therapy but who were randomly allocated to low (systolic/diastolic pressures of < 130/80 mmHg) or usual (diastolic pressure <90 mmHg) blood pressure targets [69].

Notably, the above studies targeted therapy to different parameters (mean, diastolic, or systolic blood pressure), and none of them evaluated the impact of blood pressure and its reduction on the risk of developing microalbuminuria. The UK Prospective Diabetes Study (UKPDS) found a lower incidence of macrovascular complications and retinopathy in type 2 diabetic patients randomized to intensified blood pressure control but failed to detect a significant protective effect of lower blood pressure against the risk to develop microalbuminuria [70]. Similarly, the ABCD trial found a trend to a lower incidence of microalbuminuria in type 2 diabetic patients with normal UAE allocated to the low blood pressure group, but the risk reduction versus those in the usual blood pressure group was not significant. Thus, whether and to what extent intensified blood pressure control may have a specific renoprotective effect in people with diabetes remains to be addressed, ideally in a prospective clinical trial in patients on the same background RAS inhibitor therapy and randomly allocated to two different blood pressure targets.

Preventing kidney disease in people with diabetes

Preventing (or delaying) the development of microalbuminuria is a key treatment goal for renal protection and, possibly, cardioprotection. Recent clinical trials suggested that RAS inhibition may actually prevent nephropathy. Post hoc analyses of the Heart Outcomes Prevention Evaluation (HOPE) study [71] and of the Losartan Intervention for Endpoint Reduction in Hypertension (LIFE) study [72] found a lower incidence of overt nephropathy in the subgroup of patients with type 2 diabetes given RAS inhibitor therapy compared to controls. However, these analyses included both patients with normo- or microalbuminuria, and they were not powered to compare the incidence of microalbuminuria between the two treatment groups among patients with normal

albumin excretion rate at study entry. A randomized prospective trial of enalapril versus placebo in normotensive patients with type 2 diabetes found a lower incidence of microalbuminuria in those on ACE inhibitor therapy who, however, also had greater blood pressure reduction compared to controls. The design of the trial did not allow the authors to differentiate the beneficial effect of RAS inhibition therapy from that of blood pressure reduction [73].

The Bergamo Nephrologic Diabetes Complication Trial (BENEDICT) was a prospective, randomized, double-blind, parallel group study aimed to compare the protective effect against the development of persistent microalbuminuria (taken as an early marker of diabetic kidney disease) of the ACE inhibitor trandolapril, the ndCCB verapamil, and of the trandolapril plus verapamil combination (VeraTran), compared to placebo in 1204 patients with type 2 diabetes and arterial hypertension but a normal UAE rate [74,75]. Baseline characteristics and simultaneous treatments of patients randomized in the four treatment groups were comparable. Over a median follow-up of 3.6 years, significantly fewer patients in the VeraTran group received additional antihypertensive treatment (in particular, with dCCBs and sympatholytic agents) than in the placebo group ($P < 0.01$). Fewer patients on verapamil than on placebo required concomitant treatment with dCCBs. HbA$_{1C}$ levels were comparable in all four groups and remained below 7% throughout the study, showing that optimal metabolic control was attained in these patients. The blood pressure was relatively well-controlled, with small but statistically significant differences between groups. Microalbuminuria developed in 17 of 300 patients in the group receiving verapamil SR plus trandolapril (5.7%) and in 30 of 300 patients in the placebo group (10%). The Kaplan-Meier curves separated starting at 3 months and continued to diverge. The onset of microalbuminuria was significantly delayed by a factor of 2.6 ($P = 0.02$). The relative reduction of risk of progression from normo- to microalbuminuria with verapamil SR plus trandolapril was 61% (95% CI, 0.19–0.80; $P = 0.01$). The difference between the groups remained significant also after adjustment for follow-up systolic and diastolic blood pressures. Hence, the results exceeded expectations based on blood pressure changes alone. The effect of the two experimental drugs used alone was also analyzed. Microalbuminuria developed in 18 of 301 patients on trandolapril alone (6.0%) and in 36 of 303 patients on verapamil (11.9%). Hence, compared to placebo, trandolapril delayed the onset of microalbuminuria by a factor of 2.1 ($P = 0.01$) and decreased the risk of microalbuminuria by 53% ($P = 0.01$), whereas verapamil had no significant effects.

Three patients in the placebo group one in the trandolapril group, and one in the verapamil group had a fatal cardiovascular event. No fatal cardiovascular events were reported in patients who received VeraTran. These data confirm that, provided that intensified metabolic and blood pressure control is pursued, diabetic patients with normal UAE do not have a substantial excess cardiovascular risk compared to subjects without diabetes. One patient receiving verapamil had a second degree atrioventricular block and one on VeraTran had a sinoatrial block with junctional rhythm. Hospitalization was required in both cases, and the patients recovered fully with treatment withdrawal.

Thus, the BENEDICT study showed that persistent microalbuminuria can be prevented by early intervention. The renoprotective effect of ACE inhibition did not appear to be enhanced by combined ndCCB therapy. These findings suggest that in hypertensive patients with type 2 diabetes and normal renal function, an ACE inhibitor may be the medication of choice for controlling blood pressure. The apparent advantage of ACE inhibitors over other agents includes a protective effect on the kidney against the development of microalbuminuria, which is a major risk factor for cardiovascular events and death in this population.

The findings of the BENEDICT study have been recently extended by a meta-analysis of 7603 patients included in 16 trials of ACE inhibitors or ARBs versus placebo or other antihypertensive agents, showing that only ACE inhibitors effectively prevent microalbuminuria in patients with diabetes and no evidence of kidney disease [76]. Overall, ACE inhibitors reduced the risk of microalbuminuria by 42%. On the basis of these data, it has been calculated that approximately 25 people with diabetes and hypertension should be treated to prevent 1 new case of microalbuminuria over 3–4 years.

Conclusions

Most guidelines recommend any antihypertensive agent in patients with diabetes and hypertension and without nephropathy and only ACE inhibitors or ARBs once nephropathy occurs. The use of any class of antihypertensive agents in patients with diabetes is justified by the significant reduction in mortality and cardiovascular outcomes from the primarily nondiabetic trials of hypertension, but only ACE inhibitors have been proved to reduce the onset of microalbuminuria in this population, and the results of ACE inhibitors look more favorable than those of the other classes of drugs evaluated. Thus, ACE inhibitors have an incremental effect on renal outcomes in patients with diabetes, compared with other agents, and so should be the treatment of choice unless other antihypertensive agents are evaluated against ACE inhibition in the setting of a randomized, controlled trial. Future trials of antihypertensive agents in patients with diabetes and no kidney disease should consider microalbuminuria and other renal outcomes as well as the usually considered outcomes, such as all-cause mortality and cardiovascular end points.

ACE inhibitors should be the key component of a multimodal regimen that includes life-style modifications and optimized control of arterial hypertension, hyperglycemia, and dyslipidemia.

Definition and epidemiology of lupus nephritis

Systemic lupus erythematosus (SLE) is a disease characterized by autoantibodies directed against self-antigens, immune complex formation, and immune dysregulation and can result in damage to any organ, including the kidney, skin, blood cells, and the nervous system. SLE carries significant mortality and morbidity in the younger, female population. Renal involvement, defined as lupus nephritis, is one of the most serious manifestations of SLE [1]. It usually arises within 5 years of diagnosis, and its prevalence varies, according to published studies, from 30 to 90%. Urinary abnormalities (with or without renal function impairment) are present in approximately 50% of patients at the time of diagnosis and are found in around 75% of patients in the long term [2,3]. Renal impairment eventually develops in 30% of patients with SLE. According to the data of the US Renal Data System [4], lupus nephritis is the cause of about 2% of all end-stage renal disease. Interestingly, the mortality rate at 1 year for this group of patients is 7.7%, or half the mortality rate for the end-stage renal disease population as a whole [5].

Lupus nephritis occurs about nine times more frequently in women than men, but men who develop SLE are more likely to develop renal disease and have a worse prognosis [6]. Most patients develop lupus nephritis early in their disease course. The peak age for the development of SLE is during the third decade of life. SLE is more common in African Americans, Asians, and Hispanic people than in White people, and the spectrum of lupus nephritis also is worse in these groups [7].

Diagnosis and monitoring lupus nephritis

Included among the criteria of the American College of Rheumatology for SLE are minimal criteria for the diagnosis of renal involvement. They are 1) persistent proteinuria greater than 0.5 g/day or greater than 3+ urine dipstick reaction for albumin and 2) cellular casts (may be erythrocytes, granular, tubular, or mixed) [8,9]. Patients with known SLE should be regularly checked for urinary abnormalities by including urinalysis in the panel of laboratory tests, and the test should be repeated during follow-up, because a proportion of patients develop lupus nephritis years after the onset of the disease and because lupus nephritis is often asymptomatic [10].

For a number of patients with SLE, nephritis is the presenting feature of the disease. Proteinuria is the main feature of renal damage in SLE, and the reference standard is the measurement of protein excretion over 24 h. Recently, determination of the protein/creatinine ratio on a random spot sample of urine has emerged as a valid and more feasible test than a timed urine collection [11]. Not only is it a valid method of screening but also it is a reliable index of the effect of treatment in glomerular diseases [12].

Serum creatinine is the screening test for detecting renal function changes, although the normal range is wide. Serum creatinine concentration is affected by factors other than glomerular filtration rate (GFR), such as tubular secretion and generation and extrarenal excretion of creatinine. Due to variation in these processes amongst individuals and over time within individuals, especially for creatinine generation, there is a wide range of serum creatinine levels in people without kidney disease. As a result, there are several significant limitations to estimating kidney function solely from serum creatinine. Creatinine clearance is not accurate in determining the GFR, especially when GFR is only mild to moderately impaired, but more reliable tests, such as clearance of inulin or of a radiolabeled compound, are not routinely available and not practical in the clinical setting. Equations for calculation of GFR are now widely used, such as the Cockcroft-Gault formula, or the Modification of Diet in Renal Disease (MDRD) study formula [13]. However, it is important to note that in most clinical conditions, what matters is not the absolute value of GFR but rather the change in GFR over time in the same individual. For monitoring the kidney function of renal lupus patients therefore it is usually sufficient to monitor serial serum creatinine levels.

The course of the disease may also be monitored with serologic tests. Anti-double-stranded DNA (anti-dsDNA) autoantibody titers correlate roughly, at best, with lupus nephritis activity [14]. Similar to GFR, changes in anti-dsDNA autoantibody titers, rather than absolute values, are more useful clinically. An increase in anti-dsDNA autoantibody titers are a warning sign of possible disease flare but are not accurate enough to justify automatic escalation of the therapy. Rather, an increasing titer suggests the need for strict monitoring for clinical signs of exacerbation. Because methods for measuring anti-dsDNA autoantibodies have not been standardized, it may be difficult to compare data from different laboratories, even for the same patient [15]. Anti-C1q autoantibodies also correlate with disease activity and are a useful test to monitor disease activity and to predict flares [16]. Development of new surrogate markers of disease activity for monitoring long-term outcome of the disease is an interesting field of investigation.

Renal pathology

Lupus nephritis is a term that comprises complex and diverse histopathological manifestations that have different prognoses and require different therapeutic approaches. The different patterns of kidney damage were classified for the first time in a coherent fashion in 1982 (modified in 1995) by the World Health Organization (WHO) [17,18]. Recently under the aegis of the International Society of Nephrology and the Renal Pathology Society (ISN/RPS), a group of renal pathologists, nephrologists, and rheumatologists developed a new classification system, although it is still based on the 1982 WHO classification [19].

Before describing the patterns of kidney damage in lupus nephritis, a few words should be said on the indication for renal biopsy. Renal biopsy is definitely indicated in patients with acute kidney failure, active urinary sediment, or flare-ups of lupus serology with *de novo* renal abnormalities. Although these features are most often associated with diffuse proliferative glomerular disease, a renal biopsy can also reveal other types of lesions that may modify the therapeutic approach. Moreover, an index biopsy allows a clinician to establish activity and chronicity indexes of renal damage and reveal vascular lesions that have unfavorable prognostic value. More often than in other glomerular diseases, a repeat renal biopsy is indicated in lupus nephritis, especially when there is a lack of improvement to appropriate therapy, a relapse, or a late deterioration of renal function. In this case, repeat renal biopsy may help distinguish between active lupus nephritis and chronic sclerotic lesions that are not amenable to aggressive immunosuppression.

The classification of lupus nephritis according to the classic 1982 WHO definitions comprises six classes, defined as follows:

Class I: Normal glomeruli on light microscopy; immune deposits are found on immunofluorescence and electron microscopy

Class II: Pure mesangial alteration; mesangial widening and/or proliferation

Class III: Focal proliferative glomerulonephritis; less than 50% of the glomeruli present segmental or global proliferation with mesangial involvement

Class IV: Diffuse proliferative glomerulonephritis; more than 50% of glomeruli are the site of severe mesangial involvement, endocapillary proliferation, and subendothelial deposits; in both class III and IV, there are subclasses based on the presence of necrotizing lesions and active or chronic lesions

Class V: Membranous glomerulonephritis; may be characterized by pure membranous lesions or may be associated with typical lesions of classes II, III, and IV

Class VI: Advanced sclerosing glomerulonephritis; more than 90% of glomeruli are sclerosed

The recently proposed new classification of the ISN/RPS (Table 22.1) proposes that classes I and II be used for purely mesangial involvement (I, mesangial immune deposits without mesangial hypercellularity; II, mesangial immune deposits with mesangial hypercellularity); class III be used for focal glomerulonephritis (involving <50% of total number of glomeruli) with subdivisions for active and sclerotic lesions; class IV be used for diffuse glomerulonephritis (involving ≥50% of the total number of glomeruli) either with segmental (class IV-S) or global (class IV-G) involvement and also with subdivisions for active and sclerotic lesions; class V be used for membranous lupus nephritis; and class VI be for advanced sclerosing lesions. The aim of this new classification is to provide an unequivocal description of the various lesions and classes of lupus nephritis, allowing a better standardization and lending a basis for further clinicopathologic studies.

We conducted a retrospective analysis of a large cohort of 659 patients with a diagnosis of lupus nephritis followed in 32 nephrology centers in Italy [20]. A renal biopsy had been performed in 82% of patients. Distribution of renal histology classes was as follows. The largest group of patients was in class IV (53.8% of all renal biopsies), followed by class V (16.6%), class III (14.4%), and class II (8.2%). A 6.7% proportion of patients had mixed forms of kidney damage. There was a close relationship between serum creatinine and urinary protein excretion rate at the time of diagnosis and histology class. This distribution may not actually reflect the true incidence of each WHO class, because renal biopsy may not have been performed for milder clinical manifestations of lupus nephritis.

Outcome

Survival of patients with lupus nephritis has improved significantly over the last 40 years, thanks to changes in the specific treatment of lupus nephritis and general medical care. Whereas in the 1950s the 5-year survival rate for patients with lupus nephritis was near 0%, in 1990 patient survival was 83–92% at 5 years and 74–84% at 10 years [1]. Renal survival (living without dialysis) is also reasonably good. Our retrospective analysis of 659 patients with

WHO		ISN/RPS	
CLASS I	Normal glomeruli	CLASS I	Minimal mesangial lupus nephritis
CLASS II	Pure mesangial alterations (mesangiopathy)	CLASS II	Mesangial proliferative lupus nephritis
CLASS III	Focal segmental glomerulonephritis a) Active necrotizing lesions b) Active and sclerosing lesions c) Sclerosing lesions	CLASS III	Focal lupus nephritis A, active lesions A/C, active and chronic lesions C, chronic inactive lesions with glomerular scars
CLASS IV	Diffuse glomerulonephritis a) Without segmental lesions b) Active necrotizing lesions c) Active and sclerosing lesions d) Sclerosing lesions	CLASS IV	Diffuse lupus nephritis A. active lesions A/C, active and chronic lesions C. chronic inactive lesions with glomerular scars
			Each subclass should be further subdivided: S, segmental G, global
CLASS V	Diffuse membranous glomerulonephritis	CLASS V	Membranous lupus nephritis
CLASS VI	Advanced sclerosing glomerulonephritis	CLASS VI	Advanced sclerotic lupus nephritis

Table 22.1 WHO and ISN/RPS lupus nephritis classifications.

lupus nephritis found that the overall probability of renal survival was 80% at 10 years after diagnosis. The probability of maintaining life-supporting kidney function was evaluated according to several variables (clinical characteristics at presentation and WHO histological classification). The presence at the time of diagnosis of hypertension and diffuse proliferative nephritis (WHO class IV) was associated with a worse prognosis [20].

Treatment of lupus nephritis

General principles

The treatment of lupus nephritis is aimed to induce remission of the inflammation, thereby achieving control over renal and extrarenal signs of the disease. Even though there is no universal consent on definitions of remission, the current understanding is that remission of lupus nephritis is characterized by resolution of urinary abnormalities, reduction of proteinuria, and amelioration or stabilization of renal function. Ideally, all these objectives should be achieved with the least possible toxicity [21].

In many patients, irreversible injury may occur that prevents recovery of renal function. Also, healing of the inflammatory process may lead to glomerular sclerosis, for which the hallmark is persistent proteinuria [22]. Therefore, the treatment of lupus nephritis should include supportive, nonimmunological measures in association with immunosuppression.

Supportive therapy

Nonimmunological therapy for lupus nephritis is aimed to reduce proteinuria and to control hypertension. The role of proteinuria as a risk factor for progression of chronic nephropathies has been recognized over the last decade [23]. A number of randomized clinical trials, and substantial noncontrolled evidence, have established angiotensin converting enzyme inhibitors (ACEi) as effective in reducing proteinuria and preventing renal disease progression [24]. They may be used alone or in combination with angiotensin II receptor blockers (ARBs), which have also been demonstrated to exert kidney-protective effects. In general clinical trials assessing the protective role of ACEi or ARBs, patients with lupus nephritis are always excluded, because the concomitant immunosuppressive therapy may complicate the interpretation of results. However, there is no reason to suggest that the trials in non-lupus patients cannot be extrapolated to lupus patients. Moreover, there have been a few uncontrolled studies on small numbers of patients who were treated with aggressive renoprotective therapy that showed that this approach is feasible and probably effective [25,26].

High blood pressure is the other major risk factor for both chronic kidney disease progression and cardiovascular complications. Indeed, in our series of 659 patients, hypertension was associated with a worse prognosis, and cardiovascular events were the primary cause of death in our cohort (24.7% of patients). Again, ACEi and ARBs are the drugs of choice for chronic kidney disease patients, according to many guidelines. The target blood pressure

should be <130/80 mmHg, and probably even lower (<120/70 mmHg) if proteinuria exceeds 1 g/day. In non-lupus patients, these goals are usually achieved with a combination of drugs.

Other supportive measures, such as a low-protein diet, blood lipid control, and smoking cessation, even though they have not reached the same degree of evidence compared to the above-mentioned measures, are recommended [28,29].

Immunosuppressive therapy for proliferative lupus nephritis

Although immunosuppressive therapy is not indicated for the treatment of class I and II lupus nephritis, which have an excellent prognosis, it is recommended for proliferative forms of lupus nephritis with the aims of reducing glomerular inflammation and restoring or preserving kidney function.

Treatment regimens have been based on an induction phase aimed to induce remission of the disease in the shortest possible time and a maintenance phase aimed to preserve remission in the long term. The optimal therapy for both phases remains somewhat elusive, for several reasons. There is no consensus on the definition of remission, and as a consequence it is not known how long treatment should be prolonged. Also, the optimal regimen to be instituted in the induction phase is not universally established.

A study conducted at the National Institutes of Health (NIH) 20 years ago showed that kidney function was better-preserved in patients who received various cytotoxic drug therapies, but the difference was statistically significant only for intravenous cyclophosphamide pulses associated with low-dose prednisone compared with high-dose prednisone alone [30]. Treatment of lupus glomerulonephritis with intravenous cyclophosphamide rapidly became standard therapy.

Subsequent studies have focused on the optimal duration of the treatment. This was addressed by studies that compared the effects of short-term versus long-term treatments. Another study of the NIH showed that a regimen of prolonged intravenous cyclophosphamide administration (six monthly pulses followed by pulses every 3 months for 2 years) gave better results in term of preservation of renal function and reduction of the risk of relapses than six monthly pulses of methylprednisolone [31]. Also, this regimen gave better long-term results than a 6-month cycle of intravenous cyclophosphamide. A final study of the same group [32] showed that the combination of intravenous cyclophosphamide pulses with methylprednisolone for 1 year gave better results than either of the drugs given as sole therapy.

Protracted cyclophosphamide regimens, however, carry a significant burden of side effects, most notably a high rate of gonadal toxicity, severe infections, and osteoporosis. In at least one trial the mortality rate was higher in the cyclophosphamide group [33]. The concern over toxicity of these regimens has driven clinicians to investigate whether short-term treatment may be equally effective in controlling renal disease. One important study in this direction was the Euro-Lupus Nephritis Trial, published in 2002 [34]. In this study 90 patients with proliferative lupus nephritis were assigned to a high-dose intravenous cyclophosphamide regimen

Table 22.2 Treatment of patients with class III and IV lupus nephritis based on the available evidence.

Induction phase
Recommended
● Monthly intravenous pulse cyclophosphamide (0.75–1 g/m^2) for 6 mos
associated with
● High-dose prednisone, 1 mg/kg orally, tapered in 4–6 wks
or
● Intravenous pulses of methyprednisolone
Alternative
● MMF, 2–3 g/day in two divided doses for 6 months
associated with
● High-dose prednisone, 1 mg/kg orally, tapered in 4–6 wks
or
● Intravenous pulses of methyprednisolone
Maintenance phase
Optimal therapy for maintenance phase cannot be established by currently available
evidence. Possible choices are:
● MMF, tapered to 1–2 g/day in two divided doses
● Azathioprine, 1–3 mg/kg/day
● Intravenous pulse cyclophosphamide every 3 mos until in complete remission for 1 yr

---

All regimens are associated with low-dose oral prednisone.

(six monthly pulses and two quarterly pulses; initial dose, 0.5 g/m^2, then changed according to white blood cell counts) or a low-dose intravenous cyclophosphamide regimen (a pulse every 2 weeks, for a total of six pulses, at a fixed dose of 500 mg), each of which was followed by azathioprine (2 mg/kg/day). The follow-up period was 41 months. Renal remission was achieved in 71% of the low-dose group and 54% of the high-dose group (not statistically significant). Renal flares were noted in 27% of the low-dose group and 29% of the high-dose group. Although episodes of severe infection were more than twice as frequent in the high-dose group, the difference was not statistically significant. These data, in the authors' opinion, put into question the practice, based on the NIH trials, of treating all lupus nephritis patients with an extended course of intravenous cyclophosphamide. There were, however, evident differences between the populations studied. The European patients had a less severe kidney disease than patients recruited in the NIH trials. According to the authors, this was not due to selection bias of milder cases but represented the spectrum of patients in most European lupus clinics who were referred to the trial. Also, the ethnic composition of the European study, where 84% of patients were Caucasians, compared to a prevalence of 43% black patients in the NIH trials, is an important difference. Nonwhite ethnicity has been recognized as an unfavorable prognostic factor. In conclusion, the results of the European study indicate a promising and probably safer alternative to the traditional NIH regimen, but more data are needed before it becomes the new standard of care for lupus nephritis (Table 22.2).

The most recent systematic review on the treatment of lupus nephritis was published in 2003 by Flanc *et al.* [35]. A total of 920

articles were identified and 25 randomized controlled trials were considered suitable for inclusion, with an overall population of 915 patients. The majority of the studies were comparisons between cyclophosphamide or azathioprine plus steroids versus steroids alone (when the meta-analysis was performed, studies with mycophenolate mofetil (MMF) were under way and so they were not included in the review). Cyclophosphamide plus steroids reduced the risk of doubling of serum creatinine compared to steroids alone but had no impact on end-stage renal failure or mortality. Azathioprine plus steroids reduced the risk of all-cause mortality compared to steroids alone but did not alter renal outcomes. No benefit was found with the addition of plasma exchange to cyclophosphamide or azathioprine plus steroids in terms of risk of mortality, deterioration of kidney function, or uremia. Cyclophosphamide increased the risk of ovarian failure by about twofold (95% confidence interval, 1.10–4.34), while none of the immunosuppressive therapies increased the risk of major infection. The authors of this systematic review concluded that, whereas waiting for new therapeutic agents to be examined in clinical trials, cyclophosphamide combined with steroids remains the best option to preserve kidney function in lupus nephritis and that the smallest effective dose and shortest duration of treatment should be used to minimize gonadal toxicity, without compromising efficacy. The finding that azathioprine reduced all-cause mortality to a greater extent than cyclophosphamide is interesting but should be interpreted with caution. Indeed, this was an indirect comparison, because no study directly compared the two drugs except for one of the NIH studies, which was actually underpowered for this purpose [30]. Moreover, the studies that showed an advantage of azathioprine in terms of mortality (only three studies, for a total of 78 patients) were done in the early 1970s, when mortality for lupus nephritis was very high. Overall, the authors of this meta-analysis found that the quality of the studies was greatly variable. Many of them were done many years ago and presented serious methodological problems. Numbers of subjects enrolled were small in many studies. Moreover, the distribution of ethnic groups and severity of renal involvement varied among studies, making comparisons difficult.

Mycophenolate mofetil

MMF has been proposed as an alternative to cyclophosphamide for the induction of remission of lupus nephritis. As early as 1997 we investigated the effect of MMF in New Zealand Black × New Zealand White (NZBxW) F_1 hybrid mice, a model of genetically determined immune complex disease that mimics SLE in humans [36]. Results showed that the percentage of proteinuric mice was significantly reduced by MMF treatment, and serum blood urea nitrogen levels were also lower than in the vehicle-treated group. MMF had a suppressive effect on autoantibody production and protected animals from leukopenia and anemia. Life survival of MMF-treated lupus mice was significantly improved compared to untreated animals. Thus, MMF delayed kidney function deterioration and prolonged life survival in murine lupus nephritis.

Several clinical studies (not examined in the above-mentioned meta-analysis) have been published since then. The first randomized clinical trial was done in China [37]. In 42 patients with diffuse proliferative lupus nephritis, the efficacy and side effects of a regimen of prednisolone and MMF given for 12 months were compared with those of a regimen of prednisolone and cyclophosphamide given for 6 months followed by prednisolone and azathioprine for 6 months. Eighty-one percent of the 21 patients treated with MMF and prednisolone had a complete remission, and 14% had a partial remission, compared with 76% and 14%, respectively, of the 21 patients treated with cyclophosphamide and prednisolone followed by azathioprine and prednisolone. The improvements in the degree of proteinuria and the serum albumin and creatinine concentrations were similar in the two groups. The rates of relapse were 15% and 11%, respectively, whereas the prevalence of side effects of treatment was greater in the cyclophosphamide group. The follow-up was short, however, and the number of patients was low.

Results from an extended long-term study, with a median follow-up of 63 months, were reported by the same investigators in 2005 [38]. Serum creatinine in both groups remained stable and comparable over time. Creatinine clearance increased significantly in the MMF group, but the between-group difference was not significant. A total of 6.3% in the MMF group and 10.0% of cyclophosphamide-treated patients showed doubling of baseline creatinine during follow-up. The relapse rate was similar in the two groups, while MMF treatment was associated with fewer infections or infections that required hospitalization.

The most recently published trial was done in USA, sponsored by the US Food and Drug Administration [39]. It was a 24-week randomized, open-label, noninferiority trial comparing oral MMF (initial dose, 1000 mg/day, increased to 3000 mg/day) with monthly intravenous cyclophosphamide (0.5 g/m^2 body surface area, increased to 1.0 g/m^2) as induction therapy for active lupus nephritis. A total of 140 patients were recruited; 71 were randomly assigned to receive MMF, and 69 received cyclophosphamide. In the intention-to-treat analysis, 16 of the 71 patients (22.5%) receiving MMF and 4 of the 69 patients (5.8%) receiving cyclophosphamide had complete remission, for an absolute difference of 16.7% ($P = 0.005$), meeting the criterion for noninferiority and demonstrating actually the superiority of MMF to cyclophosphamide.

Partial remission occurred in 21 of the 71 patients (29.6%) and 17 of the 69 patients (24.6%), respectively ($P = 0.51$). Three patients assigned to the cyclophosphamide group died, two during protocol therapy. Fewer severe infections and hospitalizations but more diarrhea occurred among those receiving MMF. This study, however, generated some criticism [40], because patients with relatively mild disease were enrolled, including 20% of patients with membranous nephropathy, a form of lupus nephritis for which optimal treatment has not been established [41].

The efficacy of MMF as a maintenance therapy was assessed in a small trial by Contreras *et al.* [42]. Fifty-nine patients with lupus nephritis received induction therapy consisting of a maximum

of seven monthly boluses of intravenous cyclophosphamide plus corticosteroids. Subsequently, the patients were assigned to one of three maintenance therapies: quarterly intravenous injections of cyclophosphamide, oral azathioprine, or oral MMF for 1–3 years. During maintenance therapy, five patients died (four in the cyclophosphamide group and one in the MMF group), and chronic kidney failure developed in five (three in the cyclophosphamide group and one each in the azathioprine and MMF groups). The 72-month event-free survival rate for the composite end point of death or chronic kidney failure was higher in the MMF and azathioprine groups than in the cyclophosphamide group. The rate of relapse-free survival was higher in the MMF group than in the cyclophosphamide group. The incidences of hospitalization, amenorrhea, infections, nausea, and vomiting were significantly lower in the MMF and azathioprine groups than in the cyclophosphamide group.

MMF is clearly less toxic than cyclophosphamide, making it an attractive alternative. However, before it can be adopted as the new standard induction therapy for lupus nephritis, more data are needed. Available studies have had relatively short follow-up periods, and we do not know yet the optimal duration of MMF treatment. Studies are under way to establish the efficacy and safety of a long-term treatment protocol.

Treatment for patients resistant to induction therapy

Some patients do not respond to induction therapy, although it is difficult to define how frequently this occurs, as clinical trials have used different criteria. The optimal therapy for resistant cases is uncertain and cannot established by evidence-based criteria because of the sparse data. In patients resistant to cyclophosphamide after 6 months, a more prolonged course is advisable if side effects are not an obstacle; alternatively, the patient could be switched to MMF [43]. Vice versa, in resistant patients initially treated with MMF, cyclophosphamide should be used. Limited data are available for a number of other treatment modalities, such has intravenous immunoglobulin [44] or high-dose cyclophosphamide with stem cell transplantation [45]. In the previously mentioned systematic review by Flanc *et al.* [35], plasmapheresis did not offer any advantage.

New treatments

Based on new pathogenetic studies, several new therapeutic agents are being tested in preliminary studies or have been simply proposed as potentially effective agents (Table 22.3). Rituximab, a monoclonal antibody directed against the CD20 molecule found on pre-B cells and mature B cells, was introduced in the late 1990s for the treatment of non-Hodgkin's lymphoma [46]. Recently, this antibody has been used to treat glomerular diseases, including lupus [47]. A small study of 10 patients with proliferative nephritis treated with a standard protocol of rituximab and oral steroids was reported by Sfikakis and colleagues [48]. Seven of the 10 patients had already experienced episodes of nephritis requiring steroids plus cyclophosphamide or MMF. Four patients achieved complete remission (normalization of serum creatinine and serum albumin, inactive urinary sediment, and proteinuria of <0.5 g/day) at 1 year. One attained temporary complete remission, and three had partial remission (>50% improvement in all renal parameters). Other series of patients with SLE treated with rituximab have been reported, but these have contained only a proportion of patients with lupus-related kidney disease. Overall, the majority of patients with SLE in whom B-cell depletion is achieved derive some clinical and biochemical benefits [49].

The interaction of B7-related molecules on antigen-presenting cells with CD28 or CTLA-4 antigens on T cells provides a second signal for T-cell activation. Selection inhibition of the B7-CD28 or B7–CTLA-4 interactions produces antigen-specific T-cell unresponsiveness in vitro and suppresses immune function in vivo [50]. A B7-binding protein was generated by genetic fusion of the extracellular domain of murine CTLA-4 to the Fc portion of a mouse immunoglobulin G2a monoclonal antibody (muCTLA4Ig). In lupus-prone NZB/NZW mice, treatment with muCTLA4Ig blocked autoantibody production and prolonged life, even when treatment was delayed until the most advanced stage of clinical illness [51].

Another receptor–ligand pair, CD40 on B cells and CD40 ligand on T cells, is an important costimulatory signal to T- and B-cell activation. Selective blockade of this interaction with an anti-CD40L monoclonal antibody (ruplizumab) ameliorated nephritis in a murine model of lupus [52]. The compound was also tested

Table 22.3 New treatments for lupus nephritis.

Treatment	Type of agent(s)	Mechanism of action	Clinical data
Rituximab	Chimeric antibody directed against CD20 on B lymphocytes	Antibody-dependent cell-mediated cytotoxicity and induction of apoptosis	Clinical benefit reported in patients refractory to conventional therapy in open studies; good tolerability reported.
Abetimus sodium (LJP 394)	Construct of four dsDNA epitopes attached to a polyethylene glycol platform	Induces B-cell tolerance by binding anti-dsDNA antibodies, resulting in B-cell apoptosis or anergy	Reduces number of renal flares and prolongs interval between flares in patients with high-affinity antibodies to its DNA epitope.
Ruplizumab	Anti-CD40 ligand antibody	Blocks costimulatory signal on B cells that induces activation, proliferation, and class switching	A phase II RCT showed improvement in serology and hematuria but was terminated because of thrombotic complications
IDEC-131	Humanized monoclonal antibody against CD154	Blocks costimulatory pathways	In clinical studies, no significant benefit over placebo

in a clinical study of 28 patients with active proliferative lupus nephritis. A reduction of anti-dsDNA antibodies, increase in C3 concentrations, and decrease in hematuria were observed, but the study was terminated prematurely because of thromboembolic events in patients [53].

A humanized monoclonal antibody against CD154 (IDEC-131) was tested in 85 patients with active SLE in a phase II, double-blind, placebo-controlled, multiple-center, multiple-dose study [54]. Efficacy was assessed at week 20, primarily by the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) and, secondarily, by multiple measures of disease activity. Safety was assessed through week 28 by clinical and laboratory evaluations. SLEDAI scores improved from the baseline levels of disease activity in all groups, including the placebo group. The type and frequency of adverse events were similar between the IDEC-131 and placebo groups.

LJP 394 (Abetimus sodium) is a synthetic toleragen molecule consisting of four double-stranded oligodeoxyribonucleotides attached to nonimmunogenic polyethylene glycol [55]. Abetimus is an immunomodulating agent that induces tolerance in B cells directed against dsDNA. It does this by cross-linking surface antibodies. In a multicenter, partially randomized, placebo-controlled, double-blind, dose-ranging trial, 58 patients were randomly assigned to receive 1, 10, or 50 mg of LJP 394 or placebo [56]. The greatest reductions in mean dsDNA antibody titers were observed in the group of patients who received 50 mg of LJP 394 weekly (38.1% and 37.1% at weeks 16 and 24, respectively). A reduction (29.3%) in dsDNA antibody titers was also observed at week 24 in the group of patients who received 10 mg of LJP 394 weekly. The frequencies of adverse events were comparable in the placebo and active treatment groups. This clinical trial demonstrated the capacity of LJP 394 to reduce dsDNA antibodies.

Another study was designed to determine whether LJP 394 delays or prevents renal flare in patients with lupus renal disease [57]. A total of 230 patients were randomized to receive 16 weekly doses of 100 mg of LJP 394 or placebo, followed by alternating 8-week drug holidays and 12 weekly doses of 50 mg of LJP 394 or placebo. Anti-dsDNA antibodies decreased and C3 levels tended to increase during treatment with LJP 394. In the intent-to-treat population, the time to renal flare was not significantly different between treatment groups, but patients taking LJP 394 had a longer time to institution of high-dose corticosteroids and/or cyclophosphamide and required 41% fewer treatments. In the high-affinity antibody population, the LJP 394 group experienced a longer time to renal flare, 67% fewer renal flares, longer time to institution of high-dose corticosteroids and/or cyclophosphamide, and 62% fewer treatments than the placebo group. Serious adverse events were observed in 25 of the 114 LJP 394-treated patients (21.9%) and 34 of the 116 placebo-treated patients (29.3%). In conclusion, treatment with LJP 394 in patients with high-affinity antibodies to the DNA epitope prolonged the time to renal flare, decreased the number of renal flares, and required fewer high-dose corticosteroids and/or cyclophosphamide treatments compared with placebo.

Membranous nephropathy

Data on treatment of class V (membranous) lupus nephritis are scarce, and optimal therapy for this form of disease is not established. A small study of 41 patients at the NIH showed that patients treated with a combination of cyclophosphamide and steroids or cyclosporine had a higher rate of remission at 1 year than did patients treated with steroids alone [58]. Patients with lupus membranous nephropathy also have been treated by following a regimen of alternate cycles of steroids and chlorambucil, which is used for idiopathic membranous nephropathy [59]. The combination regimen offered a higher rate of remission and lower rate of renal flares, but this study was retrospective.

Recently we have shown that remission can be obtained in idiopathic membranous nephropathy with rituximab [60]. In a prospective, observational study we evaluated the 1-year outcome of eight patients with idiopathic membranous nephropathy and persistent (>6 months) urinary protein excretion greater than 3.5 g/day. They were given four weekly infusions of rituximab (375 mg/m^2). At 3 and 12 months, proteinuria significantly decreased by 51 and 66% from baseline, respectively. At 12 months, two of eight patients were in complete remission (proteinuria of ≤0.5 g/day) and three more had partial remission (proteinuria of ≤3.5 g/day).

Recently, Jacobson and collegues described a patient with membranous lupus nephritis with persistent nephrotic syndrome despite intensive immunosuppression who had a remission of nephrotic syndrome and recovery of renal function after a course of intravenous rituximab [61].

In the absence of randomized trial data, it is difficult to give a recommendation concerning rituximab. A prudent approach would be to advise to treat conservatively those patients with asymptomatic, nonnephrotic proteinuria. Patients with more aggressive disease (unremitting nephrotic-range proteinuria, declining kidney function) are usually treated as diffuse proliferative forms. However, when a patient known to have membranous lupus nephritis develops such features of worsening disease, a new renal biopsy to ascertain a change of histology class may be warranted. Rituximab is potentially a new effective treatment for resistant cases.

Conclusions

Optimal treatment of lupus nephritis is still a challenge to the clinician, even though there are now more treatment options than in the past. Several questions must be addressed in future studies. First, better definitions of clinical status, remission, and relapse are needed to establish appropriate therapeutic goals. Also, new markers of disease activity for monitoring patients during follow-up are required. Improvement of quality of clinical studies, using more homogeneous clinical and pathological criteria for selection and stratification of patients, is also required.

With regard to newer treatments, the long-term efficacy and safety of MMF as induction therapy have to be established by appropriately designed clinical studies. An important issue that studies have neglected is the optimal dose and duration of steroid therapy. Glucocorticoids lead to substantial long-term toxicity, and studies aimed to identify steroid-sparing strategies are required, although commercially less appealing. The role of the new biological agents, in particular for resistant and rapidly relapsing patients, remains to be explored.

It is interesting that, despite the great deal of knowledge concerning the pathogenesis of lupus nephritis that has been produced in the last decade [61] and the host of new molecules specifically targeted to interfere with the pathogenetic mechanisms, the accepted standard of treatment is based on combinations of old drugs. More independent clinical research is still needed.

23   Infection-Related Nephropathies

Monique E. Cho & Jeffrey B. Kopp

Kidney Disease Section, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, US Department of Health and Human Services, Bethesda, USA.

Introduction

Kidney disease is an increasingly important complication of human immunodeficiency virus type 1 (HIV-1) infection. The association between HIV-1 infection and kidney disease was first recognized in 1984 by investigators in New York City and Miami; they described a renal syndrome marked by proteinuria and a rapid progression to renal failure [1–3]. Most of these patients had focal segmental glomerulosclerosis with collapsing features, now referred to as HIV-associated collapsing glomerulopathy, or more commonly as HIV-associated nephropathy (HIVAN). In subsequent years, the existence of a specific HIV-associated renal disease remained controversial, partly because of the similarity of HIVAN to heroin nephropathy and the frequent intravenous drug use in this population. Reports demonstrating HIVAN in patients without intravenous drug use, including children, helped to establish HIVAN as a distinct clinical entity and directly linked HIV-1 infection with the development of renal complications [4,5].

Until the advent of highly active antiretroviral therapy (HAART), the annual incidence of end-stage renal disease (ESRD) attributed to HIV-1 infection increased by over 75% between 1990 and 1995 in the USA (Figure 23.1) [6]. Coincident with the widespread use of HAART, however, the incidence of ESRD attributed to HIV reached a plateau in 1996 and even showed a moderate decrease during the years 1995–1999 [7]. Nonetheless, prevalent ESRD cases increased more than twofold during the same period, and this increase in prevalent ESRD cases reflects a longer survival of HIV-infected patients after development of kidney failure [8]. In the era of HAART, therefore, HIV-1 infection has evolved into a chronic disease in patients with access to care, with kidney disease becoming a progressively more significant source of morbidity and mortality.

The prevalence of chronic kidney disease in different stages of HIV-1 infection is unknown. Proteinuria and increased serum creatinine levels have been reported in 7.2–32% of HIV-1-infected patients [9,10]. Although 60% of renal biopsies in HIV-1-infected patients with chronic kidney disease in the USA show HIVAN [11], HIV-1 infection is also associated with other various forms of renal disease. These include HIV-associated glomerulonephritis, thrombotic microangiopathy, and drug-induced nephropathy, with increasing recognition of renal complications of HAART. In addition, renal complications can occur in HIV-infected patients co-infected with hepatitis B or C virus, a topic that has been reviewed elsewhere [12]. This chapter will review renal diseases associated with HIV-1 infection with a central focus on HIV-associated collapsing glomerulopathy and will discuss treatment based on available clinical evidence.

HIVAN and collapsing glomerulopathy

Clinical manifestations and background

Patients of African descent have a striking susceptibility to developing HIV-associated collapsing glomerulopathy, with nearly 90% of cases occurring in African Americans. Estimates of the prevalence of HIV-associated collapsing glomerulopathy in African Americans have ranged from 3.5% to 12% [13,14]. HIV-associated collapsing glomerulopathy is the third leading cause of ESRD in black people ages 20–64 years, after diabetes mellitus and hypertension [7]. Analysis of data from the US Renal Data System (USRDS) indicates that the relative risk for ESRD from HIV-associated nephropathy is approximately 18-fold increased among African American compared to Caucasian patients [15].

Although HIV-associated collapsing glomerulopathy can occur at any stage of the disease, including the time of seroconversion, it is most commonly seen in patients with advanced HIV disease [16]. In patients who are not receiving antiviral therapy, the nephropathy may lead to rapid deterioration to ESRD within weeks to months. Patients with HIV-associated collapsing glomerulopathy present with massive proteinuria and are less likely to have
Figure 23.1 Annual incidence of HIV cases, HIV deaths, and ESRD due to HIVAN. The rate of new HIV infections peaked in the early 1990s, probably due to public health campaigns related to blood transfusion, safe sex, and avoiding needle reuse. Since the induction of HAART in 1996, the incidence of HIV deaths (left axis) and ESRD due to HIVAN (right axis) have also declined. All three rates reached a plateau in the past few years, although the prevalence rates for HIV continue to rise (not shown). Data are from the CDC and USRDS.

peripheral edema or hematuria than patients with idiopathic focal segmental glomerulosclerosis. These patients also tend to be normotensive. Urinalysis is remarkable mostly for proteinuria with hyaline casts. Renal ultrasound classically shows enlarged, echogenic kidneys. Renal biopsy is the only method to reliably diagnose HIV-associated collapsing glomerulopathy, as HIV infection may be associated with other renal diseases characterized by proteinuria.

Pathology

Collapsing glomerulopathy, including both HIV-associated and idiopathic varieties, has distinctive histologic features. By light microscopy, the diagnostic features include glomerular capillary collapse combined with podocyte hypertrophy and hyperplasia (Figure 23.2A); one glomerulus with both features is considered sufficient to make the diagnosis of collapsing glomerulopathy [17]. Importantly, these features may be segmental or global, focal or diffuse, and glomerulosclerosis may be absent early in the disease process. Therefore, including HIV-associated collapsing glomerulopathy in the broad category of focal segmental glomerulosclerosis does not seem appropriate [18]. Podocyte proliferation overlying a single capillary loop may appear as "crowning"; more extensive proliferation and detachment from the glomerular basement membrane may appear as a pseudocrescent.

A unique feature of collapsing glomerulopathy is that podocytes undergo dedifferentiation (losing maturity markers, such as synaptopodin and podocin) and transdifferentiation (losing expression of WT-1). Although most investigators have argued that the proliferating cells within Bowman's space are derived from podocytes, it has also been proposed that these cells are parietal epithelial cells [19]. Collapsing glomerulopathy also manifests as extraglomerular disease that often is surprisingly severe

for the extent of glomerular disease, suggesting that this syndrome is a pan-nephropathy. These manifestations include acute and chronic tubular changes, often with microcystic tubular dilatation and an interstitial infiltrate composed of lymphocytes and macrophages (Figure 23.2B). Immunofluorescence analysis of collapsing glomerulopathy typically shows immunoglobulin M (IgM) and C3 in the collapsed and sclerotic segments and also in the mesangium of uninvolved glomeruli. Electron microscopy shows glomerular capillary wrinkling and collapse and podocyte abnormalities, including diffuse foot process effacement and microvillous transformation. Glomerular capillary cells may show tubuloreticular inclusions, which are more common in HIV-associated collapsing glomerulopathy than in idiopathic collapsing glomerulopathy and are never seen in focal segmental glomerulosclerosis.

Pathogenesis of HIV-associated collapsing glomerulopathy

HIV-1 infection of renal epithelium

Possible pathogenic factors in HIVAN are outlined in Table 23.1. Increasing evidence suggests that direct viral infection of renal cells by HIV-1 is at the core of pathogenesis of HIV-associated collapsing glomerulopathy. Until recently, direct infection of renal parenchymal cells by HIV-1 remained controversial because of conflicting data regarding the presence of HIV-1 in renal tissue of patients with HIVAN. Studies using transgenic mouse models of HIV-associated collapsing glomerulopathy have strongly implicated the expression of HIV proteins in the pathogenesis of the renal disease [20–22]. These studies demonstrated that HIV-1 accessory proteins can induce features characteristic of HIV-associated collapsing glomerulopathy, including podocyte hyperplasia and
Figure 23.2 Renal pathologic features of HIV-related kidney diseases. (A) Collapsing glomerulopathy (methenamine trichrome stain). The glomerulus shows a collapsed tuft and markedly hyperplastic podocytes partially filling Bowman's space. (B) Collapsing glomerulopathy (methenamine trichrome stain). Microcystic tubular dilatation is present, together with interstitial inflammation and fibrosis. (C) Diffuse proliferative glomerulonephritis with a pattern resembling membranoproliferative glomerulonephritis, type I (Masson trichrome stain). The glomerulus is enlarged with global mesangial and endocapillary hypercellularity and appears mildly hyperlobular. There is partial occlusion of a preglomerular arteriole by thrombus and rare red blood cell fragments within the glomerular tuft (arrows), indicative of thrombotic microangiopathy. (D) Tenofovir-associated tubular injury (hematoxylin and eosin stain). The tubules show degenerative and regenerative changes. Tubular cells have irregular shapes and lack a brush border. Occasional intratubular eosinophilic casts are also noted. Images provided courtesy of Dr. James Balow (panel A), Dr. Laura Barisoni (panels B and D), and Dr. Mark Haas (panel C). Panel C is reprinted with permission from *Kidney International* (Haas *et al.* 2005 [80]).

hypertrophy, microcystic tubular dilatation, mononuclear cell interstitial infiltrate, proteinuria, and renal failure. Bruggeman *et al.* demonstrated that the HIV-1 transgene is expressed in renal glomerular and tubular epithelial cells and that this expression in renal epithelium is required for the development of the HIVAN phenotype [20].

In a further attempt to definitively determine whether HIV-1 infects renal epithelium in HIVAN, Bruggeman *et al.* reported on a renal biopsy series in HIV-1-infected patients with HIVAN [23]. In 11 of 15 patients, HIV-1 was detected in renal epithelial cells by RNA *in situ* hybridization. In many samples, the result was confirmed using riboprobes specific for both the *nef* and *gag* genes and by DNA *in situ* hybridization. HIV-1 RNA was detected in renal tubular epithelial cells, glomerular visceral and parietal epithelial cells, and interstitial leukocytes. Ross *et al.* also discovered that the distribution of HIV-1 infection of renal tubules is similar to the pattern of microcystic tubular disease [24]. These data further support the direct infection of the renal parenchyma by the HIV-1 virus.

The mechanism by which HIV-1 enters renal epithelial cells is unknown. New insights into the pathogenesis of HIV-related disease stem from the recognition that chemokine receptors CCR5 and CXCR4 serve as major coreceptors together with CD4 in

Pathogenic factors	Reference(s)	Evidence

mammalian cells [25,26]. Expression of these receptors appears to be a key to understanding which tissues are permissive for direct HIV infection. No studies, however, have definitively established their constitutive expression in normal renal parenchymal cells or their upregulation in kidney biopsy tissue obtained from HIV-1-infected patients with HIVAN [27,28].

Infection of renal epithelial cells by HIV-1 has an important implication: the kidney may serve as a reservoir for HIV-1. Marras *et al.* detected variations in the HIV-1 envelope sequences in the renal tubular epithelium of HIV-infected patients, indicating that the renal tubular epithelium can support viral replication [29]. Furthermore, the envelope sequences of HIV-1 found in the renal tubular epithelium were distinct from the sequences derived from the same patient's peripheral blood samples, suggesting that the renal epithelium is a distinct reservoir for viral replication from the blood.

Viral genes responsible for HIVAN pathogenesis

Once HIV-1 infects renal tissue, one of the pathways through which the virus inflicts renal injury may be its peptides. The HIV-1 genome contains nine genes (*gag, pol, vif, vpr, vpu, rev, tat, env,* and *nef*) that encode 15 proteins. These viral accessory proteins have pleiotropic effects on cell function and are implicated in renal disease. Vpr, for example, induces G_2 cell cycle arrest, perturbs mitochondrial function, induces (and in some cells prevents) apoptosis, and alters gene transcription by acting as a coactivator or corepressor. Increased levels of apoptosis in renal tissue have been shown in patients with HIVAN compared to non-HIV-infected patients [30], in transgenic models [20], and in proximal tubular epithelial cells infected with HIV-1 [31]. It is unclear if the enhanced apoptosis in HIV-1-infected renal cells predominantly reflects direct toxicity of HIV proteins or indirect effects, such as induction of profibrotic cytokines.

Roles of other accessory proteins inducing renal injury have been investigated. Tat and Nef each induce proliferation of cultured podocytes, a distinctive feature of HIV-associated collapsing glomerulopathy [32,33]. A series of studies using transgenic mice bearing various portions of this genome have suggested which genes may be responsible for renal injury. HIV-1 transgenic mice carrying a replication-defective HIV-1 provirus that lacks *gag* and *pol* develop renal injury characterized by podocyte dysplasia and proliferation, glomerular capillary tuft collapse, and tubular injury. This characteristic renal injury occurs even in the absence of immunosuppression and viral replication [21,22]. Deletion of *nef* from the transgenic line reduced the severity of interstitial nephritis, but it did not prevent the development of glomerular disease in one transgenic line [34]. More recently, mice bearing *tat* and *vpr* or *vpr* alone developed focal segmental glomerulosclerosis [35]. These data indicate that *vpr* induces focal segmental glomerulosclerosis and that *nef* contributes to interstitial nephritis in transgenic mice [35–37].

Host factors

Although renal parenchymal cell infection and expression of HIV-1 gene products play a crucial role in disease initiation, a variety of host factors likely contribute to the phenotype and the outcome of the disease. The renal epithelial cell proliferation and apoptosis induced by viral products in turn trigger profibrotic pathways. Epidemiologic studies have demonstrated that HIV-1-infected patients do not have equal risk of developing HIVAN. Twenty-five percent of patients with HIV-associated collapsing glomerulopathy have first-degree or second-degree family members with ESRD, suggesting a genetic predisposition to glomerular injury [38]. These data suggest a familial susceptibility to renal injury following diverse stimuli, including HIV-1 infection. The striking predominance of the disease in patients of African descent, particularly in men, is another important observation suggesting inherent risk factors. How the genetic variability or traits may be associated with higher risk of developing HIVAN is unknown. Possible explanations may involve differences in host-specific antibody or cellular responses to viral infection, differences in sclerosing mechanisms, differences in activation of coreceptors for HIV attachment to renal cells and subsequent infectivity, and diminished host ability to repair.

Treatment

Although HIV-associated collapsing glomerulopathy is an important cause of renal failure in the USA, no randomized controlled trials have been carried out to assess various therapies. Thus, recommendations must be based on retrospective or uncontrolled studies or on expert opinion.

Table 23.2 Summary of reports suggesting efficacy of HAART in patients with HIVAN.

Study authors [reference]	Year	Design	Results
Wali *et al.* [42]	1998	Case report	• A patient with HIVAN with dialysis-dependent kidney failure became dialysis-free after 15 wks of triple-agent antiretroviral therapy
Winston *et al.* [16]	2001	Case report	• A patient with HIVAN with dialysis-dependent kidney failure recovered renal function (serum creatinine from 6.3 to 1.4 mg/dL and proteinuria from 17 to 1.5 g/day) after 6 wks of HAART
Betjes *et al.* [39]	2002	Case report	• 3 patients with HIVAN had stable improvement of kidney function after initiating HAART
Szczech *et al.* [41]	2002	Retrospective cohort study of 19 patients	• Use of protease inhibitors as part of HAART regimen significantly slowed decline in GFR compared to group not receiving protease inhibitors
Lucas *et al.* [40]	2004	Retrospective analysis of 12-yr cohort study of 3976 patients with HIV-1 infection in Baltimore, MD	• HIVAN risk was 60% lower in patients treated with HAART • No patient developed HIVAN when HAART was started prior to development of AIDS
Schwartz *et al.* [43]	2005	Analysis of data from CDC and USRDS	• HAART reduced rate of progression to ESRD by 38% in patients with HIVAN

HAART

The abrupt leveling-off in the incident ESRD case rate coincident with the widespread use of HAART suggests that effective antiviral therapy probably prevents the onset or slows progression of HIV-associated collapsing glomerulopathy. Several observational studies have consistently suggested the benefit of HAART in treatment of HIVAN [16,39–42] (Table 23.2). In particular, two case reports have described resolution of HIVAN on antiretroviral therapy, a condition deemed irreversible in the pre-HAART era [16,42]. The authors reported that two patients with dialysis-dependent renal failure associated with HIVAN became dialysis-free following several weeks of HAART. Remarkably, the on-treatment biopsy indicated almost complete resolution of the hypertrophy of podocytes and glomerular collapse and normalization of tubular architecture.

Schwartz *et al.*, using a statistical model to analyze the data from the USRDS and Centers for Disease Control and Prevention (CDC), estimated that HAART had reduced the rate of progression of HIVAN to ESRD by 38% [43]. In addition, HAART may also prevent the development of HIVAN: a retrospective analysis of a 12-year cohort study of 3976 patients with HIV-1 infection suggested that the risk of nephropathy was 60% lower among patients treated with HAART and that no patient developed HIVAN when HAART was started prior to development of AIDS [40].

Angiotensin converting enzyme inhibitors

Available data suggest that angiotensin converting enzyme (ACE) inhibitors may slow the loss of renal function in patients with HIVAN (Table 23.3). In one nonrandomized study of 18 patients with biopsy-proven HIVAN, those treated with captopril had significantly improved renal survival compared to subjects who were not treated with captopril [44]. In another nonrandomized study that evaluated 20 patients with HIVAN, patients treated with fosinopril had a reduction in proteinuria with a small increase in serum creatinine [45]. In contrast, the untreated patients developed marked increases in protein excretion and serum creatinine within 12–24 weeks, suggesting that ACE inhibitors may prolong renal survival. A more recent study of 44 patients with HIVAN also

Table 23.3 Summary of reports suggesting efficacy of ACE inhibitors in patients with HIVAN.

Authors [reference]	Date	Design	Results
Kimmel *et al.* [44]	1996	Case control study of 18 patients	• Improved renal survival in captopril group (mean renal survival, 156 ± 71 vs. 37 ± 5 days)
Burns *et al.* [45]	1997	Prospective cohort study of 20 patients (12 on fosinopril and 8 controls)	• Nonnephrotic patients treated with fosinopril had mild fall in proteinuria (1.7 to 1.3 g/day) and increased serum creatinine (1.3 to 1.5 mg/dL) at 24 wks • Patients without fosinopril deteriorated rapidly with increase in proteinuria (0.8 to 8.5 g/day) and serum creatinine (1.0 to 4.9 mg/dL) • Similar results seen in nephrotic patients within 12 wks
Wei *et al.* [46]	2003	Prospective cohort of 44 patients (28 on fosinopril and 16 controls)	• Risk of kidney failure significantly reduced with ACE inhibitor therapy (risk ratio, 0.003) • Significant mortality benefit also noted with ACE inhibitor therapy (88% of untreated patients died, vs. 33% of treated patients)

found that patients treated with an ACE inhibitor had a 3.3-fold increase in median renal survival time [46].

Immunosuppressive therapy

The role of immunosuppressive therapy is less clear. Studies using prednisone in patients with renal dysfunction and HIV-1 infection show some efficacy in preserving renal function and reducing proteinuria [47,48]. These studies, as with the trials evaluating the efficacy of ACE inhibitors, were not well-controlled, and not all patients underwent renal biopsy. Another retrospective study suggested efficacy of combination therapy with HAART and glucocorticoids [49]. The mean renal survival to ESRD was 26 months for those treated with the combination therapy, 6 months for those given HAART alone, and 3 months for those given neither HAART nor glucocorticoids. Although no studies have suggested efficacy of glucocorticoids in children with HIV-associated collapsing glomerulopathy, a very small study reported remission of proteinuria with cyclosporine therapy in three children who had steroid-resistant renal disease [50]. Again, the study was not a controlled trial and was done before the era of HAART, making it difficult to draw any firm conclusions.

HIV-associated glomerulonephritis

HIV-associated glomerulonephritis is most prevalent among Caucasian, Hispanic, and Asian patients. In the absence of a national registry of renal biopsy findings, the true prevalence of HIV-associated glomerulonephritis is unknown. Several different histologic descriptions have been reported for HIV-associated glomerulonephritis, including IgA nephropathy, a lupus-like pattern, postinfectious glomerulonephritis, membranoproliferative glomerulonephritis, membranous nephropathy, and fibrillary and immunotactoid glomerulonephritis. An example of diffuse proliferative glomerulonephritis is shown in Figure 23.2C. It is not always possible to discern if the renal disease is a consequence of the HIV-1 infection or if it is a coincidental occurrence. For example, patients with HIV disease are often co-infected with hepatitis B virus or hepatitis C virus, each of which have been associated with glomerular diseases such as membranous glomerulopathy and membranoproliferative glomerulonephritis.

The pathogenesis of these forms of HIV-associated glomerulonephritis is not clear. In IgA nephropathy, immune complexes containing HIV proteins have been found in the mesangium, possibly delivered preformed from plasma or forming *in situ*, leading to renal parenchymal inflammation [51]. Guidelines for treatment are limited by the lack of randomized controlled trials, but therapies have included antiretroviral therapy, ACE inhibitors, and prednisone [52,53].

Thrombotic microangiopathy

Since the first report of HIV-associated thrombotic microangiopathy (TMA) in 1984, it has been increasingly recognized in this infection, although clinically evident TMA is infrequent [54]. A retrospective study demonstrated that 15 of 224 AIDS patients (7%) had evidence of TMA at the time of death [55]. The pathologic findings include occlusive thrombi in small arteries and arterioles and detachment of glomerular endothelial cells from the basement membrane. Affected patients typically present with hemolytic uremic syndrome characterized by renal insufficiency, microangiopathic hemolytic anemia, and thrombocytopenia. The mechanisms that account for microvascular damage in HIV-1 infection are poorly understood. There are no data to suggest that HIV-associated TMA should be treated differently from idiopathic or autoimmune forms of TMA. Therapies have included plasmapheresis and/or prednisone, with limited success in HIV-associated TMA.

Drug-induced nephrotoxicity in HIV-1 infection

With the widespread introduction of HAART in 1996, the course of HIV disease has been irrevocably changed. Patients with access to care have benefited from the greatly improved survival associated with HAART, but at a significant cost of increased morbidity from its complications. Acute kidney failure remains common among ambulatory and hospitalized patients with HIV-1 infection, and those with acute kidney failure are more likely to have received HAART [56]. Several antiretroviral agents and medications used to treat complications of HIV-1 infection are known to have nephrotoxicity. Many of these nephrotoxicities stem directly from the processes of drug metabolism, elimination, or drug–drug interactions. In addition, antiretroviral agents may lead to indirect nephrotoxicity by promoting metabolic aberrations, such as insulin resistance, diabetes, dyslipidemia, and hypertension. Renal abnormalities associated with antiretroviral therapy are summarized in Table 23.4. There have been excellent reviews of renal complications of antiretroviral therapy published recently [57–59].

Mechanisms of direct drug nephrotoxicity
Crystallization

Among protease inhibitors, indinavir is most commonly associated with renal or urologic complications, with a 10-fold increase in the incidence of such complications compared to other protease inhibitors in one observational cohort study [60]. Crystallization of indinavir can cause renal colic and acute urinary obstruction due to frank nephrolithiasis or to crystal-laden sludge. Indinavir crystals can also cause dysuria, acute and chronic interstitial nephritis, renal atrophy, and hypertension [61–64]. Indinavir crystalluria is common; in a longitudinal study of 54 patients, 67% developed indinavir crystals on at least one occasion [65]. Therefore, the finding of indinavir crystalluria in an asymptomatic patient is not clinically useful. In addition to indinavir, both saquinavir and nelfinavir have been associated with reports of nephrolithiasis.

Table 23.4 Summary of common renal injuries induced by antiretroviral drugs.

Antiretroviral agent	Metabolism/excretion	Nephrotoxicity	Special consideration
Protease inhibitors			
Indinavir	Liver/kidney	Crystal nephropathy, interstitial nephritis	Maintain urine output >2–3 L/day
Ritonavir	Liver	Acute kidney failure	May potentiate nephrotoxicity of other agents (indinavir, tenofovir)
Nucleoside reverse transcriptase inhibitors			
Abacavir	Liver	Acute kidney failure, interstitial nephritis	Nucleosides are associated with lactic acidosis
Didanosine	Liver/kidney	Acute kidney failure (proximal and distal tubulopathy)	
NRTI			
● Tenofovir	Kidney (elimination via tubular secretion)	Acute kidney failure with prominent proximal tubulopathy	Monitor for Fanconi syndrome
Nonnucleoside reverse transcriptase inhibitors	Liver	None reported	

Drug interactions

Ritonavir has also been associated with acute kidney failure and impaired kidney function, particularly when it is combined with tenofovir and indinavir. The interactions of ritonavir with other drugs metabolized by the cytochrome P450 system have been well-established. Another explanation may involve its inhibition of drug efflux mechanisms in tubular epithelial cells. Ritonavir is a potent inhibitor of P-glycoprotein, a luminal membrane transporter of organic cations, and thus may lead to accumulation of other drugs and potentiate toxicity.

Tubular cytotoxicity

Nucleotide reverse transcriptase inhibitors (NRTIs), such as cidofovir, adefovir, and tenofovir, are eliminated as unchanged drugs in urine by active secretion into the proximal tubule via organic anion transporters. Intracellular accumulation of these nucleotide analogs likely results in cytotoxicity to proximal tubular epithelial cells, resulting in a proximal tubular dysfunction and acute kidney failure. NRTIs may exert cytotoxicity via mitochondrial toxicity. Phosphorylated forms of some NRTIs are potent inhibitors of mitochondrial DNA polymerase [66]. The resulting deficiencies in the mitochondrial oxidative phosphorylation system may lead to disruption in pyruvate oxidation and increased lactic acid production. Thus, organs rich in mitochondria, such as muscle, liver, and kidney (particularly proximal tubules), are at increased risk for clinical toxicities, which can manifest as myopathy, liver steatosis, lactic acidosis, and Fanconi syndrome.

Although tenofovir, a newer NRTI, did not initially demonstrate any significant nephrotoxicity, increasing numbers of reports have described adverse renal outcomes (Figure 23.2D) [67–73]. In these studies, patients had been taking tenofovir at daily doses of 300 mg for varying periods ranging from 2 weeks to 16 months when they developed renal failure. The renal toxicity was predominantly characterized by proximal tubular dysfunction, demonstrated by normoglycemic glucosuria, proteinuria, hematuria, and hypophosphatemia. Some patients also developed signs of distal tubular toxicity, presenting with diabetes insipidus [67,70]. The proteinuria associated with tenofovir is usually mild, but nephrotic-range proteinuria has also been described [73]. Continued administration of tenofovir may lead to chronic kidney disease in some patients. Renal function improves in most patients upon discontinuation of the drug, but patients have experienced persistent glucosuria and proteinuria with elevated creatinine, suggesting irreversible damage. Renal biopsy in these patients has shown acute tubular necrosis, involving particularly the proximal tubules.

Patients taking tenofovir should be monitored regularly, especially those also on ritonavir, which can increase the serum concentration of tenofovir.

Indirect effects of antiretroviral therapy promoting chronic kidney disease

Antiretroviral agents such as protease inhibitors and NRTIs have been associated with insulin resistance, diabetes, dyslipidemia, and hypertension [74–76]. In particular, lipodystrophy, which is most prevalent with protease inhibitor therapy, has been associated with a cluster of metabolic disturbances and hypertension [77,78]. The underlying mechanisms linking HAART with the increased risk for atherosclerotic vascular disease are incompletely understood but may include decreased peroxisome proliferator-activated receptor γ function and altered hormonal status. Given the importance of mitochondrial oxidative stress as the unifying mechanism underlying diabetic complications, the mitochondrial toxicities of NRTIs may also contribute to the pathogenesis or progression of chronic kidney disease. HIV-1-infected individuals thus represent a uniquely challenging population requiring coordination of multiple disciplines for proper care and risk modification.

Conclusions and recommendations

In the era of HAART, HIV-1 infection, once considered a rapidly fatal disease, has now become a chronic illness with increasing morbidity from multiorgan dysfunction due to both the chronic infection of the virus and the complications of antiretroviral therapy. Chronic kidney disease has emerged as a common complication of HIV-1 infection. Despite great success with HAART, renal dysfunction remains a serious clinical challenge, with some therapeutics potentially leading to chronic metabolic derangement or other toxicities.

The HIV Medicine Association of the Infectious Diseases Society of America has recently published guidelines for the management of chronic kidney disease in HIV-1-infected patients [79]. The following are based on those recommendations. It should be noted that, as outlined above, the evidence base for these recommendations is weak and is based largely upon case series and expert opinion.

Screening

• All patients should be examined for renal dysfunction with glomerular filtration rate (GFR) estimation and urinalysis for proteinuria and abnormal urine sediment at the time of diagnosis of HIV-1 infection. This recommendation is based on expert opinion.

• Among those without any evidence of renal dysfunction, individuals at high risk (African Americans, those with CD4 cell counts of $<200/\mu L$ or HIV RNA levels of >4000 copies/mL, coinfection with hepatitis B or C virus, family history of HIVAN, and other traditional risk factors, such as hypertension and diabetes) should be monitored once yearly at a minimum. These recommendations are based on evidence from observational clinical trials.

• For those with proteinuria ($\geq 2+$ by urinalysis) or GFR of <60 mL/min/1.73 m^2, additional evaluations and referral to a nephrologists are recommended. This recommendation is based on clinical observation that early intervention in chronic kidney disease is beneficial.

Management

• In HIV patients with evidence of nephropathy, the target blood pressure should be $\leq 130/80$ mmHg, with initial preferential use of ACE inhibitors or angiotensin receptor blockers, particularly in patients with proteinuria. This recommendation is based on expert opinion from clinical observation.

• Patients with HIVAN and other HIV-associated glomerulonephritis should be treated with HAART at diagnosis, regardless of the severity of renal dysfunction. This recommendation is based on observational studies.

• No specific recommendations regarding use of immunosuppressive medications such as prednisone can be made at this time.

• ACE inhibitors or angiotensin receptor blockers should be added to HAART in patients with proteinuria, especially if the antiretroviral therapy does not lead to improvement in kidney function. This recommendation is based on observational studies.

• Patients receiving tenofovir should be monitored at least semiannually with measurement of renal function, serum phosphorus, and urinalysis for glycosuria and proteinuria. This is particularly important if patients are being treated concurrently with other medications that are eliminated via renal secretion (adefovir, acyclovir, ganciclovir, or cidofovir) or medications that may cause an increased drug level (ritonavir). This recommendation is based on observational studies.

• All patients receiving indinavir should increase fluid intake to achieve a urine output of 2–3 L, with particular attention to this regimen in hot weather or with vigorous exercise. Periodic urinalysis and determination of serum creatinine are indicated in all indinavir-treated patients, perhaps quarterly, in order to identify patients with chronic interstitial nephritis; in such patients indinavir therapy should be promptly discontinued. Certain patients are at increased risk for indinavir stones; these patients include those with prior indinavir stones and those with hepatic dysfunction, which impairs nonrenal clearance.

24 Hepatitis B Virus

M. Aamir Ali, Scott D. Cohen, & Paul L. Kimmel

Divisions of Nutritional and Gastrointestinal Disease and Renal Diseases and Hypertension, Department of Medicine, George Washington University Medical Center, Washington D.C., USA.

Hepatitis B virus

Hepatitis B virus (HBV) is among the most common chronic infectious diseases, affecting 5% of the world's population [1,2]. In high-prevalence areas, the mode of transmission is primarily vertical, from mother to neonate, as a result of perinatal exposure [3]. Lifetime risk of HBV infection in these regions exceeds 60%, while risk of infection in the USA and Western Europe is less than 20%. However, HBV infection is a significant cause of morbidity and mortality, even in low-prevalence areas. In the USA, there are approximately 1.25 million HBV carriers [4]. Globally, chronic HBV infection is the primary cause of cirrhosis and hepatocellular carcinoma, resulting in up to 1 million deaths each year.

HBV is a small 3.2-kb hepadnavirus whose DNA contains four open reading frames, encoding HBV surface antigen (HbsAg), the HBV e antigen (HBeAg), and the HBV core antigen (HbcAg) [5,6]. HBsAg is detectable in the serum 2–10 weeks after viral exposure. In patients who recover, the antigen becomes undetectable approximately 6 months after it appears. Persistence of HbsAg in the circulation beyond 6 months defines chronic infection. In patients who spontaneously clear infection, anti-HBs antibody is elaborated, usually persisting for life and conferring immunity [3]. HBeAg is a soluble protein whose presence indicates active viral replication. Loss of circulating HbeAg coincides with decreased HBV DNA levels and is a treatment end point. Loss of HBeAg is sometimes due to a precore mutation that suppresses the synthesis of HBeAg, so the antigen is undetectable even while active viral replication occurs [7]. Anti-HBc is present in the circulation in both acute and chronic HBV infection.

Acute HBV infection is subclinical in most patients. Approximately 30% of patients develop symptomatic hepatitis. Patients may experience fever, arthritis, and skin rash during a prodro-

mal period when HBs complexed with anti-HBs activates complement and precipitates in various tissues. This prodrome is followed by elevations in aminotransferase levels and the development of nonspecific symptoms, including fatigue, myalgias, nausea, and vomiting [8]. Ten percent of patients with perinatal infection and nearly all those infected in adulthood recover spontaneously from acute HBV infection [1,8,9], demonstrating that progression to chronicity is markedly decreased in the setting of normal host immunity.

HBV infection and renal disease

HBV infection is associated with a number of renal manifestations (Table 24.1). The association between HBV infection and renal disease was first reported by Combes *et al.* in 1971 [10]. Subsequently, the field of HBV-associated nephropathy expanded to include other forms of renal disease, including membranoproliferative glomerulonephritis (MPGN), renal disease associated with polyarteritis nodosa (PAN), immunoglobulin A nephropathy (IgAN), and focal segmental glomerulosclerosis (FSGS) [6,11–15]. The incidence of HBV-associated renal disease is far less than that of HBV infection, suggesting viral pathogenic mechanisms, as well as genetic background and host responses, are critical to the development of particular types of nephropathy in susceptible patients. The occurrence of kidney disease associated with HBV infection is often associated with chronic infection [6,16].

Four possible mechanisms for HBV nephropathy have been invoked: 1) direct cytotoxic effects of the virus; 2) deposition of immune complexes consisting of viral antigen and antibody in renal tissue; 3) the action of T lymphocytes and antibodies induced by viral infection; and 4) the effects of cytokines or other virus-induced immune mediators on renal cells [6,11]. The onset and progression of kidney disease in HBV-infected patients is influenced by multiple factors, including age, gender, genetic constitution, immunological profile, and socio-economic status [3,6].

Table 24.1 Reported renal manifestations of HBV infection.

Manifestation
Membranous nephropathy
Membranoproliferative glomerulonephritis
Polyarteritis nodosa
Essential mixed cryoglobulinemia
IgA nephropathy
Focal segmental glomerulosclerosis

Epidemiology

Globally, the prevalence of HBV-associated kidney disease mirrors the prevalence of HBV infection. Well-designed population-based epidemiologic studies, however, are lacking. The age of presentation in children is in infancy among children infected vertically and between 5 and 7 years in those infected horizontally [11]. There is a distinct male predominance in pediatric patients with HBV-associated renal diseases. This predominance is less pronounced in adults, but the underlying reasons are unknown. In the USA, HBV is particularly prevalent in intravenous drug users and in patients with end-stage renal disease (ESRD) treated with hemodialysis [11].

In children with HBV-associated nephropathy, renal disease is most often asymptomatic and is detected by routine laboratory analyses. HBV-associated renal disease in children commonly presents as nephrotic syndrome [11]. A history of acute hepatitis is rarely obtained, as acute HBV infection tends to be subclinical in this population. Spontaneous remission of HBV-associated nephropathy occurred after clearance of HBeAg in 33 of 37 children over a course of 90 months [12]. Renal function was preserved in over 95% of children with HBV-associated renal disease [11]. Adults with HBV-associated renal disease commonly present with nephrotic syndrome and proteinuria and are more likely to recall a history of acute hepatitis. As in children, spontaneous remission is associated with clearance of HBeAg. Progression to kidney failure occurs in one-fourth of adult patients and is associated with failure to clear HBV infection [11].

HBV-associated membranous nephropathy

Pathophysiology

Membranous nephropathy (MN) was the first described, and is the most extensively studied, form of nephropathy in patients with chronic HBV infection [6,17–19]. Combes *et al.* described a patient [10] with nephrotic syndrome and with a history of jaundice after blood transfusion. Circulating Australia antigen was detected by serologic techniques. Examination revealed thickened glomerular capillary basement membranes and mesangial hypercellularity, as well as other features of MN. The Australia antigen was detected in renal tissue by using indirect immunofluorescence. The authors suggested nephropathy was causally linked to the renal deposition of Australia antigen-containing immune complexes. Elution of HBV-associated immune complexes from renal tissue was not performed. Subsequent reports demonstrated detection of HBsAg in renal tissue of patients with MN and HBV infection [15,20].

There are several potential mechanisms for HBV-associated glomerular injury. Deposition of circulating immune complexes in renal tissue is the most widely accepted pathogenic mechanism of injury. Early series defined HBV-associated nephropathy cases in which circulating immune complexes containing HBV antigens were found concurrently with MN, without necessarily demonstrating antigen–antibody complexes in renal tissue [6,17,21]. With technical refinements, it was demonstrated that prior studies in which HBsAg was identified by indirect immunofluorescence were prone to false-positive results [6,17,22]. Glomerular immune deposits in patients with HBV-associated MN contained HBeAg, and not HBsAg, as had been previously accepted [17,23]. In addition to immune complexes, HBV DNA was detectable by *in situ* hybridization in renal tissue of children with HBV-associated glomerulonephritis. Those with HBV DNA detected in renal tubules had a longer duration of proteinuria [24]. HBcAg RNA was found in the nuclei and cytoplasm of both glomerular and tubular cells in more than half of renal biopsies of patients with MN [25]. Persistence of HBV DNA in renal tissue can lead to *de novo* synthesis of viral proteins in the kidney, which can elicit a local immune response with potential immune-mediated cytotoxicity [6,26].

Clinical course

Studies have outlined the clinical characteristics of MN associated with HBV infection [6,17,21,27,28]. Some of these studies predate molecular diagnostic techniques presently available to establish causal relationships between viral infection and renal disease. The diagnosis of HBV-associated MN in many studies was based on one or more of the following criteria: the presence of persistent HBV-associated antigenemia, absence of evidence of other causes of nephropathy, and in some studies the detection of at least one HBV antigen in renal tissue [6]. In the majority of cases, at least one circulating HBV-associated antigen, usually HbsAg, was detected. Inclusion and exclusion criteria for specific renal diseases were variable. Few studies have included renal tissue elution of specific HBV-associated immunoreactants. Therefore, many studies of "HBV-associated renal diseases" have only documented the types of renal diseases present in HBV-infected patients, without establishing causal relationships [6]. Classically, remission of the nephrotic syndrome had been noted in a variable proportion of patients, and the course in patients with persistently elevated urinary protein excretion was often indolent [6]. Clearance of HBV antigenemia has been associated with improvement of signs of renal disease [29–33].

Lai *et al.* [34] reported the clinical features of 21 adults with HBV-associated MN and persistent HBsAg antigenemia and proteinuria. Nephrotic syndrome was present in 57%. Mean urinary protein excretion was 4.1 g/day, one-third had asymptomatic proteinuria, and two patients had chronic kidney failure.

One-fourth of patients had renal insufficiency, and one-third had hypertension.

Lai *et al.* [35] studied 100 consecutive patients with glomerulonephritis and with HBV infection documented by the presence of circulating HBsAg, using appropriate diagnostic criteria for HBV-associated renal disease. Thirty-nine patients had an HBV antigen detected in kidney tissue by monoclonal antibody techniques. HBeAg was the most commonly detected antigen, and 69.2% of patients were found to have an HBV-associated protein present in renal tissue. HBsAg was detected in 53.8% of patients with an HBV protein in renal tissue. MPGN or IgAN was the most common lesion identified in patients with renal HBsAg deposition, but MN was identified in fewer such cases. In contrast, of the patients with renal HBeAg, 55.6% had MN.

Clinical inferences regarding the natural history of HBV-associated MN are hampered because there are few data regarding long-term outcomes in adult patients in whom the diagnosis of HBV-associated MN has been rigorously established. HBV-associated MN has a variable outcome, although the lack of well-controlled longitudinal studies precludes definitive characterizations of outcomes. Progression to advanced chronic kidney disease (CKD) appears to be relatively uncommon [6], and the course may be more favorable in children. Spontaneous remission of nephrotic syndrome has been reported in 30–60% of MN linked to HBV [11]. Development of antibodies to HBeAg has been associated with decreased proteinuria [17]. Clearance of antigenemia appears to be associated with improved renal outcomes, but there are few data available with which to make definitive prognoses.

HBV-associated MPGN

Shortly after the report of MN associated with HBV infection, a study linked a heterogenous set of renal outcomes, including MPGN and FSGS, with HBV [15]. MPGN is also thought to result from deposition of HBV antigen–antibody complexes in mesangial and subendothelial tissues. Lai and colleagues showed MPGN is the most common lesion in patients with HBsAg detected in renal tissue [36]. Lee *et al.* [21] studied 87 patients with chronic HBsAg antigenemia with glomerular disease. One-third had MPGN, but only 21% had MN. MPGN types I and III have been described in association with HBV infection [11]. Caution is necessary in evaluating studies of HBV-associated MPGN preceding the cloning of HCV [6], since coinfection with HCV, which has been well-associated with MPGN, may have been the cause of the renal disease in such cases [6].

The clinical manifestations of HBV-associated MPGN are similar to those of idiopathic MPGN. The most common presentation is nephrotic syndrome with microscopic hematuria. Nearly half the patients have hypertension, and one-fifth have impaired renal function [36]. The prognosis is unfavorable, with a 50% risk of developing ESRD or mortality in 10 years [37].

Treatment

The literature on the treatment of HBV-related MN or MPGN is sparse, consisting primarily of case reports, case series, and treatment studies with historical untreated controls. The large randomized clinical trials that established benefits of various antiviral therapies in chronic HBV infection did not evaluate renal end points. Indeed, patients with renal disease were excluded in several of these trials, as was the case for HCV infection [38]. Despite the lack of a robust evidence-based literature to recommend it, antiviral treatment of HBV-associated nephropathy is warranted in patients with persistent proteinuria, particularly adults, to forestall the initiation of renal disease and progression to ESRD as a complication of the viral illness [11]. Patients at risk for progressing to kidney failure are those with persistent HBe Ag positivity. Eradication of HBV in this population serves the threefold purpose of preventing progression to kidney and liver failure and preventing hepatocellular carcinoma.

Corticosteroids

Success in treatment of idiopathic MN with corticosteroids led to its use in HBV-associated nephropathy. However, although corticosteroids have been used to treat idiopathic MN [39–42], there is currently no clear standard for the treatment of HBV-associated MN. A prospective trial of corticosteroids that compared eight patients treated with a 6-month course of steroids to seven historical controls treated supportively had disappointing results, revealing no improvement in any renal parameter [43]. In addition, corticosteroids were potentially harmful, as increased HBV viral load and persistence of HBeAg were noted in corticosteroid-treated patients [43]. Rapid steroid withdrawal can result in potentially fatal hepatotoxicity in HBV-infected patients maintained on long-term steroids, as the increased viral loads resulting from unchecked viral replication during immunosuppression encounter abruptly reconstituted immune responses. Because of the lack of demonstrable benefits and the potential for adverse events, corticosteroid treatment should not be considered a primary therapy for HBV-associated nephropathy.

Alpha interferon

Alpha interferon (IFN-α) is a cytokine elaborated by B lymphocytes and macrophages and has antiviral and immunomodulatory effects [11]. A randomized, controlled trial of IFN-α was conducted in 40 Taiwanese children with HBV-associated nephropathy [45]. Twenty patients each were randomized to IFN-α treatment or supportive therapy. After 3 months, all patients receiving IFN-α had resolution of proteinuria, whereas all patients receiving supportive treatment had varying degrees of proteinuria. Another study compared 19 children with HBV nephropathy treated with IFN-α for 16 weeks to 20 children with HBV nephropathy treated supportively [45]. Of the IFN-α-treated patients, 53% demonstrated HBeAg clearance and resolution of proteinuria. None of

the patients with persistent HBe antigenemia had resolution of proteinuria. While these findings are encouraging, IFN-α treatment involves daily injections and may be poorly tolerated due to flu-like symptoms and leukopenia. As such, this treatment should be weighed against nucleoside analog therapies.

The renal toxicity of IFN therapy has been well-documented [46–55]. Fifteen to 20% of cancer patients treated with IFN had proteinuria that was predominantly mild, clinically insignificant, and reversible on cessation of therapy [56,57]. While the majority of reported nephrotoxicity related to IFN therapy has been in patients with underlying malignancy, there are case reports of its occurrence in patients receiving IFN for chronic viral hepatitis [53,57,58]. Less common presentations of IFN-induced nephrotoxicity in patients with HBV infection are nephrotic syndrome and acute kidney failure [46–54,59]. The histological correlates of acute kidney failure with IFN therapy are variable, including minimal change disease, acute interstitial nephritis, acute tubular necrosis, FSGS, MN, and MPGN [46–54,58]. There is an increased likelihood of nephrotoxicity with IFN therapy in patients with underlying renal disease. Twenty-two of 23 patients with underlying glomerulopathy developed proteinuria while receiving IFN therapy for chronic HCV infection [60]. Proteinuria resolved in the majority after withdrawal of IFN. Although clinically severe renal impairment is rare, these findings underscore the need to monitor renal function closely during IFN therapy.

Pegylated interferon (PEG IFN) is composed of a polyethylene glycol moiety bound to IFN-α [61,62]. The polyethylene glycol increases the IFN half-life and may decrease immunogenicity [61,62]. Because of its prolonged half-life, PEG IFN only needs to be administered weekly. The safety and efficacy of PEG IFN in the treatment of chronic HBV has been demonstrated in several clinical trials, but none of them evaluated renal end points [63–65]. There are currently no reports of the effects of therapy with PEG IFN in HBV-associated renal disease.

Lamivudine

Lamivudine is an orally administered nucleoside analog with efficacy in chronic HBV infection [66]. Since the start of widespread use of lamivudine in the treatment of chronic HBV infection, improvement of HBV-associated renal disease with lamivudine has been the subject of multiple case reports [67–70]. A study comparing 10 patients with HBV-associated MN treated with lamivudine with supportively treated historical controls demonstrated reduction in proteinuria and increased serum albumin concentration in treated patients [66]. Lamivudine at 100 mg daily was administered to the intervention group [66]. At 3 years, 100% of treated patients and 58% of untreated patients had not developed ESRD ($P = 0.024$). In addition, there was a reduction in proteinuria after 6 months in the lamivudine group compared to controls [66]. Unfortunately, relapse of HBV infection after cessation of lamivudine occurs, and there is currently no standard duration of treatment. Therefore, open-ended treatment for a prolonged duration is usual for treatment of chronic HBV infection and may also be required in the setting of HBV-associated renal disease.

With prolonged treatment, however, there is a significant risk of developing viral resistance. After 1 and 5 years of treatment, the risk of resistance was 23 and 65%, respectively [71].

Adefovir dipivoxil

Adefovir dipivoxil is an adenosine triphosphate analog with benefit in chronic HBV infection [72,73]. Nephrotoxicity has been reported at the higher doses of this medication that are used to treat human immunodeficiency virus infection [74]. The dose of adefovir dipivoxil used to treat chronic HBV infection (10 mg daily) is lower and is associated with a risk of nephrotoxicity no greater than placebo [72–74]. The safety of adefovir dipivoxil was demonstrated in 12 patients with lamivudine-resistant HBV infection and varying degrees of renal dysfunction [75]. However, because of the availability of other less nephrotoxic therapeutic options, using adefovir dipivoxil to treat HBV nephropathy should generally be avoided in patients with renal dysfunction.

Adefovir at a 30-mg dose had a 35% incidence of renal toxicity, defined by increased serum creatinine or hypophosphatemia [74]. Adefovir nephrotoxicity is related to proximal tubular accumulation of the drug via an organic anion transporter found on the basolateral membrane of cells [74]. The drug is transported out of the proximal tubule via multidrug resistance-associated protein 2 (MRP2) [74]. Higher doses of the drug may overwhelm the ability of the luminal MRP to transport it out of the proximal tubule cell, resulting in intracellular accumulation and subsequent nephrotoxicity. Larger studies are needed to evaluate the safety and efficacy of adefovir in patients with CKD.

Other agents

Entecavir has been shown in large randomized controlled trials to be superior to lamivudine in the treatment of chronic HBV infection [76,77]. Although there are no reports regarding its use in the treatment of HBV-associated renal disease, it holds promise in view of its high potency and favorable side effects profile. Tenofovir is another nucleoside currently being evaluated for efficacy in treatment of chronic HBV infection. However, tenofovir treatment is associated with renal toxicity via a mechanism similar to adefovir [78,79]. Anelli *et al.* described an HBV-infected patient treated with infliximab, who had rheumatoid arthritis and secondary amyloid-associated amyloidosis [80]. The patient had complete cessation of HBV replication and improvement in creatinine clearance after 1 year of treatment [80]. However, larger clinical trials are needed before conclusions regarding the safety of tumor necrosis factor alpha blockers in HBV infection can be made.

Vaccination

Vaccination against HBV infection has decreased the incidence of HBV-associated renal disease. Prior to widespread vaccination, the incidence of HBV-associated renal disease was 0.3 cases/100,000 children age 0–14 years in 1990–1991 in South Africa. After introduction of widespread vaccination against HBV in 1994–1995,

the incidence of HBV-associated renal disease decreased 10-fold in 2000–2001 [1].

HBV and PAN

Epidemiology

PAN is a necrotizing vasculitis involving the medium-sized and small arteries. It is an uncommon complication of HBV infection, affecting 1–5% of those chronically infected [81]. However, older studies suggested as many as 70% of patients with PAN are HBsAg positive [82]. This association has been documented extensively in North America and Europe. In Asia, where HBV is regionally endemic, no association of the viral infection with PAN has been reported [81].

Pathophysiology

The pathophysiology of HBV-associated PAN may be mediated by circulating immune complexes, consisting of HBV-associated antigen, antibody, and complement [83]. Levels of circulating immune complexes have been reported to be proportional to PAN disease activity [84], and complex deposition has been demonstrated histologically in affected arteries [85,86]. HBeAg may be the predominant antigen in immune complexes associated with PAN [87]. The mechanism underlying immune complex tropism to the target vessels is unknown. Antineutrophil cytoplasmic antibodies are rarely found in patients with HBV-associated PAN [88].

PAN-associated vasculitis is notable for necrosis and perivascular inflammation of small and medium-sized blood vessels. The acute polymorphonuclear leukocyte infiltrate promotes a predominantly chronic mononuclear infiltrate that may lead to vascular occlusion and necrosis. Angiography demonstrates microaneurysms, stenosis, and occlusion. Renal angiography typically demonstrates microaneurysms [81].

Clinical course

PAN is a multisystem disease with protean manifestations extending beyond the gastrointestinal tract and the kidneys [81]. Nervous system, rheumatologic, cardiac, and dermatologic involvement have all been described [81]. The initial presentation is often with fever, hypertension, rash, and abdominal and joint pain. Laboratory studies show elevated erythrocyte sedimentation rate, anemia, leukocytosis, and abnormal liver-associated enzymes. Eosinophilia is seen in 10–40% of patients. With progression of disease, as vascular compromise occurs, visceral infarction involving the gastrointestinal tract, kidney, spleen, brain, heart, testicles, and prostate may occur. Gastrointestinal bleeding and perforation have been seen in 16% of patients. Pancreatitis and cholecystitis have also been reported [81].

Although the kidneys are involved in most cases of PAN, there is no classic pathognomonic pattern of renal injury. Hypertension related to renal vessel vasculitis is a common presenting symptom. In classic PAN with large and medium vessel involvement,

renal ischemia and infarction are typical. Fibrinoid necrosis is a frequent pathologic finding. Untreated PAN has a dismal prognosis, with 5-year survival rates of less than 15%. Early mortality results from acute gastrointestinal hemorrhage or ischemia, acute myocardial infarction, or kidney failure. Late mortality is often from complications of ESRD or congestive heart failure [88].

Treatment

Whereas plasma exchange and immunosuppression with corticosteroids and cyclophosphamide are cornerstones of treatment of idiopathic PAN, patients with HBV-associated PAN are at risk of increased viral proliferation and progressive liver disease with prolonged immunosuppression. In addition, rapid withdrawal of immunosuppression in HBV-infected patients may result in the development of fulminant hepatic failure. For these reasons, treatment of the underlying chronic viral infection is important in HBV-associated PAN. Antiviral treatment alone, without addressing the acute vasculitis and its life-threatening consequences, may also be inadequate [89].

There is a dearth of large, well-designed clinical trials evaluating the effectiveness of antiviral therapies in patients with HBV-associated PAN. One approach is to control the acute manifestations of PAN with plasma exchange while treating the underlying viral disease. A study of IFN and plasma exchange therapy in HBV-associated PAN demonstrated HBeAg seroconversion in four patients [90]. In a nonrandomized prospective trial that combined antiviral treatment (vidarabine or IFN) with plasma exchange in 41 patients with HBV-associated PAN, viral replication ceased in over half the patients, and long-term symptom-free survival was achieved in 80% [91]. Because renal disease was present in one-third of these patients and information regarding improvement in renal parameters is unavailable, specific conclusions regarding treatment of nephropathy with this protocol cannot be reached. Another approach is to treat the acute vasculitis with a short course of immunosuppression, followed by plasma exchange and antiviral therapy. Prevention of HBV infection by widespread vaccination has accounted for a remarkable decrease in the proportion of PAN cases associated with HBV infection. In 1972–1976, 38.5% of PAN cases were associated with HBV. In 1997–2002, this proportion decreased to 17.4% [92].

HBV and essential mixed cryoglobulinemia

The association between HBV infection and cryoglobulinemia is controversial. Serologic markers of HBV infection were demonstrated in the cryoproteins of 74% of patients with essential mixed cryoglobulinemia (EMC) [93]. Subsequent larger studies in the post-HCV era have challenged this finding on the basis of study population, accuracy of serologic tests used, and the possibility that HBV was transmitted by transfusion in patients with anemia. A notable challenge came from Ferri and colleagues, who found HBV infection to be causative in only 4 of 231 patients with EMC [94]. In contrast, HCV RNA was detected in 90% of patients

with EMC [94]. Furthermore, renal disease in the setting of HBV-associated cryoglobulinemia has never been reliably demonstrated to be caused by HBV antigens. There are no therapeutic trials of antiviral agents in the setting of HBV-associated cryoglobulinemia.

HBV and IgAN

There are increasing cases linking HBs antigenemia with IgAN. However, data are limited to studies of populations where HBV is endemic, which are therefore potentially subject to bias. Wang *et al.* evaluated 50 Chinese patients with IgAN, positive HBV serology, and/or HBV antigens found by renal immunohistochemistry [95]. They concluded HBV infection may have a role in the development of IgAN [95]. However, a Japanese study concluded that there was no association between IgAN and HBV [96]. A total of 130 patients with IgAN were identified. HbsAg was positive in only 4 of 130, or 3.1% [96], which was not different from the general population rate of 2.0% [96]. Lai *et al.* examined the possible role of HBV in the development of IgAN [97]. A total of 125 patients were diagnosed with IgAN [97]. Ten of the 125 patients with IgAN were HBsAg positive. Renal biopsies of these 10 patients were stained with immunoperoxidase for HBsAg, HBcAg, and IgA [97]. There was a control group with renal biopsies from 20 patients with IgAN without HBV antigenemia. Immunoperoxidase staining showed HBcAg in glomerular mesangial cell nuclei in 6 of 10 patients. HbsAg was found in the cytoplasm of one mesangial cell. They concluded that HBsAg and HBcAg in the cytoplasm and nuclei of glomerular cells were potential evidence for a pathogenic role of HBV in IgAN [97].

There are few studies examining the renal outcomes of HBV-infected patients with IgAN. Lai reported a decline in GFR in 19% of patients with IgAN linked to HBV over 40 months [98]. Of these patients, 25% eventually required renal replacement therapy [98]. Further studies are needed to clarify the potential association between HBV and IgAN.

HBV and FSGS

There may be a link between HBV and FSGS; however, research is limited. There is some speculation that FSGS, seen on biopsies of patients with HBV, could be a reflection of the advanced stages of other types of HBV-associated renal diseases [99]. Larger studies are needed to further evaluate this possible association.

HBV and ESRD

There has been a decrease in the incidence of HBV infection among US ESRD patients treated with hemodialysis, largely due to preventive measures implemented since the 1970s [100]. An analysis of data from the Dialysis Outcomes and Practice Patterns Study

(DOPPS) evaluated 308 dialysis units across the world and found a mean HBV prevalence of 3.0% across all centers [101], with 79% of centers having an HBV prevalence of 0–5% [101]. There was a higher prevalence of HBV infection in dialysis patients in France, Germany, and Italy compared to Japan, the UK, and the USA [101]. Universal precautions, including use of gowns and gloves when handling biohazardous materials, monthly testing for HbsAg, and separation of HbsAg-positive patients from negative patients, have all been associated with reduced incidence of HBV in hemodialysis units [100]. Acute infection with HBV tends to show milder clinical manifestations, with decreased levels of aminotransferases compared to patients acutely infected with HBV without ESRD [100]. The development of complications associated with HBV, including cirrhosis and hepatocellular carcinoma, is typically slow and often is longer than the average lifespan of patients maintained on hemodialysis [100]. Nevertheless, it is still essential to prevent transmission of this blood-borne pathogen in hemodialysis units.

Vaccination schedules are important for all patients with CKD, ideally in the predialysis phase, when immune responses to a vaccine may be optimal. In ESRD patients, additional doses beyond the standard three-dose schedule should be considered. Antibody testing for HbsAb to determine the optimal responses may be needed [100].

There have been limited studies on IFN use in hemodialysis patients with HBV. Rodrigues *et al.* studied 13 patients on hemodialysis with HBV and/or HCV infection who were treated with IFN-α 2B [102]. Eight of 13 patients responded to therapy [102]. Nevertheless, the frequency of adverse events with IFN therapy is higher in the ESRD patient population, limiting its use and effectiveness [100].

Several trials have investigated the use of lamivudine in ESRD patients, and these studies noted positive responses with clearance of HbeAg, although the studies were small [100]. Lamivudine therapy may play a role in improving overall patient and graft survival in HBsAg-positive kidney transplant recipients. Lamivudine at 100 mg daily was administered to 11 patients who underwent kidney transplantation between 1996 and 2000 and to 15 patients who had a kidney transplant between 1983 and 1995 [103]. These patients met inclusion criteria, which included rising HBV DNA levels or liver biopsy indicating active inflammation [103]. Patients in the group transplanted between 1996 and 2000 were treated with lamivudine for 32.6 $\pm$ 13.3 months, whereas those in the 1983–1995 group were treated for 36.3 $\pm$ 11.4 months [103]. Survival of those transplanted between 1996 and 2000 and subsequently treated with lamivudine was similar to HBsAg-negative patients [103]. However, the group transplanted between 1983 and 1995 had a lower survival rate compared to the HBsAg-negative control group [103]. The authors concluded that prompt administration of lamivudine once HBV DNA levels increase may improve survival of HBV-infected kidney transplant recipients [103].

There is concern that immunosuppressive medications used in kidney transplant patients may cause activation of HBV. Calcineurin inhibitors, azathioprine, and steroids may enhance viral replication [100]. Fornairon and colleagues evaluated the effect of

kidney transplantation in chronic HBV infection in 151 patients [104]. Over a period of 66 months in which liver biopsies were done, cirrhosis was found in 28% of patients [104]. HBV infection was not associated with differences in survival in this study [104]. However, data are conflicting and further information is needed before conclusions can be reached. Aroldi et al. found that death related to hepatic causes was more frequent in HBV-infected transplant patients than in HCV-infected transplant recipients [105].

The incidence of de novo glomerulonephritis in HBV-infected kidney transplant recipients was evaluated by Schwarz et al. Twenty-one patients of 848 who received a kidney transplant developed de novo MN [106]. Eight of these 21 patients also were found to have active infection with either HBV, HCV, or human immunodeficiency virus [106].

Conclusions

Although the incidence of HBV-related renal disease is decreasing with the widespread use of vaccination, it nevertheless remains an important cause of nephropathy, especially in the developing world. HBV infection has been linked to MN, MPGN, PAN, and possibly to IgAN as well as FSGS. MPGN may be an important renal complication of HBV infection. The chronicity of the viral infection and the host responses are likely factors in the pathogenesis of the associated nephropathies. Further studies are needed to determine the exact pathogenic role HBV infection may play in these nephropathies. A number of novel therapeutic approaches exist to treat HBV-related kidney diseases, including IFN-α, lamivudine, and adefovir. However, several of these treatments are associated with the development of nephrotoxicity.

25 Infection-Related Nephropathies: Hepatitis C Virus

Dirk R. J. Kuypers

Department of Nephrology and Renal Transplantation, University Hospitals Leuven, University of Leuven, Belgium.

Introduction

Hepatitis C virus (HCV) infection not only causes chronic hepatitis and hepatocellular carcinoma but can also lead to extrahepatic disease, like mixed essential cryoglobulinemia (MEC), glomerulonephritides, and lymphoproliferative disorders. Autoimmune disorders and cutaneous and neurological diseases associated with HCV infection are less frequently reported [1]. The prevalence of blood donors carrying anti-HCV antibodies ranges geographically from 0.1 to 2.0% with generally increasing rates as one goes geographically from the north to the south of the globe with the exception of the African continent, in which HCV is more prevalent. HCV infection is also more prevalent in populations at risk of contamination, such as intravenous drug abusers, hemophiliacs, and dialysis patients. The prevalence of anti-HCV-positive patients undergoing maintenance dialysis in developed countries ranges from 3.4% (the Netherlands) to as high as 22.3% (Italy). Several genotypes of HCV (genotypes 1 to 5) have been identified and determine, to some extent, the outcome of liver disease and the response to antiviral therapy. Some genotypes (e.g. genotype 1b) are thought to be more virulent, whereas others are associated with low viremia (e.g. genotype 2). The geographical predominance of the different genotypes is well-documented [2–4].

Glomerular disease associated with HCV infection

The association between HCV infection and glomerulopathy or albuminuria has been extensively demonstrated by surveys of large at-risk populations as well as in autopsy studies, while the presence of cryoglobulinemia is a strong indicator of renal insufficiency in patients with HCV-associated glomerulonephritis [2,5–7]. Not all

types of glomerular disease that have been described in association with HCV infection are actually causally related. HCV infection is prevalent in 15% of patients diagnosed with membranoproliferative glomerulonephritis (MPGN), which is much higher than the expected HCV prevalence, and this number increases to as high as 96% when MPGN is associated with cryoglobulinemia. A much lower prevalence of HCV infection is documented in other types of glomerulonephritis, such as membranous glomerulonephritis (5.5%), minimal change glomerulopathy (4.4%), immunoglobulin A (IgA) nephropathy (2.1%), and focal glomerulosclerosis (4.4%), except when the latter occurs in intravenous drug abusers and HIV/AIDS patients, who are at increased risk for HCV infection. Fibrillar and immunotactoid glomerulopathy and thrombotic microangiopathy have been occasionally described in HCV-positive patients but without any evidence for a causal relationship.

Role of HCV infection in MPGN with type II mixed cryoglobulinemia

HCV-associated MPGN is triggered by the glomerular (subendothelial and mesangial) deposition of circulating immune complexes containing HCV RNA and anti-HCV IgG antibodies, possibly enhanced by impaired clearance of these complexes through the reticuloendothelial system of the HCV-infected liver [8,9]. Several studies have indicated the presence of viral RNA or proteins in renal tissue by using electron microscopy, antibodies against viral proteins, and reverse transcription-PCR (RT-PCR) techniques. Recently, with laser capture microdissection, it has been demonstrated that viral RNA is present in glomeruli of patients affected by different types of HCV-associated glomerulopathies while the viral core protein is predominantly present in the renal tubules [10–12]. It is hypothesized that this viral RNA and protein subsequently activate mesangial cell expression of Toll-like receptors (e.g. TLR3), triggering chemokine/cytokine release (e.g. RANTES, MCP, CCL) and *in situ* complement activation via the lectin (mannose-binding lectin) pathway with engagement of specific Fc receptors on leukocytes, leading to mesangial proliferation, inflammation, and

apoptosis [13–15]. The strong coincidence of MPGN with type II MEC and HCV infection (prevalence of 95% vs. 3% in patients with MPGN without MEC) seems to be the result of the high incidence of cryoglobulins (54%) in the latter group [7]. Some reports suggest that the appearance of cryoglobulins in HCV-infected patients with MPGN is determined by the viral genotype, viral load in peripheral blood leukocytes, anti-HCV IgG titer, and the presence of anti-endothelial cell autoantibodies, but none of these findings has been confirmed in larger controlled studies. Anti-HCV antibodies also bind to the vessel wall in skin biopsies of patients with cryoglobulins and cutaneous vasculitis, further illustrating a causal relationship between these two entities.

Clinical manifestations

Patients with HCV-associated MPGN present with moderate to severe proteinuria, microscopic hematuria, and signs of mild to moderate renal insufficiency in the majority of cases. An acute nephritic syndrome (macroscopic hematuria, severe proteinuria, hypertension, and renal insufficiency) at onset occurs in approximately 25% of cases, while more than 20% of patients are diagnosed with nephrotic syndrome [7,8]. Symptoms of cryoglobulinemia, such as palpable purpura and petechiae (leukocytoclastic vasculitis), arthritis/arthralgia, or peripheral neuropathy (mononeuritis multiplex), Raynaud's phenomenon, weakness, fever, and leg ulcers are present in only half of HCV-associated MPGN cases. Rare cases of pulmonary or myocardial involvement with myocarditis and cardiomyopathy have been reported. Signs of MEC can become manifest years before the renal diagnosis is made or appear concurrently in 10–15% of cases. Extrarenal symptoms fluctuate strongly and can be associated with exacerbations of the renal disease, but they are not always present. Physical signs of liver disease are rare, whereas 60–70% of patients have mildly elevated transaminases. Arterial hypertension requiring therapy occurs in 80% of patients [1,7,8].

The clinical course of HCV-associated MPGN varies, with nearly one-third of patients experiencing a spontaneous remission of renal symptoms. In another one-third of patients urinary abnormalities persist, and renal disease is characterized by an indolent course without progression to kidney failure. About 20% of patients suffer from reversible clinical relapses, sometimes accompanied by signs of systemic involvement. Prognostic factors for MPGN with MEC II are age (>50 years), purpura, high cryocrit (>10%), low serum C3 levels, proteinuria, and high serum creatinine (>1.5 mg/dL). Although some degree of renal function impairment will eventually develop in the course of disease (or is already present at the time of diagnosis), end-stage renal failure occurs in only 10–15% of patients [1,8,16]. A recent large US survey confirmed an age-dependent association between HCV seropositivity and albuminuria, but no association with a low glomerular filtration rate (GFR) [17]. Patients with cryoglobulinemic GN have a 10-year survival of 50–60%; mortality is the result of cardiovascular complications, infections, liver failure, and malignancies.

Cryoglobulins can be detected in about 50–66% of affected patients, and HCV RNA is concentrated over 100-fold relative to serum in the cryoprecipitate. Cryoglobulins are typically composed of polyclonal IgG anti-HCV antibodies and a monoclonal IgMκ rheumatoid factor (type II MEC); occasionally, a type III mixed cryoglobulins is found. Hepatitis C virus RNA and antibodies are detected in more than 90% of affected patients. Hypocomplementemia (low CH50, C4, C1q, and to a lesser extent C3) is present, as is a positive monoclonal IgMκ rheumatoid factor. None of the latter laboratory parameters seems to correlate with clinical disease activity. Other symptoms related to extrahepatic manifestations of HCV infection include monoclonal gammopathy, lymphoma (B-cell non-Hodgkin's lymphoma, immunocytoma, extranodal marginal zone B-cell lymphoma of MALT type), autoimmune hemolytic anemia or thrombocytopenia, porphyria cutanea tarda, lichen planus, necrolytic acral erythema, chronic corneal ulcerations (Mooren's ulcer), polyarteritis nodosa, autoimmune thyroiditis, and other autoimmune disorders like sialadenitis, leading to sicca syndrome and autoimmune hepatitis (with anti-LKM-1 antibodies). Low titers of autoantibodies (ANF, anti-LKM-1, anti-GOR, anti-smooth muscle, and anti-cardiolipin antibodies) are detected in 40–65% of HCV-positive patients but rarely cause clinical disease [1].

Renal pathology

MPGN is the most common type of glomerulonephritis associated with HCV infection, accounting for approximately 54% of patients. The light microscopic histological pattern of HCV-associated type I MPGN, sometimes called "cryoglobulinaemic glomerulonephritis," is that of an exudative type of MPGN with thickening of the glomerular basement membrane with a "double-contour" appearance caused by interposition of monocytes rather than mesangial cells [2]. A picture of lobular glomerulonephritis is sometimes evident in cases of massive mesangial proliferation and infiltration by monocytes together with mesangial matrix expansion. Endocapillary proliferation is usually extensive (monocytes), and a striking feature of MPGN with MEC II is the presence of amorphous eosinophilic periodic acid-Schiff-positive intraluminal deposits that fill or completely obliterate the capillary lumen (intraluminal thrombi) (Figure 25.1A). These deposits are precipitated cryoglobulins of variable sizes and diffusion rates and consist of IgG and IgM, the latter having the identical idiotype of the circulating monoclonal IgM rheumatoid factor. Immunofluorescence shows not only diffuse granular staining of IgG, IgM, and C3 in peripheral glomerular loops, similar to idiopathic MPGN, but also strong intraluminal staining of the intraluminal thrombi (Figure 25.1C and D). Interstitial infiltration by a mixed monocyte–lymphocyte cell population is usually found in the acute stages of disease and can progress to interstitial fibrosis, while about one-third of biopsies show small and medium-size vessels with signs of fibrinoid necrosis and vascular wall infiltration by monocytes (vasculitis), especially in strong exudative forms of MPGN. Electron
Figure 25.1 (A) On light microscopy, glomeruli show hypercellularity and mesangial expansion. The glomerular capillary walls are thickened with interposition of predominantly monocytes (arrows). Note the intraluminal presence of thrombi consisting of cryoglobulins. (Original magnification, 200×.) (B) On electron microscopy, electron-dense deposits are present in the subendothelial space (asterisk) and the mesangium (arrowhead). These deposits consist of densely packed fibrils or microtubules (cryoglobulins). Note the presence of the same material in the lumen of the glomerular capillary (cl). (Original magnification, 10,000×.) (C) C3 positivity along the capillary walls and in the thrombi. (Original magnification, 200×.) (D) IgM positivity along the capillary walls and in the thrombi. microscopy can identify the fibrillar structure of the subendothelial cryoglobulin deposits with cylindrical bodies of 0.1–1 μm in length and an annular shape on cross-section consisting of a dense ring with a clear center (Figure 25.1B). A picture of mild mesangial proliferation without significant capillary wall thickening or intraluminal thrombi is encountered in about 10% of patients and is more difficult to distinguish from idiopathic MPGN. Other types of glomerulonephritis associated with HCV infection, like membranous glomerulonephritis, focal glomerulosclerosis, and IgA nephropathy, have been frequently described and their histological appearance does not differ dramatically from the primary

glomerulopathies. These types of glomerulonephritis are discussed elsewhere in this textbook.

Treatment

Although specific studies demonstrating an effect of nonimmunosuppressive therapy on HCV-related nephropathy are lacking, symptomatic treatment, similar to that advocated for any proteinuric nephropathy, is advised in all patients with HCV-related glomerulonephritis. It consists of rigorous blood pressure control

using salt restriction and angiotensin converting enzyme inhibitors alone or in combination with angiotensin receptor antagonists and loop diuretics. If additional antihypertensive therapy is required, calcium channel blockers might have a theoretical advantage over beta-blockers, as the latter could potentially aggravate extrarenal disease symptoms like Raynaud's phenomenon, necrolytic acral erythema, and leg ulcers. In case of nephrotic syndrome, statins are recommended for the treatment of hyperlipidemia, whereas guidelines concerning routine anticoagulation are lacking. Often, prophylactic dosing of low-molecular-weight heparin is necessary because of the presence of additional prothrombotic risk factors [18].

Antiviral therapy has been extensively tried in HCV-positive patients presenting with glomerulonephritis in an attempt to clear the virus from the serum and thereby improve renal outcome [19,20]. In the 1990s, subcutaneous alpha interferon (IFN-α) was tested in various small uncontrolled studies and described in numerous case reports. The overall results of these trials were disappointing; even with initial clearance of HCV and stabilization or improvement in renal function and/or proteinuria, relapses occurred in the majority of patients as soon as IFN-α therapy, even prolonged therapy lasting 6–12 months, was stopped. The concomitant use of corticosteroids did not significantly alter outcome. The combination of IFN-α or pegylated IFN-α with ribavirin, a guanosine analog with immune-modulating properties, has now become standard treatment for HCV-infected patients without kidney disease, because of a higher efficacy, compared with prolonged IFN-α monotherapy, which resulted in a sustained virological response in only 30% of treated patients [21]. Subsequently, this combination strategy was tested in HCV-related glomerulonephritis. Sabry *et al.* combined IFN-α therapy, 3 million units (MU) three times weekly, with ribavirin at a daily dose of 15 mg/kg body weight for 12 months, in cases where 3 months of IFN-α therapy alone did not clear the virus from serum. Five of 20 patients completely cleared the HCV, while C3 and C4 levels normalized in all patients. Furthermore, proteinuria decreased from 4 to 1.1 g/24 h, and renal function stabilized in the majority of patients (75%). Gastrointestinal and flu-like symptoms attributed to IFN-α were less pronounced in patients receiving combined therapy [22]. Alric *et al.* combined IFN-α (3 MU, three times per week) or pegylated IFN-α (1.5 μg/kg weekly) with ribavirin at 600–1000 mg/day for a mean period of 18 months in 18 patients with HCV-related cryoglobulinemic MPGN after completion of first-line treatment with prednisone or plasmapheresis. During a mean follow-up period of 17 months, a sustained virological response was obtained with this regimen in 67% of patients, whereas renal function stabilized and proteinuria and cryocrit decreased significantly [23]. These and other [24] studies illustrate that it is important to prolong combined IFN-α and ribavirin therapy for a sufficient length of time in order to reduce the number of flare-ups. Until data from controlled studies are available, it is advised that this combination be administered for at least 48 weeks (Table 25.1). Strong dose reductions of ribavirin are frequently necessary because of side effects, like hemolytic anemia, and in the event of impaired renal function. Anemia can occur at therapeutic drug concentrations

Table 25.1 Treatment of HCV-related glomerulonephritis.

Treatment steps

Step I: Symptomatic therapy
- Loop diuretics, angiotensin converting enzyme inhibitors, angiotensin receptor antagonists
- Statins, anticoagulation in case of associated nephrotic syndrome

Step II: Antiviral therapy for 48 wks
- Standard IFN-α therapy, 3×10^6 U, 3 times/wk, or pegylated IFN-α, 1.5 μg/kg/wk in combination with ribavirin, 15 mg/kg/day adapted to creatinine clearance
- Supportive therapy with erythropoietin and low-dose iron when required

Step III: Immunosuppressive induction therapy in cases of severe acute disease
- Methylprednisolone pulse therapy, 0.5–1 g/day for 3 days, followed by oral maintenance therapy and/or cyclophosphamide, 1–2 mg/kg/day
- Plasma exchange, 3 L plasma, 3 times/wk for 2–6 wks
- Rituximab, 375 mg/m²/wk for 4 wks[a] followed by antiviral therapy for 48 wks (Step II)

[a] See text for details.

(trough plasma concentrations between 10 and 15 μmol/L) and often requires supportive therapy with erythropoietin and low-dose iron.

Acute flares of HCV-related cryoglobulinemic MPGN with rapidly progressive renal function deterioration and/or severe cryoglobulinemic disease will often not respond to antiviral therapy alone and require additional immunosuppressive therapy in order to control inflammatory reactions and vascular manifestations due to cryoglobulin deposition. Short courses of corticosteroids (preferably pulses) with cytotoxic drugs, with or without plasmapheresis, may be needed to decrease cryoglobulin production and deposition [18,19] (Table 25.1). This aggressive induction therapy, although effective, is usually poorly tolerated and is associated with serious infectious complications. Therefore, the judicious use of corticosteroids and cyclophosphamide with or without plasmapheresis should be based on the severity of symptoms and should be reserved for patients with rapid renal function deterioration, nephrotic syndrome, and/or vascular manifestations [8,19]. The clinical indications for plasmapheresis in addition to corticosteroids and cytotoxic agents have not yet been clearly defined. Plasmapheresis is often initiated in order to achieve rapid removal of circulating cryoglobulins, thereby preventing further deposition. The latter is especially important in cases of massive glomerular precipitation, signs of renal vasculitis, and severe extrarenal systemic vasculitis [8]. Prolonged plasmapheresis treatment for 2–6 weeks in combination with immunosuppressive therapy is advised in order to avoid early rebound. After the acute phase is controlled, causative antiviral treatment should be rapidly commenced, especially because prior induction immunosuppressive therapy will have increased HCV viral load with potentially detrimental effects on the underlying liver disease.

Recently, rituximab, a monoclonal anti-CD20 antibody selectively targeting B lymphocytes, has been used successfully in patients with HCV-related cryoglobulinemic MPGN, both as first-line treatment and after failure of conventional therapy [25,26].

Rapid and sustained renal responses were observed in 50–100% of cases, taking into account that only small heterogeneous patient groups were studied until now. Disease relapses seem to respond to rechallenge with the drug, while side effects have been overall limited except in one small study where serious infectious complications (*Cryptococcus neoformans* meningoencephalitis and herpes simplex type 2 pneumonitis) were encountered. Close vigilance for opportunistic infections is therefore warranted. Initial dosing of rituximab is four consecutive weekly intravenous courses of 375 mg/m^2 of body surface. HCV viral load remains remarkably stable or even decreases mildly during rituximab therapy, in contrast to other immunosuppressive therapies. Interestingly, a patient homozygous for the high-affinity (VV) allele of FcγRIIIa (CD16) had a long sustained remission after one course of rituximab, suggesting that, as described for systemic lupus erythematosus, FcγRIIIa genotyping could play a future role in predicting responses to anti-CD20 therapy in HCV-related MPGN. Randomized controlled studies with sufficient prolonged follow-up are of course necessary in order to establish the efficacy of rituximab in HCV-related cryoglobulinemic MPGN in comparison to combined IFN-α–ribavirin therapy. Until efficacy and safety data from these studies are available, rituximab should only be considered in cases of failure of antiviral therapy for moderate HCV-related MPGN or if the combination of corticosteroids and cyclophosphamide (with or without plasmapheresis) cannot control progression of severe disease (kidney failure, nephrotic syndrome, or vascular manifestations) or is poorly tolerated.

Introduction

Polyomavirus-associated nephropathy (PVAN) currently represents the most challenging infectious cause of renal dysfunction in kidney transplant recipients. Centers from around the world report PVAN rates of 1–10% during the first 2 years post-transplant [1,2]. Over the following 6–62 months from diagnosis of PVAN, irreversible graft dysfunction and return to dialysis is seen in more than half of the cases [1–4]. Molecular genetic techniques have identified polyomavirus hominis type 1, also called BK virus (BKV), as the principle etiologic agent [5,6]. Less than 10% of PVAN cases with a seemingly milder clinical course have been attributed to the closely related human polyomavirus type 2, also called JC virus [7,8], which is known as the primary cause of a rare demyelinating central nervous system disease in HIV/AIDS, but also occasionally in kidney transplant patients called progressive multifocal leukoencephalopathy [9]. No specific antiviral agent is licensed for treating polyomavirus diseases, and current interventions rely on improving antiviral immunity.

Although single cases of PVAN were reported in the 1970s [10], the recent surge of PVAN after almost 50 years of kidney transplantation is remarkable and, given the unchanged epidemiology of BKV, points to significant changes in current transplant protocols as the cause. BKV infects more than 80% of the world's population during childhood and without specific clinical symptoms. Subsequently, the viral DNA genome persists latently in the reno-urinary tract. In approximately 5% of BKV-infected seropositive adults, asymptomatic BKV shedding is intermittently detectable, typically at low viral loads of $<10^6$ per mL [11,12]. Among patients with impaired immune function, for example, following cancer chemotherapy, advanced HIV infection, or immunosuppression associated with transplant procedures, the prevalence of urinary BKV replication increases to 20–60% and with higher BKV loads of $> 10^7$ per mL. Outright BKV disease is rare and almost always associated with significant immune dysfunction in conjunction with specific procedures, such as kidney transplantation for PVAN or bone marrow transplantation for late-onset hemorrhagic cystitis [11]. Here, we review the current evidence and recommendations regarding diagnosis and clinical management of PVAN in kidney transplantation.

Definitions

Grading of the evidence and strength of recommendations is based on a multidisciplinary position paper published in 2005 [1] and standards proposed by the Infectious Diseases Society of America (summarized in Table 26.1) [13]. Note that the grading system in this chapter is different from that presented in the rest of this book, but it has been retained to ensure consistency with how the recommendations were developed. The grading system used for quality is largely study design-based and does not explicitly consider other dimensions of quality of evidence, such as consistency, precision, design, and reporting quality, and relevance of outcomes measured and reported. The strength of recommendations is also largely determined by study design and other components; for example, benefit–harm trade-offs are not explicitly considered. Generally, however, it is likely that a level A recommendation would correspond to a level I recommendation using the GRADE system adopted for this book.

To better compare the results of the various studies, BKV infection, replication, and disease are defined as evidence for past virus exposure, active multiplication, and organ-invasive disease, respectively [14]. Possible PVAN is defined as detectable BKV replication in urine after kidney transplantation. Presumptive PVAN is defined as plasma BKV loads for ≥ 4 weeks of $>10,000$ copies/mL or an equivalent threshold [15], whereas definitive PVAN is defined as histological evidence of BKV replication and cytopathology in tissue samples (Table 26.2) [1].

Table 26.1 Evidence levels and clinical recommendations according to IDSA standards.

Category and grade	Definition
Strength of recommendation	
A	Good evidence to support a recommendation for use
B	Moderate evidence to support a recommendation for use
C	Poor evidence to support a recommendation
D	Moderate evidence to support a recommendation against use
E	Good evidence to support a recommendation against use
Quality of evidence	
I	Evidence from ≥1 properly randomized, controlled trial
II	Evidence from ≥1 well-designed clinical trial, without randomization; from cohort or case-controlled analytic studies (preferably from >1 center); from multiple time series; or dramatic results from uncontrolled experiments
III	Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees

Pathogenesis of PVAN

The pathogenesis of PVAN is not well-understood in detail, but it is undisputed that persistent BKV replication in renal tubular epithelial cells is the central process. Mathematical modeling of BKV dynamics in kidney transplant patients has provided first estimates of fast kinetics with a short BKV half-life of <2 h giving rise to high daily BKV plasma turnover rates of 99% and direct replication-attributable loss of >10^6 tubular epithelial cells per day [evidence level II] [16]. Failure to mount and maintain sufficient BKV-specific immune control is viewed as the key permissive factor [level II] [17–20]. In addition, factors (re-)activating BKV replication may come from epithelial injury and regeneration following ischemia, allo-immune responses, drug toxicities,

and drug effects in accordance with murine models [level III] [10,21–23]. Thus, long-lasting disruption of the balance between BKV-activating and -restricting host factors gives rise to progressive organ pathology [24,25] and eventually to outgrowth of more pathogenic BKV variants [26]. In clinics, onset of BKV viruria has been the first indicator of BKV replication which precedes BKV viremia and histologically confirmed "definitive" PVAN by 1–3 months [II] [6,27–29]. Conversely, declining BKV loads in blood and urine are the first marker of resolving PVAN after reducing immunosuppression [evidence level II] [6,27,28]. Thus, quantification of BKV replication has become the pivotal surrogate marker of the risk of PVAN [1].

Risk factors

Various risk factors in the triad of recipient, graft, and virus have been associated with PVAN in kidney transplantation [14]. However, the results of individual studies were often not independently confirmed, making it difficult to interpret the evidence level. In larger retrospective series of more than 60 adult cases, older age (53 vs. 46 years; $P = 0.001$), male recipients, and white ethnicity were found to be associated with PVAN, whereas prior rejection episodes or type of calcineurin inhibitor use were not [2,30]. In a recent adult case–control study matched 1:3 for PVAN in 4-month control biopsies enrolling 19 cases, PVAN was not associated with age, male gender, or white race, but with female donor gender [31]. However, an analysis of a large US database comprising 267 cases of PVAN identified younger age of <20 years, black ethnicity, deceased donor kidney, and prior rejection episodes in addition to male gender as risk factors of PVAN [32]. Despite the large number of patients in this study, uncertainties may have resulted from inclusion of pediatric patients, who are known to develop PVAN at a younger age [33,34]. Preliminary results from a large prospective multicenter study enrolling more than 500 adult *de novo* kidney transplant patients identified no association of BKV viruria, viremia, or viral loads with age, gender, or race but with tacrolimus-compared to cyclosporine-based immunosuppression, and steroid

Table 26.2 PVAN screening, diagnosis, and management in kidney transplant recipients.

Management approach	Testing result	PVAN	Intervention indicated?
Step 1) screening	Positive, with decoy cells in urine cytology, BKV DNA in urine or plasma, BKV RNA in urine	Possible	No [D-III]
Step 2) confirmation	Plasma BKV DNA load >4 $\log_{10}$/mL for >4 weeks	Presumptive	Yes [B-II]
	Urine BKV VP1 mRNA load >6 $\log_{10}$/mL		
Step 3) biopsy	Positive	Definitive	Yes [A-II]
	PVAN A: viral cytopathology, mild inflammatory infiltrates, tubular atrophy and fibrosis		
	PVAN B: significant inflammatory infiltrates, mild or moderate tubular atrophy or fibrosis		
	PVAN C: significant fibrosis, variable scores for tubular atrophy, inflammatory infiltrates, or viral cytopathology		
Step 4) monitoring	Negative	Resolved	No [D-II]
	Plasma BKV DNA load <2 $\log_{10}$/mL		

exposure [35]. Clearly, future validation of risk factors for adult and pediatric kidney transplant recipients will depend on well-designed prospective randomized studies or cohort studies of sufficient sample size.

Intensified immunosuppression with newer, more potent agents has reduced acute rejection episodes in the past decade but also coincided with the emergence of PVAN [1]. With few exceptions, PVAN has been diagnosed in patients receiving triple combinations of immunosuppressive drugs from all classes. However, combinations of tacrolimus and mycophenolate mofetil are more frequently encountered compared to cyclosporine and mycophenolate mofetil [evidence level II] according to retrospective series and case–control studies [5,36,37], cohort studies [38], and large prospectively randomized studies enrolling 200 [28] and >500 patients [35]. The use of steroids [evidence level II] [3,5,27,35,37,39] or antilymphocyte preparations [III] [27,39,40] for the treatment of rejection was associated with BKV replication if maintenance immunosuppression was continued or intensified. This is in contrasted to more favorable courses of PVAN with concurrent acute rejection when steroid treatment for acute rejection is coupled to decreasing maintenance immunosuppression [III] [27,39,41].

Clinical management

Screening for polyomavirus BKV replication

Polyomavirus replication emerged as the single common feature of all kidney transplant patients at risk of PVAN [I] [6,12,25,27,33,42]. The results from prospective studies indicate that BKV replication in the urine examined by either urine cytology or DNA PCR precedes BKV viremia by a median of 4 weeks and histologically documented PVAN by a median of 12 weeks [II] [27,28,35]. Screening for BKV replication may allow for earlier diagnosis and intervention with improved allograft outcome [II] [27–29,43,44]. Conversely, the negative predictive value of polyomavirus replication of >90% is helpful to rule out PVAN [II] [6,8,33]. In a medical decision analysis from North America, screening for BKV viremia was estimated to be cost-saving and to increase the quality of life if PVAN rates exceeded 2.1% [45]. Since transient, self-limiting BKV replication has been observed in renal allograft recipients [II] [6,27,28,43], repeat testing and quantification of BKV DNA load in plasma [27,46] or VP1 mRNA load in urine has been proposed [42]. For viral loads increasing above thresholds, that is, BKV load of >10,000 copies/mL of plasma or VP1 mRNA load of 1,000,000 copies/ng of total urine RNA, a specificity and sensitivity of ≥93% for biopsy-positive PVAN has been reported [II] [1,42,47]. Persisting BKV loads above the threshold equivalents for >3 weeks are highly suggestive of PVAN ("presumptive PVAN") (Table 26.2) [II] [1,46,48], but assay standardization is needed to validate center-specific thresholds [15].

To balance cost and screening efficiency, patients may be screened at least every 3 months during the first 2 years posttransplantation [A-II] and annually thereafter until the fifth year posttransplantation [B-III]. In addition, screening assays ought to be part of the work-up for the subpopulation of kidney transplant patients with allograft dysfunction [A-II] or undergoing allograft biopsy for surveillance [B-II]. Positive screening results ("possible PVAN") (Table 26.2) should be confirmed within 4 weeks [A-II]. For BKV replication above thresholds levels (presumptive PVAN) (Table 26.2), confirmation by allograft biopsy should be sought [A-II] and reduction of maintenance immunosuppression should be considered [B-II]. To monitor the course of BKV replication, quantitative polyomavirus testing in plasma and urine should be performed every 2–4 weeks [B-II], until a decrease below detection is observed [B-III].

Diagnosis of PVAN

PVAN is characterized by intranuclear polyomavirus inclusion bodies in tubular epithelial and/or glomerular parietal cells [I] [3,49,50]. The alterations seen by light microscopy are characteristic, but not pathognomonic, for PVAN and need to be distinguished from other etiologies, for example, cytomegalovirus or adenovirus inclusion, by confirmatory studies, such as immunohistochemistry or *in situ* hybridization to identify polyomavirus proteins like large T-antigen or VP-1, or viral nucleic acids, respectively [I]. Although immunohistochemistry may increase the sensitivity of PVAN diagnosis, discordance of PVAN detection in simultaneously obtained needle biopsy cores may be as high as 30%, pointing to a significant risk of false-negative diagnosis [II] [25]. BKV replication tends to affect nephrons focally with initially predominantly cytopathic changes (PVAN A) followed by more extensive spread with increasing inflammatory infiltrates (PVAN B) and eventually significant tubular atrophy and fibrosis (PVAN C) [II] [25,50]. Clinically, progression from PVAN A to PVAN B and C is associated with increasing rates of kidney transplant loss from 10 to 50% and >90%, respectively [25,46,51]. However, PVAN B and C are morphologically and molecularly difficult to distinguish from acute rejection and chronic allograft nephropathy, respectively [II] [10,54,55].

Thus, the definitive diagnosis of PVAN requires evaluation of a renal biopsy, with demonstration of polyomavirus cytopathic changes and confirmation with an ancillary technique such as immunohistochemistry ("definitive PVAN") (Table 26.2) [A-II]. PVAN histology should be semiquantitatively assessed as PVAN A, B, or C by taking into account the extent of viral cytopathic changes and the extent of inflammatory infiltrates, tubular atrophy, and fibrosis according to the Banff classification [B-II]. Negative biopsy results and signs of acute rejection are best interpreted in the light of BKV load testing in blood and urine [A-II]. In cases with significant BKV replication above threshold levels (presumptive PVA) (Table 26.2) and a negative initial biopsy, adjunct studies (e.g. immunohistochemistry) should be used and, if negative, a rebiopsy should be considered [B-III].

Treatment of PVAN

Antiviral drugs with proven clinical benefit are currently not available for treatment of polyomavirus infection. Nevertheless, control

of viral replication has been reported in case series [56] which used sole reduction of immunosuppression [2,4,27,41,51,57], combined treatment of reducing immunosuppression with the antiviral drug cidofovir [51,58–61], with intravenous immunoglobulin preparations (IVIG) [51,62], or with the immunosuppressive drug leflunomide [63,64]. Given the lack of controlled trials and the heterogeneity of intervention protocols, there is as yet no consensus on a "standard" approach to the treatment of PVAN (Table 26.3).

Reduction of immunosuppression

Immunological studies have suggested that reducing immunosuppression allows for recovery of BKV-specific immunity [17,20]. Reduction of calcineurin inhibitor levels or reduction or discontinuation of mycophenolate mofetil dosage prevented progression of persistent BKV viremia ("presumptive PVAN") to histologically proven "definitive PVAN" [II] [28,44]. Rescue of functional allografts could be obtained in more than 90% of prospectively diagnosed cases with definitive PVAN [II] [27,29,44,65], but glomerular filtration rates often remained permanently impaired [II] [4,14,29,51,52,53]. Analysis of plasma BKV load kinetics after reducing immunosuppression indicated a mean efficacy of 20% and suggested biweekly monitoring after a lag of 4–8 weeks until clearance from plasma could be expected over the next 7–13 weeks [II] [16]. Following the reduction of immunosuppression, biopsy-proven acute rejection was rarely observed, but some reported rates of 25% that remain steroid-responsive without recurrence of PVAN [III] [3,39].

The most frequently reported strategies for reducing the immunosuppressive load are as follows:
- Reduce calcineurin inhibitor trough levels. Tacrolimus C_0 trough level are targeted to <6 ng/mL. Cyclosporine C_0 levels are targeted to <125 µg/mL [B-II].
- Reduce antiproliferative agent by 50% of standard dose. Mycophenolate mofetil is then reduced to ≤1 g/day in adult patients or ≤600 mg/m^2/day in pediatric patients. Azathioprine is reduced to <75 mg/day in adult patients or <40 mg/m^2/day in pediatric patients [B-II].
- Switching from mycophenolate mofetil to leflunomide (levels >40 µg/mL) has been advocated because inhibitory activity of leflunomide on BKV replication has been reported in vitro, although with a low selectivity index [66], but a direct comparison with sole immunosuppression reduction has not been reported [B-III].
- Discontinuing components of triple-drug therapies (mostly mycophenolate mofetil) [B-II] [28,44].
- Discontinuing the antiproliferative immunosuppressant and switching from tacrolimus or cyclosporine to sirolimus [B-III] [67].

If allograft dysfunction is present and persists and/or plasma BKV loads fail to show a decrease of >2 log$_{10}$ over 8–12 weeks, reassessment should be considered, including by allograft biopsy [B-III]. If PVAN persists and acute rejection is ruled out, discontinuing individual components of the maintenance immunosuppression regimen should be considered as a next step [B-III].

Antiviral approaches

Formally, the use of cidofovir is contraindicated in patients with impaired kidney function. However, because cidofovir is selectively concentrated in tubular epithelial cells and urine, off-label use has been proposed at 10- to 20-fold-lower doses than employed to treat cytomegalovirus replication, namely, at (0.25–1 mg/kg every 2 weeks, without concomitant probenecid administration). The success of cidofovir therapy is variable and, as in the case of leflunomide, no data are available to distinguish any antiviral effect from concomitant reduction of immunosuppression. Table 26.3 summarizes reports with ≥4 patients. Thus, off-label use has been proposed for PVAN cases refractory to reduction of immunosuppression [B-III].

Commercially available preparations of IVIG have also been used in PVAN treatment protocols (Table 26.3) [51,62]. However, because the presence of neutralizing antibodies at best reduced, but did not prevent, BKV viremia and PVAN [II] [20,27,68], it is unlikely that IVIG preparations alone provide efficient anti-BKV activity. In the absence of controlled studies, it is at present difficult to dissect the respective role of the different interventions on the outcome of PVAN.

BKV screening and early intervention

Advances in the development of diagnostic tools and a better understanding of PVAN have led to treatment at early stages, before significant renal function deterioration, and this has resulted in improved outcomes (Table 26.4) [25,27,29]. Thus, identification of patients at a "preclinical" stage is paramount for the successful treatment of the disease. Recent data have shown that progression to PVAN can be safely prevented if BKV viremia is used to guide therapeutic intervention [28,44]. In two prospective studies, patients with "presumptive PVAN" cleared BKV viremia upon stopping mycophenolate mofetil or azathioprine, or reducing calcineurin inhibitor levels, without adversely affecting allograft function [28,44]. Hence, in patients with persisting polyomavirus replication (BKV viremia) above thresholds ("presumptive" PVAN) and negative allograft biopsy results, preemptive reduction of immunosuppression should be considered [B-II].

Retransplantation after renal allograft loss due to PVAN

Retransplantation after allograft loss to PVAN has been reported in 17 cases [69,70], with recurrence of BKV viremia in 3 patients (17%). "Definitive" PVAN was diagnosed in two cases (12%), one of which cleared BKV replication but with impaired graft function (6%), whereas recurrent graft loss was observed in the other case (6%). However, the incidence of PVAN after retransplantation cannot be derived from these limited data and may be higher than that seen in primary transplants. In 13 cases (76%), the first allograft had been removed, including in the three cases with PVAN recurrence. Prior to retransplantation, recovery of BKV-specific immunity is viewed as the most critical factor [69,71] and may require a period of 3–12 months of reduced or no immunosuppression.

Table 26.3 Treatment of PVAN with antiviral agents.

Agent and [reference(s)]	No. of cases	Protocol	Notes	Outcome
Cidofovir				
[2]	41	1.5 mg/kg/wk for 1.5–3 mos 0.25–0.33 mg/kg biweekly	• Lower dosage in a pediatric patient • Associated treatment: ↓ CI and MMF • All patients had advanced PVAN	• 2 graft losses • 2 major functional declines • The pediatric patient stabilized renal function and ↓ viral load
[58]	4	0.25–1 mg/kg bi- or triweekly for 1–4 doses	• Associated treatment: ↓ Tac in 3 pts and IVIG in 1 • All patients had advanced PVAN	• All patients have stable graft function at 6–26 mos posttherapy • Clearance of BK viruria in all but recurrence in 2
[59]	8	0.5–1 mg/kg/wk for 4–10 doses	• Associated treatment: ↓ Tac or switch Tac→CyA; discontinuation or ↓ MMF • Control group treated with ↓ IS alone	• No graft losses vs. 70% graft loss in control group at a median of 24-mo follow-up • No significant effect on BK viruria or viremia
[72]	4	0.25 mg/kg/week for 1 dose	• Associated treatment: ↓ CyA or switch Tac→CyA; discontinuation or ↓ MMF • Control group treated with ↓ IS alone	• No improvement of renal function at a median 35-mo follow-up • Clearance of BK viruria and viremia
[73]	21	0.25–1 mg/kg for ≥3 doses	• Associated treatment: ↓ IS + leflunomide	• 2 graft losses • 9 functional decline • 10 stable graft function
[51]	30	0.25 mg/kg biweekly for 4 doses; if no response, 0.5 mg/kg biweekly for 4–5 doses	• Associated treatment: ↓ Tac or switch Tac→CyA + ↓ MMF in 20 patients; ↓ IS + IVIG in 10 patients • Case–control study	• 50% any renal function decline at a median of 20-mo follow-up • No single intervention (cidofovir, IVIg, and CyA conversion) associated with improved outcome
IVIG			•	•
[51]	12	1.25 g/kg for 2 doses	• Associated treatment: ↓ Tac or switch Tac→CyA + ↓ MMF; + cidofovir in 10 patients • Case–control study	• 35% any renal function decline at median of 20-mo follow-up • No significant association with improved outcome
[62]	8	Total dose of 2 g/kg in 2–5 divided doses	• Associated treatment: ↓ IS	• 1 graft loss • 7 stabilization of graft function
Leflunomide			•	•
[63, 64]	26	Starting dose of 100 mg for 5 days; maintenance with 40 mg adjusted to blood levels of 50–100 μg/mL	• Associated treatment: discontinuation of MMF and ↓Tac; + cidofovir in 9 patients	• 4 graft losses • 22 stabilization or improvement of graft functions • 11 patients cleared BK viremia and 8/11 also cleared viruria
[73]	21	Starting dose of 100 mg for 3 days; maintenance with 20 mg; if no response, 40 mg	• Associated treatment: ↓ IS + cidofovir	• 2 graft losses • 9 functional declines • 10 stable graft functions

Abbreviations: CI, calcineurin inhibitors; MMF, mycophenolate mofetil; Tac: tacrolimus; CyA, cyclosporine A; IS, immunosuppression.

Table 26.4 Screening for BKV allows early diagnosis and improves outcome.

Study [reference]	Screening modality	No. of patients with PVAN	S-Crea conc (mg/dL) at diagnosis[a] [controls]	PVAN intervention	Clearance of viremia	S-Crea conc (mg/dL) at follow-up [controls]
Hirsch et al. 2002 [27]	• Screening: decoy cells • Confirm: plasma BKV load • Biopsy, if S-crea >20% or BKV load >10^4 copies/ml	5	2.34 ± 0.96 (1.6–4.0) [NA]	Tailored ↓ IS • ↓Tac or CyA • Switch to Sir • Switch MMF to AZA	5/5	1.72 ± 0.41 (1.4–2.4) [all patients 1.6, 0.8–4.2] No graft loss
Buehrig et al. 2003 [65]	• Routine surveillance biopsy	8	1.7 (1.3–2.5) [3.1; 1.5–5.3]	• ↓Tac or switch to CyA • ↓or taper MMF	NA	1.5 (1.1–2.3) [4.2; 1.7–7.0] No graft loss
Drachenberg et al. 2004 [43]	• Screening: decoy cells • Confirm: plasma BKV load • Biopsy, if S-crea >20% or BKV load >10^4 copies/mL	14	1.5 (1.0–2.2) [2.8; 1.2–5.1]	• ↓Tac or CyA • Stop or ↓ 50% MMF	11/14	2.0 (1.0–4.6) [5.1; 1.5–12.1] No graft loss
Brennan et al. 2005 [28]	• Screening: decoy cells • Confirm: plasma BKV load • Preemptive treatment if plasma BKV load >3 weeks	*23	NA (S-crea at baseline)	• Stop MMF or AZA • ↓Tac or CyA	22/23	1.5 ± 0.42 [1.4 ±0.5]; $P = 0.21$ No PVAN No graft loss
Ginevri et al. 2005 [44]	• Screening with urine BKV DNA • Adjunctive test: Q-DNA blood • Preemptive treatment if plasma BKV load >3 weeks	*5	1.1 (0.7–1.6) [NA]	Protocol defined ↓ IS: • ↓ Tac or CyA • ↓ or stop MMF or AZA	5/5	1.0 (0.8–1.3) No PVAN No graft loss

Abbreviations: S-crea, serum creatinine; NA, not available; IS, immunosuppression; Tac, tacrolimus; CyA, cyclosporine A; Sir, sirolimus; MMF: mycophenolate mofetil; AZA, azathioprine.

[a] Mean serum creatinine concentration (range in parentheses); control values are shown in brackets. Controls were represented by PVAN cohorts identified by biopsy performed after deterioration of renal function rather than surveillance biopsy.

As BKV-specific immunity is not yet available in the clinical routine, a >2-$\log_{10}$ reduction of plasma BKV loads may serve as a surrogate marker [III] [18]. In eight patients (47%), the same immunosuppressive drugs and combinations were used as for the primary graft. In nine patients, tacrolimus, mycophenolate mofetil, and prednisone were used; this group included both cases with "definitive" PVAN.

The success of >80% in this case series indicates that retransplantation remains an option for patients with allograft loss due to PVAN [B-II]. Surgical removal is not a prerequisite for successful retransplantation [D-II]. However, nephrectomy may be appropriate in patients with persisting BKV viremia at the time of retransplantation in order to reduce the risk of superinfection and to better attribute changes in renal function and BKV loads posttransplant to the new allograft [B-III] [69,70]. The same immunosuppressive drugs and combinations may be used [B-III], but intense immunosuppression and allograft injury resulting from toxicity or acute rejection should be avoided [B-III]. No recommendation on the use of induction treatment can be made, but nondepleting anti-interleukin-2 receptor agents may be appropriate [C-III]. Following retransplantation, screening for polyomavirus replication and intervention should be performed, as recommended for patients with a first renal allograft [B-III] [1,69].

Perspective

PVAN still represents a formidable challenge, but as can be gathered from the numerous abstracts presented at the most recent international conferences, high-quality studies are underway and exciting new insights can be expected in the next 12 months in this rapidly moving field.

Toxic Nephropathies

27 Toxic Nephropathies: Nonsteroidal Anti-Inflammatory Drugs

Wai Y. Tse[1] & Dwomoa Adu[2]

[1]Department of Nephrology, Derriford Hospital, Plymouth PL6 8DH, UK.

Introduction

Nonsteroidal anti-inflammatory drugs (NSAIDs) are one of the most commonly prescribed groups of drugs for the treatment of pain and inflammation. It is estimated that, worldwide, more than 30 million people take NSAIDs daily [1]. The widespread use of NSAIDs means that renal complications are likely to be seen frequently. These include salt and water retention, acute tubular necrosis, acute interstitial nephritis, hyperkalemia, and acute and chronic kidney failure [2–6].

In addition to renal side effects, NSAID use risks also include significant gastrointestinal complications and cardiac events, such as myocardial infarction and acute coronary syndromes. Nonselective NSAIDs inhibit both constitutive cyclooxygenase 1 (COX-1) and inducible COX-2, the rate-limiting enzymes that are involved in production of prostaglandins and thromboxane A_2. It was hoped that COX-2-selective NSAIDs would have anti-inflammatory activity but lack the deleterious effects on homeostatic functions mediated by COX-1 activation. Three highly selective COX-2 NSAIDs were originally approved by the US Food and Drug Administration, namely, celecoxib, rofecoxib, and valdecoxib. However, increased myocardial infarction and ischemic strokes seen with rofecoxib [7] and increased cardiovascular events in patients who underwent coronary artery bypass surgery and received valdecoxib [8] led to the withdrawal of these two COX-2 inhibitors in 2004 and 2005, respectively. Low-dose aspirin irreversibly inhibits platelet COX-1, thereby blocking the synthesis of thromboxane A_2, a prothrombotic factor, and has little effect on endothelial COX-2-derived prostacyclin. Prostacyclin inhibits platelet aggregation and leads to vasodilatation. Due to its selectivity, low-dose aspirin is the drug of choice for the prevention of thrombotic events, even for those patients with underlying kidney disease, without the risk of jeopardizing prostaglandin-dependent kidney function. By con-

trast, higher doses of aspirin can inhibit COX-2-derived prostacyclin production. Prostacyclin is mainly COX-2 derived and is inhibited by both nonselective NSAIDs as well as COX-2-selective NSAIDs. Therefore, a potential cardiovascular risk is seen with nonselective NSAIDs as well as COX-2-selective drugs [9–11].

Cyclooxygenases in the kidney

The enzyme phospholipase A_2 converts phospholipids into arachidonic acid, which is the substrate for three different enzymes: COX, which is inhibited by NSAIDs, cytochrome P450 monooxygenase, and lipoxygenase (Figure 27.1). Phospholipase A_2 is activated by kinins, vasopressin, angiotensin II, and extracellular hyperosmolarity and increases prostaglandin synthesis through the three pathways [12]. Each pathway influences some aspects of renal hemodynamics or tubular function. Two isoforms of COX (COX-1 and COX-2) have been identified in mammalian cells [13,14]. COX-1, which is constitutively expressed, mediates gastric cytoprotection and vascular homeostasis [15]. COX-2 expression is regulated by salt and water intake, medullary tonicity, growth factors, cytokines, and adrenal steroids [16] and produces prostaglandins in inflamed tissues [15]. COX-2-dependent prostaglandin formation is also necessary for normal kidney development [17]. In mice, the complete absence of COX-2 resulted in severe renal dysplasia characterized by a postnatal arrest of maturation in the subcapsular nephrogenic zone and progressive deterioration with increasing age [18]. Antenatal exposure of both mice and rats to an inhibitor of COX-2, but not of COX-1, had similar effects [19].

Constitutive COX-2 mRNA as well as inducible COX-2 mRNA are present in the kidney [20]. In the human kidney, COX-2 is present in podocytes, endothelium, proximal convoluted tubule and collecting duct, renal vasculature, the macula densa, and the medullary interstitial cells [21], whereas COX-1 is found in the vasculature, the collecting ducts, glomeruli, and medullary interstitial cells [22].

PGE_2 PGD_2 $PGF_{2\alpha}$
Figure 27.1 Pathway of arachidonic acid metabolism. The lipoxygenase pathway results in the production of leukotrienes; the role of these compounds in the kidney is unclear. The cyclo-oxygenase pathways leads to the production of the unstable cyclic endoperoxidase PGG2. Subsequent enzymatic conversion results in the production of the classical 2-series prostaglandins PGI_2, PGE_2, PGD_2, $PGF_{2\alpha}$, and thromboxane A_2.

Actions of renal prostaglandins

The kidney produces the vasodilator prostaglandins PGE_2, $PGF_{2\alpha}$, and PGI_2 and the vasoconstrictor thromboxane A_2. These autocoids, synthesized and metabolized by the kidney, autoregulate renal blood flow, renin release, tubular ion transport, and water metabolism [23–26] . PGI_2, which is mainly present in the afferent arteriole and glomerulus, plays a major role in controlling glomerular hemodynamics [27]. In contrast, PGE_2, which is predominantly produced in the collecting tubule and within the interstitium, regulates medullary hemodynamics [26].

Effects on COX-2 NSAIDs on renal prostaglandins

The urinary excretion of PGE_2 and 6-keto-$PGF1_a$, the stable metabolite of PGI_2, reflects renal synthesis of PGE_2 and PGI_2, respectively. In healthy older adults, rofecoxib reduces baseline urinary 6-keto-$PGF_{1\alpha}$ by 47%, and this was comparable to the 53% reduction induced by indomethacin [28]. In another study, rofecoxib reduced urinary PGE_2 and 6-keto-$PGF1_\alpha$ excretion in healthy volunteers by approximately 40–50%, similar to that induced by meloxicam or diclofenac [29]. Furthermore, excretion of urinary 6-keto-$PGF_{1\alpha}$ was comparable in response to celecoxib and traditional NSAIDs [30]. In a trial of healthy elderly volunteers on a normal sodium intake, multiple doses of twice-daily celecoxib reduced PGE_2 and 6-keto-$PGF1_\alpha$ excretion to the same degree as naproxen, by approximately 65 and 80%, respectively [31]. These data suggest that the COX-2 isoform plays an important role in renal prostaglandin biosynthesis. It is thus likely that COX-2 inhibitors will impact renal function just as nonselective NSAIDs do.

Maintenance of renal blood flow and glomerular filtration rate

Prostaglandins maintain renal blood flow and the glomerular filtration rate despite vasoconstrictor stimuli, such as leukotrienes, thromboxane A_2, angiotensin II, vasopressin, endothelin, and catecholamines. Catecholamines also stimulate the local production of prostaglandins, resulting in a feedback loop between vasoconstrictors and vasodilatory prostaglandins [32–34]. $PGF_{2\alpha}$-like peroxidation products also have major vasoconstrictive effects [35]. Thus, in patients with underlying ischemic or inflammatory renal injury, the addition of a nonselective or COX-2-selective NSAID not only decreases the production of vasodilatory prostaglandins but also results in the nonenzymatic formation of vasoconstrictor metabolites of arachidonic acid, which further jeopardizes renal blood flow and glomerular filtration. Under normal, euvolemic conditions, NSAIDs produce negligible effects on renal hemodynamics [36,37]. However, in the presence of salt depletion, an ineffective circulating plasma volume, or under conditions characterized by high circulating levels of vasoconstrictor hormones, NSAIDs may be nephrotoxic. Such conditions include cirrhosis, hypovolemia, cardiac disease, renal disease, septic shock, advanced age, diuretic use, diabetes mellitus, and following surgery [38].

In elderly, salt-replete subjects, both indomethacin and rofecoxib decreased sodium excretion, but only indomethacin reduced the glomerular filtration rate [28]. Celecoxib, like rofecoxib, affects renal function in selected groups of subjects. Whelton *et al.* in 2000 compared celecoxib with naproxen in 29 healthy elderly subjects in a single blind, randomized, crossover study [39]. Subjects were given either celecoxib at 200 mg twice daily for 5 days followed by celecoxib at 400 mg twice daily for the next 5 days or they received naproxen at 500 mg twice daily for 10 days. After a 7-day washout, subjects were crossed over to the other regimen. Glomerular filtration rate fell more with naproxen than with celecoxib, although urinary excretion of prostaglandin E_2, 6-keto-$PGF1_\alpha$, and sodium was comparable. In another study involving salt-depleted elderly subjects rofecoxib and indomethacin induced a comparable reduction of glomerular filtration rate [40]. These studies illustrate that COX-2 inhibitors and nonselective NSAIDs have similar effects on renal hemodynamics.

Postoperative use of NSAIDs

A meta-analysis of 19 trials showed that the postoperative use of NSAIDs in adults with normal preoperative renal function resulted in a 16-mL/min fall in creatinine clearance (95% confidence interval [CI], 5–28) and potassium excretion by 38 mmol/day (95% CI, 19–56) on the first day after surgery compared with placebo [41]. No cases of postoperative acute kidney failure requiring dialysis were seen. The conclusions were that NSAIDs caused a clinically unimportant reduction in kidney function in the early postoperative period in patients with normal kidney function and that these drugs should not be withheld in such patients. Others have reported, however, an overall incidence of postoperative renal insufficiency of 18% after major surgery, with a subsequent hospital mortality rate of 13% [42].

Renal dysfunction in COX-2 trials

In one study, renal adverse events were reported in 24.3% of 144 patients receiving celecoxib and in 30.8% of 143 patients receiving diclofenac and omeprazole. Kidney failure (defined as a rise in serum creatinine to above 200 μmol/L) was seen in 5.6 and 6.3% of patients, respectively [43]. Overall, renal adverse events were more common in patients with renal impairment (celecoxib, 51.4%; diclofenac plus omeprazole, 40.7%). In another study, adverse effects related to kidney function occurred in about 1% of naproxen- and rofecoxib-treated patients [44]. In a review of randomized clinical trials lasting 2 weeks or more involving celecoxib, a rise in serum creatinine was seen in 0.7% of patients treated with celecoxib and in 1.2% of patients treated with diclofenac ($P < 0.05$) [45]. In a meta-analysis of data from company clinical trial reports, there was no difference in the incidence of renal adverse events (defined as an increase in serum creatinine >1.3 times the upper limit of normal) in 15,319 patients treated with celecoxib (0.3%) or other NSAIDs (0.5%) (relative risk [RR], 0.78; 95% CI, 0.48–1.3) [46].

In summary, from these trials there are no differences in renal side effects between COX-2-selective inhibitors and nonselective inhibitors.

Renin release and potassium homeostasis

PGE_2, PGI_2, and arachidonic acid are potent stimuli of renin release [23]. Both nonselective and COX-2-selective NSAIDs can inhibit renin secretion and under some circumstances lead to hyporeninemia and hypoaldosteronism with attendant hyperkalemia. This is particularly common in patients with preexisting renal impairment [47–49]. Inhibition of prostaglandin synthesis can also lead to hyperkalemia by decreasing distal tubular flow rate and sodium delivery, both of which limit potassium secretion [50,51].

Natriuresis and diuresis

Renal prostaglandins are natriuretic and diuretic. They inhibit sodium and chloride reabsorption in the proximal and distal nephrons and in the loop of Henle [52,53], reduce the renal cortico-medullary solute gradient, and antagonize the action of vasopressin *in vivo* [54]. Although prostaglandins acutely influence salt and water excretion, they do not regulate it under normal conditions.

Clinical syndromes associated with nonselective and COX-2-selective NSAIDs

Acute renal impairment and acute tubular necrosis

Under circumstances where there is poor renal perfusion with high renin levels, nonselective and COX-2-selective NSAIDs can reduce glomerular filtration rate, resulting in acute kidney failure. This complication has been reported with most NSAIDs but only rarely with aspirin. Kidney failure has also been described after administration of topical and intramuscular NSAIDs [55–57].

A multicenter study in France examined the incidence and subsequent outcome of patients with drug-induced acute kidney failure [58]. Of the 398 patients with acute kidney failure, 147 (36.9%) had taken NSAIDs. One-third of them required dialysis, and 71.4% recovered or regained previous renal function. A renal biopsy obtained in 25 patients with NSAID-associated kidney failure disclosed acute tubular necrosis and acute interstitial nephritis in 21 patients and either minimal change nephropathy or chronic renal damage in 4. A nested case–control study using the United Kingdom General Practice Research Database reported that current users had an RR of developing acute kidney failure of 3.2 (95% CI, 1.8–5.8) compared with non-NSAID users [59]. This increased risk was higher in patients with heart failure, hypertension, or diabetes. Thus, although renal side effects from NSAID use are relatively rare, renal damage can be irreversible and the outcome can be fatal. Renal function usually improves upon drug withdrawal, although in some cases permanent renal damage may occur [60].

Acute kidney failure and hyperkalemia have been observed after the administration of COX-2-selective inhibitors to patients with risk factors for NSAID-induced acute renal insufficiency, including underlying chronic renal impairment and volume depletion [61]. Acute kidney failure was also reported in a patient with a kidney transplant 4 weeks after starting rofecoxib [62].

Acute tubulo-interstitial nephritis

NSAIDs of different classes have been associated with acute tubulo-interstitial nephritis and kidney failure [2,60,63,64]. Acute allergic tubulo-interstitial nephritis due to NSAIDs is much less common than hemodynamic kidney failure. The patients are often elderly, and the drug may have been taken for months or years before the development of acute interstitial nephritis. Clinical evidence of an allergic reaction, such as fever, rash, arthralgia, eosinophilia, or eosinophiluria, is uncommon. Of note, proteinuria, often in the nephrotic range, may occasionally appear, especially in fenoprofen-induced tubulo-interstitial nephritis [63,65,66]. Cases of interstitial nephritis have been reported with both celecoxib and rofecoxib [67–73]. In two cases, interstitial nephritis was associated with glomerulopathies, one case with minimal change disease [71] and the other one with membranous nephropathy [67]. Thus, there is little evidence that suggests a major difference between NSAIDs and COX-2 inhibitors in the incidence of acute interstitial nephritis.

NSAID-induced acute tubulo-interstitial nephritis is formally diagnosed by renal biopsy. A patchy acute tubular damage coexists with tubulo-interstitial infiltrate predominantly of T lymphocytes and, to a lesser extent, monocytes/macrophages, B lymphocytes, plasma cells, and eosinophils [66,74]. Rarely, a granulomatous interstitial nephritis is seen [75]. Immunofluorescence microscopy is usually negative or nonspecific. The predominance of T lymphocytes in the interstitial infiltrate has been taken to indicate that T-lymphocyte activation mediates this syndrome, rather than a humoral mechanism, as in other forms of drug-induced acute interstitial nephritis [65,66]. Inhibition of renal COX has also

been incriminated in the genesis of NSAID-induced acute tubulo-interstitial nephritis. The resulting stimulation of the lipoxygenase pathway of arachidonic acid metabolism produces leukotrienes, which are potent chemotactic factors for lymphocytes. Recovery of renal function may be only partial [74], and chronic interstitial fibrosis may progress to chronic renal failure [76]. Prednisolone has been successfully used in anecdotal reports, but there is no conclusive evidence that corticosteroids hasten the resolution of the renal lesion [2].

Glomerulonephritis

Membranous nephropathy with nephrotic syndrome may occur as an idiosyncratic reaction to various classes of NSAIDs [77–79]. The temporal association with the intake of NSAIDs, the prompt and complete recovery after drug discontinuation, and the absence of recurrent disease may help distinguish NSAID-associated membranous nephropathy from the idiopathic form [80]. As with NSAIDs, glomerulopathies with the nephrotic syndrome can occur with COX-2 inhibitors [72]. Membranous nephropathy with acute interstitial nephritis secondary to celecoxib has been described [67].

Renal papillary necrosis

Renal papillary necrosis has been infrequently reported in patients treated with ibuprofen, indomethacin, phenylbutazone, fenoprofen, or mefenamic acid [60,76,81–83] or with paracetamol [84,85]. One case of celecoxib-related renal papillary necrosis has been reported [86].

Chronic kidney failure

Sandler *et al.* in 1991 evaluated the risk for chronic kidney disease associated with regular use of non-aspirin NSAIDs in 554 patients with newly diagnosed chronic renal dysfunction [5]. They found a twofold-increased risk for chronic kidney disease in patients with a history of previous daily use of NSAIDs (adjusted odds ratio, 2.1; 95% CI, 1.1–4.1). The increased risk was predominantly limited to men older than 65 years, for whom the odds ratio was 10.0 (95% CI, 1.2–82.7) after adjusting for use of other analgesics. The NSAID-associated risk was also greater among those with a history of conditions that might indicate an enhanced susceptibility to the effects of NSAIDs, including previous myocardial infarction, congestive heart failure, heavy alcohol consumption (as a surrogate for cirrhosis), or diuretic use. These observations were confirmed in a recent case–control study of 716 patients with end-stage renal failure and 361 controls [6]. In this study a high cumulative intake of NSAIDs (>5000 tablets) was associated with a 4.5-fold excess risk of end-stage renal failure, although the CI was wide (1.0–19.5) and, curiously, this excess risk was not seen when an average annual intake of NSAIDs was examined. Other studies of NSAID usage in hospitalized patients [87,88] and also cohort studies, however, did not show this association [89,90]. The reasons for these discrepant findings are unclear. On balance, it seems likely that chronic usage of NSAIDs may be associated with a slightly increased risk for the development of chronic kidney failure.

Some patients with chronic kidney failure rely on prostaglandin-mediated vasodilatation to maintain renal blood flow [91–93]. Addition of NSAIDs may cause further deterioration of renal function [48,91,93,94].

Salt and water retention

NSAID therapy may aggravate the sodium retention induced by renal hypoperfusion in heart failure, cirrhosis, or nephrotic syndrome [3]. Hyponatremia may occur if water retention is disproportionate to sodium retention [95], especially when thiazide diuretics are given simultaneously [2].

Hypertension

Two large meta-analyses encompassing more than 90 studies have demonstrated that NSAIDs may increase blood pressure, especially in previously hypertensive patients [96,97]. NSAIDs elevate supine mean blood pressure by 5 mmHg [97], a rise known to increase hypertension-related morbidity and mortality [98]. This complication is of importance in the elderly, who are frequently prescribed NSAIDs for musculoskeletal disorders and also have a high prevalence of other chronic disorders, including hypertension.

Whelton *et al.* performed a post hoc analysis on the renal safety of celecoxib, incorporating more than 50 clinical studies with more than 13,000 subjects [31]. The most common events, peripheral edema (2.1%), hypertension (0.8%), and exacerbation of preexisting hypertension (0.6%), were not dose or time related. Their incidence and profile were similar to those of nonselective NSAIDs. A similar post hoc analysis of rofecoxib revealed peripheral edema in 3.8% of the patients [99].

Whelton *et al.* also compared the effects of celecoxib at 200 mg and rofecoxib at 25 mg over a 6-week period in 810 hypertensive patients with osteoarthritis, aged over 65 years [100]. Edema developed in nearly twice as many rofecoxib-treated than celecoxib-treated patients (9.5% vs. 4.9%; $P = 0.014$). Systolic blood pressure increased significantly in 17% of rofecoxib-treated patients, compared with 11% of celecoxib-treated patients ($P = 0.032$). In conclusion, celecoxib induces edema less frequently and results in smaller rises in blood pressure than rofecoxib. A meta-analysis of COX-2 inhibitors and their effects on blood pressure showed that they were associated with a nonsignificant higher risk of causing hypertension compared with placebo (RR, 1.61; 95% CI, 0.91–2.84) or nonselective NSAIDs (RR, 1.25; 95% CI, 0.87–1.78) [101]. Thus, both NSAIDs and COX-2 inhibitors can raise blood pressure, especially in hypertensive, elderly patients, and there is no substantial evidence to suggest that COX-2 inhibitors are safer in this respect.

Hyperkalemia and hyporeninemic hypoaldosteronism

NSAIDs may cause hyperkalemia, and this is seen more commonly in patients with chronic kidney failure, diabetes mellitus, and type IV tubular acidosis through previously outlined mechanisms [48,102,103]. Increases in potassium levels are also expected to occur with COX-2 inhibitors. Indeed, rofecoxib raises serum

potassium levels by more than 0.8 mM, with a similar incidence as NSAIDs [104]. NSAIDs must be used with caution in patients taking other drugs known to decrease renal potassium excretion, such as potassium-sparing diuretics, angiotensin converting enzyme inhibitors, and β-blockers.

Therapeutic use of NSAIDs in nephrotic syndrome

NSAIDs reduce proteinuria in patients with nephrotic syndrome [105,106], probably by reducing renal blood flow and glomerular filtration rate [107]. The occurrence of irreversible kidney failure in patients with a nephrotic syndrome treated with NSAIDs [58] suggests great caution for the use of these drugs in this clinical setting.

Conclusions

The increasing use of NSAIDs both by prescription and from over-the-counter sales has increased the prevalence of nephrotoxicity. A history of NSAID use should be sought in all patients with unexplained impairment of renal function and/or proteinuria. In patients with volume depletion or decreased organ perfusion, the use of NSAIDs should be avoided. NSAIDs should not be prescribed in patients with chronic renal impairment or with a functioning kidney transplant. Patients with an NSAID-induced, interstitial nephritis or papillary necrosis should not be given NSAIDs again. In some individuals who have developed NSAID-induced acute kidney failure and who have recovered kidney function, NSAIDs may be reintroduced if clinically necessary, provided that the risk factors for enhanced susceptibility have been corrected and that renal function is closely monitored. COX-2-selective inhibitor use requires the same cautions as with traditional NSAIDs.

28 Toxic Nephropathies: Environmental Agents and Metals

Richard P. Wedeen

Department of Veterans Affairs New Jersey Health Care System, 385 Tremont Avenue, East Orange, New Jersey, USA; University of Medicine and Dentistry of New Jersey, The New Jersey Medical School, 185 South Orange Avenue, Newark, New Jersey, USA

Introduction

Environmental nephrotoxins include materials found in the workplace and pharmaceutical agents used for the diagnosis and treatment of disease (Table 28.1). In this chapter, I will not review the long list of drugs for which renal damage is a side effect. Non-pharmaceutical toxins recognized as producing kidney disease are those substances that cause occupational kidney diseases. Kidney diseases resulting from high-dose occupational exposure in a few workers serve as models for understanding kidney disease among whole populations exposed to low doses of toxins. The clinically important industrial nephrotoxins include lead, mercury, cadmium, silica, and a variety of (sometimes poorly defined) organic hydrocarbons (aliphatic, aromatic, and halogenated). Uranium, chromium, and arsenic rarely produce kidney disease and will not be discussed further.

It should be recognized that there are no randomized controlled trials for the treatment of kidney diseases caused by these environmental agents. The cornerstone of treatment is prevention and the termination of exposure.

Heavy metals

Lead

Severe acute lead poisoning occurring over days or weeks was common among poor urban children in the USA in the early part of the 20th century. Blood lead levels exceeded 70 μg/dL (current mean blood lead in the USA is <2 μg/dL). Acute childhood lead poisoning usually occurred because of the ingestion of lead-based paint in deteriorated housing (pica). Renal symptoms of acute lead poisoning, called the Fanconi syndrome, consist of transient proximal tubular reabsorptive defects manifested by aminoaciduria, phosphaturia, and glycosuria. The Fanconi

syndrome is regularly reproducible in experimental animals exposed to sufficiently high doses of lead and is reversed by chelation therapy or removal from exposure [1].

Acute symptomatic lead poisoning with encephalopathy, abdominal colic, peripheral motor neuropathy, and anemia is distinctly uncommon today. Far more common is chronic lead poisoning, which is either asymptomatic or accompanied by non-specific complaints. Long-term, low-dose exposure in adults is also associated with hypertension, gout, and tubulo-interstitial nephritis that is histologically indistinguishable from hypertensive nephrosclerosis. In the past, lead nephropathy was identified in lead workers after many years of exposure to lead dust in the industry. Blood lead in these workers was often above 40 μg/dL on the job, which is the exposure limit promulgated in the federal occupational lead standard. It was widely assumed that blood lead levels of 60 μg/dL or higher, sustained for many years, were required to induce lead nephropathy. However, recent epidemiologic evidence using blood and bone lead measurements (by noninvasive *in vivo* K X-ray fluorescence) indicate that the adverse effects of lead on blood pressure and kidney function occur at much lower levels than previously recognized. Ninety-five percent of the body stores of lead are retained in bone, with a biological half-life approximating 2 decades, whereas blood lead has a biological half-life of about 30 days. Bone lead therefore reflects cumulative lead absorption, whereas blood lead primarily reflects recent exposure.

Blood lead and bone lead predict blood pressure even when both are within the range traditionally considered "normal." Epidemiologic evidence that low-level lead absorption (blood lead of <10 μg/dL) has deleterious effects on blood pressure and renal function was obtained from National Health and Nutrition Evaluation Survey III, 1988–1994. Analysis of data on over 15,000 Americans showed that hypertensive people had significantly higher blood lead levels (4.21 vs. 3.30 μg/dL) than people without hypertension [2]. Two large, cross-sectional studies also reported a significant association between low-level lead exposure and serum creatinine [3,4]. The adverse effects of low-level lead exposure on renal function are further supported by longitudinal observations [5]. Because lead does not accumulate in patients with kidney

Table 28.1 Environmental nephrotoxins.

Substance	Pathology			Comments
	ATN	**TIN**	**G**	
Metals				
Pb	+	+	−	Fanconi syndrome, tubular proteinuria, hypertension, gout
Cd	−	+	−	Fanconi syndrome, Ca^{++} wasting, tubular proteinuria
Hg[1]	+	+	+	G → immune, genetic control, nephrotic syndrome; $HgCl_2$ → ATN
As	+	+	−	AsH_3, hemolysis
Cr[1]	+	+	−	Cr^{+++} → tubular proteinuria, nasal perforation, cancer; Cr^{+++++} → ATN
U	+	+	−	tubular proteinuria
Si	−	−	+	immune adjuvant, immune complexes, ANCA, Wegener's granulomatosis
Organics				
CCl^4	+	+	−	liver damage, alcohol enhanced, dry cleaner
Toluene	−	−	−	tubular proteinuria, glue sniffing
Solvents	−	−	+	immune G, tubular proteinuria
Selected Drugs[2]				
Aminoglycosides	+	+	−	ARF after 8 days, lysosomal accumulation S_1 and S_2
Amphotericin B	−	+	−	distal RTA, $K^+\downarrow$, $Mg^{++}\downarrow$, Uosm ↓, tubular calcification
Penicillins	−	+	−	allergic component, acute, after 15 days, interstitial edema, lymphocytic infiltration
Vancomycin	+	+	−	ARF
Sulfonamides	−	+	−	intra-luminal crystals, kidney stones, ARF, microhematuria, soluble in alkaline urine
Acyclovir	−	+	−	intraluminal crystal deposition, flank pain, microhematuria
Cyclosporin A Tacrolimus	+	+	−	ARF, vasomotor, proximal tubule vacuolization, striped fibrosis, arteriolar hyalinosis
Gold salts	−	+	+	membranous glomerulopthy, gold in tubular epithelium, separate tubular disease
D-penicillamine	−	−	−	membranous glomerulopthy, vasculitis
Cis-platinum	+	+	−	ARF, usually reversible
Mitomycin	−	+	−	thrombosis, hemolytic uremic syndrome

1. Depends on valance and organic form.

2. Often in clinically complex settings with multicausal renal damage.

Abbreviations: ATN, acute tubular necrosis; TIN, tubular interstitial nephritis; G, glomerulopathy; ARF, acute renal failure; RTA, renal tubular acidosis.

failure of nonlead etiology, these observations point to low-level lead exposure as a contributor to hypertension and kidney disease.

Bone lead levels were found to be significant predictors of hypertension in community-exposed men [6]. The mean blood lead level in these men was 6 μg/dL. Similarly, bone lead levels were found to be a significant predictor of hypertension in nurses [7]. A study in pregnant women with a geometric mean blood lead level of 1.9 μg/dL found increases in bone lead were associated with an increased risk of pregnancy hypertension [8]. Increases in both diastolic and systolic blood pressures in pregnant women were significantly associated with blood lead, and the major portion of the effect was found with blood lead levels under 5 μg/dL. These observations on the adverse effects at blood lead levels below 10 μg/dL in diverse groups indicate that, even at levels traditionally considered acceptable, important adverse health effects occur.

Treatment of lead-induced hypertension and kidney failure with calcium ethylenediaminetetraacetic acid ($CaNa_2$–EDTA; also called calcium disodium versenate or edetate calcium disodium) may improve the glomerular filtration rate (GFR) or reduce the rate of progression of kidney failure. The reversible component of lead nephropathy reported following $CaNa_2$–EDTA therapy in lead workers (mean blood lead, 18 μg/dL) may have resulted from the correction of acute lead absorption superimposed on chronic lead nephropathy [9]. Similar therapeutic effects have been noted in kidney failure at much lower levels of lead exposure. Lin *et al.* [10] treated kidney patients (mean creatinine, 2.1 mg/dL; mean

blood lead, 5.3 µg/dL) with CaNa$_2$–EDTA , 4–13 g intravenously, over 2 years. The treated group had an increase in GFR averaging 3.4 mL/min, whereas untreated controls had a decrease in GFR of 1.0 mL/min during this period. The same laboratory demonstrated that low levels of lead absorption correlate significantly with the rate of progression of kidney failure in type 2 diabetics and that CaNa$_2$–EDTA therapy, averaging 7 g over 3 months, significantly reduced the rate of progression of kidney failure compared to untreated diabetic controls [11]. These results suggest that reducing even very low levels of lead may improve GFR in a variety of non-lead-related kidney diseases. Moreover, if the beneficial effect of CaNa$_2$–EDTA is, in fact, due to the removal of lead from the body, these observations indicate that there is no threshold for the deleterious effects of lead on kidneys.

However, the mechanism of the beneficial effect of CaNa$_2$–EDTA on the kidneys is by no means clear. There were no controls with normal renal function or with minimal body lead stores in Lin's studies. The effect of chelating lead on subjects with low-level lead absorption by succimer has not been evaluated. It therefore remains possible that the beneficial effect of CaNa$_2$–EDTA on GFR is due to actions other than the removal of lead. Modification of potential mediators of hypertension and reduced GFR, such as other cations, reactive oxygen species [12], or uric acid [13], may have accounted for the improvement in GFR found by Lin *et al.*

Prevention remains the most effective method of treatment of lead poisoning. Chelation transiently increases the rate of removal of lead, causing the urinary excretion of up to several milligrams of lead in heavily exposed individuals within a few days. If, on the other hand, excessive exposure is terminated, the expected urinary excretion of 100–200 µg of lead/day will achieve a negative balance of 35–70 mg/year. Because a lifetime of occupational exposure can result in bone lead stores of 500 mg or more, a course of chelation therapy (e.g. 1–2 g CaNa$_2$–EDTA) eliminates only about 0.2–0.4 % of the body burden, whereas terminating exposure reduces bone stores by about 10% per year. Although it is not feasible to eliminate all lead intake, similar calculations for individuals with low-level exposure indicate that, in the long term, prevention is more effective than chelation in lowering the body lead stores. In summary, chelation therapy is justified in cases of symptomatic lead poisoning or when the blood lead exceeds about 70 µg/dL, but when no symptom end point is clearly defined, chelation for blood lead of <70 µg/dL is not usually justified.

Mercury

The toxicity of mercury depends on both its chemical form and the route of absorption. Although preferentially accumulated in the kidney, neurologic disease, but not kidney disease, regularly follows exposure to elemental mercury. Once in the environment, elemental mercury undergoes biotransformation to both organic and inorganic salts, which are absorbed by living organisms and thus enter the food chain. Methyl, ethyl, and phenoxyethyl mercury are important organomercurial contaminants arising from industrial and agricultural processes. Whereas certain organomercurials (e.g. chlormerodrin) are potent diuretics, others that are also con-

centrated in the proximal tubule (e.g. *p*-chloromercuribenzoate) have no diuretic effect. In contrast, the mercuric salt, corrosive sublimate (mercury bichloride [HgCl$_2$]), is highly nephrotoxic and, at 1 mg/kg, uniformly produces acute tubular necrosis [14]. Similar nephrotoxicity is induced by phenyl and methoxy methyl mercuric salts. Another mercurous salt (calomel [Hg$_2$Cl$_2$]) was widely used for therapy until the 20th century and is relatively nontoxic.

In addition to diuresis and acute tubular necrosis, mercury has been sporadically reported to cause nephrotic syndrome in what has usually been considered an idiosyncratic response. Observations in rats may provide a framework for understanding mercury-induced glomerular disease in humans. In 1971, Bariety *et al.* [15] reported that multiple subcutaneous injections of HgCl$_2$ in specific rat strains, in doses too small to produce tubular necrosis, induced membranous nephropathy. Kidney disease characterized by glomerular deposition of immune complexes and heavy proteinuria developed in about 2 months. Subsequent studies showed that the immune response is actually biphasic; immune complex deposition is preceded by anti-glomerular basement membrane antibody and complement deposition. The response to mercury in the rat is under precise genetic control. As little as 0.05 mg/kg of body weight will elicit immunologically mediated glomerular disease in selected strains. As in humans, mercury-induced glomerular disease in rats is self-limited.

There are no randomized clinical trials for the treatment of acute tubular necrosis or nephrotic syndrome due to mercury. Chelation therapy has been employed for excessive mercury exposure, often defined as more than 5 µg Hg/dL in blood or 50 µg Hg/L in urine, but evidence for the effectiveness of chelation therapy is lacking. Traditional use of BAL (British antilewisite, dimercaprol) for chelating mercury is currently being replaced by its soluble congeners, dimercaptopropane sulfonic acid (unithiol, or Dimaval) and succimer (dimercaptosuccinic acid; Chemet). Dimercaptopropane sulfonic acid is the chelator of choice for inorganic mercury intoxication, whereas succimer is the agent of choice for organic mercury [16]. Case reports suggest that in the presence of severe kidney failure the mercury-chelate complex can be removed by hemodialysis or hemofiltration.

Cadmium

Acute absorption of as little as 10 mg of cadmium as dust or fumes induces severe gastrointestinal symptoms and, after a delay of 8–24 h, fatal pulmonary edema. Chronic low-dose exposure causes slowly progressive emphysema, anosmia, and proximal tubular reabsorptive defects characterized by hypercalciuria, low-molecular-weight proteinuria, enzymuria, aminoaciduria, and renal glycosuria [17]. Hypercalciuria (with normocalcemia), phosphaturia, and distal renal tubular acidosis result in clinically important osteomalacia, pseudofractures, and urinary tract stones [18]. Proximal tubular dysfunction is followed by interstitial nephritis, which can progress to chronic kidney failure. The biologic half-life of cadmium in humans exceeds 15 years, and one-third of the total body stores (10–20 mg) is retained in the kidneys. Absorbed cadmium is initially sequestered in the liver and kidney, where it is bound to

a cysteine-rich apoprotein, metallothionein. Although uptake in the liver initially exceeds that in the kidney, most of the cadmium is eventually bound to protein in the proximal tubules, where it is accumulated until a "critical concentration," approximately 200 µg/g of renal cortex, is achieved. At this tissue level, adverse renal effects become evident, including tubular proteinuria and increased cadmium excretion. Significant abnormalities of proximal tubular function are associated with urinary cadmium excretion in excess of 30 µg/day.

Clinical symptoms associated with cadmium nephropathy derive primarily from the increased calcium excretion that accompanies the renal tubular dysfunction. Hypouricemia, hypophosphatemia, intermittent renal glycosuria, or elevated serum alkaline phosphatase (in the absence of kidney failure or hyperparathyroidism) may bring the acquired Fanconi syndrome to a clinician's attention, but ureteral colic is more likely to be a cadmium worker's chief complaint. Although both osteomalacia and kidney failure are distinctly uncommon in cadmium workers, urinary calculi have been reported in up to 40% of those subjected to industrial exposure [19].

Itai-itai disease

In Japan, a painful bone disease associated with pseudofractures due to cadmium-induced renal calcium wasting was recognized in the 1950s. Attributed to local contamination of food staples by river water polluted with industrial effluents, the syndrome known as itai-itai, or "ouch-ouch" disease, primarily afflicted postmenopausal, multiparous women. Sustained deficiencies in iron, zinc, calcium, and vitamin D rendered these women particularly vulnerable to cadmium toxicity. The women with itai-itai disease tended to have reduced GFR, anemia, lymphopenia, and hypotension as well as osteomalacia. They exhibited a waddling gait, short stature, anemia, glycosuria, and elevated serum alkaline phosphatase levels. Hypertension was absent. β_2-Microglobulin excretion exceeded the normal maximum (1 mg/g of creatinine) by 100-fold, and GFR was substantially reduced in the most severely affected individuals. Long-term follow-up studies showed that excessive urinary excretion of the low-molecular-weight protein β_2-microglobulin predicts the later development of kidney failure in patients with itai-itai disease and that kidney damage progresses even after exposure has ceased. Succimer is effective for chelation in acute cadmium poisoning [16]. No agent has been found effective for mobilizing hepatic or renal stores of cadmium.

Silicon

Silicon is a semi-metal found as the dioxide (SiO_2, silicon dioxide) in 28% of the earth's crust. It has been reported to induce interstitial nephritis by direct deposition of crystalline material in the renal parenchyma [20] and by immunologic mechanisms, acting as an adjuvant to stimulate the immune response [21]. Tubular proteinuria is found in workers exposed to silica dust. The odds of a sandblaster developing end-stage renal disease is 3.8 compared to matched controls. In the accelerated form of silicosis known as silicoproteinosis, silicon dust appears to be indirectly responsible for

rapidly progressive, immune complex-mediated focal glomerulosclerosis [22]. In addition to severe pulmonary disease, these patients develop an overwhelming autoimmune response that frequently includes lupus erythematosus [23] or rheumatoid arthritis (Caplan's syndrome). Glomerular disease, sometimes in association with silica-induced systemic sclerosis, systemic lupus erythematosus, and small vessel vasculitis, has also been described as a result of exposure to silica dust independent of silicosis [24]. Antineutrophil cytoplasmic antibody (c-ANCA)-positive Wegener's granulomatosis has been associated with exposure to silica dust as well as to silica-containing compounds, such as grain dust. No specific therapies have been reported for silica-induced glomerular disease other than those in current use for immunologically medicated glomerular disease.

Solvent nephropathy

Halogenated hydrocarbons have often been implicated in the induction of acute tubular necrosis or Fanconi syndrome in both humans and experimental animals. Low-level occupational absorption by inhalation of volatile hydrocarbons or absorption through the skin may also induce tubular proteinuria, which does not necessarily signify the presence of clinical kidney failure.

At least 40 case–control studies have examined the relationship between glomerulonephritis and exposure to organic solvents. A number of these studies concluded that patients with chronic glomerulonephritis had been exposed to organic solvents (aliphatic and aromatic) more frequently than patients with other diseases. Initially, solvent nephropathy was associated with antiglomerular basement membrane antibody-mediated glomerulonephritis and pulmonary hemorrhage, i.e. Goodpasture's syndrome, but later reports of solvent nephropathy have included many different types of glomerulonephritis [25].

The etiologic role of solvents remains controversial because the dose and exact chemical composition of industrial solvents are usually unknown. Moreover, of the thousands of workers exposed, very few develop immunologically mediated glomerular disease. The genetic and environmental factors that make specific individuals susceptible to solvent nephropathy have not been delineated. The experimental mercury-induced immunologically mediated glomerular disease in rodents described above may provide a model for understanding solvent nephropathy in humans. No specific therapies have been recommended for solvent nephropathy. Avoidance of exposure to volatile hydrocarbons and their derivatives remains an essential preventive approach.

29 The Kidney in Pregnancy

Phyllis August[1] & Tiina Podymow[2]
[1]Weill Medical College of Cornell University, New York, New York
[2]Division of Nephrology, McGill University, Montreal, Quebec, Canada

Pregnancy, in the setting of significant maternal kidney disease, is hazardous and frequently unsuccessful, due in part to the failure to adapt to pregnancy-associated hemodynamic alterations. Pregnancy imposes a hemodynamic strain on maternal renal function, so that in some women with preexisting kidney disease, renal function deteriorates during or after pregnancy. Alterations in immune function and increased inflammation associated with pregnancy may also contribute to worsening of kidney disease during gestation. In general, the closer to normal the glomerular filtration rate (GFR) and blood pressure are, the greater the chance of a successful pregnancy. Management of gravidas with kidney disease may be complicated and requires an understanding of the physiologic changes associated with pregnancy, as well as close cooperation between obstetrician and nephrologist. This chapter will focus mainly on clinical issues related to kidney disease in pregnant women. Although some areas in obstetric medicine have been extensively studied with randomized controlled trials (e.g. prevention of preeclampsia), kidney disease in pregnancy is less common, and the quality of the evidence guiding clinical practice in this field of medicine is not of the highest level. There are, however, many clinical questions which have been studied well with randomized controlled trials. Summaries of these trials can be found in the pregnancy and childbirth module of the Cochrane Library, the largest single section of the Cochrane Library. Most evidence consists of case series with modest numbers of subjects. Recent epidemiologic surveys have highlighted the problem of unrecognized chronic kidney disease in the US population [1] and, based on extrapolation of these data, the prevalence of chronic kidney disease in women of childbearing age may be only approximately 0.2% .

Renal anatomy and physiology in pregnancy

A brief review of some of the important physiological alterations in pregnancy is useful for guiding therapeutic principles. Much of

the data on renal function and physiology during pregnancy were collected more than 25 years ago. More recent studies in animal models of pregnancy have begun to examine some of the mediators of the renal alterations, including steroid hormones, nitric oxide, and relaxin**.** The difficulties in studying pregnant women have clearly been an impediment in this field.

Anatomic and functional changes in the urinary tract

Kidney length increases approximately 1 cm during normal gestation, and overall kidney volume increases by up to 30% [2]. The major anatomic alterations of the urinary tract during pregnancy, however, are seen in the collecting system, where calyces, renal pelves, and ureters dilate, often giving the erroneous impression of obstructive uropathy. The cause of the ureteral dilation is disputed and has been attributed to hormonal mechanisms [3] as well as mechanical obstruction by the enlarging uterus. These morphologic changes result in stasis in the urinary tract and a propensity of pregnant women with asymptomatic bacteriuria to develop frank pyelonephritis, particularly in women with a history of prior urinary tract infection [4].

Renal hemodynamics

Pregnancy is characterized by marked vasodilatation, which is detectable early in the first trimester, by 6 weeks of gestation. In fact, recent studies of the menstrual cycle demonstrated that vasodilation is also present in the late luteal phase, prior to conception [5]. This early vasodilation is accompanied by a decrease in blood pressure, increase in cardiac output, and increases in renal plasma flow and glomerular filtration, all of which persist until late gestation. Since renal plasma flow increases slightly more than GFR, the filtration fraction remains constant or slightly lower in pregnancy [6]. Increases in renal hemodynamics reach a maximum during the first trimester and are approximately 50% greater than nonpregnancy levels [7]. Micropuncture studies performed in the gravid rat suggest that renal vasodilatation and increased glomerular plasma flow are the primary determinants of the increased renal hemodynamics in pregnancy. In humans, using clearance techniques (inulin, PAH, and neutral dextrans), the increment in GFR has

been largely attributed to increased renal plasma flow, decreased oncotic pressure, and an increased glomerular ultrafiltration coefficient, but not with increments in transglomerular hydrostatic pressure difference. The implications of these observations are that although GFR is significantly increased throughout the duration of normal pregnancy, there is little evidence for increased intraglomerular pressure and, therefore, little risk that the hyperfiltration associated with gestation is associated with additional strain on diseased kidneys, a conclusion that has not been tested in clinical trials. Increased progesterone, estrogen, nitric oxide, and relaxin have all been implicated as mediators of the systemic and renal vasodilation of pregnancy [8–10].

Creatinine production is unchanged during pregnancy; thus, increments in clearance result in decreased serum levels. There is also increased excretion of glucose, amino acids, calcium, and urinary protein, resulting in an increase in the upper limit of normal for urinary protein excretion (from 150 to 300 mg/day).

Acid–base regulation in pregnancy

In the resting state there are increases in respiratory rate, tidal volume, and alveolar ventilation, all of which result in a reduced arterial PCO_2 [11]. Augmented respiratory sensitivity in pregnancy has been attributed to the increased circulating level of progesterone, which directly stimulates the medullary respiratory center. There is a partly compensated respiratory alkalosis, with reductions in hydrogen ion concentration, PCO_2, and serum bicarbonate, changes that are apparent in the first trimester [12]. It has recently been demonstrated that exercise-induced increases in acid concentration are similar in pregnancy and nonpregnancy [11]. Finally, it should be appreciated that a PCO_2 of 40 mmHg signifies considerable carbon dioxide retention in pregnancy.

Water metabolism

Pregnancy is associated with a decrease in plasma osmolality of 5–10 mOsm/kg below that of nongravid women. This decrease in plasma osmolality is associated with appropriate responses to water loading and dehydration and suggests a resetting of the osmoreceptor system and thirst occurring at lower serum osmolality. Clinical studies demonstrating decreased osmotic thresholds for thirst and arginine vasopressin (AVP) release in pregnant women support this hypothesis [13,14]. In addition, pregnant women metabolize AVP more rapidly as a consequence of increased production of placental vasopressinases [14]. Pregnant women may develop syndromes of transient diabetes insipidus due to the increased metabolism of AVP. These syndromes may be treated with dDAVP, which is effective owing to a different N terminus that is resistant to the circulating vasopressinases.

Along with decreased serum osmolality, serum sodium is also lower in pregnancy. This may be due in part to relaxin, a peptide hormone in the insulin family, secreted by the corpus luteum and placenta during human gestation [15,16]. Relaxin is associated with early pregnancy osmoregulatory changes, as well as increases in GFR and vasodilatation [15]. β-Human chorionic gonadotropin appears to cause release of relaxin, which then stim-

ulates the hypothalamus, resulting in thirst and AVP secretion [17]. Chronic administration of relaxin to rats mimics several of the hemodynamic and osmotic changes of pregnancy, whereas antirelaxin antibodies reverse these changes.

Volume regulation

Total body water increases by 6–8 L during pregnancy, 4–6 L of which is extracellular. Plasma volume increases 50% during gestation, the largest rate of increase occurring in mid-pregnancy [5]. There is a gradual cumulative retention of about 900 mEq of sodium during pregnancy, which is distributed between the products of conception and the maternal extracellular space. Despite the increase in plasma volume during pregnancy, there is no evidence for a hypervolemic (i.e. overfilled circulation) state during pregnancy. Indeed, the marked vasodilation that is observed as early as the first trimester may be the stimulus for increased sodium retention and increased plasma volume. The observations that blood pressure is significantly lower and that the renin–angiotensin system is stimulated during normal pregnancy are consistent with primary vasodilation preceding and causing the increase in plasma volume.

Blood pressure regulation

Normal pregnancy is characterized by generalized vasodilation so marked that despite increases in cardiac output and plasma volume in the range of 40%, mean arterial pressures decrease approximately 10 mm [18]. The decrement in blood pressure is apparent in the first trimester, reaching a nadir by mid-pregnancy and then increasing gradually to approach prepregnancy values at term. Potential mediators of the vasodilation of pregnancy include placental hormones, nitric oxide, relaxin, prostacylin, and vascular endothelial growth factor. In response to the vasodilation and lower blood pressure, the renin–angiotensin system is markedly stimulated in pregnancy. Increases in plasma renin activity are apparent early in pregnancy, and levels increase to reach a maximum of about four times nonpregnant values by mid-pregnancy [18]. The increase in plasma renin activity is accompanied by increases in aldosterone secretion. Angiotensin II levels have not been studied extensively in pregnancy but are likely to be increased as well. Despite the increased renin and aldosterone levels, blood pressure and electrolytes are normal during pregnancy. Indeed, normotensive gravidas demonstrates exaggerated responses to *acute* converting enzyme inhibition, suggesting that the stimulated renin–angiotensin system is an important defense against hypotension during pregnancy [19].

Assessment of renal function in pregnancy

The GFR increases by 40–65% in pregnancy, but creatinine production is unchanged, resulting in decreased serum creatinine levels. One study reported average values of 0.83 mg/dL (73 μmol/L) in nonpregnant women and 0.74, 0.58, and 0.53 mg/dL (65, 51, and 46 μmol/L) in the first, second, and third trimesters of pregnancy,

respectively, with values for the upper limit of normal of 0.96, 0.9, and 1.02 mg/dL (85, 80, and 90 μmol/L) [20]. Calculation of GFR by creatinine-based formulae is challenged by increasing maternal weight that is not muscle weight, and neither the MDRD formula nor Cockroft-Gault GFR estimates have been validated in pregnancy [21]. Measurement of serum cystatin C had been proposed as a more sensitive marker for GFR, as it was thought to be independent of age, weight, height, or muscle mass; however, this has not been found when studied in pregnancy [22]. At this time, creatinine clearance measured by 24-h urine collection remains the most-well-validated method for measuring renal function.

Proteinuria is measured using 24-h urine collection, urine dipstick, and the protein/creatinine ratio, but the gold standard remains the 24-h urine protein measurement. A 24-h protein level greater than 300 mg is abnormal in pregnancy and correlates with a urine dipstick protein measurement of 1+. Although commonly used to detect significant proteinuria, urine dipstick testing is susceptible to error due to variations in urine concentration and may miss up to 10% of hypertensive pregnant women with true proteinuria [23]; thus, if the level of suspicion is high, 24-h urine testing should be performed. The total protein/creatinine ratio has been shown to estimate 24-h urine protein in nonpregnant patients; however, in pregnancy it does not appear to exclude the equivalent of 0.3 g/24 h proteinuria and underestimates severe proteinuria, so it cannot be recommended as an alternative to 24-h measurement [24].

Kidney disease in pregnancy

Kidney disease during pregnancy may be due to 1) preexisting kidney disease that was diagnosed prior to conception, 2) chronic kidney disease that was unappreciated prior to pregnancy and diagnosed for the first time during pregnancy, or 3) kidney disease that develops for the first time during pregnancy. Overlapping categories occur with some diseases. For example, lupus nephritis may be a chronic condition or it may develop for the first time during pregnancy.

Chronic kidney disease: general principles

Fertility and ability to sustain an uncomplicated pregnancy are related to the degree of renal functional impairment, rather than to the specific underlying disorder. The greater the functional impairment, and/or the higher the blood pressure, the less likely the pregnancy will be successful. Patients with preserved renal function and normal or well-controlled blood pressure have favorable maternal and fetal outcomes. Those with moderate renal insufficiency (serum creatinine of 1.2–2.5 mg/dL [110–220 μmol/L]) are at increased risk for preeclampsia (20–30%) and preterm delivery. Women with moderate or severe renal dysfunction should be discouraged from conceiving, because up to 40% of these pregnancies are complicated by hypertension or deterioration in renal function that may be irreversible [25]. The level of blood pressure at the time of conception is an important variable in pregnancy outcome. In the absence of hypertension there is significantly less chance of irreversible deterioration in renal function during pregnancy. When hypertension is present, and especially when it is severe, pregnancy outcome is rarely uncomplicated. Premature delivery and deterioration in renal function are expected. Urine protein excretion may increase markedly in pregnant women with underlying kidney disease. Although the increments in protein excretion during pregnancy may not necessarily reflect worsening of underlying kidney disease, increased proteinuria is associated with worse fetal prognosis.

Kidney diseases associated with systemic illness

Diabetes is one of the most common medical disorders encountered during pregnancy, and the majority of cases are due to gestational diabetes. Preexisting diabetes poses significant risks to pregnancy. Many younger women with pregestational diabetes have type 1 diabetes, and if their disease has been present for 10–15 years, they may show early signs of diabetic nephropathy. Women with microalbuminuria (compared to macroalbuminuria), well-preserved renal function, and normal blood pressure have a good prognosis for pregnancy, although they are at increased risk for preeclampsia and urinary tract infection [26,27]. In one prospective cohort study from Denmark, 240 pregnant women with type 1 diabetes were followed during pregnancy, of whom 26 (11%) had microalbuminuria and 11 (5%) had diabetic nephropathy. A 62% proportion of women with microalbuminuria and 91% of women with diabetic nephropathy had preterm deliveries (compared with 35% of women with normal albumin excretion). Preeclampsia developed in 6% of women with normal albumin excretion compared with 42% and 64% of women with microalbuminuria and diabetic nephropathy, respectively [27]. In another study of 72 pregnancies in 58 women with diabetic nephropathy, high serum creatinine at enrollment, independent of urinary protein excretion, was associated with preterm delivery, very low birth weight, and neonatal hypoglycemia. With respect to progression of maternal kidney disease as a consequence of pregnancy, one study from Denmark reported that 26 women with type 1 diabetes who became pregnant had similar rates of deterioration in renal function over a 16-year follow-up, compared to 67 control subjects with comparable disease who had never been pregnant [28]. Thus, when baseline renal function and blood pressure are still normal, pregnancy is not likely to accelerate the progression of early diabetic nephropathy [28], although it is not unusual for urinary protein excretion to increase significantly during pregnancy, and there are only limited data that have specifically addressed this problem. Women with non-nephrotic-range proteinuria preconception may develop nephrotic-range proteinuria during pregnancy, but it is usually reversible. Women with overt nephropathy preconception, particularly those with impaired renal function and hypertension, have a high incidence of premature delivery and deterioration in maternal renal function [26]. Women with type 1 diabetes with microalbuminuria and normal renal function and normotension should be encouraged *not* to postpone pregnancy because of the worse prognosis once overt nephropathy develops.

There are no published studies of pregnancy and nephropathy associated with type 2 diabetes; however, given the increasing prevalence of this condition, it is an important area for future study.

Tight glucose control is critical because of the established association between glucose control and fetal outcome [29]. Thus, all women with diabetes should be managed by physicians experienced with diabetes in pregnancy. Blood pressure control is also important; however, because angiotensin converting enzyme inhibitors and angiotensin receptor blockers are contraindicated during pregnancy, women should be switched to other agents prior to conception.

Women with lupus nephritis during pregnancy present unique problems. Although similar considerations apply regarding the relationship between level of renal function and blood pressure to pregnancy outcome, in general, lupus is a much more unpredictable illness because of the tendency of the disease to flare. Recent data suggest that pregnancy duration, total disease duration, and disease activity and damage prior to pregnancy are associated with increased organ damage following pregnancy in women with lupus [30]. Whether or not pregnancy per se is a risk factor for lupus flares has been disputed [31]. Although some studies report no increase in flares attributable to pregnancy in patients in remission [32], prospective data from other studies suggest that pregnancy is associated with a greater chance of disease exacerbation [33,34]. Women with lupus are advised not to conceive unless their disease has been "inactive" for the preceding 6 months, as there is a higher incidence of fetal demise with active disease [35]. Additional complications associated with lupus and pregnancy include placental transfer of maternal autoantibodies, which can cause a neonatal lupus syndrome characterized by heart block, transient cutaneous lesions, or both. Women with lupus are also more likely to have clinically significant titers of antiphospholipid antibodies and the lupus anticoagulant, which are associated with spontaneous fetal loss, hypertensive syndromes indistinguishable from preeclampsia, and thrombotic events including deep vein thrombosis, pulmonary embolus, myocardial infarction, and strokes [36]. Thus, all women with systemic lupus erythematosus should be screened for antiphospholipid antibodies early in gestation. When titers are elevated (more than 40 GPL), daily aspirin (80–325 mg) is recommended. If there is a history of thrombotic events, then heparin in combination with aspirin is recommended [37].

One of the difficulties in managing lupus nephritis during pregnancy is that increased activity of lupus may be difficult to distinguish from preeclampsia. Both are characterized by an increase in proteinuria, a decrease in GFR, and hypertension. Thrombocytopenia may also be observed in both conditions. Hypocomplementemia is not a feature of preeclampsia, whereas increases in liver function tests may be observed in preeclampsia but are not characteristic of lupus activity. If disease activity is present before 20 weeks of gestation, then the diagnosis is more likely to be a lupus flare. In the latter half of pregnancy, it may be impossible to distinguish between a renal lupus flare and preeclampsia. In fact, frequently both are present simultaneously, and what starts as increased lupus activity appears to trigger preeclampsia. Spun urine microscopy for red blood cell casts can also signal lupus nephritis activity. Unfortunately, delivery may be necessary if immunosuppressive therapy and supportive care fail to stabilize the condition. The approach to treatment of lupus nephritis during pregnancy is based largely on anecdotal experience and knowledge regarding treatment of lupus in nonpregnant patients, as well as information on fetal toxicity of immunosuppressants that has been gained from treatment of other conditions, such as organ transplantation. Steroids and azathioprine are the mainstays of treatment. A recent prospective, observational study of women with lupus exposed to hydroxychloroquine during pregnancy suggested that this agent was associated with improved outcomes and absence of fetal toxicity [38]. Cyclophosphamide is generally not recommended during pregnancy, because of potential fetal toxicity [39], and should only be used when the mother's life is in jeopardy. We are unaware of published data regarding use of mycophenolate mofetil during pregnancy for treatment of lupus nephritis. It is embryotoxic in animal studies and has been associated with fetal malformations in humans [40].

Chronic glomerulonephritis

Child-bearing women may be afflicted with any of the forms of chronic glomerulonephritis common in this age group. These include immunoglobulin A nephropathy, focal and segmental glomerulosclerosis, membranoproliferative glomerulonephritis, minimal change nephritis, and membranous nephropathy. We are unaware of data that would support the notion that histologic subtype confers a specific prognosis for pregnancy. Rather, the previously mentioned principles are applicable to women with chronic glomerulonephritis; when renal function is normal and hypertension is absent, the prognosis is good.

Polycystic kidney disease

Young women with autosomal dominant polycystic kidney disease are frequently asymptomatic, with normal renal function and normal blood pressure, and indeed they may be unaware of their diagnosis. Little has been written about polycystic kidney disease and pregnancy, because many patients with this condition have well-preserved kidney function until after childbearing. A series consisting of 235 women with autosomal dominant polycystic kidney disease and 108 unaffected family members evaluated pregnancy outcomes and reported an increased incidence of maternal complications in affected compared to unaffected women [41]. Preexisting hypertension was the most common risk factor for maternal complications during pregnancy [41]. Pregnant women with polycystic kidney disease should be considered at increased risk of urinary tract infection. Estrogen is reported to cause liver cysts to enlarge, and repeated pregnancies may result in symptomatic enlargement of liver cysts. Given the association between cerebral aneurysms and autosomal dominant polycystic kidney disease in some families, screening for such aneurysms should be considered prior to natural labor. All patients should undergo genetic counseling before pregnancy to ensure they are aware that their offspring have a 50% chance of being affected.

Chronic pyelonephritis

Dilation and stasis in the urinary tract make chronic pyelonephritis (nephropathies associated with recurrent urinary tract infection, often in association with urinary tract abnormalities, e.g. vesicoureteral reflux) in gravidas more prone to exacerbation. These women should have a high fluid intake and should be screened frequently for bacteriuria. Women with reflux nephropathy have been reported to have an adverse prognosis during pregnancy. A prospective study of 54 pregnancies in 46 women with reflux nephropathy found that preeclampsia was present in 24% and more common in women with preexisting hypertension [42]. Nine (18%) experienced deterioration in renal function during pregnancy, and those with preexisting reduced renal function were at greater risk. One-third of the infants were delivered preterm, and 43% had vesicoureteral reflux. These high-risk women should be screened with urine cultures and should be treated promptly when infections are present, with consideration to suppressive antibiotic therapy for the duration of pregnancy in some cases.

Chronic kidney diseases that may be first diagnosed during pregnancy

The presence of chronic kidney disease may be diagnosed for the first time during pregnancy, in part because pregnant women are scrutinized more closely and also because the renal hemodynamic alterations during pregnancy may cause proteinuria to increase and be clinically detectable for the first time. Frequent measurement of blood pressure may also lead to diagnosis of kidney diseases accompanied by hypertension. Furthermore, the presence of even mild preexisting kidney disease is associated with an increased risk of preeclampsia; thus, underlying kidney disease may first become apparent after preeclampsia has developed in later pregnancy. Kidney diseases that may have been relatively silent preconception but that may "present" during pregnancy include immunoglobulin A nephropathy, focal and segmental glomerulosclerosis, polycystic kidney disease, and reflux nephropathy. Renal diagnostic testing during pregnancy can include blood and urine testing and ultrasonography. Renal biopsy is usually deferred until after delivery, unless there is acute deterioration in renal function or morbid nephrotic syndrome. Although experienced operators have reported few complications of renal biopsy during pregnancy, increased renal blood flow, hypertension, and difficulty positioning the patient are concerns [43–45]. The timing of renal biopsy after delivery depends on the clinical circumstances. If renal function is normal, and only proteinuria is present, it is reasonable to delay biopsy by at least 1–2 months, because proteinuria may improve once the hemodynamic alterations associated with pregnancy have resolved. If renal function is impaired, then biopsy should be considered within a few weeks of delivery.

Kidney diseases that develop for the first time during pregnancy

Pregnant women are at risk for any of the kidney diseases that occur in childbearing-age women, including pyelonephritis, glomerulonephritis, interstitial nephritis, and acute kidney failure.

Pyelonephritis in pregnant women is more likely to be associated with significant azotemia compared with nonpregnant women and should be treated aggressively. Glomerulonephritis and interstitial nephritis are not more likely to develop during pregnancy, although they do occur. Acute kidney failure in association with pregnancy, a rare complication in developed countries, is also decreasing in incidence in the developing world, with only 190 cases observed in a 20-year period in eastern India [46]. Recent estimates suggest that the incidence of acute kidney failure from obstetric causes is less than 1/20,000 pregnancies [47].

When acute kidney failure occurs early in pregnancy (12–18 weeks), it is usually in association with septic abortion or prerenal azotemia due to hyperemesis gravidarium. Most cases of acute kidney failure in pregnancy occur between gestational week 35 and the puerperium and are primarily due to preeclampsia and bleeding complications. Preeclampsia, particularly the HELLP variant (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelet count) is an important cause of acute kidney failure in pregnancy [26]. Although most cases of preeclampsia are not usually associated with kidney failure, the HELLP syndrome may be associated with significant renal dysfunction, especially if not treated promptly. Most women without preexisting kidney or hypertensive disease do not require long-term renal replacement therapy. Additional important clinical entities causing kidney failure during pregnancy are discussed next.

Thrombotic microangiopathy

Although rare, thrombotic microangiopathies (thrombotic thrombocytopenic purpura [TTP] and hemolytic uremic syndrome [HUS]) are an important cause of pregnancy-associated acute kidney failure because they are associated with considerable morbidity. They also share several clinical and laboratory features with pregnancy-specific disorders, such as the HELLP variant of preeclampsia and acute fatty liver of pregnancy; thus, distinction of these syndromes is important for therapeutic and prognostic reasons. Features that may be helpful in making the correct diagnosis include timing of onset and the pattern of laboratory abnormalities. Preeclampsia typically develops in the third trimester, with only a few cases developing in the postpartum period, usually within a few days of delivery. TTP usually occurs antepartum, with many cases developing in the second trimester, as well as the third. HUS is usually a postpartum disease. Symptoms may begin antepartum, but most cases are diagnosed postpartum.

Preeclampsia is much more common than TTP or HUS, and it is usually preceded by hypertension and proteinuria. Kidney failure is unusual, even with severe cases, unless significant bleeding or hemodynamic instability or marked disseminated intravascular coagulation (DIC) occurs. In some cases, preeclampsia develops in the immediate postpartum period, and when thrombocytopenia is severe, it may be indistinguishable from HUS. However, preeclampsia spontaneously recovers, whereas TTP or HUS is often associated with persistent renal insufficiency and hypertension, with many patients requiring long-term dialysis or transplantation [48].

In contrast to TTP and HUS, preeclampsia may be associated with mild DIC and prolongation of prothrombin and partial thromboplastin times. Another laboratory feature of preeclampsia and HELLP syndrome that is not usually associated with TTP or HUS is marked elevation in liver enzymes. The presence of fever is more consistent with a diagnosis of TTP than preeclampsia or HUS. The main distinctive features of HUS are its tendency to occur in the postpartum period and the severity of the associated kidney failure. Treatment of preeclampsia and HELLP syndrome is delivery and supportive care. More aggressive treatment is rarely indicated. Some centers have reported the use of steroids in cases of severe HELLP syndrome, although this therapy has not been rigorously evaluated in placebo-controlled clinical trials [49]. Treatment of TTP and HUS includes plasma infusion or exchange and other modalities used in nonpregnant patients with these disorders.

Acute tubular necrosis

Acute tubular necrosis, either induced by volume depletion or exposure to nephrotoxins, may occur during pregnancy, although the incidence is low. In the first trimester, acute tubular necrosis is usually associated with hyperemesis gravidarium, whereas later in pregnancy and in the peripartum period, it is usually associated with abruptio placenta or other causes of obstetric hemorrhage. Occasionally, nonsteroidal anti-inflammatory agents, used for postpartum analgesia, may precipitate acute kidney failure in patients who are volume depleted from either hemorrhage, decreased fluid intake, or both. In severe cases of obstetric hemorrhage, acute cortical necrosis with associated DIC may be present, and ultrasonography or computed tomography may demonstrate hyperechoic or hypodense areas in the renal cortex. Most patients ultimately require dialysis, but 20–40% with cortical necrosis have partial recovery of renal function.

Acute fatty liver of pregnancy

Acute fatty liver is a rare complication of late pregnancy that is characterized by rapidly progressive liver failure. Women usually present with nausea, vomiting, and anorexia, and many patients have coincident diagnoses of preeclampsia or HELLP syndrome [50]. Other laboratory abnormalities (in addition to marked elevations in aspartate aminotransferase and alanine aminotransferase) frequently observed include elevated bilrubin, hypofibrinigemia, prolonged partial thromboplastin time, hypoglycemia, anemia, and low platelet count [51]. Many cases are associated with significant azotemia, and one series compared AFLP to HELLP syndrome and observed that acute kidney failure was significantly more common with AFLP [52]. Those authors hypothesized that because AFLP is believed to be a disease of mitochondrial dysfunction [53], it is possible that the kidney dysfunction associated with AFLP reflects inhibition of β-oxidation of fats in the kidney. Autopsy data have demonstrated microvesicular fat in the kidneys of women with AFLP. Delivery is indicated, and most patients improve shortly afterwards. This disorder was formerly associated with a more ominous outcome, which may have been a consequence of late diagnosis, although in a recent case series maternal mortality was reported in two of six cases [51]. When diagnosed early, long-term morbidity is reduced.

Urinary tract obstruction

Pregnancy is associated with dilation of the collecting system, which is not usually accompanied by renal dysfunction. Rarely, complications such as large uterine fibroids that enlarge in the setting of pregnancy can lead to obstructive uropathy. Occasionally, acute urinary tract obstruction in pregnancy is caused by a kidney stone. Diagnosis can usually be made by ultrasonography. Often the stone will pass spontaneously, but occasionally cystoscopy is necessary for insertion of a stent to remove a fragment of stone and relieve obstruction, particularly if there is sepsis or a solitary kidney. ESW lithotripsy is contraindicated during pregnancy because of the possibility of adverse effects on the fetus.

Acute renal failure during pregnancy

Management of acute kidney failure occurring in pregnancy or immediately postpartum is similar to that in nongravid subjects, although there are several important considerations unique to pregnancy. Uterine hemorrhage near term may be concealed and blood loss underestimated; thus, any overt blood loss should be replaced early. Both peritoneal dialysis and hemodialysis have been used successfully in patients with obstetric acute kidney failure. Neither pelvic peritonitis nor the enlarged uterus is a contraindication to the former method. In fact, this form of treatment is more gradual than hemodialysis and thus less likely to precipitate labor. Because urea, creatinine, and other metabolites that accumulate in uremia traverse the placenta, dialysis should be undertaken early, with the aim of maintaining the blood urea nitrogen at approximately 50 mg/dL (8 μmol/L). In essence, the advantages of early dialysis in nongravid patients are even more important for the pregnant patient. Excessive fluid removal should be avoided, because it may contribute to hemodynamic compromise, reduction of uteroplacental perfusion, and premature labor. On the other hand, polyhydramnios is also thought to contribute to premature labor. In some cases it may be advisable to perform continuous fetal monitoring during dialysis, particularly after mid-pregnancy.

Therapy of end-stage renal disease during pregnancy

Dialysis

Fertility is reduced in dialysis patients, due to abnormalities of pituitary leutinizing hormone release leading to anovulation. Pregnancy that does occur in patients undergoing maintenance dialysis is extremely high risk, and conception should not be encouraged due to very high fetal mortality; in large surveys, only 42–60% of such pregnancies resulted in a live-born infant. Prematurity, very low birth weight, and intrauterine growth restriction are common, and approximately 85% of infants born to women who conceive after starting dialysis are born before 36 weeks of gestation.

Management of patients on dialysis who are pregnant includes several considerations, but the single most important factor influencing fetal outcome is the maternal plasma urea level [54]. In patients undergoing hemodialysis, both the number of dialysis sessions per week as well as the time per session must be increased to a minimum of 20 h/week, aiming for a predialysis urea of 30–50 mg/dL (5–8 mmol/L) [54,55]. Heparinization should be minimal, to prevent obstetric bleeding. Dialysate bicarbonate should be decreased to 25 mEq/L, in keeping with the expected physiologic metabolic acidosis of pregnancy. If peritoneal dialysis is being used, decreased exchange volumes by increasing exchange frequency or cycler use are recommended [56]. Adequate calorie and protein intakes are required; 1 g/kg/day protein intake plus an additional 20 g/day has been suggested [57]. After the first trimester, maternal "dry" weight should be increased by ~1 lb. (400 g)/week to adjust for the expected progressive weight increase in pregnancy. Antihypertensive therapy should be adjusted for pregnancy by discontinuing angiotensin converting enzyme inhibitors and angiotensin receptor blockers and aiming for maintenance of maternal diastolic pressure of 80–90 mmHg by using methyl-DOPA, labetalol, and sustained-release nifedipine in standard doses to achieve the target. Anemia should be treated with supplemental iron, folic acid, and erythropoietin. Erythropoietin is safe in pregnancy, and pregnancy-related erythropoietin resistance requires a dose increase of approximately 50% to maintain hemoglobin target levels of 10–11 g/dL. Frequent monitoring of iron stores and treatment with intravenous iron should be prescribed as necessary [57]. Due to placental 25(OH)-vitamin D_3 conversion, decreased supplemental vitamin D may be required and should be guided by levels of vitamin D, parathyroid hormone, calcium, and phosphorus. Magnesium supplementation may be needed to maintain serum magnesium levels at 5–7 mg/dL (2–3 mmol/L). Low-dose aspirin to prevent preeclampsia has been suggested. Babies born to mothers on dialysis may require monitoring for osmotic diuresis in the immediate postpartum period if maternal urea was high at the time of delivery.

Kidney transplantation

Menstruation and fertility resumes in most women from 1–12 months post-kidney transplantation. Several thousand women have undergone pregnancy following kidney transplantation, and pregnancy in this population appears to involve much lower risk to mother and baby than pregnancy in patients on dialysis. Although pregnancy has become more common after transplantation, there have been little more than case reports and cases series to guide practice decisions; a Consensus Conference generated a report in 2005 summarizing the literature and provided practice guidelines as well as identified gaps in knowledge [58]. Most pregnancies (greater than 90%) that proceed beyond the first trimester succeed; however, there are maternal and fetal complications due to immunosuppressant effects, preexisting hypertension, and renal dysfunction. These include maternal complications of steroid therapy, such as impaired glucose tolerance, hypertension (47–73%), preeclampsia (30%), and increased infection. Fe-

tal complications include a higher incidence of premature delivery and intrauterine growth restriction with lower birth weight. Best practice guidelines have outlined criteria for considering pregnancy in kidney transplant recipients [58–60], and it is suggested that those contemplating pregnancy should meet the following criteria:

1) Good health and stable renal function for 1–2 years after transplantation with no recent acute or ongoing rejection or infections

2) Absent or minimal proteinuria (<0.5 g/day)

3) Normal blood pressure or easily managed hypertension

4) No evidence of pelvicalyceal distention on ultrasonography prior to conception

5) Serum creatinine less than 1.5 mg/dL (133 μmol/L)

6) Drug therapy of prednisone at 15 mg/day or less, azathioprine at 2 mg/kg or less, cyclosporine at >5 mg/kg/day.

Management of all pregnant transplant patients should be by a high-risk obstetrician, due to risk of intrauterine growth restriction and preeclampsia. Future studies are required to address optimal immunosuppression in pregnancy. Although cyclosporine levels tend to decrease during pregnancy, there is no information regarding whether the drug dosage should be increased. Experience with tacrolimus is increasing, but it has not been used as widely in pregnancy as cyclosporine, although growing experience suggests that is safe, with a similar side effect profile to cyclosporine. Considerations regarding hypertension and growth restriction are important; there is no established blood pressure target, although 140/90 mmHg is suggested by the authors, and antihypertensives should be switched to those safe in pregnancy. Pregnancy safety has not been established for either mycophenolate mofetil or sirolimus [61]. Mycophenolate mofetil has been reported to be embryotoxic in animals and is associated with ear and other deformities in humans. This drug should be discontinued during pregnancy, and women should be switched to azathioprine if indicated. Sirolimus has caused delayed ossification in animal studies and although successful live-born human outcomes have been reported, its use is contraindicated in humans until more data are available. Finally, data from the National Transplantation Pregnancy Registry and the European Dialysis and Transplant Association suggest that pregnancy rarely negatively affects the graft, though there may be minor increases in serum creatinine postpartum compared with prepregnancy creatinine [59,61]. Rejection is difficult to diagnose in pregnancy, and renal biopsy may be required; the consensus opinion was that steroids are a safe treatment, as is intravenous immunoglobulin, but the safety of antilymphocyte globulins or rituximab in pregnancy is unknown [58].

Hypertensive disorders of pregnancy

A comprehensive discussion of hypertensive disorders of pregnancy is beyond the scope of this chapter, but preeclampsia will be briefly discussed because renal manifestations are an important feature. Although maternal death is a rare event in most Western nations where access to prenatal care is adequate, hypertensive

disorders are one of the leading causes of maternal death worldwide, accounting for 15–20% of all maternal deaths in the developing as well as the developed world [62]. In the USA, approximately 8–10% of all pregnancies are complicated by hypertension, with half of these cases attributable to the pregnancy-specific disorder preeclampsia. Hypertensive disorders in pregnancy are significantly more common than kidney disease in pregnancy, and because of the burden on both maternal as well as neonatal health, there are many examples of well-controlled multicenter randomized controlled trials and meta-analyses that have addressed such issues as prevention of preeclampsia, treatment and prevention of eclamptic seizures, and to a lesser degree, use of antihypertensive agents in pregnancy.

The classification scheme of hypertensive disorders in pregnancy is one that has been in use for many years in the USA and has been endorsed by The National High Blood Pressure Education Program and the American College of Obstetricians and Gynecologists. It includes four designations: chronic or preexisting hypertension, preeclampsia/eclampsia, preeclampsia superimposed on chronic hypertension, and gestational hypertension.

Screening tests for preeclampsia

Because most of the morbidity attributable to hypertension in pregnancy is due to preeclampsia or superimposed preeclampsia, considerable efforts have been made to evaluate various clinical, hormonal, and biochemical tests to identify early in pregnancy those at risk for the condition later in pregnancy or for those who manifest early, "preclinical" signs of the disorder. Although there are currently no effective preventive strategies for most women, the argument has been made that early identification would lead to closer surveillance and institution of certain lifestyle adjustments (e.g. stopping work, increased rest). To date, no single test has been shown to meet standard criteria for a useful screening test, and a recent comprehensive review of the subject emphasized this point [63].

Prevention of preeclampsia

Many strategies have been investigated in well-conducted clinical trials (including thousands of women) on the use of antiplatelet therapy, nutritional supplementation, and antioxidant vitamins for the prevention of preeclampsia. These trials, and subsequent meta-analyses, demonstrated a small benefit (10–15% reduction in relative risk) for low-dose aspirin in the prevention of preeclampsia and its clinically important adverse maternal and fetal outcomes [64]. With respect to nutritional strategies, calcium supplementation appears to have some benefit in women ingesting a baseline low-calcium diet [65], whereas to date, antioxidant supplementation with vitamins C and E has not shown benefit in two large randomized controlled trials [66,67].

Antihypertensive therapy during pregnancy

There remain many unanswered questions regarding the appropriate use of antihypertensive treatments in pregnant women. Neither the indications for antihypertensive therapy, the target blood pressures after treatment is initiated, the optimal antihypertensive agent, nor the role of lowered blood pressure in preventing complications has been adequately assessed. The reader is referred to recently published reviews of this subject [68].

Anticonvulsant therapy in women with eclampsia

There is strong evidence from randomized trials to support the use of magnesium sulfate for prevention and treatment of eclampsia [69]. This agent reduces the incidence of eclampsia in women with preeclampsia and lowers the risk of maternal death in women with eclampsia. It is superior to other agents, such as phenytoin and diazepam.

Conclusions

Kidney disease in pregnancy poses considerable risk to maternal as well as fetal health. Based on case series published over the last several decades, pregnancy outcome appears directly related to the level of baseline renal function and degree of hypertension. Because the kidney disorders discussed in this chapter are relatively uncommon, multicenter efforts are needed to better identify risks and determine optimal therapeutic strategies.

5   Chronic Kidney Disease, Chronic Renal Failure

30 Progression of Kidney Disease: Diagnosis and Management

Anil K. Agarwal, Nabil Haddad, & Lee A. Hebert

Department of Internal Medicine, The Ohio State University Medical Center, Columbus, USA

Introduction

Progression of kidney disease refers to irreversible loss of glomerular filtration rate (GFR) due to structural damage to the kidney. Progression to end-stage renal disease (ESRD) usually involves two mechanisms: those of the primary kidney disease, and those of "natural progression." The latter refers to a vicious cycle in which GFR loss begets more GFR loss. The vicious cycle is induced by the systemic hypertension, glomerular hyperperfusion, proteinuria, and systemic metabolic dysfunctions set in motion by nephron loss [1]. Details of the mechanisms of natural progression are discussed in chapter 3. This chapter focuses on therapies to slow natural progression [1–3], which should be used along with the therapies to treat the primary kidney disease. The goal is to preserve enough nephron function to avoid the vicious cycle of natural progression.

GFR loss and risk of natural progression

The threshold for natural progression attributable to GFR loss appears to be crossed when loss of nephron function exceeds 50%. For example, unilateral nephrectomy, as with living kidney donors, does not usually lead to natural progression [4]. However, partial nephrectomy of a solitary kidney does lead to natural progression [5]. A normal solitary kidney can be vulnerable to natural progression if it is congenital or acquired early in life [6] or if it is accompanied by hypertension, obesity, hyperlipidemia, or hyperglycemia [2–4,7]. A patient with a 50% loss of nephron function may also be vulnerable to natural progression if the nephron loss is the result of hypertension, as observed in black people [8] or as the result of glomerulonephritis (GN) [9]. The latter is suggested by scenarios in which the clinical manifestations of biopsy-proven severe acute

GN resolve, based on return of serum creatinine and proteinuria to near normal levels. Over the ensuing years, however, proteinuria increases, hypertension develops, and serum creatinine begins to rise. A repeat kidney biopsy shows complete resolution of the inflammatory GN, but it is replaced by a segmental sclerosing glomerulopathy [9]. This is now recognized as secondary focal and segmental glomerulosclerosis attributed to natural progression [10] (see chapter 13). These observations suggest that a 50% GFR loss in which the surviving glomeruli show diffuse segmental damage (e.g. resolved GN) carries a higher risk of natural progression than a 50% GFR loss in which the surviving nephrons are normal (e.g. unilateral nephrectomy in a live donor).

Proteinuria magnitude and risk of natural progression

In most chronic kidney diseases (CKDs), proteinuria magnitude is the single strongest risk factor for progression [2,3,11]. The threshold for natural progression attributable to proteinuria appears to be crossed when proteinuria exceeds 500 mg/day [12]. Nonselective proteinuria (large amounts of protein with molecular weights exceeding that of albumin) is mainly responsible for the natural progression attributed to proteinuria [2]. Indeed, highly selective proteinuria (when urine protein is almost entirely albumin) can persist in the nephrotic range for more than 10 years without causing structural damage to the kidney [13].

Monitoring kidney disease progression

Progression represents irreversible kidney damage. Generally it is not feasible to monitor the damage itself [14]. Instead, surrogate measures, especially changes in proteinuria and GFR, are used. In most CKD patients the first evidence of natural progression is a progressive increase in proteinuria. Only later does evidence of declining GFR appear [9]. Important exceptions are the nephropathy

of type 2 diabetes mellitus [15] and hypertensive nephrosclerosis in African Americans [16]. Under these conditions serum creatinine can increase to 2.0 mg/dL with only minimal proteinuria.

Monitoring proteinuria trends

Accurate monitoring of a patient's proteinuria trends is critically important to CKD management, because proteinuria magnitude predicts progression and therapy that reduces proteinuria slows progression [2,3,11]. The reason for these associations is that proteinuria is likely nephrotoxic, probably through multiple mechanisms [2]. The MDRD study and the REIN trial showed that for each 1.0-g/day reduction in proteinuria achieved by 4–6 months of therapy, subsequent GFR decline was slowed by 1–2 mL/min/year [2]. GFR loss in CKD usually occurs at about 4–10 mL/min/year [2,3]. Thus, each therapy-induced 1.0-g/day proteinuria reduction should substantially prolong time to onset of ESRD (Figure 30.1).

The recommended method for assessing proteinuria trends is from the urine protein/creatinine (P/C) ratio of intended 24-h urine collections [2,17]. The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines recommend the spot urine P/C ratio to monitor proteinuria trends [18]; however, the spot urine P/C ratio is reliable only for detecting large changes in 24-h proteinuria. For moderate proteinuria changes (e.g. 0.5–3.0 g/day) a more reliable measure is the P/C ratio of intended 24-h urine collections that are 50% or more complete based on creatinine content [19].

Once it is established that the proteinuria is glomerular in origin (i.e. most of the protein is albumin), it is acceptable to monitor proteinuria trends by measuring urine total protein rather than urine albumin. The two measures are highly correlated, and measuring urine total protein is less expensive than measuring urine albumin [20].

Monitoring GFR trends

In individual patients, it is usually sufficient to monitor GFR trends by measuring serum creatinine serially. However, if the serum creatinine level changes, one must keep in mind the conditions that can increase serum creatinine by increasing creatinine production (eating cooked meat, creatine ingestion, increased exercise, or increased muscle mass) or can decrease creatinine production (vegetarian diet, muscle wasting, or decreased exercise) [2]. If a chronic change in creatinine production is occurring (e.g. muscle wasting), GFR trends can be monitored by measuring serial 24-h urine creatinine clearance, which is not affected by changes in creatinine production. If creatinine clearance is used, an accurate 24-h collection is essential [2].

The MDRD-4 equation is now widely used to monitor GFR trends in individual patients. Its strengths are its simplicity (the required variables are age, sex, race, and serum creatinine), accuracy in many CKD patients, and the ability to take into account the influence of age. The latter is important in assessing a patient's GFR trend over 10 years or more [21]. MDRD-4 shortcomings include inaccuracy in K/DOQI CKD stages 1 and 2, which includes the majority of CKD patients [18]. As discussed above, in these patients, trends in GFR can be inferred from serial measurement of serum creatinine, ideally expressed to the second decimal point (in milligrams per deciliter) or the nearest whole number (in micromoles per liter). MDRD-4 is also inaccurate in those with high-normal creatinine production (GFR is underestimated) or low-normal creatinine production (GFR is overestimated) [22]. The Cockroft-Gault equation takes into account body weight and its effect on creatinine clearance. However, in general, the Cockroft-Gault and MDRD-4 equations provide similar estimates of GFR, especially in the mid-range of estimated GFR values [21]. Nevertheless, MDRD-4 is easier for clinical laboratories to implement
Figure 30.1 Average rate of GFR decline due to aging (top curve) in comparison to hypothetical patients each with onset of a progressive kidney disease at age 25 years but with different rates of GFR decline superimposed on the GFR decline of aging (left panel, men; right panel, women). Note that small differences in the GFR decline rate can result in large differences in time to onset of ESRD. The top curves are adapted from Stevens [21] with permission.

because its calculation does not require body weight. The role of cystatin C in monitoring GFR trends remains to be established [23,24].

Therapy of natural progression

Because of the gravity of ESRD and the benefit of even small decreases in CKD progression rate (Figure 30.1), a strong argument can be made for the general use of an aggressive, multiple risk factor intervention involving both the therapies that are of proven benefit and those that are of plausible benefit but considered prudent to use [1–3]. However, we do not recommend an aggressive approach in those with kidney conditions with low ESRD risk. These patients include those with steroid-responsive minimal change disease, a solitary kidney that is normal, was acquired in adulthood, and not accompanied by other CKD risk factors, hereditary nephritis, or thin glomerular basement membrane disease in a normotensive adult whose only renal manifestation is microscopic hematuria or in an elderly patient with idiopathic and moderately elevated serum creatinine (1.30–2.00 mg/dL) and minor proteinuria (24-h urine P/C ratio of <1.0) and whose renal parameters have been stable for at least 1 year. The latter group is much more likely to die of cardiovascular disease (CVD) than progress to ESRD [25,26].

Described next are the recommended therapies, listed according to level of recommendation. A level 1 (highest) recommendation is based on one or more large randomized clinical trials (RCTs) that have documented effects on GFR decline. Level 2 recommendations are based on secondary analyses of the level 1 RCTs, or on RCTs that have documented effects on proteinuria but not GFR decline, or that appear to be of high quality but may not be definitive because therapy involved a relatively small number of patients.

The goals of progression therapy are 1) to reduce proteinuria as much as possible, ideally to <500 mg/day, which appears to approach the maximum benefit of proteinuria reduction [12], and 2) to slow GFR decline as much as possible, ideally to about 1 ml/min/year, which is the rate of GFR decline attributable to aging [21] (Figure 30.1).

Level 1 recommendations to slow natural progression
Recommendation 1: Control blood pressure
The "low BP goal" is recommended [2,3,18,27–29]. Based on the relevant RCTs, we suggest a sitting systolic blood pressure (BP) in the 120s or less, if tolerated [2,3]. The qualification "or less, if tolerated" is based on the evidence that "optimal" BP (systolic BP of <120 mmHg) is associated with significantly lower CVD risk than "normal" BP (systolic BP of 120–129 mmHg) [30], and there is no convincing evidence that systolic BP of <120 mmHg is harmful to CKD function [12,29]. Sitting is the recommended position for measuring BP, because it is the position that was used in the relevant RCTs. Systolic BP is the recommended goal because in the relevant RCTs, achieved systolic BP strongly correlated with GFR decline but achieved diastolic BP did not [2,31]. Specifying a goal with both a systolic and diastolic BP component

is not recommended. It can be confusing to the physician and the patient and can lead to overtreatment [32]. For example, under current guidelines [18], a CKD patient with BP of 108/86 mmHg would require more antihypertensive therapy. However, the "optimal" systolic BP likely places the patient at low CV and renal risk, and the modestly increased diastolic BP (isolated diastolic hypertension) likely represents an artifact, particularly in white hypertensive patients [32].

The greater the proteinuria the greater the benefit of the low BP goal in slowing GFR decline [2,3]. In addition, in CKD patients with low-level proteinuria, the low BP goal slows the progression of proteinuria from low levels to high levels more than the usual BP goal (135/85 mmHg) and likely reduces CVD risk more than the usual BP goal [2,3]. Thus, the low BP goal can also be recommended in those with low-level proteinuria, even though the current guidelines do not recommend that [18,27].

Home BP monitoring is recommended to assess whether the patient is achieving the BP goal [33]. Treating nocturnal hypertension, assessed by ambulatory BP monitoring, may also provide benefit [34]. An evidence-based and experienced-based algorithm for BP control is shown in Figure 30.2. The low BP goal should be achieved early in the course of CKD. Delay in achieving the low BP goal increases the risk for progression to ESRD [28]. If the systolic BP is 20 mmHg or more above goal, generally two or more antihypertensive agents will be needed to bring the blood pressure to goal [18].

Recommendation 2: ACE inhibitor
The drug class of angiotensin converting enzyme inhibitors (ACEi) is recommended as first-line therapy in all CKD patients [1,2]. It has been suggested, however, that a diuretic should be first-line therapy for CKD in those with low-level proteinuria [18,35]. This recommendation is based on the ALLHAT study [35]. However, ALLHAT's protocol did not use ACEi optimally (with diuretic, if needed). As a consequence ALLHAT's design may have biased the outcome in favor of diuretics, particularly at the expense of ACEi [36]. Also, a diuretic as monotherapy may induce metabolic dysfunctions that include hypokalemia, hyperglycemia, hyperuricemia, and stimulation of the renin–angiotensin–aldosterone system [2,3,36]. However, if the diuretic is used along with an ACEi (or angiotensin II receptor blocker [ARB]), most of the metabolic dysfunctions that have been associated with diuretic use in observational studies and which are felt to increase CVD risk appear to be largely mitigated [36,37].

Although both ACEi and ARB are kidney protective [2], ACEi is the first choice because it is not clear if ARB are cardioprotective to the level of ACEi [2,38–41]. ACEi should be used even if the patient is not clinically hypertensive [2,12]. Measures that may increase ACEi kidney protection include a low-salt and reduced-protein diet [2], diuretic therapy [2,42], the low BP goal [2,3], and statin therapy [2]. ACEi are antiproteinuric even in inflammatory glomerulonephritis [2]. ACEi should be continued even though GFR declines to stage 4 CKD (15–29 mL/min/1.73 m^2) [43]. To prevent hyperkalemia, dietary potassium restriction and

Algorithm 1. Initial antihypertensive therapy[a]

> Begin low-dose ACEI, even if BP is at goal.
> Low dose is the pharmaceutical company's recommended starting dose. Use angiotensin receptor blocker (ARB) if ACEI intolerant.

↓

If BP not at goal after 2–4 weeks

↓

> Titrate ACEI dose upward.
> Begin at moderate dose (2 to 4 times the recommended starting dose). If BP not at goal, increase to maximum recommended dose if tolerated.

↓

If BP not at goal after 2–4 weeks

↓

> Add diuretic therapy [b]

↓

If not at goal after 2–4 weeks

↓

> Add ARB therapy.
> Begin at recommended starting dose. If BP not at goal, titrate to maximum recommended dose.

↓

If BP not at goal after 2–4 weeks

↓

> Reassess the following:
> - BP measuring technique and equipment
> - Medication adherence
> - Diet adherence: measure 24-hr urine Na (or Cl if taking sodium bicarbonate)

↓

> If assessment does not lead to achieving the BP goal, go to Algorithm 2 or consider adding an aldosterone antagonist, particularly if the serum potassium is normal and the plasma aldosterone level has not been suppressed to the lower limits of normal.

[a] Assumes nonpharmacologic therapy to control BP is in place (see text) and that the patient does not have renovascular hypertension, congestive heart failure, ischemic heart disease, or hypertensive urgency. The above approach focuses on BP control in proteinuric nephropathies, but is also appropriate for nephrosclerosis, polycystic kidney disease, and interstitial nephropathies.

[b] The suggestion to add diuretic before ARB is arbitrary but can be justified by the evidence that diuretic increases the antihypertensive effect of angiotensin-converting-enzyme inhibitor (ACE inhibitor), is often needed in chronic kidney disease (CKD) to control fluid retention, is inexpensive, and may increase the renoprotective effects of ACE inhibitor, angiotensin receptor blocker (ARB), or the combination [57]. Emphasize salt restriction in autosomal dominant polycystic kidney disease (ADPKD) rather than diuretic therapy, which may promote cyst growth [3]. Details of diuretic therapy are discussed previously [3].

Figure 30.2 Antihypertensive regimens in CKD

Algorithm 2. Recommended therapy if Algorithm 1 fails to control BP.

Suggested regimen, in order of preference:
1. ACEI + ARB + diuretic + beta blocker
2. ACEI + ARB + diuretic + nondihydropyridine calcium channel blocker (NDH-CCB)[a]
3. ACEI + ARB + diuretic + clonidine[b]
4. ACEI + ARB + diuretic + alpha−1 blocker

Note: If serum potassium is normal, consider adding an aldosterone antagonist, particularly if the plasma aldosterone level has not been suppressed to the lower limits of normal by the current therapy.

If BP not at goal after 2–4 weeks

Reassess the following:
- BP measuring technique and equipment
- Medication adherence
- Diet adherence: measure 24-hr urine Na (or Cl if taking sodium bicarbonate)

If assessment does not lead to achieving BP goal

24-hour Ambulatory Blood Pressure Monitoring; if sustained hypertension documented then investigate for secondary cause of hypertension, particularly renal artery stenosis and primary hyperaldosteronism.

If BP remains above goal

Intensify therapy, usually starting with an increase in diuretic dose

If BP not at goal after 2–4 weeks

Suggested regimen, in order of preference:
1. ACEI + ARB + diuretic + NDH-CCB + DH-CCB
2. ACEI + ARB + diuretic + beta blocker + DH-CCB
3. ACEI + ARB + diuretic + beta blocker + minoxidil
4. ACEI + ARB + diuretic + beta blocker + alpha−1blocker
5. ACEI + ARB + diuretic + beta blocker + clonidine[c]

[a]Diltiazem and verapamil sustained release preparations are recommended.

[b]Clonidine recommended for individuals receiving insulin, because it does not importantly affect glucoregulation, and for those who have difficulty with beta blocker (eg., bronchospasm, cardiac conduction).

[c]Beta blocker/clonidine combination is usually well tolerated, but may cause bradycardia.

Figure 30.2 (*Continued,*)

the concomitant use of furosemide and sodium bicarbonate may be indicated [44].

The benefits of ACEi appear to be shared by all ACEi [2,45]. The longer-acting ACEi are preferred over captopril [38,44]. Advancing the ACEi dose to tolerance increases its antiproteinuric effect [2] and decreases the likelihood of aldosterone escape (increasing plasma aldosterone levels during stable ACEi therapy), which could in turn diminish the ACEi renoprotection [46].

A recent meta-analysis suggested that ACEi may not have kidney-protective effects apart from BP control [47]. However, that analysis included the ALLHAT study, which did not use ACEi optimally, and 126 other RCTs of varying sizes, many of which may not have had the same methodologic rigor of the large RCTs discussed above. Also, a recent retrospective analysis of ACEi use in diabetic patients suggested more rapid progression in those receiving ACEi than those not receiving ACEi [48]. However, that study lacked BP measures and contradicted the long-term results of trials of diabetic nephropathy [49,50].

Recommendation 3: ARB therapy

ARB are kidney protective in the nephropathy of type 2 diabetes and likely in other nephropathies as well [2]. ARB are recommended as first-line therapy in those who are ACEi intolerant (with cough, angioedema, or allergy). In CKD, ARB may raise serum potassium less than ACEi [2], perhaps because in usual doses ARB do not suppress aldosterone as much as ACEi [51]. The highest tolerated ARB dose is recommended because it is the most antiproteinuric [52,53] and more likely to result in regression of left ventricular hypertrophy [54] than usual ARB doses. ARB may be especially effective in those who are homozygous for deletion of the ACE gene (DD genotype) [55].

Recommendation 4: Combination ACEi and ARB

The combination of the ACEi and ARB classes of medications is more antiproteinuric [56] and slows progression better than either drug alone [57]. Combination therapy generally improves BP control [58,59], although the effect may not be large [58]. Combination ACEi and ARB is recommended as the next step if the CKD patient fails to achieve the BP and proteinuria goals after 2 months of ACEi-plus-diuretic therapy (Figure 30.2). Diuretic therapy may increase the renoprotective effects of combination ACEi and ARB therapy [57].

An alternative to adding an ARB to ACEi-plus-diuretic therapy is the addition of a nondihydropyridine calcium channel blocker (NDHCCB; verapamil or cardiazem) [60–62].

Recommendation 5: Avoid dihydropyridine calcium blockers unless needed for BP control

Generally, the dihydropyridine CCB (DHCCB) amlodipine lowers BP better than an ACEi or a beta blocker; however, in those with hypertensive nephrosclerosis, it can lead to accelerated GFR decline and an increased risk of the composite end point of doubling of serum creatinine, ESRD, or death [2]. There are other lines of evidence that DHCCB are not kidney protective [2]. However,

the clearest evidence has come from the recent REIN-2 trial [31], in which nondiabetic proteinuric renal disease patients receiving ramipril were randomized to the usual or the low BP goal. DHCCB (felodipine) was used to achieve the low BP goal. Despite achieving the low BP goal, the DHCCB group did not experience slower GFR decline or proteinuria reduction compared to those maintained at the usual BP goal. This suggests that the DHCCB group had sustained glomerular hypertension, despite concomitant ramipril therapy and despite achieving the low BP goal [44,60,61]. It is likely the DHCCB provided cardiovascular protection because it lowered systemic BP. Its addition to ramipril did not, however, provide additional kidney protection (proteinuria reduction or slowed GFR decline) beyond that achieved with the baseline dose of ramipril in this study. For alternatives to DHCCB that should provide systemic BP control and kidney protection, see recommended therapies 2–4, 7–12, and 15 in the context of the algorithm shown in Figure 30.2. Further insight into the kidney-protective effects of the combination ACEi plus DHCCB should be forthcoming from the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial [63].

Recommendation 6: Control protein intake

Reducing dietary protein intake from the usual level (about 1–1.5 g/kg of ideal body weight/day) to about 0.7 g/kg ideal body weight/day (low-protein diet) slows GFR decline in those with proteinuria of >1 g/day [2]. A further benefit of the lower protein intake is that it slows proteinuria progression in CKD, even in those who at baseline have low-level proteinuria (e.g. <250 mg/day) [2]. Soy proteins may be less proteinuric than animal proteins [2,64]. Dietary protein intake should be monitored periodically, for example, every 4–6 months, by urine urea excretion in 24-h urine collections [2,17]. Monitoring urine protein intake is particularly important in those who are not achieving their proteinuria goal. CKD patients who are men or who have glomerular disease may particularly benefit from the low-protein diet [65].

Level 2 recommendations to slow natural progression

Recommendation 7: Restrict NaCl intake, diuretic therapy

A high salt intake (e.g. 200 mmol NaCl/day; 4.6 g sodium) can completely override the antiproteinuria effects of ACEi, ARB, or NDHCCB therapy [2,66]. The recommended NaCl intake in CKD (assuming that renal salt wasting is not present) is about 80–120 mmol/day (2 to 3 g Na). The NaCl intake of the average North American adult is about 170 mmol/day (3.9 g Na). Salt intake should be monitored periodically (e.g. every 4–6 months) by 24-h urine collection [2,17]. The monitoring of 24-h urine sodium content is particularly important in those not achieving the BP or proteinuria goal. In patients receiving $NaHCO_3$ therapy, urine chloride rather than sodium should be monitored. Concomitant KCl therapy needs to be taken into account in assessing NaCl intake in such patients [2]. Diuretic therapy improves BP control and proteinuria reduction in those receiving ACEi or ARB [2,42,57]. Nevertheless, the ideal treatment may be to avoid use of a diuretic,

if possible, because of multiple metabolic dysfunctions [41]. These metabolic dysfunctions, however, may be mitigated by concomitant ACEi–ARB therapy. Note that 40% of the AASK and 60% of the MDRD patients did not receive a diuretic, and they generally achieved their BP goals [2].

Recommendation 8: Control fluid intake

A retrospective analysis of MDRD Study A showed that urine volumes exceeding 2 L/day were associated with faster GFR decline, especially in polycystic kidney disease patients [67]. The patients with the higher urine volumes showed higher BP, lower serum sodium, and frankly hypotonic urine, suggesting that they were "pushing fluids." It is not uncommon that CKD patients are advised to increase fluid intake [68]. However, in patients with CKD there is no evidence of benefit, and it may cause harm based on data from both the MDRD [67] and AASK [69] studies.

Recommendation 9: NDHCCB therapy

The class of NDHCCB drugs, which includes diltiazem and verapamil, is antiproteinuric and may be renoprotective [2,60–63]. NDHCCB used together with a DHCCB is a potent antihypertensive combination when used along with other antihypertensive therapies. It can be recommended in CKD patients with poorly controlled hypertension that is resistant to the usual measures [2].

Recommendation 10: Control each component of metabolic syndrome

The metabolic syndrome is defined as any three of the following conditions [70,71]:

1 BP of ≥135/85 mmHg or BP requiring therapy for hypertension

2 Fasting blood glucose of >110 mg/dL, or treatment for hyperglycemia

3 Serum high-density lipoprotein cholesterol of <40 mg/dL for men or <50 mg/dL for women

4 Serum triglycerides of ≥150 mg/dL or drug therapy needed to control hypertriglyceridemia

5 Waist circumference of >40 in. (102 cm) in men or above 35 in. (88 cm) in women.

Each component of the metabolic syndrome has been found to be a risk factor for CKD progression. Also, the prevalence of microalbuminuria and CKD increases proportionately with the number of components of the metabolic syndrome that are present in a given patient [71].

Obesity increases the risk of CKD and is associated with glomerulomegaly, focal and segmental glomerulosclerosis, and proteinuria, which can be progressive [2]. Reducing even moderate obesity can reduce proteinuria [2]. In a randomized trial in moderately obese CKD patients (mean body mass index, 32; mean proteinuria, 2.8 g/day) a 4% decrease in body weight over 5 months reduced proteinuria by 31% [2].

With regard to statins, there have been numerous trials showing that statins have antiproteinuric effects and appear to be kidney protective. However, it is widely believed that the definitive trial has

not been done [72]. This is discussed in greater detail in chapter 32. However, in progress is the SHARP trial, in which CKD patients are being randomized to placebo or combined simvastatin–ezetimibe therapy [72].

With respect to kidney protection by fibrates, gemfibrozil does not appear to slow progression of CKD [73]. However, fenofibrate has an antiproteinuric effect in diabetic humans and animal models [74]. This drug, however, causes an increase in serum creatinine in CKD patients. The mechanism is unclear. It has been suggested that fenofibrate is nephrotoxic or that it increases creatinine production. However, our recent analysis of 13 fenofibrate-treated patients followed for up to 5 years did not find evidence for either of those mechanisms. Indeed, although serum creatinine increased acutely during follow-up, when the fenofibrate was discontinued, the serum creatinine returned to or below baseline, which is remarkable because each patient previously showed evidence of progression [75].

Some authors advise against the routine use of lipid-lowering therapy in CKD because of lack of proof of a kidney-protective effect [72]. We suggest, however, that given the clear evidence that CKD itself is a CVD risk factor and that there is substantial evidence that statins are antiproteinuric and kidney protective by means of their lipid-lowering effect or anti-inflammatory, antithrombotic, "pleiotropic" effects [76–78], a strong argument can be made for the routine use of lipid-lowering therapy in CKD with a goal of reducing low-density lipoprotein cholesterol to <100 mg/dL and raising high-density lipoprotein cholesterol as much as feasible [2,3]. With regard to statin dose, in general, high-dose statin therapy shows better cardiovascular protection than low-dose therapy (typical starting dose of statins) [79] and generally is as well-tolerated as the low doses [80]. A complete discussion of this topic is found in chapter 32.

Recommendation 11: Aldosterone antagonists

Spironolactone and the more selective aldosterone antagonist eplerenone have substantial antihypertensive [81], cardioprotective [2], and antiproteinuric effects even when administered in low doses and in the presence of ACEi therapy [46,82]. The mechanism is not clear. However, it could involve effects of aldosterone blockade on the endothelium and the profibrotic effects of aldosterone [46]. If these drugs are used in combination with an ACEi or ARB, careful monitoring to avoid hyperkalemia is in order. Spironolactone may increase the risk of upper gastrointestinal bleeding [83].

Recommendation 12: Beta blocker therapy

The AASK study showed that beta blocker therapy is more antiproteinuric and slows GFR decline better than amlodipine [2]. However, beta blockers increase the likelihood of diabetes and, as monotherapy or combined with a diuretic, increase the mortality rate of hypertension management compared to ACEi plus a diuretic [84]. Thus, beta blockers should be avoided in CKD unless required to manage heart disease [85]. Carvedilol, however, may be better tolerated [86].

Recommendation 13: Smoking cessation

There is strong epidemiologic evidence that cigarette smoking promotes progression of all forms of kidney disease and that this effect may be of greater magnitude in African Americans [2]. Also, cigarette smoking combined with obesity increases CVD mortality by 6- to 11-fold [87].

Recommendation 14: Correct severe anemia

Correction of anemia by erythropoietin-stimulating agents (ESAs) has the potential to slow progression of CKD by multiple mechanisms, including mitigation of renal hypoxia and increasing the antioxidant activity of blood [88]. Erythropoietin can prevent apoptosis of cells by altering cell signaling pathways [89]. Additionally, erythropoietin inhibits proinflammatory cytokines and has a protective effect on endothelial cells [90,91].

Low hematocrit has been shown to be an independent predictor of progression of nephropathy in type 1 diabetes mellitus [92], type 2 diabetes mellitus [93], and nondiabetic renal disease [94–96]. Lower hematocrit is linked, in a linear fashion, to development of ESRD [97–99]. ESA treatment of CKD anemia in observational studies is associated with slowing of GFR decline, especially in nondiabetic CKD patients [100–104]. In a small RCT involving ESA treatment of anemic nondiabetic CKD patients, the ESA showed a 60% reduction in death or the need for renal replacement in patients in the early treatment arm [105].

Recently, the Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) study, which used erythropoietin alpha therapy in 1432 CKD patients randomized to either a high hemoglobin goal (13.5 g/dL) or a low hemoglobin goal (11.3 g/dL) was stopped prematurely because of increased CV events in the patients assigned to the high hemoglobin goal group. The Cardiovascular Reduction Early Anemia Treatment with Epoetin Beta (CREATE) study randomized 603 anemic CKD patients in an open-label fashion to receive epoetin beta to achieve target hemoglobin levels of 13–15 or 10.5–11.5 g/dL. During the 3-year follow-up, the primary end point of a composite of eight CV events was not significantly different between the two groups. The estimated GFR decline was similar, although dialysis was required in more patients in the high hemoglobin target group. Still ongoing in Europe and North America is the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT) study. This double-blind, randomized, placebo-controlled study has enrolled 4000 diabetic patients with nephropathy to assess the effect of anemia correction on CV and renal outcomes.

Until the results of the TREAT study become fully available, treatment of anemia in CKD can be recommended if the hemoglobin level is <9.0 g/dL, because of the documented improvement in quality of life. The recent update of the K/DOQI anemia recommendations suggests a target hemoglobin of 11–12 g/dL that should not exceed 13 g/dL [106]. A more complete discussion of this topic is found in chapter 31.

Recommendation 15: Control elevated uric acid levels

In a placebo-controlled, randomized trial, allopurinol therapy resulted in a 40% lesser increase in serum creatinine over 1 year of follow-up and improved BP control (∼13-mmHg-lower systolic BP) [107]. The mechanisms may involve inhibition of uric acid effects that induce arteriopathy, which may induce CV and kidney disease [108].

Recommendation 16: Renin inhibition

Aleskiren, a direct renin inhibitor, is antiproteinuric, appears to be kidney protective alone or in combination with ARB, and is well-tolerated [109,110]. Its role in kidney protection remains to be established.

Other measures to consider to slow CKD progression

It should be noted that the strength of the evidence for the application of the following for slowing progression of CKD is not as strong as data for BP control, proteinuria control, and renin–angiotensin–aldosterone system blockade.

• Avoid multiple daily doses of acetaminophen, particularly in women, because of the evidence that it is significantly associated with rising serum creatinine during prolonged follow-up [111]
• Avoid nonsteroidal anti-inflammatory drugs altogether, or at most take them no more than once or twice weekly, because of their known nephrotoxicity [2]; daily low-dose (baby) aspirin, however, appears to provide net benefit in CKD [112]
• Avoid herbal therapy unless the safety of the herb has been proved; many herbal products appear to be nephrotoxic [113]
• Avoid prolonged severe hypokalemia because it can cause progressive renal interstitial fibrosis [2]
• $NaHCO_3$ to correct metabolic acidosis should be considered because of its anticatabolic effects [2]. Also, the nephrotoxicity of nonselective proteinuria appears to be strongly related to activation of the alternative complement pathway in the renal tubular compartment [2,114]. $NaHCO_3$ inhibits this process by raising tubular fluid pH [2]
• Control hyperphosphatemia and hyperparathyroidism; in animal models and in human studies, controlling hyperphosphatemia slows CKD progression. Also, active 1,25-(OH)-vitamin D therapy, which has effects on calcium, phosphorus, and parathyroid hormone, was found to be potentially antiproteinuric (dipstick protein) in CKD in one post hoc analysis of an RCT, and by this mechanism it might be kidney protective [115].

31 Treatment of Anemia in Chronic Kidney Disease, Stages 3–5

Robert N. Foley

Chronic Disease Research Group, Minneapolis, USA

Introduction

Anemia is common in chronic kidney disease (CKD), and a dose-dependent relationship exists between the severities of both conditions. Recombinant technology has revolutionized the therapy of anemia in CKD, and many controlled trials, primarily examining hemoglobin targets and how to achieve these targets, have been performed. For many other components of anemia management, clinical precedent, opinion, and observational studies have been the foundation for treatment.

Evaluation of anemia in CKD

Anemia is virtually the rule in late-stage CKD, irrespective of the underlying primary disease process [1]. Although anemia is often multifactorial, erythropoietin deficiency and resistance are thought to be major contributing factors, and most guidelines are primarily based upon these beliefs. This being said, it is vital that other potential causes be considered when treating anemia in CKD. As the differential diagnosis of anemia can be extremely wide, most guidelines take a pragmatic approach and clearly cannot replace expert hematological opinion with regard to identifying other contributing or exacerbating factors. Hints that anemia is caused by conditions other than CKD include anemia severity that is not commensurate with the level of kidney function, iron deficiency, and the presence of leukopenia or thrombocytopenia.

Few clinical trials have been performed to test the effectiveness of different anemia evaluation strategies in CKD populations. Several national guidelines suggest that glomerular filtration rates (GFRs) of less than 60 mL/min/1.73 m^2 should stimulate a search for anemia. It is likely that this opinion is based on experience from referral populations, and the utility of this approach in other

settings is unknown. Typical guidelines for initial assessment of anemia are as follows [2]:

• Complete blood counts, including hemoglobin concentration, mean corpuscular hemoglobin, mean corpuscular volume, mean corpuscular hemoglobin concentration, white blood cell count (and differential), and platelet count
• Absolute reticulocyte count
• Serum ferritin to assess iron stores
• Serum transferrin saturation (or reticulocyte hemoglobin content or percent hypochromic red cells, where available) to gauge the adequacy of iron available for erythropoiesis

Fluid retention and expansion of extracellular fluid volume are typical features of advancing kidney disease, and hemodilution can affect hemoglobin concentrations. Hence, in patients receiving hemodialysis, interdialytic fluid shifts need to be considered when evaluating hemoglobin levels. Several guidelines recommend that hemoglobin levels be measured before dialysis, midweek, partly reflecting the fact that virtually all the observational and trial data are based on this parameter [2].

Serum ferritin is the main marker of storage iron in common use. Several tests for assessing the adequacy of iron availability for erythropoiesis are available, such as transferrin saturation, percent hypochromic red blood cells, and reticulocyte hemoglobin content. In practice, only the first of these tests, iron availability, is in routine clinical use.

Several definitions of anemia have been used in national guidelines for CKD anemia management. For example, the US National Kidney Foundation Disease Outcomes Quality Initiative (K/DOQI) guidelines recommend a minimum frequency of hemoglobin testing of once per year in all patients known to have CKD, irrespective of disease severity [2]. Unfortunately, no controlled studies are available to guide the optimum frequency for anemia testing.

In the K/DOQI guidelines, anemia was defined as hemoglobin values of <13.5 g/dL in adult men and 12.5 g/dL in women [2]. The relationship between hemoglobin and estimated GFR (eGFR) was investigated in the National Health and Nutrition and Examination Survey III (NHANES III), a cross-sectional survey of

nutritional and health status in 15,419 individuals approximately randomly selected from the general US population [3,4]. This survey showed that hemoglobin levels declined when GFR fell below 75 mL/min/1.73 m^2 in men and 45 mL/min/1.73 m^2 in women. As expected, the prevalence of anemia depended heavily on the hemoglobin levels used to define it. For example, when hemoglobin levels of less than 13 g/dL were used to define anemia, a relationship with eGFR became apparent below 60 mL/min/1.73 m^2 in men and 45 mL/min/1.73 m^2 in women. For hemoglobin levels less than 11, a relationship with GFR was not apparent until eGFR values fall below 30 mL/min/1.73 m^2, with no apparent gender differences. It is likely that the prevalence of anemia is much higher in populations referred for specialist nephrology care [5,6]. In addition, studies from referral populations suggest that patients with diabetes mellitus develop anemia at higher eGFR levels and sooner than otherwise expected [7–12].

The relationship between serum ferritin and hemoglobin levels has also been studied in general population settings. In subjects with CKD, abnormally low hemoglobin levels are not apparent until ferritin levels fall below 25 ng/mL in men or 11 ng/mL in women, closely paralleling findings in the general population without overt kidney disease [13]. In patients on maintenance hemodialysis, the association profile between ferritin and hemoglobin is less straightforward, in part because inflammation is so common (with high ferritin levels acting as an acute phase reactant). In the latter group, while low ferritin levels imply deficient iron stores, high levels do not exclude this possibility. The association between transferrin saturation and hemoglobin appears to be continuous and approximately linear in nature [13]. In other words, no single threshold value for transferrin saturation appears to discriminate anemic from nonanemic hemoglobin values.

Hemoglobin targets in CKD

Hemoglobin target trials suffer from all the limitations of randomized trial designs, including cost, use of selected populations, and problems with generalizability of trial results to latter-day patients, because time must elapse before sufficient outcomes can be accumulated to identify between-group differences. Hemoglobin target trials also have limitations that are not present with typical placebo-controlled trials in which the experimental intervention is not defined by physiological variables, like hemoglobin. Most hemoglobin target trials suffer from this unattractive design feature, in that they randomly assign subjects to hemoglobin targets and not to treatments; in contrast, the anemia treatment is typically not part of the experimental design. In these trials, therefore, one is left in a situation where the main treatment is a co-intervention. This leads to the unfortunate possibility that hemoglobin target trials may not be completely comparable, because anemia treatment becomes a variable that is outside the control of the experimental design. Although this may be unavoidable, it is unfortunate because it becomes difficult to decide whether differences in out-

comes in different trials reflect differences in hemoglobin targets or in the methods used to achieve these targets.

Another typical trial strategy involves studying patients with declining hemoglobin levels; one group is randomly assigned to receive anemia treatment to maintain current hemoglobin levels ("now"), while hemoglobin levels are allowed to continue to decline in the other group until they reach a predefined low value which triggers salvage treatment ("later"). The later arm differs in several ways from the early intervention arm, including hemoglobin level at which treatment is instituted, severity of kidney disease at which treatment is instituted, and era of time. Critically, none of these variables is completely controlled by the experimental process, so that the nature of the intervention, by design, is allowed to vary from patient to patient.

In summary, although experimental designs appear to be the best way forward, target hemoglobin trials may have unique limitations not shared by other trials.

Many trials of hemoglobin targets, or erythropoiesis-stimulating agent (ESA) dose, have included death, cardiovascular events, left ventricular size, quality of life, and rates of loss of kidney function as outcomes [14–38]. Table 31.1 summarizes major findings from those studies with 100 or more subjects and at least 6 months of follow-up. When one examines these trials, a noteworthy overall finding is the heterogeneous nature of hemoglobin target effects, with the possible exception of quality of life, and even that outcome is not entirely homogenous in direction. Another notable feature of Table 31.1 is that most of the larger recent trials have compared intermediate to high targets, without an untreated (or placebo or low hemoglobin) arm. Lack of no-treatment arms naturally generates a degree of caution. For example, showing that intermediate and high target hemoglobin levels have similar treatment effects cannot refute the hypothesis that the effects of low targets are intrinsically different from those of intermediate and high targets. This situation is somewhat clearer for quality of life assessments, because initial trials included untreated arms and an earlier generation of trials showed superiority of treatment with respect to quality of life [23].

Mortality and major cardiovascular events

Many of the studies reported to date have been underpowered to detect differences in major outcomes like death and cardiovascular events. The US Normal Hematocrit Study and the Correction of Hemoglobin and Outcomes in Renal Insufficiency trial are the most obvious exceptions [14,31]. The first of these studies examined hemodialysis patients with symptomatic cardiac disease. The finding that patients assigned to the higher hemoglobin target of 14 g/dL had increased rates of the primary outcome (death or nonfatal myocardial infarction) did not reach statistical significance when the multiple interim analyses used in the trial were considered. In the second of these trials, involving patients with CKD not on dialysis, neither futility nor efficacy boundaries were crossed at the time the study was terminated early. When all events were subsequently examined, increased rates of the primary outcome variable were observed with the higher hemoglobin target.

Table 31.1 Major findings from randomized trials with at least 100 subjects and 6 months of follow-up, reporting on death, cardiovascular events, left ventricular size, quality of life, or rates of change of renal function.

Abbreviations: ND, nondialysis; HD, hemodialysis; PD, peritoneal dialysis; EPO, epoetin; Hgb, hemoglobin; CESG, Canadian Erythropoietin Study Group; CVA, cerebrovascular accident; LVH, left ventricular hypertrophy; LVD, left ventricular dilation; URR, urea reduction ratio; QoL, quality of life.

a Among the studies, Hgb levels were reported in many ways; values reported here (in grams per deciliter) are indicative.

b An asterisk denotes the primary outcome. ↑, better or higher; ↔, equivalent; ↓ worse or lower.

c The primary end point was a composite of death, myocardial infarction, hospitalization for congestive heart failure (without renal replacement therapy), and stroke. The study was terminated early, even though futility and efficacy boundaries had not been reached. When further events were considered, primary outcome rates were higher in the high target group.

d The primary outcome was a composite of death or nonfatal myocardial infarction.

e The primary efficacy end point was a composite for first cardiovascular event, including sudden death, myocardial infarction, acute heart failure, stroke, transient ischemic attack, angina pectoris, peripheral vascular disease with amputation or necrosis, or cardiac arrhythmia.

f Even though rates of loss of GFR were identical, patients in the high target group had higher rates of need for dialysis.

g The sample included hemodialysis, peritoneal dialysis, and nondialysis CKD patients. A total of 70% were on hemodialysis.

h Criterion added during the progress of the trial, in response to the findings of the US Normal Hematocrit Study [13].

The latter trial had some issues that could potentially threaten validity and generalizability, not the least of which were the use of an initial dose of ESA far larger than typical for a population with non-dialysis CKD and a large rate of unexpected dropouts. In another trial of hemodialysis patients without symptomatic heart disease or dilated left ventricles, the 13.5–14.5 g/dL group had unexpectedly higher rates of cerebrovascular events compared to the control arm (9.5–11.5 g/dL). This latter trial showed no differences in the rates of other cardiovascular events or death [17].

Left ventricle size

There is little evidence for the widely held belief that partial treatment of anemia improves left ventricular hypertrophy in CKD patients. In fact, the controlled evidence for this belief appears to have come from three trials that involved approximately 50 patients [27,34]. As shown in Table 31.1, most of the evidence has been generated from trials of intermediate or high targets and, so far, the available evidence suggests neutral effects.

Quality of life

Most, but not all, studies have shown that higher hemoglobin targets improve quality of life in patients with CKD. These effects have been most obvious in the domains of vitality and fatigue and have been seen with hemoglobin targets up to 15 g/dL and achieved hemoglobin values up to approximately 13 g/dL (Table 31.1).

Hemodialysis access

Some studies have shown that higher hemoglobin targets lead to higher rates of vascular access problems in hemodialysis patients. These effects have been less obvious in recent trials that have excluded hemodialysis patients with ongoing vascular access problems. For example, in the US Normal Hematocrit Study, vascular access thrombosis rates were approximately one-third higher in the higher hemoglobin group [14].

Blood pressure

Several of the trials reported to date have shown that higher hemoglobin targets lead to higher blood pressure levels or greater antihypertensive requirements for antihypertensive therapy (Table 31.1). Whereas this effect was more apparent in earlier trials, two recent trials in CKD patients not on dialysis showed discordant effects with respect to raising blood pressure levels [35,36].

Dialysis adequacy and change in GFR

Compared to intermediate hemoglobin targets, higher hemoglobin targets have been associated with lower measures of intradialytic urea clearance in several studies of hemodialysis patients (Table 31.1). In general, the between-target differences were small, and the clinical significance of these differences is unclear [39].

The effect of hemoglobin targets on rates of progression of CKD is unclear. Whereas the larger, more recently published studies (Table 31.1) have not shown an effect in either a harmful or beneficial direction, it is likely that the currently available evidence does not allow definitive conclusions. It should be noted that one recent large trial showed that patients in the high hemoglobin arm were more likely to require hemodialysis earlier than controls, even though rates of loss of kidney function were identical in the two arms [35]. Good clinical practice would mandate that higher hemoglobin targets not be attempted without frequent clinical monitoring and should probably be avoided in comparatively noncompliant patients.

Transfusions

Avoidance of blood transfusions is highly desirable for many reasons, and it is clear from the studies performed to date that higher hemoglobin targets are associated with lower transfusion rates (Table 31.1).

Target recommendations

The available evidence suggests that an initial hemoglobin target of ≥11.0 g/dL has a reasonable evidence base [2,40]. Beyond this, a clear-cut upper bound for hemoglobin target is difficult to define from the current evidence base, especially given the divergence between benefits in quality of life and potentially harmful effects. It is also apparent that hemoglobin levels vary considerably and that keeping levels within narrow ranges is extremely difficult among individuals. Safety issues, considered in isolation, clearly suggest that hemoglobin levels above 12 g/dL should not be a routine recommendation. However, many patients might accept the potential incremental risk associated with higher hemoglobin levels in return for quality-of-life benefits. With this approach, lengthy risk–benefit discussions with patients, families, and caregivers are needed. One fervently hopes that this unsatisfactory situation, where an upper hemoglobin target remains unclear, even after almost 20 years of target hemoglobin trials, will be clarified by the completion of ongoing intervention trials.

Use of ESAs

ESAs are molecules that increase rates of red blood cell production, acting through the erythropoietin receptor, either directly or indirectly. At present, the ESAs in clinical use include epoetin alfa, epoetin beta, and darbepoetin. Although the first two entities are very similar to endogenous erythropoietin in terms of molecular structure and biological activity, the third of these entities, in contrast, has a longer half-life than the native hormone.

The optimum frequency of hemoglobin measurement under ESA therapy is unknown. In particular, no trial has been performed in which the primary intervention was randomization to different frequencies of hemoglobin monitoring, without alteration of ESA therapy. Clinical judgment should be exercised in less stable situations, such as initiation of ESA therapy, hemoglobin levels above or below target, rapid changes in hemoglobin level, and unstable clinical circumstances. Similarly, no trial has been performed among patients initiating ESA therapy in which the intervention has been

Table 31.2 Major findings from trials with at least 50 subjects comparing subcutaneous or intravenous administration of a single ESA.

Study [reference], CKD type, sample size	Intervention, ESA strategy, treatment group allocation	Target hemoglobin (g/dL)	Single ESA dose?	Iron replete?	Duration	Result
Kaufman 1998 [41], HD, $n = 208$	i.v. vs. s.c. epoetin alfa 3 times weekly, open label	10–11	No	Ferritin >100 ng/mL	26 wks	Lower epoetin dose with s.c.
Muirhead 1992 [42], HD, $n = 128$	i.v. vs. s.c. epoetin alfa 3 times weekly, open-label	10.5–12.5	No	TSAT >20%	24 wks	Lower epoetin dose with s.c.
Leikis 2004 [43], HD, $n = 81$	i.v. vs. s.c. epoetin alfa (and 1 vs. 2 vs. 3 times per wk), crossover, open label	None, withdrawn if <9 or >14	Yes	Ferritin 300–800 ng/mL and TSAT 25–50%	3 mos/treatment	Higher hemoglobin with s.c.
Aarup 2006 [44], HD, $n = 71$	i.v. vs. s.c. darbepoetin once weekly, crossover, open label	11.0–13.7	No		20 wks/treatment	No difference in darbepoetin dose
Cervelli 2005 [45], HD, $n = 53$	i.v. vs. s.c. darbepoetin once weekly, crossover, allocation concealed	11.0–13.0	No	Ferritin ≥200 ng/mL and TSAT ≥25 %	6 mos/treatment	No difference in darbepoetin dose

Abbreviations: HD, hemodialysis; i.v., intravenous; s.c., subcutaneous; TSAT, transferrin saturation.

different target rates of change of hemoglobin level. Finally, no trials have compared different frequencies of dose adjustment of ESA. In the absence of such information, most guidelines have recommended a minimum frequency for hemoglobin measurement of at least monthly measurements in stable patients and have suggested rates of increase in hemoglobin levels of 1–2 g/dL/month during the initiation phase.

Table 31.2 summarizes findings from trials that have compared subcutaneous and intravenous routes of administration of ESAs [41–45]. These studies suggest that the subcutaneous route is associated with lower epoetin alfa dose among hemodialysis patients. They also suggest that darbepoetin is equally efficacious with regard to hemoglobin level attainment whether used subcutaneously or intravenously. In practice, concerns that subcutaneous epoetin may cause pure red cell aplasia in hemodialysis patients has led to the recommendation, in many guidelines, that it be given intravenously in this population [46], even though pure red cell aplasia rates appeared to have declined worldwide since 2003 [47].

Table 31.3 summarizes findings from trials comparing different frequencies of administration of subcutaneous epoetin [28,48–50]. These trials suggest equivalent efficacy regarding attained hemoglobin levels, whether epoetin is administered once, twice, or three times per week or once every 2 weeks.

Table 31.4 summarizes findings from major trials that compared different ESAs with hemoglobin level as the outcome variable. These studies suggest that darbepoetin once per week is as efficacious as epoetin two or three times per week, and darbepoetin once every 2 weeks is as efficacious as epoetin once per week in dialysis patients.

In practice, the use of ESAs varies widely according to factors like practice setting and patient preference. In addition, hemoglobin levels alone have been the major efficacy criterion in the trials performed to date. Clearly, structurally different biological molecules

may have different actions at many sites beyond the bone marrow, and the comparative safety profiles of different ESAs and how they are used remain to be determined in adequately powered randomized trials.

Iron therapy

No iron intervention trials have been performed that had sufficient power to adequately examine safety issues, which is unfortunate, given the fact that iron is a potent oxidizing agent, in addition to being an essential component of heme. The optimum frequency for iron testing has never been determined using experimental methods. As a result, guidelines that suggest that the minimum frequency should be at least once per month in stable patients are only opinion-based.

Iron status markers
Although small studies in hemodialysis patients have suggested that intravenous iron-based treatment based on transferrin saturation targets between 30 and 50% lowered the epoetin dose (vs. 20–30%) [51], as did a ferritin target of 400 ng/mL (vs. 200 ng/mL) [52], the evidence base appears to be inadequate for formulation of firm recommendations. Hence, recommendations that lower bounds for ferritin and transferrin saturation levels should be 200 ng/mL and 20% [2], respectively, probably should be viewed as less than definitive, and further trials are clearly needed. An even stronger disclaimer may be required for establishing upper bounds for optimum ferritin and transferrin saturation targets, if these are to be based, ideally, on evidence from randomized controlled trials.

Two randomized trials have used reticulocyte hemoglobin content as an indicator of iron status in hemodialysis patients. In the first of these trials, 157 patients were randomly assigned to iron

Table 31.3 Major findings from trials with at least 50 subjects comparing different frequencies of administration of a single ESA.

Study [reference], CKD type, sample size	Intervention, ESA strategy, treatment group allocation	Target Hgb (g/dL)	Iron replete?	Duration (wks)	Result
Provenzano 2006 [48], ND, $n = 519$	QW, Q2W, Q3W, or Q4W, open label	>11		16	Similar hemoglobin with QW and Q2W, lower with Q3W and Q4W
Covic 2006 [49], HD, $n = 207$	Epoetin beta s.c., QW vs. Q2W, open label	10–12	Ferritin 100–800 ng/mL and TSAT 20–50%	24	No difference in Hgb or epoetin beta dose
Locatelli 2002 [50], HD, $n = 173$	Epoetin beta s.c., QW vs 3 times/wk, open label	9.3	Ferritin 100–800 ng/mL and TSAT 20–50%	24	No difference in Hgb or epoetin beta dose
Weiss 2000 [28], HD, $n = 158$	Epoetin beta s.c., QW vs. 2 or 3 times/wk, open label	10–13	Ferritin 200–500 ng/mL	24	No difference in Hgb or epoetin beta dose

Abbreviations: ND, nondialysis; HD, hemodialysis; QW, once every week; Q2W, once every 2 weeks; Q3W, once every 3 weeks, Q4W, once every 4 weeks; s.c., subcutaneous; Hgb, hemoglobin; TSAT, transferrin saturation.

management based on serum ferritin level (treatment threshold of <100 ng/mL) and transferrin saturation (threshold of <20%), or on reticulocyte hemoglobin content (threshold, 29 pg), with 6 months follow-up and intravenous iron dextran (100 mg for 10 consecutive treatments) as iron therapy. Although hemoglobin levels and epoetin doses were the same in both groups, weekly doses of iron dextran were lower when reticulocyte hemoglobin content was used to determine therapy [53]. The other trial used a reticulocyte hemoglobin content of <32.5 pg or a transferrin saturation of <20% to diagnose iron deficiency and used 240 mg of iron colloid intravenously over 2 weeks as treatment, with follow-up lasting 16 weeks. In this study, use of transferrin saturation as a trigger for iron therapy led to lower epoetin doses to achieve equivalent hemoglobin levels [54]. Hence, the available literature does not definitively support the use of reticulocyte hemoglobin content as an indicator of iron deficiency, and more randomized trials are needed. Similar comments apply to other markers of this

deficiency, including hypochromic red blood cells, zinc protoporphyrin, and soluble transferrin receptors.

Modes of administration of iron

Although several trials [55–62] have studied the effect of iron on hemoglobin levels in patients with CKD, the patient populations and methodologies employed have been quite heterogeneous, especially with regard to proportions with overt iron deficiency, simultaneous use of ESAs, use of untreated control arms, sample sizes, and study durations. Table 31.4 shows findings from the larger trials that compared different modes of iron therapy, or one mode of iron therapy versus no iron therapy (as opposed to different doses of the same therapy without a control arm). Although much evidence remains to be gathered, these trials tend to show that intravenous iron therapy is more efficacious than oral iron therapy for achieving target hemoglobin levels in hemodialysis patients. The situation is less clear in CKD patients not requiring

Table 31.4 Major findings from trials with at least 50 subjects comparing different formulations of iron.

Study [reference], CKD type, sample size	Intervention, treatment group allocation	Iron critria	ESA	Duration	Result
Van Wyck 2005 [56], ND, $n = 188$	i.v. iron sucrose, 1 g in divided doses (2 or 5) over 14 days vs. ferrous sulfate 325 mg orally t.i.d. for 56 days; open label	Ferritin ≤300 ng/mL and TSAT ≤25%	Epoetin or darbepoetin at constant dose	56 days	Higher hemoglobin with i.v. iron
Charytan 2005 [57], ND, $n = 96$	i.v. iron sucrose, 5 doses of 200 mg weekly vs. 29 days of oral $FeSO_4$, 325 mg t.i.d.		Epoetin	42 days	Similar hemoglobin with oral and i.v. iron
Agarwal 2006 [55], ND, $n = 75$	i.v. sodium ferric gluconate complex 250 mg wkly x 4 vs. oral ferrous sulfate 325 mg t.i.d. x 42 days; open label	Ferritin <100 ng/mL or TSAT <20%	None	42 days	Similar hemoglobin with oral and i.v. iron
Fishbane 1995 [60], HD, $n = 52$	i.v. iron dextran 100 mg twice wkly	Ferritin >100 ng/mL and TSAT >15%	Epoetin	4 mos	Higher hemoglobin and lower epoetin dose with i.v. iron

Search strategy employed: randomized trial, iron, intravenous or oral, dialysis, or kidney or renal.
Abbreviations: ND, nondialysis; HD, hemodialysis; i.v., intravenous, t.i.d., three times/day; TSAT, transferrin saturation.

dialysis, and it seems reasonable to recommend either oral or intravenous iron therapy if achieving target hemoglobin levels with the lowest possible ESA dose is the therapeutic objective.

Limitations of body of evidence

All the studies of iron therapy described above have used early surrogate markers as primary outcomes, including hemoglobin, ferritin levels, transferrin saturation levels, and ESA doses. Given the nature of the therapy, however, there is clearly a requirement for randomized trials evaluating long-term safety parameters, including death, progression of kidney disease, and natural history of adverse events. These trials should include placebo-controlled trials of individual agents and placebo-controlled trials of multiple agents, so that safety and efficacy can truly be determined.

32 Dyslipidemia in Chronic Kidney Disease

Vera Krane & Christoph Wanner

Department of Medicine, Division of Nephrology, University of Würzburg, Würzburg, Germany

Introduction

Today, clinicians use serum total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, and triglycerides (lipid profile) for diagnosis and treatment of hyper- or dyslipidemia. These lipids are transported within lipoproteins, which have been isolated and used in patient-oriented research and for in vitro experiments. Lipoproteins not only contain lipids but also proteins, so-called apolipoproteins. Integrating all these components into the discussion, lipidologists use terms such as "composition of lipoprotein particles" that may not be familiar or routinely understood by clinicians. Quite often, statins are mistakenly prescribed for patients with very high triglycerides that arise from triglyceride-rich lipoproteins. This is unfortunate, because statins work via receptors that mediate absorption of cholesterol-rich lipoproteins by the liver. Therefore, it is of advantage for nephrologists to have some basic knowledge about lipids, lipoproteins, and apolipoproteins in order to diagnose and treat lipid disorders adequately in a patient population prone to suffer from complex forms of dyslipidemia as well as significant cardiovascular disease (CVD). For a better understanding, Figure 32.1 and Table 32.1 are provided. This figure and table are complementary, as they combine knowledge about lipoproteins and the lipid components.

Types of dyslipidemia in different stages of chronic kidney disease and renal replacement therapy

General aspects

Qualitative characteristics of dyslipoproteinemia are similar in early renal insufficiency and in advanced kidney failure. Hypertriglyceridemia and delayed catabolism of triglyceride-rich lipoproteins resulting in increased concentrations of very low density lipoproteins (VLDLs) and intermediate density lipoproteins (IDLs) and reduced levels of HDL appear to be the main metabolic abnormality. Plasma cholesterol concentration is usually normal, even reduced, and only occasionally elevated. Dyslipidemia is detected in an early stage of chronic kidney disease (CKD, stage 2) and is best characterized by abnormalities in the composition of apolipoproteins. Increased levels of apoC-III and decreased levels of the apoA-I/apoC-III ratio are considered to be the hallmarks of an altered apolipoprotein profile in kidney disease [1].

CKD and proteinuria: impact on serum lipids and lipoproteins

Dyslipidemia is present in 70–90% of patients with nephrotic syndrome. Combined hyperlipidemia, with an increase in the serum total cholesterol/LDL cholesterol ratio and increased serum triglycerides, is the most common form (50%) [2–4]. One-third of patients have an exclusive elevation of LDL cholesterol, whereas only 4% of patients show pure hypertriglyceridemia. Changes in the composition of lipoprotein particles also have been described, with cholesterol enrichment in IDL but not LDL [5,6]. The levels of HDL cholesterol may vary [7,8]. This could be due to high serum lipoprotein (a) [Lp(a)] contaminating the HDL samples when cholesterol is assayed. The reasons why patients with nephrotic syndrome present different accumulations of triglycerides and cholesterol may include factors such as genetic apolipoprotein phenotypes, concomitant drug therapy, and the catabolic state of the individual. Two separate processes impede the removal of triglyceride-rich lipoproteins in nephrotic syndrome. One is an abnormality in VLDL that decreases the ability to bind to endothelial surfaces in the presence of saturating Lipoprotein Lipase (LPL) [9]. This defect in VLDL function, and presumably structure, results from proteinuria [10]. The second defect is the inability of LPL to bind effectively to vascular endothelium [11]. Whereas VLDL levels are high due to reduced catabolism, LDL levels are increased because of increased synthesis[12]. The presence of uremia in nephrotic patients leads to further changes [13].
Figure 32.1 Relative density of lipoproteins in human plasma.

Markedly elevated Lp(a) concentrations have been found in the majority of patients with proteinuria [14,15] and nephrotic syndrome and resolve when remission of the nephrotic syndrome is induced [16,17]. There are data that suggest increased synthesis, rather than decreased catabolism, causes elevated plasma Lp(a) concentrations in nephrotic syndrome [18].

Hemodialysis and dyslipidemia

Dyslipidemia in hemodialysis patients is more frequent than in the general population [19,20] and is characterized by hypertriglyceridemia and low levels of HDL [21–29]. However, levels of total cholesterol and LDL usually are normal [30–34]. This translates into the most characteristic feature of the end-stage renal disease (ESRD)-associated dyslipidemia represented by an accumulation of triglyceride-rich lipoproteins (VLDL remnants) and IDL [23,31,35]. Catabolism of IDL and LDL is severely impaired, resulting in a markedly prolonged residence time of both particles [36]. Additionally, qualitative changes of LDL with formation of small dense LDL are found [37–40]. On the level of apolipoproteins, the dyslipidemia can also be classified as an accumulation of apoB-containing triglyceride-rich lipoprotein particles containing apoC-III and Lp(a) or lipoprotein B complex particles [41–43]. Besides a defect in postprandial chylomicron remnant clearance, abnormal HDL apoA-I and apoA-II kinetics have been described, with increased catabolism of apoA-I and decreased production rate of apoA-II resulting in reduced plasma levels of both apolipoproteins [44,45].

Continuous ambulatory peritoneal dialysis and dyslipidemia

Continuous ambulatory peritoneal dialysis (CAPD) patients present with higher plasma cholesterol, triglyceride, LDL, and Lp(a) levels than hemodialysis patients [46–52]. This additional increase is most likely due to two factors [53]: 1) loss of protein (7–14 g/day) into the peritoneal dialysate [54], and 2) absorption of glucose (150–200 g/day) from the dialysis fluid [55–57]. This was in part reflected in the data from Prinsen *et al.*, who reported VLDL-1 apoB100 and VLDL-2 apoB100 pool sizes were increased due to disturbances in both synthesis and catabolism. VLDL-1 apoB100 production is, at least partially, explained by increased free fatty acid availability secondary to peripheral insulin resistance; thus, insulin resistance might be a potential therapeutic target in peritoneal dialysis patients [58]. In general, qualitative lipoprotein abnormalities are similar to those found in hemodialysis patients, and most mechanisms altering lipoprotein metabolism are probably also qualitatively the same [59,60], even though a study in normolipidemic CAPD patients demonstrated less-pronounced abnormalities of cholesterol transport in normolipidemic CAPD patients than in hemodialysis patients [61].

Lipid abnormalities after kidney transplantation

Posttransplant dyslipidemia is qualitatively and quantitatively dependent on age, gender, body weight, and type, and dose of immunosuppressive agents [62]. The prevalence of lipid changes in

Abbreviations: TG, triglyceride; FC, free cholesterol; CE, cholesteryl ester; PL, phospholipids; Pr, protein.

kidney transplant recipients is very high. Particularly common are increases in cholesterol and LDL. HDL is usually normal, and triglycerides are often increased [63–66].

Dyslipidemia and impact on CVD

The risks of cardiovascular morbidity and mortality are profoundly increased in patients with CKD [67]. For instance, the majority of patients with CKD die of cardiovascular events before reaching ESRD [68].

Nephrotic syndrome

There is no reason to doubt that the severe, persistent elevation of cholesterol, LDL, IDL, and Lp(a) represent a highly atherogenic condition. Relatively little and conflicting information has been published on the risk of atherosclerotic vascular disease [69–71]. All of these studies were retrospective, however, and flawed by small sample numbers, selection bias, and lack of control for other atherosclerotic risk factors. Some studies included patients with minimal change disease, and these patients would most likely not remain nephrotic and hence not remain at risk for the long-term complications of hyperlipidemia. According to Ordonez *et al.*, the adjusted relative risks of myocardial infarction and coronary death in nephrotic syndrome are 5.5 and 2.8, respectively. Data were obtained for 142 patients matched with healthy controls and followed prospectively for 5.6 and 1.2 years [72].

Dialysis

CVD is the leading cause of morbidity and mortality in hemodialysis patients; cardiac disease accounts for 44% of overall mortality [73,74]. Approximately 22% of these deaths from cardiac causes are attributed to acute myocardial infarction. In patients who survive a myocardial infarction, the mortality from cardiac causes is 59% at 1 year, 73% at 2 years, and nearly 90% at 3 years [75,76]. After adjusting for age, gender, race, and diagnosis of diabetes, mortality from CVD is far greater in hemodialysis patients than in the general population. It ranges from 500-fold in individuals aged 25–35 years to 5-fold in individuals aged >85 years [77]. This might be due to an increased prevalence of traditional and further kidney disease-related risk factors [78]. In this context, lipid abnormalities have been suggested as a major cause of vascular disease in hemodialysis patients [79–81]. Whereas the log-linear relation between risk of coronary artery disease and blood cholesterol is well-established in the general population, most cross-sectional studies with longitudinal follow-up have failed to demonstrate that plasma total cholesterol, LDL cholesterol, and triglycerides are associated with increased cardiovascular mortality in hemodialysis patients [82,83]. Even inverse associations have been observed among hemodialysis patients between blood cholesterol and all-cause or cardiovascular mortality. The relationship between serum cholesterol and mortality has been described as U-shaped and, recently, as a J-shaped curve. The risk of death is 4.3 times greater in hemodialysis patients with serum cholesterol of <100 mg/dL (<2.6 mmol/L) than in those with values between 200 and 250 mg/dL (5.2–6.5 mmol/L) [84,85]. This phenomenon is known as reverse risk factor causality and is embedded in the condition of reverse epidemiology [86]. Concomitant chronic illnesses that induce a compensatory decrease in cholesterol synthesis are also associated with an increased risk of death, producing artifactual negative associations (confounding) between cholesterol and mortality [87]. This hypothesis was supported by Liu *et al.*, who demonstrated that hypercholesterolemia was an independent risk factor for all-cause and cardiovascular mortality in a subgroup of ESRD patients without serologic evidence of inflammation or malnutrition but not in patients with inflammation [88]. In another prospective study of 1167 hemodialysis patients, low serum cholesterol levels were associated with all-cause mortality in patients with low serum albumin [89]. These effects may limit the extent to which standard observational studies can identify the true impact of serum cholesterol on the development of vascular disease in this and other populations [90,91]. In the largest and longest study to date, 419 dialysis patients were followed prospectively over a 21-year period. During this time 49% died of CVD and 23% experienced fatal or nonfatal ischemic events. Smoking, hypertension, and hypertriglyceridemia were identified as independent risk factors for CVD [92]. Another "positive" study in a group of 196 diabetic patients receiving hemodialysis demonstrated elevated cholesterol levels with high LDL/HDL ratios that were associated with an increased risk of cardiac death during a 45-month follow-up [93].

Data on the effects of lipids on cardiovascular risk in peritoneal dialysis patients are sparse. Only two studies that examined the relationship between dyslipidemia and CVD were identified. Both had major design limitations [94,95].

Kidney transplantation

Kidney transplant recipients suffer from a high morbidity and mortality due to premature CVD [96]. Several studies have reported a positive association between total cholesterol and CVD, but unfortunately few of them have examined the relationship between LDL and CVD. Lower levels of HDL were associated with CVD in most studies. In about half of the studies higher levels of triglycerides were associated with CVD [97–106]. Recently, the findings of an observational study of 1200 patients up to 15 years after kidney transplantation were in line with these results, showing associations between diabetes, prior transplant, body mass index at the time of transplant, cholesterol level, and LDL level with early acute coronary syndrome [107]. Another recent observational study did not prove these findings [108]. No significant association between triglyceride and total cholesterol levels with patient mortality has been observed. Similarly, no associations were found with allograft loss. This study was done in a

much smaller cohort (154 patients) with clearly shorter follow-up (6.1 years).

Cardiovascular end point studies on lipid-lowering therapy in CKD patients

CKD stages 1–4

Until now, no prospective, randomized, controlled trials on lipid-lowering therapy in patients with CKD stages 1–4 have been published. The effect of lipid-lowering therapy on cardiovascular, cerebrovascular, and renal outcomes in patients with CKD stages 2 and 3 was investigated in post hoc subgroup analyses of the Pravastatin Pooling Project. In this trial, a total of 12,333 subjects with estimated glomerular filtration rates (GFRs) determined by the Cockcroft-Gault equation of 60–89.9 mL/min/1.73 m^2 and 4491 subjects with estimated GFRs of 30–59.9 mL/min/1.73 m^2 were analyzed; the results showed that 40 mg/day pravastatin produced a significant 23% relative risk reduction for the combined risk of nonfatal myocardial infarction, coronary mortality, and coronary revascularization in people with moderate CKD. Similar results were obtained in patients with mild CKD. In the subgroup of diabetic patients (i.e. the patients with the highest baseline risk), the highest absolute risk reduction was observed (6.4%) [109,110].

Furthermore, a prespecified subgroup analysis of 6517 patients with kidney dysfunction from the ASCOT study revealed that atorvastatin significantly reduced the risk of the combined primary end point of nonfatal myocardial infarction and cardiac death [111]. Of the 1329 patients with serum creatinine levels of 110–200 μmol/L (1.21–2.26 mg/dL) who entered the Heart Protection Study, 182 of those who received simvastatin and 268 of those in the placebo group experienced a vascular event, indicating a proportional risk reduction with simvastatin treatment of about one-fourth [112]. Finally, a recent pooled analysis of 30 double-blind, randomized trials testing fluvastatin versus placebo in patients with moderate (creatinine clearance of ≥50 mL/min) to severe (creatinine clearance of ≤50 mL/min) renal insufficiency described a 41% and 30% reductions in the relative risk of cardiac death and nonfatal myocardial infarction in patients with severe and moderate renal impairment [113]. The analysis of adverse effects in the above-mentioned trials showed no special safety concerns in patients with CKD. Serum lipids were adequately lowered.

Other lipid-lowering agents to be considered are fibrates. Gemfibrozil has been shown to lower the risk of coronary death or nonfatal myocardial infarction in 1046 patients of the VA-HIT trial with impaired renal function, but the risk of sustained increases in serum creatinine was elevated in gemfibrozil-treated participants compared with placebo [114].

In conclusion, there is indirect evidence that patients with CKD stages 2 and 3 may benefit from statin therapy with respect to cardiovascular events. Patients with stage 4 CKD (GFR of <30 mL/min/1.73 m^2) were either absent or their numbers were too small to be analyzed.

CKD stage V: dialysis

In light of the findings described above, the results of the 4D study came as a surprise. A total of 1255 patients with type 2 diabetes on maintenance hemodialysis were randomized to receive 20 mg atorvastatin or matching placebo. After a median follow-up of 4 years, a nonsignificant 8% relative risk reduction in the primary composite end point (cardiac death, nonfatal myocardial infarction, and stroke) was observed. Atorvastatin reduced the rate of all cardiac events combined (relative risk, 0.82; 95% confidence interval, 0.68–0.99; $P = 0.03$, nominally significant) but did not reduce the rate of all cerebrovascular events combined or total mortality. Of note, there was a higher incidence of fatal stroke in the atorvastatin group compared with placebo (27 versus 13; relative risk, 2.03; $P = 0.04$). The overall incidence of adverse events was comparable between groups [115].

According to these data, we would not recommend initiation of statin treatment in patients with type 2 diabetes mellitus undergoing hemodialysis and with LDL levels of <190 mg/dL. Large-scale randomized controlled trials on lipid-lowering therapy in peritoneal dialysis patients and nondiabetic hemodialysis patients are currently under way: the AURORA study, comparing rosuvastatin with placebo in more than 2750 hemodialysis patients [116], and the SHARP trial [117], which is a randomized study of about 9000 patients with CKD (including kidney transplant recipients) partly on dialysis treatment (hemodialysis and peritoneal dialysis) and receiving either simvastatin in combination with ezetimibe or a placebo. Results from both trials are anticipated in the next few years.

CKD stages 1–4 T, kidney transplant recipients

The final CKD subpopulation considered in this chapter is kidney transplant recipients. The ALERT study [118] was the first large-scale cardiovascular outcome trial to be conducted in kidney transplant recipients and compared fluvastatin with placebo in 2102 patients followed for 5–6 years. Fluvastatin showed no significant reduction in the composite primary end point of cardiac death, nonfatal myocardial infarction, and coronary intervention procedure. The reductions observed in two of three subcomponents of the primary end point, cardiac death or nonfatal myocardial infarction, were interpreted as a great success for this therapy. Notably, the overall incidence of adverse events and study discontinuations with fluvastatin treatment was similar to placebo. The authors suggested that the trial was too small to detect a significant effect on the composite primary end point because the event rate was lower than expected. Therefore, an extension study was performed in which 1652 patients were treated with open-label fluvastatin for 2 years. A 31% relative reduction in major adverse cardiac events and a 29% relative reduction in cardiac death or definite nonfatal myocardial infarction were found. Total mortality and graft loss did not differ significantly between groups [119]. Another subgroup analysis

supported an early introduction of fluvastatin therapy in kidney transplant recipients and suggested a greater benefit with respect to cardiac death and myocardial infarction in patients treated earlier [120]. Clearly, studies in patients who have received kidney transplants require a high number-needed-to-treat in their design, in line with primary prevention trials.

In summary, the results of the 4D and ALERT studies do not necessarily cast doubt on the validity of the subgroup analyses done for patients with CKD stages 2 and 3, in whom statins appear to be just as effective as in patients with normal kidney function. The issue remains undecided whether statins are still effective for reducing cardiovascular risk in those with more advanced stages of CKD.

Renal end point studies of lipid-lowering therapy in CKD patients

In addition to the effects of lipid-lowering drugs on cardiovascular and cerebrovascular outcomes, there are data that suggest that lipid lowering may slow the rate of decline in kidney function and lower urinary protein excretion. Recently, a meta-analysis of 27 studies, including 39,704 participants with a baseline mean GFR of 41–99 mL/min, addressed these questions. It showed that statin therapy leads to a small reduction in the rate of kidney function loss in patients with CVD (loss of estimated GFR, 1.22 mL/min/year slower in statin recipients) but not a significant effect based on studies of subjects with diabetic or hypertensive kidney disease or glomerulonephritis [121]. Proteinuria appeared to be modestly reduced. Gemfibrozil did not exert a clinically relevant effect on rates of kidney function loss in a comparable analysis [122].

Treatment guidelines

General remarks

Guidelines for management of dyslipidemia in CKD have been issued, including the European Best Practices guidelines (EBPG) [123] and the US National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines [124]. Guidelines on lipid-lowering therapy in CKD patients were difficult to define because of the lack of randomized controlled interventional trials showing that the treatment of dyslipidemia reduces the incidence of vascular events. Furthermore, it is possible that in some subpopulations of CKD treatment of dyslipidemia may not be as safe or as effective in reducing the incidence of vascular disease as it is in the general population. When these guidelines were prepared, the 4D and ALERT trials were still under way. Therefore, both working groups, EBPG and K/DOQI, concluded that additional trials are needed to fill this gap and advised randomization of patients into controlled clinical trials. In the following section, the main aspects of the EBPG guidelines for the treatment of hemodialysis patients and the K/DOQI guidelines are summarized.

Principles of lipid-lowering therapy for CKD patients

As patients with CKD have a very high prevalence of dyslipidemia and CVD [125–128], the EBPG working group concluded that hemodialysis patients should be treated according to existing guidelines of lipid-lowering therapy for the general population, applying a high-risk strategy. The K/DOQI working group recommended that the NCEP/ATP III guidelines [129] were generally applicable to patients with CKD stages 1–4. Some additional specific aspects of the management of dyslipidemias in CKD should be considered. These include the following:

1) CKD should be classified as a CVD risk equivalent.

2) Complications of lipid-lowering therapies resulting from reduced kidney function should be anticipated.

3) Indications for the treatment of dyslipidemia other than preventing CVD should be considered when deciding on specific treatment strategies.

4) Treatment of proteinuria as an alternative treatment of dyslipidemia may prove beneficial.

In conjunction with dyslipidemia, the assessment and management of other modifiable, conventional risk factors (hypertension, smoking, obesity, and diabetes) should be performed.

Assessment and diagnosis of dyslipidemia

A complete fasting lipid profile with total cholesterol, LDL, HDL, and triglycerides is recommended for patients with CKD. For patients with stage 5 CKD, dyslipidemia should be evaluated upon presentation, at 2–3 months after a change in treatment, or with other conditions known to cause dyslipidemia (change in proteinuria, GFR, etc.) and at least annually thereafter. The EBPG advises measurement of cholesterol, HDL, and triglycerides more frequently. LDL should be calculated according to the Friedewald formula if triglycerides are <400 mg/dL; otherwise, direct LDL measurement is recommended. If triglycerides are >800 mg/dL, no LDL measurement needs to be performed. Whenever possible in patients with CKD stage 5, lipid profiles should be measured after an overnight fast, because eating increases especially triglycerides and also total cholesterol. However, it is better to obtain nonfasting lipid profiles than to forgo evaluation altogether. In hemodialysis patients blood should be taken either before dialysis or on nondialysis days, at least 12 h after hemodialysis treatment, because the hemodialysis procedure may acutely alter plasma lipids [130]. Patients with dyslipidemia should be evaluated for secondary causes. Acute medical conditions (e.g. serious infections or myocardial infarction) may alter plasma lipids. It is best to wait until these conditions have resolved. Immunosuppressive medications may cause dyslipidemia. The recommendation is to assess the lipid profile 2–3 months after starting or stopping an agent that is known to influence plasma lipids.

Treatment of dyslipidemia

Three patient groups are to be distinguished:

1 In adults with stage 5 CKD and fasting triglycerides of ≥500 mg/dL (≥5.65 mmol/L) that cannot be ameliorated by correcting an underlying cause, treatment with therapeutic life-style

changes (TLC) and a triglyceride-lowering agent should be considered to prevent acute pancreatitis. Only when triglycerides are <500 mg/dL (<5.65 mmol/L) should attention be focused on LDL cholesterol reduction. According to EBPG, in patients with triglycerides of >800 mg/dL (>9 mmol/L) who are resistant to any intervention, the administration of fish oil and/or a switch to low-molecular-weight heparin as anticoagulant during hemodialysis therapy should be considered.

2 For adults with stage 5 CKD and LDL of ≥100 mg/dL (≥2.59 mmol/L), treatment should be considered to reduce LDL to <100 mg/dL (<2.59 mmol/L).

3 For adults with stage 5 CKD and LDL of <100 mg/dL (<2.59 mmol/L), fasting triglycerides of ≥200 mg/dL (≥2.26 mmol/L), and non-HDL cholesterol (total cholesterol minus HDL cholesterol) of ≥130 mg/dL (≥3.36 mmol/L), treatment should be considered to reduce non-HDL cholesterol to <130 mg/dL (<3.36 mmol/L). The EBPG chose a lower threshold for initiation of therapy with triglycerides ≥180 mg/dL (≥2 mmol/L).

Treatment of very high triglycerides

TLC is the therapy of first choice and includes diet, weight reduction, increased physical activity, abstinence from alcohol, and treatment of hyperglycemia, if present. For patients with fasting triglycerides of ≥1000 mg/dL (≥11.29 mmol/L), the NCEP/ATP III diet recommendations include a very low fat diet (<15% total calories), medium-chain triglycerides, and fish oils. Diet should be used judiciously, if at all, in individuals who are malnourished. If TLC is not sufficient to reduce triglycerides to <500 mg/dL (<5.65 mmol/L), treatment with a fibrate or nicotinic acid should be considered. Statins cause less triglyceride lowering, and bile acid sequestrants (BASs) may actually increase triglyceride levels. In any case, the benefits of drug therapy for hypertriglyceridemia should be weighed against the increased risks (particularly for myositis and rhabdomyolysis) in CKD.

Treatment of high LDL
Treatment with TLC

It may be possible to reduce the level of proteinuria and thereby improve a patient's lipid profile [131,132]. For patients with LDL of 100–129 mg/dL (2.59–3.34 mmol/L), it is reasonable to attempt dietary changes for 2–3 months before beginning drug treatment. Diet changes should be used judiciously, if at all, however, when there is evidence of protein–energy malnutrition [133], because there have been no randomized trials that have examined the safety and efficacy of a low-fat, low-cholesterol diet in patients with CKD. There are data that suggest that exercise improves cardiovascular function in hemodialysis patients [134] and decreases triglycerides in CKD patients [135]. The role of weight reduction in CKD patients [133] is unclear. Additional studies are needed to define the role of diet, exercise, and weight reduction in patients with CKD.

Treatment with a statin

In patients who cannot reduce LDL to <100 mg/dL (<2.59 mmol/L) by TLC, a statin should be added because of the strong evidence from studies in the general population that statins reduce CVD and all-cause mortality and the lack of any strong evidence to the contrary in patients with CKD. Whether statins cause hepatotoxicity is controversial. EBPG recommend liver function tests every 6 weeks. Patients should be monitored for signs and symptoms of myopathy. Creatine kinase monitoring is mandatory if muscle symptoms develop. The risk of myopathy from statins is increased by CKD, advanced age, small body frame, and concomitant medications [136]. Patients who develop muscle pain or tenderness should discontinue statin therapy immediately and have a creatine kinase level determined. Doses of lovastatin, fluvastatin, or simvastatin are recommended to be reduced by approximately 50% in patients with CKD stages 4 and 5 according to K/DOQI, whereas the EBPG states that statin doses are usually the same in hemodialysis patients as in the general population.

Medications known to increase statin blood levels should either be avoided or the statin should be reduced or stopped. Cyclosporine has been shown to increase the blood levels of virtually every statin. Even fluvastatin and pravastatin, which are not metabolized by cytochrome P450 3A4, show two- and fivefold increased plasma levels. Accumulating evidence suggests that statins can be used safely with cyclosporine if the dose of the statin is reduced [137–140]. The addition of a third agent that is also metabolized by the cytochrome P450 system increases the risk of myositis and rhabdomyolysis. Such combinations should be avoided. Because of the lack of sufficient data, it should also be assumed that tacrolimus may cause elevations in statin blood levels [141]. Everolimus has minimal effects on blood levels of atorvastatin and pravastatin [142]. The effects of sirolimus on statins are not well known.

Adding a second LDL-lowering agent to a statin

There are very few data on the safety and efficacy of combination therapies in patients with CKD. The K/DOQI guidelines state that in general, it is wise to avoid the use of a fibrate together with a statin. EBPG recommended avoiding combining a fibric acid analog with a statin due to the high risk of rhabdomyolysis. BASs can be considered in combination with a statin in patients with LDL of ≥100 mg/dL (≥2.59 mmol/L) despite TLC and optimal treatment with a statin [143]. They are contraindicated in patients with triglycerides of ≥400 mg/dL (≥4.52 mmol/L) because they may increase triglycerides in some patients. Sevelamer hydrochloride lowers lipid levels by mechanisms similar to those of BASs [144]. Furthermore, nicotinic acid can be considered an alternative second agent in combination with a statin for patients with high triglycerides or for those not tolerating a BAS. There are no data on the use of a combination therapy with a statin and nicotinic acid in patients with CKD.

Treating high LDL in patients who cannot take a statin

Patients with minor adverse effects from a statin may tolerate a reduced dose or a different statin; sometimes a second-line agent needs to be used. BASs, nicotinic acid, and sevelamer [145,146] are possible alternatives.

Use of BASs in kidney transplant recipients

Using BASs in kidney transplant recipients may be difficult because of a possible interference with the absorption of immunosuppressive medications that bind to lipids. Even though two small studies did not find a reduction in cyclosporine levels [147,148], it may be prudent to avoid administering a BAS from 1 h before until 4 h after the administration of cyclosporine and to monitor blood levels of cyclosporine. For many patients, the potential risk of transplant rejection resulting from poor absorption of immunosuppressive medication may outweigh the benefits of a further reduction in LDL.

For kidney transplant recipients who have LDL levels of ≥100 mg/dL (≥2.59 mmol/L) despite maximal medical management, consideration should be given to changing the immunosuppression protocol. In deciding whether to change immunosuppressive agents, the risk of rejection should be weighed against the risk of CVD. Moreover, the effects of immunosuppression on overall CVD risk should be taken into account, not just their effects on dyslipidemia. For example, different immunosuppressive agents have different effects on blood pressure and posttransplant diabetes, both of which can affect the incidence of CVD.

Treating non-HDL cholesterol in patients with high triglycerides

Non-HDL cholesterol is defined as total cholesterol minus HDL. High fasting triglycerides (180–499 mg/dL; 2–5.7mmol/L) are not used as goals of therapy, but they are markers of increased coronary risk and should be treated in the absence of increased LDL [129]. The finding that elevated triglycerides were an independent cardiovascular risk factor in some studies suggests that some triglyceride-rich lipoproteins are atherogenic [149,150]. The latter are partially degraded VLDL, commonly called remnant lipoproteins. Non-HDL cholesterol was demonstrated to remain one of the strongest predictors for intima media thickness in 897 hemodialysis patients [151]. Non-HDL cholesterol also was a predictor of aortic atherosclerosis in a cohort of 205 hemodialysis patients [152]. Therefore, non-HDL cholesterol is an independent factor affecting arterial wall thickening and stiffness. Recent data suggest that non-HDL cholesterol may actually be a better predictor of coronary mortality than LDL [153]. Non-HDL cholesterol is also a reasonable surrogate marker for apoB, the major apolipoprotein of all atherogenic lipoproteins [154]. In one study, hemodialysis patients showed higher levels of VLDL and IDL, and lower levels of HDL, than age- and sex-matched controls with similar levels of plasma triglycerides [155]. However, so far no evidence has linked low HDL, high fasting triglycerides, and increased non-HDL cholesterol directly to CVD in patients with CKD. Clearly, additional studies are needed to establish whether therapy targeting lower levels of VLDL and IDL is safe and effective in patients with CKD.

TLC for high triglycerides and non-HDL cholesterol

There are virtually no studies on the effects of alcohol consumption in patients with CKD. Even if studies from the general population have produced conflicting results as to whether intensive glycemic control reduces the risk for CVD, CKD patients with low HDL and or high triglycerides should be assessed for diabetes, and diabetic patients with this lipid profile should have as good glycemic control as possible without causing excessive hypoglycemia. Obesity is associated with low HDL and/or high triglycerides. There are a few studies demonstrating successful weight reduction in obese patients with CKD. A limited number of studies suggest that low-fat diets [156] and increased physical activity [135] may be effective in patients with CKD. A few studies have examined the effects of fish oil supplements on lipoproteins in patients with CKD; their results have been inconclusive [157–161].

Drug therapy for high triglycerides and non-HDL cholesterol

Patients who are not already receiving a statin for treatment of LDL cholesterol who have fasting triglycerides of ≥200 mg/dL (≥2.26 mmol/L) (K/DOQI) or ≥180 mg/dL (≥2 mmol/L) (EBPG) and non-HDL cholesterol of ≥130 mg/dL (≥3.36 mmol/L) and who do not have liver disease should be started on a statin along with TLC. The safety and efficacy of statins for preventing CVD have been more conclusively established in randomized trials in the general population. If a statin cannot be used, a fibrate may be considered. The blood levels of bezafibrate, clofibrate, and fenofibrate are increased in patients with decreased kidney function compared to controls with normal kidney function [162–165]. In contrast, blood levels of gemfibrozil do not appear to be altered by decreased kidney function. Bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil have been reported to cause increased serum creatinine and blood urea nitrogen levels [166,167]. Since dose modification for decreased kidney function is not required for gemfibrozil, unlike other fibrates, gemfibrozil should probably be considered the fibrate of choice for most CKD patients. Nicotinic acid can be used in place of fibrates for patients with elevated triglycerides. However, there are almost no data on blood levels of nicotinic acid in patients with CKD. Furthermore, the use of polysulfone or polyamide high-flux dialysis has been shown to ameliorate hypertriglyceridemia in some patients [168–171]. Treatment of renal anemia with erythropoietin in hemodialysis patients has beneficial effects on plasma lipid concentrations [172].

Isolated low HDL cholesterol

Patients with isolated low HDL cholesterol should be treated with TLC. Pharmacological treatment of isolated low HDL cholesterol is not recommended because the risks of pharmacological therapy to raise HDL probably outweigh the benefits.

Other lipid-lowering agents

Ezetimibe was approved after publication of the above-presented guidelines. There are data on ezetimibe treatment in patients, including peritoneal dialysis, hemodialysis, and CKD patients [173,174] as well as kidney transplant recipients [175] that show it to be an effective lipid-lowering agent when added to other lipid-lowering therapies as well as to be safe in patients with reduced renal function and in patients who do not tolerate statin therapy.

At this time, there are no data about its influence on cardiovascular events.

33 Chronic Kidney Disease and Hypertension

Sangeetha Satyan[1] & Rajiv Agarwal[1,2]
[1]Division of Nephrology, Department of Medicine, Indiana University School of Medicine, Indianapolis, USA
[2]Richard L. Roudebush, VA Medical Center, Indianapolis, USA

Hypertension (HTN) is very common among patients with chronic kidney disease (CKD). Using ambulatory blood pressure (BP) monitoring in patients with CKD, Andersen *et al.* [1] found that in 232 veterans, 35% had isolated systolic HTN, 3% had isolated diastolic HTN, 27% had combined systolic and diastolic HTN, and 35% had normotension or well-controlled BP. Elevated BP is an important cardiovascular (CV) risk factor in the general population as well as in those with CKD. In addition, high BP is a well-recognized risk factor for the development and progression of kidney disease. The prevalence of end-stage renal disease (ESRD) is rising rapidly. Physicians are confronted with a major challenge of preventing ESRD among patients with CKD, and treatment of HTN is a cornerstone for such intervention. Several prospective trials have been performed to determine the goal BP, outcome, and choice of antihypertensive therapy in patients with HTN and CKD. The optimal level of BP in CKD is still unclear despite the numerous studies. Based on the available data, the National Kidney Foundation (NKF) [2] and the Joint National Committee (JNC) [3] have recommended a goal BP of less than 130/80 mmHg in patients with CKD. In this chapter we discuss the rationale for these recommendations.

CKD burden in the general population

The burden of CKD in the general population is increasingly acknowledged. In a cross-sectional study of 16,589 adults aged 17 years and older (Third National Health and Nutrition Examination Survey, conducted from 1988 to 1994), 3% had elevated serum creatinine, defined as ≥1.6 mg/dL for men and ≥1.4 mg/dL for women [4]. HTN, defined as BP of ≥140/90 mmHg or use of antihypertensive medications, was noted in 70% of these individuals. What was more astonishing was the fact that among the hypertensive individuals, only 11% had a BP of <130/85 mmHg (the goal

BP for CKD without proteinuria, as recommended by JNC-6). In each category of BP, elevated serum creatinine was more prevalent among treated than untreated individuals with HTN, and the relationship between elevated serum creatinine and BP was linear among untreated individuals and was J-shaped among treated individuals. Despite the inherent limitations of this cross-sectional study and that the data signified an association rather than causation, the study revealed a high burden of CKD in the general population and the suboptimal control of BP in such individuals.

Misclassification of HTN with BP monitoring in clinic

Measurement of BP via a sphygmomanometer and a stethoscope is the most common method for estimation of arterial pressure in a clinical practice. Clinical diagnosis and HTN management are based almost entirely on office measurements. However, these measurements may be prognostically less reliable than BP obtained outside the office setting. When home BP monitoring (self-measured BP) is performed, HTN is less frequently misclassified and better correlation is achieved with putative markers of kidney disease progression [5]. Masked HTN, that is, normotension in the clinic and HTN at home, is associated with higher risk of ESRD in patients with CKD [5]. Conversely, "white coat" HTN, which is HTN in the clinic and normotension at home, is associated with better renal outcomes. Ambulatory BP monitoring is also prognostically superior to clinic BP but does not further refine the prognosis made by home BP monitoring [6]. In patients on hemodialysis, home BP, not the predialysis and postdialysis BP values, shares a combination of high sensitivity and high specificity of greater than 80% to make a diagnosis of HTN with the reference standard of ambulatory BP monitoring [7]. In addition, home BP is a better predictor of left ventricular hypertrophy in patients on hemodialysis compared with peridialysis BP [8]. These data suggest that self-measurement of BP by patients with CKD can serve as a useful addition to assessing the level of HTN control and prognosis.

Role of angiotensin converting enzyme inhibitors and angiotensin II receptor blockers in CKD and HTN

A significant interaction between proteinuria and BP has been delineated among patients with CKD and HTN that seems to be important especially with reference to outcomes. The introduction of agents blocking the renin–angiotensin–aldosterone system was an important milestone in the management of patients with CKD and HTN, particularly in those with diabetes mellitus and proteinuria. Drugs inhibiting the renin–angiotensin system have the added benefit of reducing glomerular HTN and other nonhemodynamic benefits. In addition, angiotensin converting enzyme inhibitors (ACEi) preferentially improve arterial stiffness and lower central aortic pressures more than beta-blockers or calcium channel blockers, which may offer an additional mechanism of improvement in CV outcomes seen with this class of drugs [9].

Diabetic nephropathy is a major cause of ESRD and enhances the mortality rate in the diabetic population. A landmark study by Lewis *et al.* [10] provided initial evidence that use of an ACEi (captopril) in patients with type 1 diabetes mellitus and proteinuria of ≥500 mg/day was superior to placebo in preventing the progression of kidney disease and lessened the mortality and ESRD rates. There was no significant difference in BP control in the two groups. Proteinuria reduction was overall greater in the captopril group than in the placebo group. The study led to the widespread use of ACEi in diabetic nephropathy. Whether ACEi would be equally beneficial in those with less or no proteinuria was not answered by this study.

The benefit of ACEi in nondiabetic nephropathies has been shown in several studies. The Italian investigators of the Ramipril Efficacy in Nephropathy (REIN) study reported that among patients with chronic nondiabetic nephropathies, ramipril was superior to conventional antihypertensive therapy in attenuating the loss of renal function over the long term [11,12]. The GFR decline per month was significantly lowered with ramipril among patients with baseline proteinuria of >3 g/day, even during the short follow-up, but not in those with baseline proteinuria of 1–2.9 g/day. However, ramipril was more effective in reducing proteinuria and progression to ESRD, even in patients with non-nephrotic-range proteinuria. The goal BP in this study was <90 mmHg diastolic BP, which at the time of the study was the recommended target for these patients. Thus, pretreatment proteinuria is highly predictive of the benefit of ACEi on long-term kidney function, with a greater benefit in those with higher proteinuria. ACEi gained a pivotal role in preventing progression of CKD in both diabetic and nondiabetic nephropathies, with benefits extending beyond BP reduction and became the mainstream treatment in CKD.

The Irbesartan Diabetic Nephropathy Trial (IDNT) assessed the role of irbesartan, an angiotensin II receptor blocker (ARB), in slowing the progression of nephropathy (median urine protein excretion of 2.9 g/day) in patients with type 2 diabetes [13]. Irbesartan, compared to placebo and amlodipine, significantly lowered the risk of doubling of serum creatinine and development of ESRD. These results could not be explained by differences in the mean arterial pressure (MAP) during follow-up. The MAP was significantly higher by 3.3 mmHg in the placebo group than the irbesartan and amlodipine groups. Proteinuria reduction on average was 33, 6, and 10% in the irbesartan, amlodipine, and placebo groups, respectively. The overall mortality and CV event rates were not significantly different between the groups. Irbesartan was well-tolerated.

In another study of patients with nephropathy and HTN associated with type 2 diabetes (RENAAL), losartan, compared to placebo, resulted in a 16% risk reduction in the composite end point of doubling of serum creatinine, ESRD, or death [14]. Overall mortality and morbidity and mortality from CV causes were similar in the two groups. There was no significant difference in the BP between the two groups at the end of the study, although the losartan group had a significantly lower MAP at the end of 1 year. Albuminuria reduction on average was about 35% in the losartan group, whereas it increased in the placebo group ($P < 0.001$ between the groups). The ARBs in these two studies involving patients with nephropathy from type 2 diabetes led to significant improvement in the renal outcomes that was beyond that attributable to BP reduction and appeared to be in part related to albuminuria reduction. Two post hoc analyses from this trial demonstrated that baseline albuminuria and reduction in albuminuria were predictive of primary outcome, ESRD outcome, CV outcomes, and hospitalization due to heart failure [15,16]. Whether ARB is superior to ACEi in patients with nephropathy from type 2 diabetes is unclear, but certainly remains an obvious alternative to those who do not tolerate ACEi. ACEi could be used when ARBs are cost prohibitive.

BP level and progression of nephropathy

Post hoc analysis of the RENAAL study was also done to evaluate the impact of systolic BP on renal outcomes [17]. A baseline systolic BP of 140–159 mmHg, compared to <130 mmHg, increased the risk of ESRD or death by 38%. In a multivariate model that also included the urinary albumin/creatinine ratio, each 10-mmHg rise in baseline systolic BP increased the risk for ESRD or death by 6.7%; a similar rise in diastolic BP decreased the risk by 10.9%. Thus, the predictive capability for renal outcomes is stronger for baseline systolic BP and widening pulse pressure in patients with nephropathy from type 2 diabetes. Among patients with a baseline pulse pressure of >90 mmHg, the losartan group compared to the placebo group had a 53.5% and 35.5% risk reduction for ESRD alone and ESRD or death, respectively. One explanation for these favorable results may be the known effects of ARBs on improvement in central pressures and arterial stiffness [18].

Goal BP in CKD and HTN

The Modification of Diet in Renal Disease (MDRD) study tested whether dietary protein restriction and BP control delayed the progression of renal disease [19,20] (Table 33.1). Patients with insulin-requiring diabetes were excluded, and ACEi use was encouraged but was not mandatory. Although the mean decline in the GFR was overall not significantly different between the two groups in either study (Table 33.1), a higher follow-up MAP was significantly associated with a faster decline in GFR. In the first study, GFR decline was steeper for MAP of >98 mmHg in those with baseline proteinuria of 0.25–3.0 g/day and for MAP of >92 mmHg in those with proteinuria of ≥3 g/day. In the second study (more advanced CKD), GFR decline demonstrated an inverse relationship with follow-up BP only for patients with baseline proteinuria of ≥1 g/day. In addition, there was a significant reduction in proteinuria in the low-BP groups in both studies. The studies signified the importance of BP control in ameliorating GFR decline, particularly in those with proteinuria, even in patients without insulin-requiring diabetes. This led to the JNC-6 guideline of target BP of <125/75 mmHg in those with proteinuria of ≥1 g/day. However, there was a disproportionate use of ACEi in the usual BP and low target BP groups, 32% and 51%, respectively, which could have contributed to the observed results.

After the completion of the MDRD study, which was conducted from 1989 to 1993, those patients were followed long-term through 2000 in an observational fashion, and no specific target BP was mandated [21]. ESRD developed in 62% in the low BP target (MAP <92 mmHg) and 70% in the usual BP target (MAP 102–107 mmHg) groups. The adjusted hazard ratios in the low BP group for ESRD and the composite outcome of ESRD or all-cause death were 0.68 ($P < 0.001$) and 0.77 ($P = 0.0024$), respectively. These results did not vary considerably after adjustment for ACEi use. However, there were no BP measurements during the long-term follow-up, and therefore the exact mechanism by which assignment to the low BP group resulted in these better outcomes is unclear.

The REIN-2 trial tested whether BP lowering in addition to ACE inhibition is beneficial in CKD [22]. Patients with nondiabetic proteinuric nephropathies who were already being treated with ramipril were randomized to either conventional (diastolic BP <90 mmHg) or intensified (BP < 130/80 mmHg) BP control. Felodipine was used in the intensive treatment group to further lower the BP. Concomitant antihypertensive drugs were used in both groups as needed to attain target BP. Urinary protein excretion was similar in both groups at baseline and throughout follow-up. BP decreased from 137/84 to 130/80 mmHg ($P < 0.0001$) in the intensified BP control group and from 136/84 to 134/82 mmHg in the conventional control group ($P = 0.02$ for systolic and 0.03 for diastolic BP). A separation in MAP by about 3 mmHg was maintained throughout the study. The study was stopped after a short follow-up based on futility. There was no significant difference in the percentage of patients reaching ESRD in the two groups (23% vs. 20%; $P = 0.99$). The median rate of GFR decline was similar in both groups throughout the study period. However, as expected, GFR decline was slower in patients with <3-g/day proteinuria than in those with >3-g/day proteinuria (0.19 mL/min/month vs. 0.49 mL/min/month; $P = 0.001$). These results suggest that the use of felodipine to further lower the BP does not confer renal protection in nondiabetic patients with overt proteinuria. The study provokes the thought that perhaps one should focus on variables other than BP, such as protein excretion, to evaluate the renoprotective effects of drugs.

In the African American Study of Kidney disease and HTN (AASK), patients with hypertensive renal disease were assigned to MAP goals of 102–107 mmHg and ≤92 mmHg [23]. The achieved BP was on average 128/78 mmHg and 141/85 mmHg, respectively, in the low and usual BP groups, with a mean separation in MAP of approximately 10 mmHg throughout the follow-up. There was no significant difference between the two groups in the GFR slope or the composite outcome (GFR decline of ≥50% from baseline, ESRD, or death). Thus, the low BP goal in this study had no added benefit in improving renal outcome. GFR decline was significantly lower in patients with baseline urinary protein/creatinine ratios of ≤0.22 compared to those with a ratio of >0.22. No significant differences in all-cause and cardiovascular mortality were noted between the groups. The results of this study do not support the low BP goal in African Americans with hypertensive renal disease in terms of decreasing the rate of GFR decline and the composite outcome. However, the study did not have sufficient power to identify differences in mortality and ESRD. Although cardiovascular outcomes were not an end point of the study, subsequent analyses of the AASK trial did not show a significant effect of BP level on cardiovascular events [24]. The hazard ratios in the low versus usual BP goal comparison for CV deaths, CV composite outcome (first CV hospitalizations and CV deaths), CV composite outcome or ESRD, and all CV events, respectively, were 0.98 (95% confidence interval [CI], 0.48–2.01; $P = 0.96$), 0.84 (95% CI, 0.61–1.16; $P = 0.29$), 0.91 (95% CI, 0.72–1.15; $P = 0.42$), and 1.06 (95% CI, 0.76–1.49; $P = 0.73$). These findings of no apparent benefit could have been due to the inadequate power of the study.

The NKF guidelines for HTN recommend a goal BP of < 130/80 mmHg for all patients with CKD and HTN [2]. A patient-level meta-analysis supports the need for systolic BP control to 110–129 mmHg in patients with CKD and proteinuria of greater than 1 g/day [25]. These guidelines seem reasonable considering the available data. However, an individualized approach needs to be taken for each patient with CKD in determining the goal BP. For example, a more aggressive reduction in BP and nonpharmacologic measures may be attempted in patients who have persistent proteinuria or increasing proteinuria.

Choice of antihypertensive therapy in CKD and HTN

The benefits of ACEi and ARB in CKD among diabetic and nondiabetic patients with proteinuria and HTN were described above.

Table 33.1 Trials reporting outcomes in patients with HTN and CKD

Study	Total number of patients randomized n	Primary Aim	Study Population	Study Design	Outcomes evaluated	Duration of follow-up	Results	Reference
The effect of Angiotensin-Converting Enzyme Inhibition on Diabetic Nephropathy	409	To determine whether captopril has kidney-protecting properties independent of its effect on BP in diabetic nephropathy	Age: 18–49; IDDM for at least 7 years; serum creatinine ≤2.5 mg/dl; Urine protein excretion ≥ 500 mg/24 hours	DBRCT in 30 centers; Captopril 25 mg po tid (n = 207), Placebo (n = 202); Goal SBP < 140 mm Hg, DBP < 90 mm Hg	Primary end point -Doubling of baseline serum creatinine to at least 2.0 mg/dl ; Secondary end points - Length of time to the combined end points of death, dialysis, and transplantation and changes in renal function	Median: 3 years	Serum creatinine doubled in 25 patients in the captopril gp, vs 43 patients in the placebo gp (P = 0.007). The risk reduction in the captopril gp was 48% as a whole, and 78% in the subset of patients with a baseline serum creatinine of 2.0 mg/dl. Risk reduction was 50% for the combined end point in the captopril group.	10
The effects of dietary protein restriction and BP control on the progression of CKD (MDRD)	Study 1–585; Study 2–255	To test whether restricting protein and controlling HTN delay the progression of renal disease	Age: 18–70; Serum creatinine: (M) 1.4–7.0; (F) 1.2–7.0 mg/dl; MAP ≤ 125 mm Hg; Study 1–GFR–25–55 ml/min, Study 2–GFR–13–24 ml/min. Insulin requiring diabetics and those with proteinuria > 10 g/d were excluded.	RCT in 15 centers. Assigned to a usual (MAP ≤ 107 mm hg) or low (MAP ≤ 92 mm Hg) BP group; to usual or low-protein diet (study 1) and low and verylow protein diet (study 2) groups. Step-wise approach of pharmacologic therapy for BP was used, and ACEI were encouraged as agents of first choice	Primary outcome: Decline in GFR measured by I-iothalamate clearance, stratified by BP and proteinuria	Mean: 2.2 years	The mean decline in GFR was overall not significantly different in both studies. Among patients with higher baseline proteinuria, the low-BP group had a significantly slower rate of GFR decline in both studies.	20
Effect of Ramipril on decline in GFR and risk of terminal renal failure in proteinuric, non-diabetic nephropathy (REIN)	352	To test the hypothesis that glomerular protein traffic, and its modification by an ACEI, influences renal disease progression	Age : 18–70;Cr Cl 20–70 ml/min with variation < 30% in previous 3 months, Urine protein excretion > 1g/24 hrs for at least 3 months, no ACEI for at least 2 months before study	DBRCT; Urine protein 1-2.9g/24h (stratum 1, n = 186); ≥ 3g/24h (stratum 2, n = 166); Randomized to ramipril (1.25 mg) or placebo. Dose increased every 2 weeks for a goal DBP < 90 mm Hg. Other agents used as needed to achieve goal BP	Primary outcome: Rate of GFR decline measured by iohxol clearance. Secondary outcomes; urinary protein excretion, and serum creatinine concentration. Intention to treat analyses.	Mean: 16 months (stratum 2); Median : 31 months (stratum 1)	Stratum 2 : The GFR decline per month was significantly lower in the ramipril than the placebo group (0.53 vs 0.88 ml/min, p = 0.03). Significant reduction in proteinuria in the ramipril group that correlated inversely with GFR decline. Stratum 1: The GFR decline per month not significantly different (ramipril 0.26 vs. placebo 0.29 ml/min, p = 0.06). Significant reduction in proteinuria and progression to ESRD in the ramipril group.	11, 12
Renoprotective effect of irbesartan in patients with nephropathy due to type-2 diabetes (IDNT)	1715	To determine whether the use of an ARB or a CCB would provide protection against the progression of nephropathy due to type 2 diabetes beyond that attributable to the lowering of the BP	Age: 30–70; type 2 DM, HTN–BP > 135/85 or use of antihypertensive agents, urinary protein excretion of at least 900 mg/24 hours, serum creatinine–(M) 1.2–3.0 mg/dl, (F) 1–3 mg/dl	DBRCT in 210 clinical centers; Randomized to irbesartan (n = 579, dose titration 75–300 mg/day); Amlodipine (n = 567, dose titration 2.5–10 mg/day); or placebo (n = 569)	Primary end point: Composite of a doubling of the base-line serum creatinine, onset of ESRD, or death. Secondary outcome: combined cardiovascular end point.	Mean: 2.6 years	The risk of the primary composite end point in the irbesartan group was 20% and 23% lower than the placebo (p = 0.02) and amlodipine (P = 0.006) groups respectively. No significant differences in death rates from any cause or the CV composite end point.	13

Study	N	Objective	Population	Design/Intervention	End points	Duration	Results	Ref
Effects of BP level on progression of diabetic nephropathy (RENAAL)	1513	To assess the role of the angiotensin-II-receptor antagonist losartan in patients with type 2 diabetes and nephropathy	Age–31–70, type 2 diabetes and nephropathy (urine albumin/creatinine ratio of atleast 300 mg/g or proteinuria of at least 0.5 g/day), serum creatinine 1.3–3.0 mg/dl	DBRCT, multinational study, randomized to losartan (50 mg–100 mg daily) or placebo, stratified by baseline proteinuria (urine albumin-to-creatinine ratio <2000 mg/g or ≥ 2000 mg/g). Additional open-label agents used as needed for goal BP <140/90 mm Hg.	Primary composite end point: Time to doubling of serum creatinine, ESRD, or death, whichever occurred first. Secondary end points: composite of morbidity and mortality from cardiovascular causes, proteinuria, and the rate of progression of renal disease.	Mean: 3.4 years	Osartan had a 16% risk reduction in the primary end point than placebo (p = 0.02). Similar rates of death, and cardiovascular morbidity and mortality in the 2 groups. Losartan had a 35% reduction in proteinuria (p < 0.001, compared to placebo)	14
Effect of BP lowering and antihypertensive drug class on progression of hypertensive kidney disease (AASK)	1094	To compare effects of 2 levels of BP control and 3 antihypertensive drug classes on GFR decline in African Americans with HTN	Age-17–80; African Americans; HTN; GFR 20–65 ml/min; non-diabetics.	3 × 2 factorial design; randomized to usual (102–107 mm Hg) or lower (<92 mm Hg) MAP goal. Treatment with metoprolol, 50–200 mg/d; ramipril, 2.5–10 mg/d; or amlodipine, 5–10 mg/d assigned in 2:2:1 ratio. Additional open-labeled agents added sequentially.	Primary: Rate of change in GFR (GFR slope–acute and chronic). Secondary clinical composite outcome: GFR reduction by 50% or by 25 ml/min from baseline, ESRD, or death.Other secondary outcomes: urine protein excretion, all CVE.	3–6.4 years	There was no significant difference in mean GFR slope from baseline through 4 years in the 2 BP gps and the drug gp comparisons. The secondary clinical composite outcome was similar in the 2 BP groups, but the ramipril gp had a 22% reduction compared to the other drug gps.	23, 26
Effects of BP level on progression of diabetic nephropathy (post hoc analyses of RENAAL)	1513	To evaluate the impact of baseline and treated SBP, DBP, and PP, to assess the specific effect of losartan, and the implications of dihydropyridine calcium channel blockers as concurrent therapy on composite and individual outcomes in patients with type 2 diabetes and nephropathy	Age–31–70, type 2 diabetes and nephropathy (urine albumin/creatinine ratio of atleast 300 mg/g or proteinuria of at least 0.5 g/day), serum creatinine 1.3–3.0 mg/dl	DBRCT, multinational study, randomized to losartan (50 mg–100 mg daily) or placebo, stratified by baseline proteinuria (urine albumin-to-creatinine ratio <2000 mg/g or ≥ 2000 mg/g). Additional open-label agents used as needed for goal BP < 140/90 mm Hg.	Primary composite end point: Time to doubling of serum creatinine, ESRD, or death, whichever occurred first.	Mean: 3.4 years	Baseline SBP of 140-159 mm Hg, compared to SBP <130 mm Hg increased risk for ESRD or death by 38% (p = 0.05). Patients randomized to the losartan group with a baseline PP > 90 mm hg had a 35.5% risk reduction for ESRD or death (p = 0.02) compared to the placebo gp.	17
Blood-pressure control for renoprotection in patients with non-diabetic chronic renal disease (REIN -2)	338	To assess the effect of intensified vs. conventional BP control on progression to ESRD in patients with non-diabetic proteinuric nephropathies	Age 18–70, non-diabetic nephropathy with persistent proteinuria (> 1g/24 hours for at least 3 months). Proteinuria of 1-3 g if cr cl <45 ml/min, and proteinuria ≥ 3 g if cr cl <70 ml/min	Multicenter RCT. All received background ACEI therapy with ramipril. Randomized to conventional (DBP <90 mm Hg) or intensified (BP <130/80 mm Hg) BP control. Add-on therapy with felodipine in the intensified BP group.	Primary outcome: Time to ESRD over 36 months follow-up. Secondary aims: To compare the effects of two different levels of BP control on GFR decline, residual proteinuria, and fatal and non-fatal CVE.	Median: 19 months	No significant difference in the progression to ESRD in the 2 BP gps (p = 0.99). No difference in the secondary outcomes between the two groups.	22

Table 33.1 (cont.)

Study	Total number of patients randomized n	Primary Aim	Study Population	Study Design	Outcomes evaluated	Duration of follow-up	Results	Reference
Renal outcomes in high-risk hypertensive patients treated with an ACEI or a CCB vs a diuretic (ALLHAT post hoc analyses)	33357	To determine whether, in high-risk hypertensive patients with a reduced GFR, treatment with a CCB or an ACEI lowers the incidence of renal disease outcomes compared with treatment with a diuretic	Age ≥ 55, Stage 1 or 2 HTN with at least 1 other CAD risk factor, serum creatinine <2 mg/dl	DBRCT, post hoc analyses, randomized to receive chlorthalidone (12.5–25 mg/d), amlodipine (2.5–10 mg/d), or lisinopril (10–40 mg/d) in a 1.7:1:1 ratio. Goal BP < 140/90 in each arm by adding open-label agants as needed. Stratified by baseline e GFR.	Clinical renal outcomes: Development of ESRD or death from kidney disease; composite end point of ESRD or ≥ 50% decline in GFR from baseline; mean GFR during study follow-up.	Mean: 4.9 years	No significant difference in the outcomes in patients taking chlorthalidone compared to those who received lisinopril or amlodipine, irrespective of the baseline GFR.	27
Effect of a lower target BP on the progression of kidney disease: Long-term follow-up of the MDRD study (post hoc analyses)	840	To assess the effects of a low target BP on kidney failure and all-cause mortality	Age: 18–70; Serum creatinine: (M) 1.4–7.0; (F) 1.2–7.0 mg/dl; MAP ≤ 125 mm Hg; Study A–GFR–25–55 ml/min, Study B–GFR–13–24 ml/min	Long term follow-up of patients from 1993 to 2000, after the MDRD study ended (See above for MDRD study design).	Outcomes: Kidney failure and a composite outcome of kidney failure or all-cause mortality, through extended follow-up	Approx. 7 years (1993–2000)	The adjusted hazard ratios in the low compared with the usual target BP group were 0.68 and 0.77 for development of kidney failure and the composite outcome respectively.	21

In the AASK trial (Table 33.1), patients were randomized to initial treatment with a beta blocker (metoprolol), ACEi (ramipril), or a dihydropyridine calcium channel blocker (amlodipine) [23,26]. Additional open-label agents were used to achieve the BP goals. In an interim analysis following discontinuation of the amlodipine intervention for safety reasons [26], ramipril compared to amlodipine was associated with a 36% slower mean GFR decline over 3 years and a 48% risk reduction of the clinical end points. However, the risk reduction was profoundly influenced by the subgroup of patients with baseline proteinuria. Among patients with no baseline proteinuria or with GFR of ≥40 mL/min, there was no difference in the GFR decline between the two groups at the end of the follow-up and GFR remained slightly higher in the amlodipine group than the ramipril group. Follow-up systolic BP was 2 mmHg lower for the amlodipine group than the other groups.

In the ramipril versus metoprolol comparison following the completion of the study [23], the mean GFR decline was slower during the acute phase with ramipril than with metoprolol (ramipril, −0.23 vs. metoprolol, −1.73 mL/min/1.73 m^2; $P = 0.01$). During the 4-year follow-up, GFR decline was marginally better in the ramipril group (−1.81 vs. 2.42 mL/min/1.73 m^2/year; $P = 0.07$). However, the chronic GFR slopes were similar between the two groups (ramipril, −1.87, vs. metoprolol, −2.12; $P = 0.25$). In the amlodipine versus metoprolol comparison, GFR increased in the amlodipine group during the acute phase (4.03 mL/min/1.73 m^2 −1.73 mL/min/1.73 m^2; $P <0.001$). However, the decline in GFR was faster during the chronic phase in the amlodipine group (−3.22 mL/min/1.73 m^2) compared to the metoprolol group (−2.33 mL/min/1.73 m^2; $P = 0.02$).

GFR decline was significantly slower during the 3-year follow-up in the amlodipine group than the metoprolol group (1.60 vs. 2.68 mL/min/year; $P = 0.004$), which was primarily a reflection of the change during the acute phase, which was likely a hemodynamic response. The beneficial effect on GFR in the amlodipine group during the acute phase and total GFR slopes was significantly related to baseline proteinuria and occurred only if the baseline urine protein/creatinine ratio was 0.22 or less. This interaction of baseline proteinuria was not significant for the chronic slope or the clinical composite outcome. However, among patients with baseline urine protein/creatinine ratios of >0.22, the metoprolol group compared with the amlodipine group had a risk reduction of 38% ($P = 0.03$) for the main composite outcome. In addition, mean declines in GFR were smaller for patients with higher baseline GFR but larger for those with lower baseline GFR in the amlodipine group compared with metoprolol groups. The risk reduction for the main clinical composite outcome with ramipril was 22% compared to metoprolol. Overall, although there was no difference among the three drug regimens in the primary analysis of the GFR slope, ramipril was more beneficial than the other two drugs in slowing progression of hypertensive kidney disease based on the results of secondary analyses. Metoprolol may be superior to amlodipine in improving renal outcomes, particularly among those with higher proteinuria and lower baseline GFR in African Americans with hypertensive kidney disease. Subsequent

analyses showed no difference in CV outcomes in the three drug groups [24]. The hazard ratios for CV deaths in the ramipril versus metoprolol, amlodipine versus metoprolol, and ramipril versus amlodipine comparisons were 1.06 (95% CI, 0.47–2.39), 1.18 (95% CI, 0.46–3.04), and 0.90 (95% CI, 0.35–2.30), respectively. The hazard ratios for CV composite outcomes (first CV hospitalizations and CV deaths) in the respective comparisons were 0.98 (95% CI, 0.69–1.39), 0.77 (95% CI, 0.48–1.24), and 1.27 (95% CI, 0.78–2.06) (Pnot significant, all comparisons).

In the REIN-2 trial [121], addition of the dihydropyridine calcium channel blocker felodipine for treatment of patients with nondiabetic proteinuric nephropathies receiving ACEi therapy (ramipril) did not slow the progression to ESRD or GFR decline and did not reduce proteinuria. The patients had a baseline GFR of about 35 mL/min and urine protein excretion of about 2.9 g/day.

Post hoc analysis of the ALLHAT study [27] assessed whether therapy with a calcium channel blocker (amlodipine) or an ACEi (lisinopril) improved the renal outcomes compared to a diuretic (chlorthalidone) among patients with HTN stratified by baseline estimated GFR (GFR, ≥90 mL/min, 60–89 mL/min, and <60 mL/min). All three groups required additional antihypertensive medications to achieve a target BP of <140/90 mmHg. The ALLHAT study had 33,357 participants, of whom about 17% had CKD. Proteinuria was not measured, and patients with baseline creatinine of >2 mg/dL were excluded. The baseline estimated GFR was 3–6 mL/min higher in the amlodipine group than the other two groups. Compared with the chlorthalidone group, the incidence of ESRD was not significantly different in the lisinopril or amlodipine groups across the three GFR groups for the total group or for participants who had diabetes at baseline. The major limitation of this analysis is the lack of information on baseline proteinuria.

The results, however, do not nullify conclusions from several other studies that ACEi or ARBs, usually in combination with a diuretic, slow the progression of kidney disease better than the other hypertensive agents. Moreover, BP control in CKD usually requires two or more antihypertensive agents.

Conclusions

Renoprotective strategies include both BP and proteinuria reduction in addition to others. Nonpharmacologic therapies, such as sodium restriction, weight loss, and increased physical activity, play a significant role in BP reduction in such patients. Proper use of diuretics is important for regulating the volume status and thus improving BP in these patients. Although ACEi and ARBs have a key role in BP and proteinuria reduction in CKD, they almost always require the addition of diuretics and other agents to achieve adequate BP. We need novel therapies and innovative approaches to prevent ESRD and to decrease mortality in patients with CKD. An individualized approach is recommended in managing patients with CKD and HTN. Studies determining outcomes in CKD using home BP and ambulatory BP measurements would be very informative.

34 Recognition and Management of Mineral and Bone Disorder of Chronic Kidney Disease and End-Stage Renal Disease

Donald A. Molony

Division of Renal Diseases and Hypertension and Center for Clinical Research and Evidence-Based Medicine, University of Texas Houston Medical School, Houston, USA

The recognition and therapeutic management of the metabolic bone disease of chronic kidney failure occupies a central place in the overall treatment of end-stage renal disease (ESRD) patients and is one of the unique activities that differentiates, in practice, chronic kidney disease (CKD) specialized care from the routine care of patients provided by the general internist. Much of the rationale for current treatment of chronic kidney disease mineral and bone disorder (MBD) has been based on biological reasoning: the view that if abnormalities in the hormone systems that regulate bone health and calcium and phosphorus metabolism can be corrected, then the disease states that result from these abnormalities can be treated and survival and quality of health improved. Figure 34.1 illustrates some of the important relationships between these hormone systems [1–11]. The validity for patients with CKD and ESRD of a therapeutic approach based on such pathophysiological reasoning and on evidence from animal models has been supported mostly by results from epidemiologic, observational studies; evidence arising from randomized controlled trials (RCTs) is more limited [1,12,13].

Thus, current therapies rely on a combination of approaches, including hormone replacement where hormone deficiencies are recognized [e.g. 25(OH)-vitamin D and 1,25(OH)$_2$-vitamin D] and suppression where excesses occur (e.g. parathyroid hormone [PTH]) and direct modulation of serum and/or whole-body phosphorus and calcium. This chapter will examine the evidence that supports current practice in adult patients with CKD and with ESRD. The evidence as it relates to pedeatric patients is covered in chapter 60. The biochemical targets for management of MBD recommended by national guideline committees are compared in Table 34.1 [14–23]. The oldest of these guidelines, the Kidney Disease Outcomes Quality Initiative (K/DOQI), was last updated with evidence prior to January 2001, and there have been some calls for revisions to reflect new data [24–26]. It is anticipated that the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines will address some of the expressed concerns [27]. Table 34.1

does not include KDIGO targets, as these guidelines are still under review.

It should be noted that the recommendations regarding treatment of MBD during CKD stages 3 and 4 or in earlier stages of CKD have been determined commonly by expert opinion and by the extrapolation of evidence from ESRD [13]. Furthermore, there are, to date, no published well-designed clinical trials in either ESRD or CKD that have evaluated the impact of concurrent modulation of multiple interrelated therapies (e.g. phosphate binders along with vitamin D and calcimetics) on the long-term outcomes of mortality and non-bone-related morbidity. Trials examining a limited number of these combined strategies are currently in progress [1,28].

Lending credence to an approach of arbitrating clinical decision making on the basis of biological plausibility and a mechanistic view of the disease processes responsible for MBD is the epidemiological and observational evidence that MBD is associated with bone demineralization and more importantly, clinically, with overt symptomatic bone disease and potentially with nonosseous calcification, including calcification of the vasculature. The latter is thought to contribute to the increased premature cardiovascular and all-cause mortality that occurs in CKD [29–50]. The causal link between vitamin D deficiency in CKD, secondary hyperparathyroidism, dysregulation of Ca and PO$_4$, demineralizing bone diseases of low or high turnover, MBD, and vascular disease is based principally on this epidemiologic and observational evidence [29,51–59]. Recently, some RCT evidence in ESRD patients has been obtained that supports a causal link between MBD and mortality and the potential benefits of the therapeutic interruption of this causal pathway [60]. Similarly, the evaluation of outcomes of the currently recommended therapies for management of MBD in CKD and ESRD is based principally on results from observational studies, and therefore the conclusions regarding therapy that can be drawn from these studies are subject to some uncertainty. The individual therapies or, more importantly, combinations of these therapies, should be scrutinized with well-designed RCTs of sufficient size evaluating patient-centered outcomes in patients with both ESRD and CKD [61].

Table 34.1 Comparison of guidelines and recommendations regarding targets for biochemical parameters of MBD of CKD and ESRD.

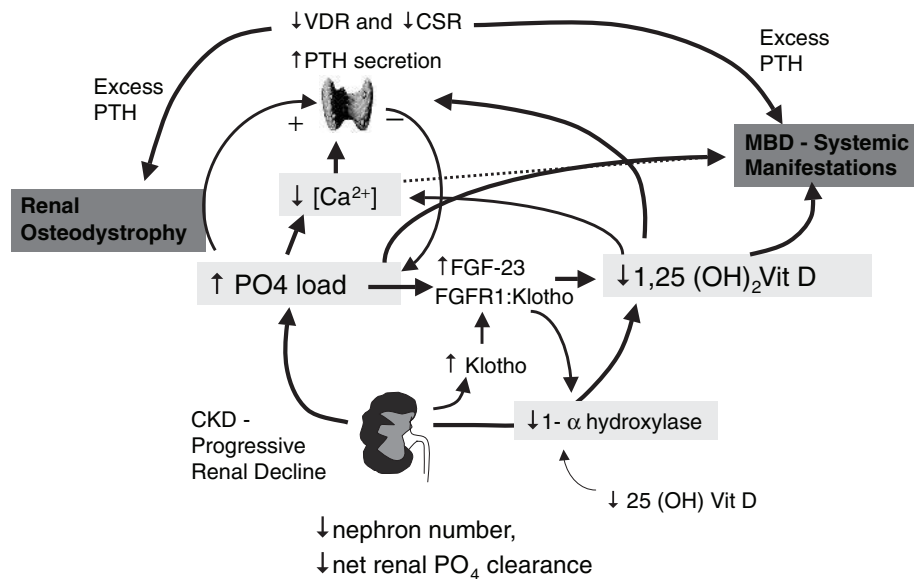
Biochemical parameter	Disease status	Recommendation from national body (yr of publication)				
		Caring for Australians with Renal Impairment (2005)	Canadian Society of Nephrology Hemodialysis Clinical Practice Guidelines (2006)	European Best Practice Guidelines (2006)	K/DOQI US National Kidney Foundation (2003)	UK Renal Assoc. (2006)
PO_4, mg/dL	CKD stages 3 & 4	Target within normal range			2.7–4.6	2.8–4.7
	ESRD	2.5–5.0		2.5–5.5	3.5–5.5	3.4–5.6
Ca, mg/dL	CKD stages 3 & 4	Target normal range			Target normal range	Target normal range
	ESRD	8.4–9.5	Target normal range		8.4–9.5	8.8–10.4
Ca $\times$ PO_4, mg^2/dL^2	CKD stages 3 & 4			<55		<60, ideally <52
	ESRD	<50		<55	<55	<60, ideally <52
iPTH, pg/mL	CKD stage 3				35–70	Within normal range
	CKD stage 4				70–110	<2$\times$ normal upper limit of assay
	ESRD	2–3$\times$ upper limit of normal	Avoid PTH <100, treat if >500 and symptoms		150–300	<4$\times$ nomal upper limit of assay


Figure 34.1 Pathogenesis of Secondary Hyperparathyroidism in CKD.
This figure illustrates some of the complex relationships between calcium, phosphorus, vitamin D, and PTH that determine normal mineral metabolism and some of the ways in which these relationships may be altered in CKD leading to the development of secondary hyperparathyroidism and the MBD of CKD. Two processes mediate the early events in the pathogenesis of SHPTH in early CKD; the renal and systemic response to excess phosphorus and the fall in active 1,25 diydroxy-vitamin D levels. The number of functioning nephron units decline as renal function worsens. The maintenance of normal serum phosphorus levels in CKD patients is dependent on an increase in phosphate excretion per nephron. High PTH and low active vitamin D levels inhibit tubular phosphate transport by decreasing sodium-dependent phosphate cotransporter activity. FGF-23 and the FGF-23 FGFR-Klotho complex may be important modulators of renal phosphate. In addition, FGF-23 appears to reduce $1,25(OH)_2$ vitamin D in part by reductions in 1-α-hydroxylase activity. The fall in 1-α-hydroxylase activity in CKD is most likely secondary to multiple mechanisms. Active vitamin D is also reduced in many patients because of insufficiency in 25 hydroxyvitamin D. Low levels of active vitamin D reduce calcium absorption from the GI tract and stimulate secretion of PTH. Additionally, low calcium levels stimulate PTH secretion; as a result calcium levels are partially restored by release of calcium from the bone. Excess PTH, hyperphosphatemia, and vitamin D deficiency each appear to contribute to the development of the systemic manifestations of CKD-MBD.

The results of a limited number of such studies have been reported.

Definition of MBD in CKD

The traditional views of bone disease in renal insufficiency (CKD) and renal failure (ESRD) have emphasized dimineralizing bone diseases representing a spectrum of bone pathologies ranging from osteitis fibrosa of secondary hyperparathyroidism to adynamic bone disease [62–65]. These definitions have been based largely on observational cross-sectional studies in CKD patient populations. Distinct bone histological patterns or disease states classified according to the American Society for Bone and Mineral Research criteria have been to varying degrees correlated to PTH, vitamin D, and mineral metabolism status [65]. The bone classification definitions and the utility of bone biopsy in identifying individuals with high-turnover and low-turnover metabolic bone disease and in monitoring treatment effects have been reviewed extensively [62–65].

The KDIGO guidelines have proposed an expansion of the definition of MBD that occurs in CKD (CKD-MBD) [27]. This new definition is necessitated by the emerging view that CKD-MBD is a systemic pathologic process that results both in bone pathology (renal osteodystrophy) and in other nonosseous abnormalities, including vascular and soft tissue calcification. This body recommended the following:

> The term *renal osteodystrophy* [should] be used exclusively to define the bone pathology associated with CKD. The many clinical, biochemical, and imaging abnormalities that have heretofore been identified as correlates of renal osteodystrophy should be defined more broadly as a clinical entity or syndrome to be called *chronic kidney disease-mineral and bone disorder*.

The latter then is a systemic disorder of mineral and bone metabolism due to CKD with one or more of the following: abnormalities in calcium, phosphorus, PTH, or vitamin D metabolism or of bone turnover, mineralization, volume, linear growth or strength, or vascular or other soft tissue calcification [27]. This revised definition of MBD of CKD is based on evidence from observational studies reported over the last 30 years. These studies have underscored the central role of secondary hyperparathyroidism in the pathogenesis of MBD; hence, the definition of the disease in large part is related to the occurrence and consequences of this secondary hyperparathyroidism. As potential biomarkers of early mineral metabolism are identified and validated, such as FGF23, the definition of MBD may need to be reframed [11,66–68].

MBD can also be framed in terms of specific vitamin D deficiency states recognized in CKD. Vitamin D deficiency [both that of 25(OH)- and "active" $1,25(OH)_2$-vitamin D] plays a central role in the development of secondary hyperparathyroidism and may antedate by some time in individuals experiencing progressive loss of renal function measurable elevations in serum intact PTH (iPTH) levels [69–73]. Thus, vitamin D deficiency has been considered a potential target for early therapeutic intervention.

Table 34.2 Vitamin D preparations evaluated with multiple cohort or RCTs in patients with CKD or ESRD.

Vitamin D class	Agent
Vitamin D	Cholecalciferol, D_3
Vitamin D, "vitamin"	Ergocalciferol, D_2
Active vitamin D, "hormone"	$1,25(OH)_2$-vitamin D
Established Active vitamin D	Calcitriol, $1,25(OH)_2$-vitamin D_3
Active vitamin D analogs	Alfacalcidiol Paricalcitol, 19-*nor*-$1,25(OH)_2$-vitamin D_2 Doxecalciferol, 1-α-(OH)-vitamin D_2

The RCT and observational study evidence supporting replacement strategies for CKD and ESRD patients deficient in vitamin D with cholecalciferol (vitamin D_3), ergocalciferol [vitamin D_2], and active forms of vitamin D_3 or D_2 [$1,25(OH)_2$-vitamin D or an equivalent] will be reviewed below. Table 34.2 lists the forms of vitamin D that have been evaluated in clinical trials in patients with either CKD or ESRD [74].

The relative contributions of 25(OH)-vitamin D and $1,25(OH)_2$-vitamin D in the pathogenesis of MBD are unknown, and to date no RCTs comparing treatment outcomes in a head-to-head study of both hydroxylated forms of vitamin D or evaluating their concurrent use have been reported. The evidence in CKD and ESRD is principally related to the effects of active 1,25-hormone on parameters of bone health and on Ca and PO_4 metabolism; fewer studies have evaluated the effects of cholecalciferol or calcidiol replacement on PTH and active vitamin D levels in ESRD [3,75–82]. By current customary practice, there is a general consensus that active vitamin D "hormone" [active $1,25(OH)_2$-vitamin D] deficiency is part of the clinical spectrum of MDB, and there is an emerging view that vitamin D deficiency [25(OH)-vitamin D] is also important in CKD and ESRD.

One of the important limitations of conducting clinical trials is the challenge of determining noninvasively, using a measure that can be employed in routine clinical practice, when MBD begins and the effectiveness of the treatment under investigation in modulating the MBD. Current assays for iPTH and vitamin D may have somewhat more limited reliability and reproducibility, as has been demonstrated when the same sample is tested in multiple different reference laboratories [83,84]. Furthermore, evidence has emerged from some investigations (but not all) that indicates that iPTH measurements may not always allow for accurate classification of a significant number of patients into those with low- versus high-turnover bone disease or to identify patients with a significant osteoporosis component [85–91]. Correct classification of patients is likely to have important implications for response to therapy [23,92]. None of the currently recommended testing regimens has been evaluated in an RCT for its utility in impacting long-term clinical outcomes. The clinical trials evidence reviewed in this chapter that relies on PTH or vitamin D levels as the primary outcome may need to be reconsidered as more sophisticated tests

are developed and validated. Ideally, therapy for treatment and/or prevention of MBD and its complications should be evaluated in terms of its effects on bone pathology, clinically relevant bone disease outcomes such as fracture risk, and on vascular health, patient survival, and the preservation of a state of optimal health [13,61]. In current practice, therapeutic success is often monitored by achievement of target PTH, PO_4 and Ca levels and, thus, this chapter will also review the therapies of MBD in terms of their effects on these biochemical disease-centered surrogate outcomes.

In the development of CKD, when does MBD begin?

If MBD is a systemic disease with severe consequences, it makes sense that initiation of specific targeted therapies either before the disease begins (primary prevention) or early in the course of disease (secondary prevention) might be able to reduce morbidity and improve overall survival among CKD patients. The most proximate initiating events in the pathogenesis of MBD of CKD are currently the focus of intense investigation. These investigations are clinically relevant in that they may allow for the development of early biomarkers of disease, allow for earlier treatment at a stage where treatment is presumably more effective, and suggest new loci for therapeutic interventions. Likely candidates include FGF-23, klotho, and phosphatonins, all of which may participate in the early pathogenesis of secondary hyperparathyroidism and MBD of CKD [6,9,10,67,68,93,94]. The utility of these "early" biomarkers of MBD in CKD has not been confirmed with cohort, epidemiologic, or RCT evidence, either as diagnostic tests that efficiently identify patients with MBD or as a way of directing therapeutic interventions and monitoring the effectiveness of these interventions. Despite the potential promise of these early biomarkers, clinical trials evidence is lacking to support the routine use of vitamin D in CKD for the prevention of MBD before overt vitamin D deficiency itself is identified. The clinical trials evidence on early recognition and treatment of MBD in the CKD patient is limited to the recognition of vitamin D deficiency and replacement strategies with vitamin D once deficiency is confirmed.

Epidemiology and definition of vitamin D deficiency

A number of recent studies have reported the frequency of vitamin D deficiency for both calcidiol [25(OH)-vitamin D] and calcitriol [$1,25(OH)_2$-vitamin D_3] and their respective vitamin D_2 counterparts for the normal adult population and for those with CKD or ESRD [72,95–104]. These studies have used definitions of vitamin D adequacy, insufficiency, and deficiency for both 25(OH)-vitamin D and $1,25(OH)_2$-vitamin D metabolities that have been determined principally from an examination of the effects of these deficiencies on PTH levels and on bone health and histology, clin-

ical phenomena that are regulated largely by active $1,25(OH)_2$-vitamin D hormone [105]. These definitions tell us little about the effects of vitamin D deficiency on nonosseous tissues. It is quite possible that higher levels are required to treat optimally the potential non-bone-related effects of vitamin D in patients with CKD [106,107]. Although epidemiologic studies demonstrate a strong association between vitamin D deficiency either assumed because of place of residence (northern climes) or measured using the normal values defined as above and a number of cellular, developmental, and immune dysfunctions, including myopathy, multiple sclerosis, psoriasis, infections, and malignancies, the converse has not been formally demonstrated, with a few exceptions [107–118], specifically, that the replacement of vitamin D either as 25(OH)-vitamin D or as active $1,25(OH)_2$-vitamin D hormone results in a reduction in cancer risk, infection risk, myopathy, anemia, and renal fibrosis in patient populations where vitamin D deficiency is the consequence of CKD.

$1,25(OH)_2$-vitamin D deficiency has long been recognized to occur in an increasing proportion of subjects as renal function levels decline. At an estimated glomerular filtration rate (eGFR) of <60 mL/min/1.73 m^2, most studies report that 50% of patients with CKD will be vitamin D hormone insufficient or deficient [69,70,72]. Recently, Levin and coworkers reconfirmed the topology of the decline in 25(OH)- and $1,25(OH)_2$-vitamin D in CKD and a correlation between the increasing prevalence of vitamin D deficiency and secondary hyperparathyroidism [72]. They reported a direct relationship of declining GFR with declining $1,25(OH)_2$-vitamin D_3 ($R^2 = 0.3827$; $P < 0.0001$), but not with 25(OH)-vitamin D levels. They also reported onset of overt hyperparathyroidism at eGFR levels of <45 mL/min/1.73 m^2, at a level where roughly 50% of the subjects in their survey population were deficient in $1,25(OH)_2$-vitamin D_3. The relationship of vitamin D deficiency and the development of hyperparathyroidism was strongest for $1,25(OH)_2$-vitamin D. They also reconfirmed that abnormal serum values for calcium and phosphorus do not occur until late in the course of CKD and as such are not good markers for either secondary hyperparathyroidism or vitamin D deficiency. Recently, Wolf and coworkers demonstrated that PTH status, late in CKD, provided a poor marker of an individual patient's vitamin D status [118]. LeClair and coworkers demonstrated significant calcidiol [25(OH)-vitamin D] deficiency in CKD, with only 17% of patients with CKD stage 3 and 12% of patients with CKD stage 4 having sufficient levels [101]. In this cohort of CKD patients, vitamin D levels did not increase during the summer months, implying that sunlight exposure was not sufficient for ensuring adequate levels of calcidiol. A cross-sectional study conducted in Hawaii demonstrated a significant number of healthy individuals with calcidiol insufficiency despite more than 30 h of sunlight/week [103]. Thus, sufficient levels of calcidiol cannot be assumed without a direct measurement in CKD patients, even among those with adequate sun exposure.

Although is it clear that patients with CKD are at significant risk for calcidiol and calcitriol deficiency and, consequently, secondary

hyperparathyroidism and MBD, the full benefits from the various vitamin D replacement strategies have not been investigated with well-designed RCTs. The hypothesis that pharmacological replacement of either calcidiol or of active $1,25(OH)_2$-vitamin D hormone will result in improvements in survival has not been evaluated with a rigorous RCT in subjects with CKD or ESRD. Vitamin D therapy in CKD and ESRD has been evaluated in terms of the effects on bone histology and fracture risk and on PTH and metabolic parameters.

Data from non-CKD patients have been reviewed in recent meta-analyses analyzing the evidence for prevention of fractures and for improvement in survival [120–128]. These clinical trials focused mainly on elderly individuals with osteoporosis. These studies included elderly individuals with unrecognized CKD. Consideration of these results might have relevance to the CKD population in the absence of similar specific CKD trials. The findings reported from RCTs in "normal" elderly subjects are similar to the findings that arise from the observational studies in CKD patients.

Vitamin D supplementation does appear to reduce the risk of hip or other clinically significant fractures in elderly women and men who have osteoporosis or are at risk for this disease. Bischoff-Ferrari conducted a meta-analysis of RCTs in which cholecalciferol was administered to elderly patients for prevention of hip or nonvertebral fractures [128]. They found five and seven RCTs that met their inclusion criteria where vitamin D therapy was evaluated for the prevention of hip and nonvertebral fractures, respectively. All of the studies identified used cholecalciferol as the active agent. They noted significant heterogeneity that disappeared when the studies employing high doses of vitamin D were analyzed separately from low-dose trials. They found that a higher dose of vitamin D (700–800 IU/day) reduced the relative risk (RR) of hip fracture by 26% (95% confidence interval [CI], 0.61–0.88) and nonvertebral fractures by 23% (95% CI, 0.68–0.87) versus either calcium or placebo. Vitamin D at a low dose (400 IU/day) did not confer benefit in these studies. In a more recent analysis that combined the low-dose and higher-dose studies, Jackson et al. did not demonstrate a similar benefit from vitamin D in preventing falls to that reported by Bishoff-Ferrair [124]. From recent studies it is uncertain whether a benefit is seen with customary doses of vitamin D or only with supraphysiologic doses and whether a benefit is seen in the absence of supplementation of dietary calcium [126,129]. In order to determine the impact of calcium supplementation, Boonen et al. recently updated the meta-analysis of Bischoff-Ferrari and found a favorable effect on hip fracture prevention with vitamin D when administered with calcium supplementation but, in contrast to the earlier meta-analysis, an absence of a significant overall benefit when cholecalciferol, even in the higher doses, was used alone. Others have also evaluated in a systematic review the benefits of achieving high serum levels of 25(OH)-vitamin D in non-renal failure patients and demonstrated limited benefits for subsets of the population, but the studies could not separate the benefits from those related to calcium and were inadequately designed to address the question of harm [123].

Does vitamin D supplementation improve other aspects of health and survival in the non-CKD population?

The observations that measured 25(OH)-vitamin D deficiency or, alternatively, residence in northern latitudes is associated epidemiologically with increased risk of infection, malignancy, myeloproliferative disorders, myopathy, neurodegenerative disorders, etc., have resulted in the recommendation that vitamin D supplementation be administered to the general population and that this might result in reduced mortality [107,110]. Autier and Gandini performed a meta-analysis of RCTs with vitamin D and demonstrated a significant survival advantage for subjects on vitamin D, especially at higher doses [130]. The effect was associated with a fivefold increase in 25(OH)-vitamin D levels in the treatment groups and was most robustly demonstrated in the RCTs that compared cholecalciferol administration to placebo rather than ergocalciferol to placebo. This differential benefit was somewhat attenuated in trials that used vitamin D in combination with calcium supplementation. Overall for all of the vitamin D trials, an RR reduction for death of 7% was determined with a number needed to treat of 169 (95% CI, 91–1178). More recently, Lappe et al. in a three-armed RCT of vitamin D plus calcium versus calcium alone or versus placebo demonstrated a substantially decreased risk for the development of cancer for the women assigned to the vitamin D plus calcium group compared to the other two study arms when the women were followed beyond the first year of therapy [111]. Whether these health benefits are attenuated or magnified in CKD patients on vitamin D supplementation has not been tested with an RCT.

Evidence from observational and epidemiological studies does support the hypothesis of a survival advantage in CKD stage 5 and likely late stage 4 from the use of active vitamin therapies. Some of this evidence as it pertains to cardiovascular risk has been summarized by Levin and Li [131]. More recently, Wolf et al. demonstrated in a prospective cohort of patients new to dialysis that those who were treated with active vitamin D (either continuing on active vitamin D started during predialysis with CKD stage 4 or initiated on vitamin D concurrent with initiation of dialysis) experienced a significant 90-day survival advantage compared to those who were not treated with active $1,25(OH)_2$-vitamin D (or its equivalent) [119]. The survival advantage in this population appeared to be obtained whether patients were deficient in 25(OH)- or $1,25(OH)_2$-vitamin D. Whether a similar survival benefit would have been observed in incident dialysis patients who were deficient in 25(OH)-vitamin D had they been treated with ergocalciferol or other forms of active vitamin D precursors could not be evaluated in this observational study.

The association of active vitamin D therapies with improved survival in ESRD has been observed in multiple cohorts of prevalent ESRD patients on dialysis [132–140]. Tang and coworkers observed that patients on hemodialysis who received active vitamin D

had a lower mortality than those who did not, irrespective of their serum PTH, PO_4, or calcium status [132]. Furthermore, they reported that those who received active vitamin D_2 (paricalcitol) appeared to do better than those treated with vitamin D_3 (calcitriol) [133]. Tentori and coworkers reported similar survival patterns with active vitamin D therapy in a different cohort in a later time period [134]. They also observed a survival advantage when active vitamin D_2 forms (paricalcitol and doxecalciferol) were compared to vitamin D_3 (calcitriol). The survival curves for paricalcitol and doxecalciferol were superimposed. In each of these observational studies the apparent survival advantage was relatively small. No head-to-head comparison in an RCT of sufficient duration of one form of vitamin D versus another or versus placebo has been performed to determine the true survival benefit of a specific vitamin D therapy for patients on dialysis. Despite sophisticated and appropriate statistical adjustments, the observational studies cannot be assumed to be entirely free of bias. Given that the magnitude of the observed benefit is small, it cannot be assumed that if this question were to be examined with an RCT that a similar survival benefit for vitamin D would be found [142]. However, in the absence of multiple robust RCTs, it is appropriate to acknowledge that a survival benefit for vitamin D sufficiency and/or its therapeutic restoration is supported by multiple lines of epidemiological reasoning. This body of evidence fulfills the major considerations attributed to Sir Austin Bradford-Hill, by which one can infer likely causal linkage between an exposure (active vitamin D deficiency) and an outcome (increased mortality), including dose response, strength of association, consistency, and biological plausibility, among others [1,143,144].

What is the evidence then that vitamin D replacement in patients with CKD results in meaningful clinical patient-centered outcomes?

Whenever possible, therapy should be informed by patient-centered outcomes that include improved survival, reduced risk of hospitalization, reductions in cardiovascular disease and cardiovascular events, reduced risk of fractures, and improved quality of life. Most of the clinical trials evaluating vitamin D therapy and informing its current clinical use in CKD measure disease-oriented and/or surrogate outcomes, such as changes in serum phosphorus, calcium concentrations, bone histology by biopsy or noninvasive measures, and serum PTH levels. The evidence that vitamin D therapies improve both patient-centered and disease-oriented outcomes is reviewed.

Before examining a recent meta-analysis of the RCT evidence, it may be useful to examine briefly the data that historically resulted in the current recommendations for use of vitamin D in CKD and ESRD. Renal osteodystrophy was recognized as a significant and progressive disease in patients with ESRD soon after effective renal replacement therapy became generally available in North American, Europe, and Asia. The disease state was recognized as demineralizing and debilitating bone disease, hypocalcemia, and

hyperphosphatemia. It was observed to be more prevalent in patients with prolonged kidney failure, especially those with chronic diseases of the renal tubulo-interstitium [145]. Bone biopsy studies demonstrated that the degree of disordered bone architecture was associated directly with the degree of hyperparathyroidism and that the latter correlated in some studies to 25(OH)-vitamin D deficiency or to $1,25(OH)_2$-vitamin D deficiency [105,146–148].

The first clinical trials with vitamin D replacement in CKD were conducted, prior to the availability of significant quantities of active vitamin D, with either supraphysiologic doses of cholecalciferol or 25(OH)-vitamin D_3 [75,76,78,79]. When these studies were performed in patients with ESRD, they were generally short term (typically 12 weeks) and included small numbers of subjects. Typically, improvements in bone pain, alkaline phosphatase, and PTH levels in patients with severe secondary hyperparathyroidism were evaluated. Typically, these early studies in ESRD cohorts did not include a control group and none evaluated hard patient outcomes, such as fracture rates and mortality. Some of these early cohort studies did include evaluations of bone histomorphology by biopsy.

Some of the earliest investigations of $1,25(OH)_2$-vitamin D therapy reported two findings that have subsequently proven to be causes for concern. First, Berl *et al.* conducted an RCT on a small number of hemodialysis patients [75], comparing the biochemical effects of oral therapy with calcitriol versus cholecalcerferol. They reported a prompt development of hypercalcemia in nearly all of their subjects receiving calcitriol (maximum dose, 1.5 μg/day), even though these patients were receiving aluminum and not calcium salts as a phosphate binder. Second, Christiansen and coworkers examined the effects of calcitriol in CKD patients [149–151]. They reported that calcitriol produced significant and abrupt increases in serum calcium levels and a doubling of renal calcium excretion. Importantly, in these studies oral calcitriol therapy significantly accelerated the rate of decline of renal function. Others have reported that calcitriol is safe without any adverse effect on renal function when used in very low doses that do not invoke a hypercalcemic response but that are sufficient to manage the early stages of secondary hyperparathyroidism in CKD [152,153]. Calcitriol is currently commonly used in CKD patients. More recently, Coburn and Coyne reported the effects of newer vitamin D analogs on urinary calcium excretion and renal function [154,155]. These investigators did not see elevations in urinary calcium excretion comparable to those reported by Christainsen *et al.* nor changes in the GFR with 6 months of oral therapy with the newer agents.

The widespread adoption of vitamin D therapy in ESRD more than 2 decades ago was based on two lines of evidence: on the effects of vitamin D replacement in ESRD patients on biochemical markers of MBD, such as PTH, PO_4, Ca, and alkaline phosphatase, that were reported from multiple mainly short-term nonrandomized trials, and on the clinical reasoning that emerged from experimental studies in laboratory animals. One of the principal initial goals of this therapy was correction of the hypocalcemia and consequent suppression of PTH based on mechanistic reasoning. This

mechanistic rationale for therapy has been summarized elsewhere [76,156].

Most recently, Palmer and colleagues reevaluated the clinical trials evidence regarding vitamin D use in ESRD and CKD using the formal analytical methods specified by the Cochrane collaboration, therefore limiting their analysis to evidence from RCTs [157,158]. They evaluated the effects of vitamin D on the magnitude of suppression of PTH and on the treatment of hyperphosphatemia, as well as the impact of vitamin D therapy on renal function, hypercalcemia, and on mortality. This analysis of the published literature demonstrated a number of findings.

Despite the promise of benefit from the observational studies in CKD patients and from the RCT results in the general population and the biological plausibility for a survival benefit, there have been no clinical RCTs specifically designed to demonstrate this survival benefit in patients treated with vitamin D in either the ESRD or the CKD population. In their meta-analysis, Palmer *et al.* referred to eight trials that reported on mortality as part of reporting of adverse events. The shortest of these trials was 12 weeks, and the longest in CKD patients, 2 years; the weighted average follow-up for the six trials that compared vitamin D to non-vitamin D therapy was approximately 1.2 years. Many of these trials excluded diabetic patients, and the average age of participants was less than 50 years. In these trials, there were a total of 16 deaths, 10 in those receiving vitamin D and 6 in the placebo group, or approximately 2 deaths for every 100 patient-years of follow-up. Thus, these trials were significantly underpowered to demonstrate any survival difference with vitamin D therapy and generally examined a healthier-than-typical hemodialysis population.

From their meta-analysis, Palmer *et al.* did conclude that active vitamin D therapy with newer agents reduced end-of-treatment PTH levels but that this potential therapeutic benefit was associated with potentially problematic albeit small increases in serum calcium and to a lesser degree with increases in PO_4 levels, but not with increased episodes of overt hypercalcemia or hyperphosphatemia. These findings of benefit versus the harm of generating hypercalcemia were more robust when a single trial using 22-oxacalcitriol, in which the rate of hypercalcemia was unusually high, was excluded from the analysis. The benefits on PTH control of therapy with an "established" vitamin D (1,25-dihydroxycholecalciferol) were not confirmed in this systematic review. Furthermore, the use of an established agent was associated with an increased risk of hypercalcemia and hyperphosphatemia. The conclusions that arise from this meta-analysis are somewhat tempered by the significant interstudy heterogeneity and by the less-than-robust methodologic quality of some of the available studies.

One of the principle findings from this meta-analysis is that there is a surfeit of robust RCT evidence underlying some of the assumptions regarding therapeutic benefits of vitamin D in CKD and ESRD. There are few direct comparisons of treatment with one form of vitamin D versus another or with a placebo. In a single RCT with 263 ESRD patients comparing head to head calcitriol versus paricalcitol, Sprague *et al.* demonstrated a more rapid reduction in PTH and less hypercalcemia with the paricalcitol treatment [159].

Much of the evidence to support the use of vitamin D comes from longitudinal studies, in which patients serve as their own control and where suppression of PTH and/or improvements in bone histomorphometry on biopsy have been the primary outcomes evaluated, or from comparisons of one active vitamin D with another [160–192]. Because many of these studies did not include random allocation, many of these would not normally be included in systematic reviews such as that performed by Palmer *et al.* Nonetheless, these studies provide some rationale for use of active vitamin D preparations to ameliorate the most severe effects of secondary hyperparathyroidism pending additional RCT evidence regarding the optimal dosing, route, and form of vitamin D for prevention of renal MBD and mortality.

The K/DOQI recommends that dialysis patients with iPTH levels of >300 pg/mL should receive active vitamin D to reduce PTH to target, that intermittent intravenous calcitriol is more effective than daily oral dosing, and that paricalcitol or doxercalciferol should be considered for patients who become more hypercalcemic or hyperphophatemic with calcitriol.

25(OH)-Vitamin D

Epidemiologic studies have identified significant 25(OH)-vitamin D deficiency in CKD populations. Clinical trials have provided evidence for the utility of vitamin D replacement therapy with cholecalciferol or ergocalciferol in the general population, where replacement therapy corrects secondary hyperparathyroidism, improves bone mineralization, reduces fracture risk, and improves motor and immune functions and may even delay the development of type 2 diabetes [104,105,109,111–120]. The epidemiologic and RCT data supporting these benefits of vitamin D replacement therapy in the general population have been extensively reviewed by Hollick and others [107,120,123]. The use of ergocalciferol or cholecalciferol in the CKD and ESRD population are less well studied. Prior to the introduction of active forms of vitamin D (calcitriol, etc.), correction of vitamin D deficiency in ESRD populations with significant renal osteodystrophy was attempted with pharmacologic doses of ergocalciferol or cholecalciferol. The results were variable. A number of the early studies failed to demonstrate a significant effect of suprapharmacologic doses of cholecalciferol or ergocalciferol on biochemical markers of MBD. Significant side effects were noted. Improvement in bone mineralization was rarely measured or reported.

Recently, Saab *et al.* reexamined the use of ergocalciferol in a prevalent dialysis cohort of 119 patients [82]. They noted no significant change in the biochemical parameters (serum calcium, PO_4, and Ca–PO_4 product) after 6 months of therapy with 50,000 IU of ergocalciferol monthly despite significant improvements in 25(OH)-vitamin D levels. They did not probe the long-term impact of this therapy on the patient-centered outcomes of bone health and survival. Zisman *et al.* demonstrated a modest improvement in PTH control in CKD stage 3 patients treated with ergocalciferol long term but no similar benefit for patients with CKD

stage 4 and more severe secondary hyperparathyroidism [193]. The implications of their findings for ESRD patients warrant further exploration. The exact role of ergocalciferol or cholecalciferol supplementation in the treatment of dialysis patients in the current era has, to date, not been evaluated with clinical RCTs.

Hyperphosphatemia

Many of the therapeutic efforts directed towards the management of the systemic disease of MBD of CKD are focused on the management of the excess phosphorus retention that is a consequence of CKD. In this regard, it is prudent to first examine the evidence that phosphorus itself contributes to increased mortality and morbidity in CKD and to examine whether reduction in phosphorus absorption either by dietary restriction or the use of phosphate binders results in improvements in this excess mortality and these morbidities.

The hypothesis that excess phosphorus retention and hyperphosphatemia result in significant human disease arises from two lines of evidence. These include experimental data from animal experiments and *in vitro* cell culture models and epidemiological data from human populations. The latter have included studies both in populations of dialysis patients and in cohorts of subjects with normal renal function or mild to moderate CKD. In studies first performed more than 20 years ago, Slatopolsky and colleagues demonstrated in animal models of renal insufficiency that secondary hyperparathyroidism, renal bone disease, and even renal failure progression could be attenuated after a 5/6 nephrectomy or other causes of acute renal failure if the animals were fed a very low phosphate diet. This body of evidence has been summarized elsewhere [194,195]. More recently the laboratories of Giachelli, Shannahan, Moe, and others have reported findings that provided a potential molecular mechanism for both direct and indirect effects of increased extracellular phosphorus (and often calcium in a synergistic manner) on fibrosis, MBD, and vascular calcification. These studies have been summarized by these three investigators in recent reviews [196–204].

Epidemiologic studies of patients with ESRD have demonstrated that there is a strong association between elevations in serum phosphorus levels, MBD of CKD, and mortality. These studies are summarized in Table 34.3 [44,205–220]. Block and coworkers analyzed a large data set of prevalent hemodialysis patients. They demonstrated that patients with baseline serum PO_4 levels of greater than 5.5 mg/dL experienced a significant dose-dependent increase in mortality over the subsequent 2 years of follow-up [207]. Block *et al.* have more recently replicated these findings [210]. Similar results have emerged from the DOPPS and other large dialysis patient cohorts [211]. Kalantar-Zadeh and coworkers, examining a large database of prevalent dialysis patients in the USA, demonstrated a similar relationship between PO_4 and mortality [44]. Kalantar-Zadeh's analysis differed from those conducted by Block and others in that they examined the time-dependent effect of PO_4 on mortality. In their fully adjusted

model (adjusted for significant comorbidities, age, gender, and nutritional status), serum PO_4 levels greater than 5.5 mg/dL and less than 2.8 were independently associated with increased mortality. On the basis of these findings, the K/DOQI and other consensus evidence-based guidelines have recommended that phosphorus levels in patients be targeted to relatively narrow ranges. A summary of the major recommendations with regards to the biochemical targets for therapy from some of the principal national bodies are shown in Table 34.1.

It should be noted that reduced survival in ESRD patients with MBD cannot be fully described by any single biochemical parameter, such as phosphorus, or by multiple parameters taken together where the target levels for these parameters have been largely determined separately. Stevens, Levin, and coworkers demonstrated in a prospective cohort the complex interplay between each of the MBD biochemical and clinical parameters and mortality [73]. Their analysis supports the hypothesis that patients may require different targets depending on their duration on dialysis. It is not surprising that the optimal calcium, phosphorus, and PTH targets for best cardiovascular and mortality outcomes might evolve as the vascular disease burden changes with duration of ESRD and time on dialysis. It is also likely that the optimal serum calcium and phosphorus targets and response to therapy might be different for individuals with some preservation of renal clearance [49,74].

Evidence is now emerging to implicate high phosphorus burdens with increased mortality risk in individuals with more normal renal function. Using a time-dependent model and the Framingham offspring cohort, Dhingra *et al.* demonstrated a significant association of serum phosphorus levels at the high end of the "normal" range, namely, above 3.5 mg/dL, with increased cardiovascular morbidity and mortality among healthy individuals with GFRs greater than 90 mL/min/1.73 m^2 followed for an average of 16 years [220]. They were also able to demonstrate an association of an increased Ca–PO_4 product with cardiovascular events. Tonelli *et al.* demonstrated a similar impact of a higher serum PO_4, albeit still within the normal range, on cardiovascular events among survivors of a myocardial infarction who participated in a secondary prevention trial [221]. The eGFRs (mean for the entire cohort, 71.95 mL/min/1.73 m^2) were similar across the spectrum of PO_4 levels, and a separate analysis conducted among participants with and without eGFRs of <60 mL/min/1.73 m^2 did not change the overall findings. In this cohort of individuals with pre-existing coronary artery disease and dyslipidemia, a fasting serum PO_4 value of >3.5 mg/dL was associated with an increased risk of mortality, and a value of >4.0 mg/dL was associated with a second myocardial infarction or congestive heart failure.

In a retrospective cohort study conducted in Veterans Affairs' (VA) Medical Centers located in the Pacific Northwest, Kestenbaum *et al.* demonstrated a linear increase in risk of mortality among patients with CKD with baseline serum PO_4 levels of >3.5 mg/dL or higher [218]. In an analysis of a separate VA population, Schwarz and coworkers observed in subjects identified with CKD by eGFRs on two separate occasions that serum PO_4 values of

Table 34.3 Observational studies identifying associations with biochemical parameters of mineral metabolism and mortality and morbidity in prevalent and incident dialysis patients and in patients with CKD.

Study and no. of subjects	Population	Calcium (mg/dL)	Phosphorus (mg/dL)	Ca × PO₄ (mg²/dL²)	iPTH (pg/mL)	Comments
		Level at which increased risk of mortality observed				
Dialysis population cohorts, incident or prevalent						
Lowrie (1990), $n = 12{,}000$	US prevalent dialysis patients, large dialysis provider (LDO, Fresenius)	<9.0; >12.0	>7.0	Not shown	Not evaluated	Principal goal of study to demonstrate association of low albumin with mortality
Leggat (1998) $n = 6251$	National samples of US prevalent HD patients (CMAS, DMMS)		>7.5			Population dichotomized into those with PO₄ above or below 7.5, as measure of nutritional and binder compliance
Block (1998) $n = 6407$	National samples of US prevalent HD patients (CMAS, DMMS)	No relationship observed	>6.5	>52		Prevalent patients with dialysis > 1 yr only, values divided by quintiles
Ganesh (2001) $n = 14{,}829$	National sample of US prevalent dialysis patients	Not evaluated	>6.5		<33; >495	
Marco (2003) $n = 143$	Prevalent Spanish HD patients	Not separately evaluated	>6.5	>52	>476	End points: cardiovascular events and all-cause mortality; follow-up 6 yrs; calcium-based phosphate binders standard
Block (2004) $n = 40{,}538$	US prevalent HD patients, large dialysis provider (LDO, Fresenius)	>9.5	>5.0	>50	>600	Case mix and multivariable adjusted results, baseline data
Young (2005) $n = 17{,}236$	Worldwide survey of prevalent dialysis patients (DOPPS)	> 11.4, <7.8 (albumin-corrected calcium level)	>6.5, <3.5	>65	Not reported	
Slinin (2005), all-cause mortality $n = 14{,}829$	National sample of US prevalent dialysis patients	>9.7	>6.4	>59.3	>480	
Slinin (2005), CVD, fatal and nonfatal MI, CHF	US prevalent HD patients, large dialysis provider (LDO, Fresenius)	>10.2	>4.5	>50.2	>480	
Rodriguez-Benot (2005) $n = 385$	Incident Spanish HD patients		>5.0			
Kalantar (2006), fixed model, time-dependent model $n = 58{,}058$	US prevalent HD patients, large dialysis provider (LDO, DaVita)	< 8.5; > 10.5	<3.0; >7.0	>55; >70	<200; >400	Case mix and multivariable adjusted results, time-dependent hazard; strong association between elevations in alkaline phosphatase and mortality

>4.3 mg/dL were associated with a more rapid progression of CKD to either a doubling of creatinine or ESRD [219].

Treatment strategies for hyperphosphatemia

Whereas serum PO_4 levels of greater than 4.5 and 5.5 mg/dL in CKD and ESRD populations, respectively, have been associated in observational studies with increased mortality, it cannot be assumed *a priori* that all therapeutic interventions to lower serum phosphorus levels in patients with CKD or ESRD to a specified "normal" range will result in similar levels of improved outcomes. Clinical trials comparing different strategies that lower PO_4, including dietary phosphorus restriction, the use of phosphate binders, and direct measures to control hyperparathyroidism, are required to determine absolutely the optimal strategies at each level of renal function and the optimal serum phosphorus targets to achieve with such treatments. Some but not all of the aspects of this clinical question are addressed by evidence that will be reviewed. Importantly, very few RCTs have examined the impact of multiple simultaneous interventions on patient-oriented "hard" outcomes.

Phosphate-restricted diet

An important component of any approach to hyperphosphatemia and the net positive phosphorus balance that occurs as a result of reduced renal excretion is the prescription of a phosphate-restricted diet. This approach is further supported by the observation from animal studies that phosphate restriction can significantly attenuate the development of secondary hyperparathyroidism [194,195]. In observations of CKD patients, renal phosphorus elimination in CKD stage 3 and early stage 4 is typically maintained as a result of compensatory changes, importantly, increased PTH secretion and consequent increased PO_4 elimination per functioning nephron. The observational data reviewed above, however, suggest that an increased phosphorus burden with normal serum phosphorus levels in the CKD patient nevertheless may result in diminished survival, mainly through premature cardiovascular events. There is no RCT that has examined the effects of phosphorus dietary restriction in CKD patients who have normal serum phosphorus levels. The focus of the evaluation of dietary phosphorus restriction has been on CKD and ESRD patients with overt elevations in serum phosphorus.

The typical North American and European daily diet contains between 800 and 1500 mg of phosphorus (800–1000 mg on a 1.2-g/kg protein-replete diet), of which approximately 50–60% is absorbed for an average weekly phosphorus load of approximately 4200 mg (2800–6300 mg) [222,223]. Judicious dietary restriction can reduce PO_4 to the lower end of this range [224]. In early stages of CKD, random serum PO_4 levels are normal but postprandial PO_4 levels may be elevated [225,226]; the latter may play a role in the pathogenesis of secondary hyperparathyroidism and in the excess mortality observed among CKD patients [227,228].

As CKD progresses, residual functioning nephrons increase net PO_4 excretion. Although PO_4 metabolism is altered early in CKD, it is only during late stage 4 and early stage 5 CKD that the GFR declines sufficiently such that this compensatory process no longer suffices and observed serum PO_4 levels increase. Patients on dialysis have negligible renal excretion of absorbed phosphorus, and a neutral phosphorus balance depends on reductions of ingested PO_4 and on augmented gastrointestinal (GI) and dialysis-related elimination [229]. Conventional thrice-weekly hemodialysis (12 h/week) will typically eliminate roughly 2400 mg of phosphorus. A net positive PO_4 balance can be greater than 1800 mg/week [230,231]. Although PO_4 elimination by dialysis is increased somewhat by newer modalities of dialysis (hemodiafiltration [232], daily dialysis [233], nocturnal dialysis [234–236], etc.), the limited availability and acceptance of the latter modalities that increase duration of dialysis, requires, that most patients rely principally on diet and on reduction of PO_4 absorption with phosphate binders to manage the PO_4 load. The latter works best to control PO_4 when some meaningful dietary PO_4 restriction is achieved [237–239].

Murphy-Gutekunst and others have evaluated sources of phosphorus in commercially available foods and demonstrated multiple sources of hidden PO_4, principally as food additives. They have addressed the impact of these sources on the PO_4 burden and the resultant challenges for PO_4 control in CKD patients [240–244]. Adequate dietary PO_4 restriction may increase the risk of protein malnutrition [245]. The safety of this excess PO_4 in the form of food additives for the general population has been called into question [246–248]. Although the impact of such food additives on the health of the CKD population is unknown, it is argued that the excess PO_4 could contribute importantly to cardiovascular disease [222,249], development of secondary hyperparathyroidism, vitamin D deficiency, and accelerated renal failure progression [195,248,250]. The inability of dialysis to adequately control PO_4 balance speaks to the inevitability of the need for phosphate binders for the majority of patients with ESRD [251,252].

Phosphate binders

Another pillar of treatment of MBD in late-stage CKD and in ESRD has been the prevention and treatment of hyperphosphatemia through reduction in PO_4 absorption from food with dietary manipulation in combination with oral PO_4 binders. The currently available phosphate binders have each been demonstrated to reduce PO_4 absorption from the GI tract and control serum PO_4 concentrations to targeted levels when utilized in recommended doses. This evidence has been reviewed by a number of investigators [253,254]. Agents currently in use for which there is either observational or study trial data demonstrating their efficacy as phosphate binders are shown in Table 34.4. Because each of these agents is effective in lowering phosphorous, the question of their appropriate use rests on whether it results in improved bone and cardiovascular health and reduced overall morbidity and mortality

Class	Agent	Comments
Mineral salts	Calcium carbonate	Extensive clinical experience in CKD and ESRD populations; limited RCT comparison to placebo
	Calcium acetate	Extensive clinical experience in CKD and ESRD populations; RCT evidence compared to other phosphate binders
	Calcium citrate	Limited trials evidence in ESRD
	Magnesium hydroxide	Limited trials evidence in ESRD and CKD
	Magnesium carbonate	Short-term RCT evidence in ESRD
Metal-based compounds	Aluminum hydroxide	Extensive clinical experience in CKD and ESRD populations; no RCT comparison with placebo
	Lanthanum carbonate	Extensive prospective cohort evidence in ESRD populations; RCT evidence compared to other phosphate binders
	Iron salts	Limited clinical trials evidence
Nonabsorbed polymers and resins	Sevelamer-HCl	Extensive prospective cohort evidence in ESRD populations; RCT evidence compared to other phosphate binders; surrogate and patient-centered outcomes.
	Sevelamer carbonate	RCT evidence compared to other phosphate binders; equivalency study compared to sevelamer-HCl

in individuals with CKD and ESRD. Additionally, for the individual patient, decisions on their use might also be influenced by tolerability and overt side effects.

The question of cost-effectiveness of one phosphate binder versus another, a public policy question of relevance for health authorities, will not be addressed in this chapter, even though this consideration has influenced importantly some of the decisions regarding the development of national guidelines. To better appreciate the potential and the limitations of such analyses, the reader is referred to four recent cost-effectiveness analyses comparing two phosphate binders, in which the analyses arrive at largely opposite conclusions [255–259]. The cost-effectiveness analysis by Manns *et al.* argues that substantial clinical benefit has not been demonstrated for any particular binder strategy, hence, the "cost minimalization" approach reported by this group [255]. Their findings are in contrast to the systematic review and cost-effectiveness analysis of Nadin and the cost-effectiveness analyses of Taylor *et al.* and of Huybrechts and coworkers [257–259].

Given the strong association between the severe elevations in PO_4 that occur in late stages of CKD and nonosseous or metastatic calcification, phosphate binders have been universally adopted into routine care of the ESRD patient without supporting RCT evidence in which outcomes with phosphate binders have been compared to outcomes with treatment strategies not including binders. This acceptance of phosphate binders without RCT evidence, in general, seems prudent for the severely hyperphosphatemic ESRD patient with severe secondary hyperparathyroidism. The evidence that has emerged from observational studies in ESRD populations does not help with the questions of when, along the spectrum of CKD, phosphate binders should be initiated, what level of serum or total body phosphorus should be targeted to obtain the best health outcomes, and whether all phosphate binders are equivalent in terms of long-term outcomes if they achieve equivalent PO_4 control. This last question drives the attention that has been paid to measuring, in short-term clinical trials, the efficacy of one binder compared to another in terms of biochemical parameters, but it begs entirely the related questions regarding the optimal PO_4 target along the continuum of CKD and whether the use of some PO_4 binders at particular stages of CKD might produce unintended adverse consequences. The uncertainty that arises from the sparseness of RCT data in CKD stages 3 and 4 has led most national guidelines groups to recommend achievement of normal PO_4 levels in these patients by relying principally on diet. These recommended target PO_4 levels, where available, are listed in Table 34.1.

This chapter will attempt to summarize the efficacy trials evidence insofar as these data inform one or more of the potential harms, namely, of hypercalcemia, hypercaluria,

Table 34.5 Comparison of epidemiologic criteria supporting a causal link of adverse outcomes for three elements.

Epidemiologic criterion	Aluminum	Calcium	Lanthanum
Strength of association	Strong	Strong	Unknown
Consistency, unbiasedness of findings	Criteria met	Criteria met	Unknown
Specificity	Criteria meet	Criteria met	Unknown
Temporality	Yes	Yes	Unknown
Epidemiology in human populations	Yes, strong	Yes moderate	Not yet demonstrated

hyperphosphatemia, renal failure progression, reduced survival, and oversuppression of PTH and development of adynamic bone disease. The focus of this section will be on a review of the evidence that relates phosphate binder choice to changes in patient-centered outcomes, focusing principally on hard outcomes, such as mortality and hospitalization rates rather than on surrogate outcomes, such as measures of vascular calcification and pulse-wave velocity.

Metal salts as phosphate binders

Aluminum salts

Aluminum hydroxide is an effective phosphate binder according to results from experience in the mid- to late 1970s, when use of aluminum hydroxide came into widespread use [260]. Aluminium hydroxide was adopted in part because of concerns with the potential for the development of hypercalcemia with the use of calcium carbonate and other calcium salts, and these concerns emerging from expert opinion in the absence of cohort or RCT evidence drove much of the change in therapy [260]. Subsequently, aluminum hydroxide fell out of favor because of case series that associated aluminum accumulation with neurotoxicity and other toxicities [261–269]. These concerns received further impetus from epidemiological data, in particular the well-studied disease outbreaks associated with parenteral aluminum from dialysate, from animal models of aluminum toxicity, and finally from the observation that chelation therapy appeared to modify the natural history of this toxicity in cases attributed to oral aluminum exposure. Chelation therapy was administered with significant associated morbidity and resource utilization. The more fulminant forms of overt dialysis dementia and aluminum-associated osteomalatia appeared to disappear in the USA after general abandonment of aluminum salts as a phosphate binder [277–280]. Whether this was

due to a true therapeutic benefit from avoidance of exposure to aluminum or an issue with case identification is unknown. Clearly, given the widely held view by many that aluminum is harmful, an RCT to interrogate its benefits and its toxicities is not feasible. The best one can do is to assess its potential for harm using the accepted criteria for determining that an exposure is likely linked causally to an adverse outcome. These criteria, attributed to Sir Bradford-Hill, are listed in Table 34.5. The evidence supporting the view that aluminum salts as a phosphate binder are harmful has been reviewed elsewhere [260,263,264,266]. These data do not allow one to conclude that there is some low level of aluminum exposure that is safe with chronic use [274,275,277]. There is significant absorption of aluminum even in individuals with normal renal function, where this excess is excreted in the urine [281]. In the patient with ESRD, this absorbed aluminum is retained.

The current K/DOQI recommends that the use of aluminum salts as phosphate binders be considered (guideline 5.8) if an individual with ESRD has a serum phosphorus level of >7.0 mg/dL (2.26 mmol/L). Furthermore, the K/DOQI recommendations state that aluminum-based phosphate binders may be used as a short-term therapy (4 weeks), and for one course only, to be replaced thereafter by other phosphate binders and where other modalities such as more frequent dialysis are also considered [22].

Lanthanum-carbonate

Other metal salts that are effective in reducing phosphate absorption from the GI tract and improving circulating phosphorus levels in short-term efficacy trials include iron salts (ferrous sulfate) and the lanthanum salt La-carbonate. These metal-based phosphate binders have been advanced as alternatives to calcium-based phosphate binders. In *in vitro* studies lanthanum carbonate was demonstrated to be a highly efficient binder of PO_4, with well-preserved effectiveness across a wide pH range [282]. Lanthanum

carbonate has been widely studied in patients and in animals for its efficacy and safety [283–287].

The available evidence on the safety and effectiveness of lanthanum carbonate, currently approved in many countries including the USA, Canada, and Europe under the brand name Fosrenol, has been reviewed. Most of the information regarding long-term safety of lanthanum has been culled from cohort studies, open-label extensions of shorter-term RCTs in which the control arm is dropped and study subjects were followed over years on La-carbonate phosphate binder therapy. These studies have included hemodialysis patients in Europe, Japan, and the USA, with some followed for more than 3 years while on lanthanum carbonate [284,286–292]. Short-term studies that have probed patient outcomes with use of lanthanum carbonate compared to placebo have shown that lanthanum is associated with substantial improvements in biochemical markers of MBD in ESRD patients, including substantial reductions in PO_4, the Ca–PO_4 product, and improvements in iPTH and bone histomorphometry [288,293,294]. When lanthanum carbonate has been evaluated in RCTs with calcium carbonate as the control phosphate binder, investigators have reported equivalent control of PO_4 with improved Ca–PO_4 product, iPTH levels, and markedly less hypercalcemia [284,286–288,292] compared to calcium carbonate phosphate binders.

In animal models, lanthanum carbonate accumulates prominently in the liver and bone, and less significantly in the kidney and other soft tissues [295–298]. Similar accumulation is noted in patients after long-term exposure despite very minimal GI absorption of lanthanum. Spasoviski noted that although lanthanum accumulation in bone is low, release of lanthanum from the bones of these dialysis patients continued even 2 years after discontinuation of the lanthanum [290]. These authors and others have observed that lanthanum does not disrupt normal bone architecture in a manner analogous to aluminum [290,294,295]. Deposition of lanthanum into the liver is not associated with elevations in liver transaminases or in reductions in hepatic synthetic function, but the results of systematic liver biopsies performed in lanthanum study subjects have not been reported, so the possibility of some long-term liver damage cannot be absolutely excluded [286,291]. Lanthanum absorption appears to be principally as La-Cl salts and not as the much less soluble La-carbonate [299]. The absorption of La from the GI tract after oral administration and its accumulation appear to be accentuated by uremia in most animal models.

Some but certainly not all investigators have reported measurable accumulations of La in the brains of uremic animals [296,297]. One group has challenged this evidence, arguing that the measurement of La in animal brain tissue is due to contamination from peripheral blood during the processing and that work completed almost 20 years ago demonstrated that the normal blood-brain barrier was impermeable to lanthanum [300]. In these earlier studies summarized by Evans, La was evaluated as a potential radiographic imaging marker, and the chemical and biological properties of La were evaluated after either a single administration or a limited number of exposures [299]. These studies demonstrated that La typically was excluded by the tight junction of the blood-brain

barrier after a single exposure, but in animal models of osmotic injury or after repeated exposure, limited lanthanum passage could be demonstrated [301,302].

Recently, Feng provided more direct evidence that La may indeed cross the blood-brain barrier in sufficient albeit still minute quantities to affect rat brain function and composition [303,304]. In a series of experimental studies that did not require direct measurement of La in the brain, they demonstrated by magnetic resonance imaging significant changes in the normal brain ion content (Ca, Fe, and Zn) and distribution in rats given lanthanum chloride in their drinking water. If such events are occurring in patients, even to a much lower degree, it would be worrisome especially in light of the stated objective of using phosphate binders in the first place, that is, extending survival and improving quality of life of ESRD patients.

An RCT comparing cognitive function in patients randomized to La-carbonate versus calcium carbonate over 24 months has been reported [305]. The authors reported no difference in cognitive function at 24 months in patients remaining in the two groups. The results, however, may have been biased by the investigators' choice to exclude from the analysis only those patients randomized to lanthanum who were withdrawn from taking La for any reason including adverse side effects but to include in the analysis all patients in the comparison group randomized to receive conventional therapy, whether they were maintained on the originally specified calcium carbonate binder or were switched to an alternative binder because of side effects. In other words, the investigators chose to compare a potentially less-healthy control group of patients to healthy La survivors group. Their observation that the patients in the La group did not perform profoundly better in the final cognitive function studies is somewhat concerning. Thus, the long-term safety of lanthanum in uremic patients has not been unambiguously established.

Non-metal-based phosphate binders

The non-metal-based phosphate binders can be divided into two categories. The first category contains the mineral salts, such as calcium carbonate and calcium acetate or magnesium hydroxide and magnesium carbonate, where some of the mineral is absorbed as part of normal physiologic processes and some remains in the GI tract to form nonabsorbable salts with phosphorus. The second of the categories consists of nonabsorbed polymer resins that bind phosphorus in the GI tract and are excreted in the feces (Sevelamer HCl and Sevelamer carbonate).

Magnesium salts
Magnesium carbonate, Mg-hydroxide, and other magnesium salts will bind phosphorus [306–310]. Magnesium has been used intermittently in ESRD patients for this purpose, but has not been widely studied because of concerns about the potential adverse effects from excessive Mg absorption in individuals with kidney failure [311,312]. Recently Spiegel *et al.* compared the efficacy for

controlling hyperphosphatemia of magnesium carbonate to calcium acetate and found that both were well-tolerated and effective [313]. This was a short-term study, so long-term events could not be evaluated and await additional clinical trials.

Calcium carbonate and calcium acetate

Both calcium carbonate and calcium acetate have been demonstrated as effective in controlling hyperphosphatemia in ESRD patients in large cohort studies and smaller controlled clinical trials. The latter was introduced approximately 20 years ago, as it was observed to result in less calcium absorption from the GI tract in animal experiments and in human balance studies, and it was advocated as superior because of a potential reduced risk of hypercalcemia [314]. Most balance studies have demonstrated a substantially lower albeit significant net positive calcium balance in ESRD patients treated with calcium acetate compared to carbonate [315–317], but many have reported equivalent rates of hypercalcemia [317,318]. In addition, patient adherence with calcium carbonate appeared in general to be better [317,319].

Calcium carbonate was recognized as a potential therapeutic agent in ESRD more than 40 years ago based on its ability to result in a net positive calcium balance and in reduced phosphorus absorption in uremic patients [320]. In comparison to aluminum hydroxide, it was equally effective in controlling the latter [229], although in one study some patients required addition of aluminum to achieve target control of PO_4 [321]. Additionally, $CaCO_3$ has been associated with an increased incidence of hypercalcemia compared either to aluminum or to calcium acetate [254,322], in part due to a relative increased GI absorption when administered with [323] or without [324] food, even though net absorption of calcium in kidney failure in the absence of vitamin D was substantially reduced [325].

It is current practice to administer vitamin D to patients with CKD usually at a point in the progression of their disease that antedates the need to initiate PO_4 binders, and virtually all ESRD patients require both agents. Shortly after Clarkson, Ginsburg *et al.* reported clinically significant hypercalcemia in dialysis patients receiving 2–6 g/day of $CaCO_3$ orally [326]. Furthermore, it was quickly established that individuals dialyzed against a higher calcium dialysate concentration (during either hemodialysis or peritoneal dialysis) experienced increased episodes of hypercalcemia and increased suppression of PTH when they received $CaCO_3$ as their binder [327–330]. These effects could be somewhat mitigated by use of lower bath calcium concentrations [297,322,331] or more $Al(OH)_3$ or $Mg(OH)_2$ as phosphate binders [310]. In the current era of dialysis, Salusky and coworkers have demonstrated that coadministration of vitamin D with $CaCO_3$ as the phosphate binder results in a significant increase in hypercalcemic episodes in pediatric peritoneal dialysis patients compared to patients not receiving calcium orally [332]. Use of $CaCO_3$ in patients with CKD stages 3 and 4 may result in a lower number of hypercalcemic episodes and produce significant suppression of PTH [333], but recent studies support the notion that long-term use of calcium

carbonate might contribute to vascular calcification even in predialysis patients [47,334–336].

Calcium acetate was introduced as a phosphate binder with a potential for reduced GI calcium absorption in part because of the exposure to roughly one-half of the elemental calcium for equivalent PO_4 binding capacity [253,254]. It was hoped that this would result in less hypercalcemia. Some of the initial clinical trials demonstrated the expected favorable serum calcium result [315,316,337]. Other investigators, however, either did not demonstrate a difference in the risk of hypercalcemia with the acetate salt compared with the carbonate in either crossover RCTs or longitudinal cohort studies [317,338,339] or found an actual worsening of hypercalcemia with calcium acetate, albeit with improved PO_4 control [313]. In the latter studies, hypercalcemia appeared to be most likely in patients who were receiving vitamin D and less likely when dialysate calcium was reduced [339]. Medication adherence appeared to be better with the carbonate than with the acetate [313,317]. It should also be noted that in healthy volunteers, calcium acetate does not increase aluminum absorption when these are administered together, whereas citrate does [340]. The latter may be an issue for CKD patients who are receiving citrate to correct metabolic acidosis [271].

The long-term consequences of the oral calcium loads at the doses typically used for binding phosphorus in ESRD patients have been debated extensively [341–344]. The evidence that informs this debate arises both from observational studies and from a limited number of RCTs, with the latter comparing the effects of different phosphate binders on long-term patient-centered outcomes. The observational data are reviewed in the next section.

Calcium-based phosphate binders: are they safe?

A general assumption that followed from the widespread use of calcium salts as PO_4 binders was that, short of causing overt hypercalcemia, some net positive calcium absorption would be beneficial as it might improve bone health and reduce cardiovascular risk. Both of these assumptions have been challenged recently by new RCT evidence in the general population. Bollard and colleagues randomly assigned postmenopausal women with sufficient vitamin D levels to receive 1 g of elemental calcium daily as calcium citrate versus placebo and followed these women for 5 years [345]. The women who were assigned to the calcium group experienced a higher rate of myocardial infarction and a trend towards reduced survival compared to women not receiving calcium. The population was principally individuals with mild CKD by virtue of their age and mild baseline elevations in creatinine. The benefits of calcium supplementation on preventing osteoporosis have been challenged by the negative results of the Women's Health Study [346]. A recent meta-analysis of the effects of calcium alone without vitamin D on bone health concluded that neither the pooled analysis of prospective cohort studies nor that of RCTs demonstrated a reduction in fracture risk. Furthermore, there was no

observed treatment benefit in RCTs for hip or vertebral fractures from calcium supplementation [347].

In patients with ESRD, it is recognized that oral calcium administration both reduces phosphorus absorption and modestly increases serum calcium in such patients with hypocalcemia. Both of these effects were previously thought to be beneficial, as they both result in suppression of PTH. Calcium salts were widely adopted as phosphate binders in an era when the correction of hypocalcemia in ESRD patients was already a specific goal of multiple simultaneous interventions, including use of high dialysate calcium concentrations [348]. The last decade has seen a significant shift away from this approach, largely due to an appreciation of a significant incidence of postdialysis hypercalcemia and the emergence of adynamic bone disease thought, in part, to be due to oversuppression of PTH by hypercalcemia [349–352]. Furthermore, a number of observational studies have demonstrated an association of decreased survival in ESRD patients with higher predialysis serum calcium concentrations. These observations further accelerated the abandonment of strategies to raise serum calcium levels after 1997. The results of these observational studies are summarized in Table 34.3.

In a seminal study, Block *et al.* reported increases in observed mortality independently associated in ESRD patients with abnormalities in the biochemical parameters of MBD [207]. Mortality was associated with elevations in baseline serum phosphorus levels (reviewed above) and the calcium–phosphorus product. These observations have been replicated by Block *et al.* and by other groups independently examining dialysis patient population data [44,208–217]. In a follow-up analysis of a large dialysis cohort, Block demonstrated that mortality increased significantly with serum calcium levels of >9.5 mg/dL and a calcium–phosphorus product of >50–55 mg^2/dL [210]. In this second analysis, they observed a continuous relationship between increasing serum calcium and mortality, and the highest survival rates were seen in patients with the lowest baseline calcium levels. Klantar-Zadeh, using a somewhat different analytical methodology, demonstrated a similar relationship between high serum calcium levels and mortality [44]. In their maximally adjusted model, patients with the highest serum calcium levels experienced the highest mortality risk, and patients with serum calcium levels of between 8.2 and 9.5 demonstrated the most favorable survival. The observations arising from all of these studies have been relatively consistent; higher levels of serum calcium, serum phosphorus, and Ca–PO_4 product are each independently associated with reduced survival, even if the magnitude of impact or the threshold for the effect reported from each study differ somewhat (Table 34.3). Based on these observational studies, current K/DOQI guidelines recommend targeting a serum calcium level of 8.4–9.5 mg/dL.

London and others have provided evidence that it is not simply the serum calcium level but rather the total calcium exposure that may determine the mortality risk. They have demonstrated from longitudinal cohort studies performed in ESRD populations that increased exogenous calcium loads are associated with increased vascular calcification [31,32,41,42] and in independent observa-

tions, with increased mortality [37,39]. Most recently this group has reported that in patients with adynamic bone disease as might occur with oversuppression of PTH by exogenous calcium loading compared to those with high-turnover bone disease, the relationship between exogenous calcium burden and mortality is strongest [51].

Although the classic Bradford-Hill considerations for a possible causal relationship between exposure to calcium and adverse outcomes are largely fulfilled (Table 34.5), there are no RCTs with masked allocation evaluating the long-term patient-oriented outcomes of phosphate binder therapy compared to placebo, therewith addressing this question with the lowest opportunity for bias and confounding. Despite a significant number of observational studies in which the use of calcium-based phosphate binders is associated with vascular calcification and premature cardiovascular disease, some equipoise with respect to the safety of calcium-based phosphate binders compared to non-calcium-based binders exists. This has permitted completion of RCTs comparing outcomes with calcium-based phosphate binders to outcomes with the non-calcium-based phosphate binder sevelamer. These studies have compared calcium-based binders to sevelamer principally in ESRD patients and have not investigated the incremental benefit of either phosphate binder compared to a no-phosphate binder control. In patients with ESRD who manifest the most severe dysregulation of PO_4 metabolism and the highest levels of serum PO_4, inclusion of a placebo arm to a phosphate binder trial is probably not ethically sustainable. However, the use of any of the currently available phosphate binders in CKD stages 3 and 4 has not been studied rigorously with multiple RCTs evaluating mortality and cardiovascular outcomes, and the benefits from these medicines in this patient population are less certain. Thus, RCTs with appropriate controls are appropriate and required in CKD stages 3 and 4 to address the following questions: 1) when to initiate phosphate binders as an individual progresses through the stages of CKD; 2) what target levels of PO_4 and PTH should be recommended at each stage of CKD to achieve optimal benefit on mortality and morbidities, including renal failure progression; 3) how to use the binders optimally in conjunction with vitamin D; and 4) what binders might be most effective in maintaining health and survival.

It is plausible that patients with moderate to moderately severe CKD (CKD stage 3 and early stage 4) might behave either similarly or differently than ESRD patients when exposed to phosphate binders. The epidemiologic and observational data and the limited RCT evidence available in CKD patients support the hypothesis that patients with late CKD stage 4 behave similarly to CKD stage 5 and ESRD patients. Thus, data from ESRD population-based studies have been used in the absence of more direct RCT evidence for CKD stage 4 to inform practice. Observational studies have identified a significant degree of vascular calcification in CKD patients [50,331,335,353], especially in those patients with diabetes or increased markers of inflammation, and that this vascular calcification is associated with a number of factors, including the quantity of calcium ingested [47,50,334,335].

What is the evidence that exposure to calcium salts in the form of phosphate binders may result in less favorable outcomes when compared to non-calcium-based binders? These data are of four types: 1) epidemiological data that demonstrate a strong positive association between calcium exposure and adverse outcomes (Table 34.3); 2) whole-animal studies and experimental models using human cells in culture; 3) short-term human trials reporting serum and urine calcium levels, PO_4, and PTH; and 4) the results of long-term RCTs comparing calcium-based phosphate binders to sevelamer and evaluating hard outcomes. The evidence from each of these sources when evaluated in the context of the totality of evidence is consistent with the remainder of this evidence. The RCT evidence is considered below.

Sevelamer

Sevelamer is a cross-linked poly(allylamine)-hydrochloride or carbonate, a calcium-free, metal-free, nonmineral, nonabsorbed polymer that binds phosphorus in the proximal intestine and bile acid more distally [354–360]. This first characteristic permits sevelamer to perform as an efficacious binder of PO_4 in the more proximal portions of the GI tract, the second as a sequestrant acting more distally to decrease low-density lipoprotein (LDL) cholesterol and triglyceride levels [356–362]. It is available in most countries as the hydrochloride. A newer form of sevelamer polymer as the carbonate is available in a limited but growing number of countries [360]. These phosphate binders have been evaluated in patients with ESRD [354–356,359–361,363,364] and CKD [336,362] with hyperphosphatemia in comparison to calcium-based phosphate binders or in comparisons of one form of sevelamer to the other. There have been three crossover trials that have probed the use of sevelamer to control phosphorus in combination with a calcium-based phosphate binder [365–369]. The principal goal of the efficacy studies has been the control of hyperphosphatemia. In addition, long-term clinical RCTs have been conducted comparing sevelamer to calcium-based phosphate binders on coronary artery and vascular calcification, on pulse wave velocity [370,371], on mortality, and on hospitalization rates. The studies of 52 weeks or longer in duration are shown in Table 34.6 [60,335,364,372–379]. RCT evidence of potentially favorable effects of sevelamer compared to calcium-based phosphate binders on biochemical parameters, including LDL and high-density lipoprotein (HDL) cholesterol levels, C-reactive protein, fetuin, FGF-23, and uric acid (many of which are candidate markers of inflammation) has also been reported [380–382]. These "pleiotropic" effects of sevelamer theoretically may provide additional long-term health benefits from sevelamer use, but the magnitude of these potential benefits has yet to be established [383].

It should be noted that most clinical trials (observational studies, single-arm efficacy trials, and RCTs) with sevelamer-HCl report consistently lower serum bicarbonate levels in patients on sevelamer-HCl for longer than a few weeks compared to the level in the same patients prior to sevelamer-HCl therapy or in comparison to patients on other phosphate binders, including sevelamer-carbonate, aluminum hydroxide, calcium-carbonate, and calcium acetate. In sevelamer-treated patients, observed serum bicarbonate levels range from 18 to 21.5 mEq/L (commonly 18.5–20.5) compared to levels of close to 22 mEq/L reported in most patients treated with other PO_4 binders. The mild acidosis is thought to be due to the absorption of additional Cl^- released from sevelamer-HCl and not an effect of the sevelamer polymer itself, since use of sevelamer as the carbonate results in correction of this acidosis [384]. The long-term clinical implication of the mild metabolic acidosis seen in patients treated with sevelamer-HCl is uncertain; to date there have been no clinical trials that have implicated the mild acidosis per se as causal of significant adverse events.

Both the HCl and the carbonate forms of sevelamer reduce phosphorus absorption and serum phosphorus levels in an identical dose-dependent fashion, as reported in two recent clinical trials. In the first trial, the investigators determined that sevelamer carbonate and sevelamer HCl were equipotent and efficacious as phosphate binders [384]. They also demonstrated that the carbonate form of sevelamer was associated with fewer GI side effects of any type (15 vs. 28%; $P < 0.007$) and with normalization of serum HCO_3 levels (22.4 vs 20.8 mEq/L) [384]. A second trial conducted in patients with CKD or ESRD demonstrated that once-daily dosing of sevelamer carbonate with a meal was not as effective in reducing PO_4 in those patients with the most severe elevations in baseline PO_4 as thrice-daily dosing with meals and/or snacks but did control PO_4 to target in some patients with more moderate degrees of hyperphosphatemia [360,385].

Both forms of sevelamer also bind bile salts and improve LDL and HDL cholesterol and triglyceride levels in these patients. The impact of the observed improvements in lipid profiles with sevelamer on patient-oriented clinical outcomes is unknown. Similar degrees of improvement in lipid profiles did not result in substantial improvements in vascular outcomes in one large RCT [386], but a meta-analysis by Stripolli et al. that also included these trial results supported the view that the pharmacologic modulation in lipid profiles in CKD patients is beneficial [387]. The recent CARE II trial of Qunibi and coworkers that included a lipid-lowering intervention (atorvastatin) did not evaluate patient-oriented outcomes and therefore does not add to the evidence informing this specific question [364].

Long-term RCT comparisons of sevelamer with other phosphate binders

The important long-term risks and benefits of sevelamer as a phosphate binder have been probed with RCTs virtually exclusively in comparison to calcium-based phosphate binders. These RCTs have evaluated the effects of a phosphate binder on disease-oriented outcomes, including coronary artery calcification, pulse wave velocity, bone mineral density, and bone histomorphology, and on patient-centered outcomes, including mortality and hospitalization rates. A single case report of reversal of calciphylaxis with high-dose sevelamer is intriguing but has not been corroborated in an RCT [388]. Table 34.6 lists RCTs of at least 12 months in duration

Table 34.6 Long-term clinical trials comparing calcium-based phosphate binders to sevelamer.

Clinical study (yr)	Calcium-based phosphate binder used	Outcome measured	Outcome reported	Duration of follow-up; no. of subjects
Studies using surrogate outcomes				
Chertow (TTG) (2004)	Acetate and carbonate	Change in CAC score	Significantly slower progression of coronary artery, aortic, and mitral valve calcification by EBCT in sevelamer group	1 yr; 200 prevalent HD patients
Braun (2004)	Carbonate	Change in CAC score	Significant progression of coronary artery and aortic valve calcification by EBCT in calcium group, no progression in sevelamer group	2 yrs; 114 prevalent HD patients
Raggi (TTG, 1 yr of follow-up) (2005)	Acetate and carbonate	Bone mineralization	Stability or improvement in trabecular bone mineralization in sevelamer group, progression of demineralization in calcium group	1 yr; 111 prevalent HD patients
Asmus (TTG, 2 yrs of follow-up, Germany and Austria) (2005)	Carbonate	Bone mineralization	Stability or improvement in trabecular bone mineralization in sevelamer group, progression of demineralization in calcium group	2 yrs; 72 prevalent HD patients
Block (RIND-18 primary study) (2005)	Carbonate and acetate	Change in CAC score	More rapid progression of coronary calcification in calcium group among those with calcification at baseline	18 mos; 127 incident HD patients
Russo (2007)	Carbonate	Change in CAC score in CKD	More rapid progression of coronary calcification in calcium group or those treated with diet only compared to sevelamer	2 yrs; 90 predialysis patients
Ferreira (2008)	Carbonate	Bone mineralization	Bone formation rate per surface area increased by sevelamer in HD patients with mostly adynamic bone disease	1 yr; 119 prevalent HD patients
Qunibi (CARE-2) (2008)	Acetate	Change in CAC score	Noninferiority (within 1.8 SD) of calcium-acetate plus atorvastatin compared to sevelamer for slowing the rate of vascular calcification by CT	1 yr; 203 prevalent HD patients
Studies using hard outcomes				
Block (RIND; 5 yrs follow-up) (2007)	Carbonate and acetate	Mortality in incident dialysis	Increased survival over 5 yrs in subjects allocated to sevelamer arm at randomization	5 yrs; 127 incident HD patients
Suki (DCOR) (2007)	Acetate 70%, carbonate 30%	Mortality	Inconclusive result for overall mortality; mortality benefit for strata over age 65 yrs	3.5 yrs; 2103 prevalent HD patients
St. Peter (DCOR) (2008)	Acetate 70%, carbonate 30%	Hospitalization rate	Reduced number of hospitalizations and hospital days in sevelamer arm; no observed difference in overall mortality between the two arms	4 yrs; 2103 prevalent HD patients

Abbreviations: HD, hemodialysis.

that compared outcomes in patients treated with sevelamer or calcium-based phosphate binders [60,335,364,372–379]. The first eight reports are from six trials that evaluated disease-oriented outcomes, and the remaining three are from two trials reporting on patient-centered outcomes. These trials demonstrated a statistically significant increase in vascular calcification (coronary arteries, heart valves, and/or aorta) in predialysis, incident dialysis, and prevalent dialysis patients treated with either diet alone or calcium-based phosphate binders alone compared to sevelamer-treated patients. In the prevalent hemodialysis patients studied in the treat-to-goal trial reported by Chertow and coworkers [372] and by Asmus et al. [375], vascular calcification progressed significantly more in the calcium-treated group compared to the sevelamer group at 1 year and yet further again at 2 years. The benefit from sevelamer treatment was greatest for those with the most intense calcification at study entry.

Most recently, Qunibi [364] compared vascular calcification scores in prevalent hemodialysis patients treated either with sevelamer-HCl or with calcium-acetate plus atorvastatin where the atorvastatin was titrated in both arms of the study to achieve the same lipid profile with both binders. They observed that the between-binder group difference in calcification scores in the patients followed for 12 months was no greater than the predetermined margin of 1.8. The authors argued that calcium acetate is not inferior to sevelamer in modulating coronary artery calcification (CAC) scores when both are used along with a statin. The study was limited by its short duration and substantial and differential dropout rates: 28 and 43% in the calcium-acetate group prior to 6 months and prior to 1 year, respectively, and 13 and 30% for the same periods in sevelamer-treated participants. There were 7 deaths during approximately 75 patient-years of observation in the calcium arm of the trial (actuarial method) compared to 3 deaths during approximately 86 patient-years in the sevelamer arm. The authors did not report whether these death rates were different statistically.

The three remaining studies in Table 34.6 report as their primary or secondary outcomes patient-centered outcomes. Block and coworkers followed the original RIND trial cohort for a total of 60 months from the date of first enrollment [60]. They demonstrated two important findings in this planned extension of the RIND trial. First, they provided the first prospective validation in ESRD patients of the CAC score as a predictor of future mortality. Second, the authors reported a statistically significant, more favorable hazard ratio (lower mortality) over the entire survival curve for study subjects enrolled in the sevelamer arm at initiation of dialysis compared to patients randomized to receive the calcium-based phosphate binders for the first 18 months of hemodialysis treatment. The difference in the annualized hazard ratio if extrapolated over 5 years might result in a substantial absolute risk reduction for mortality. (A crude estimate for the absolute risk reduction over 5 years of roughly 28% can be made with a degree of uncertainty.) Block et al. provided evidence of a potential survival benefit from using sevelamer in place of calcium-based phosphate binders that is consistent with the epidemiologic data.

Suki et al. conducted the largest trial to date comparing outcomes in prevalent dialysis patients treated either with sevelamer or calcium-based phosphate binders (70% calcium acetate, 30% calcium carbonate) [378]. This trial was inconclusive for the primary outcome of all-cause mortality for the entire study population because of a 30% lower than predicted mortality rate and the uncertainty introduced by an approximately 50% dropout rate at 2 years. For the strata of patients older than 65 years, however, a preplanned analysis revealed a significant survival advantage for those elderly patients allocated to the sevelamer arm of the trial. St. Peter and colleagues used the Centers for Medicare and Medicaid Services medical billings to determine the hospitalization rates and length of stay and overall mortality for all DCOR study subjects whether actively enrolled or lost to follow-up [379]. They demonstrated a statistically significant reduction in multiple hospitalizations and hospital days for those individuals originally allocated to sevelamer rather than calcium-based phosphate binders.

The RCT evidence does not eliminate some of the uncertainty regarding the magnitude and the topography of the survival benefit from the use of sevelamer and/or elimination of calcium salts as phosphate binders. Further clinical trials may be required. It should be noted, however, that the hypothesis that excessive calcium ingestion is associated with reduced survival is supported by substantial epidemiologic and observational data in addition to the RCTs reviewed. Furthermore, a recent observational study by Borzecki et al. demonstrated that incident dialysis patients in the VA medical system had a 33% (multivariant-adjusted) to 35% (propensity score-adjusted) improved 18-month survival if they were treated with sevelamer rather than calcium acetate or carbonate [389]. Although the magnitude of the benefit was greater in this observational study than that reported for the elderly subjects in the RCT by Suki, the effect size in the Borzecki study is large enough that it is likely that a benefit would persist were the same question interrogated in this incident dialysis population under RCT conditions [142].

Sevelamer effects on bone histology

In addition to a potential survival benefit, findings from a number of RCTs in prevalent hemodialysis patients support the hypothesis that sevelamer improves bone health in patients with MBD of CKD more than comparable control of PO_4 with calcium-based phosphate binders [332,366,374,375,377]. Each of these studies reported improvement in some measure of bone mineralization and biochemical parameters associated with improved bone health, such as alkaline phosphatase. Raggi and Asmus demonstrated increases in trabecular bone mineralization that were significantly greater in sevelamer-treated subjects [374,375]. Kokuho et al. evaluated patients with low-turnover bone disease and low iPTH and demonstrated improved biochemical bone parameters when sevelamer was used either alone or in combination with calcium carbonate in a strategy designed to reduce overall calcium exposure [366]. In an RCT in prevalent hemodialysis patients, Ferriera et al. evaluated the effects of sevelamer versus calcium carbonate on bone histomorphometry [377]. A majority (59%) of their

population (prevalent hemodialysis patients) demonstrated features of adynamic bone disease at study entry. Over the 1 year of the study, the patients randomized to receive sevelamer demonstrated improvements in their bone formation rate per bone surface area that were not seen in the opposite arm of the study. None of these studies evaluated changes in fracture rates.

Sevelamer: when should it be used

K/DOQI guidelines recommend that clinicians consider using sevelamer as a phosphate binder in place of calcium-based binders in those patients who cannot tolerate calcium binders due to the development of hypercalcemia or in those patients who already demonstrate vascular calcification or who are at high future risk of developing vascular calcification. The latter group includes elderly dialysis patients, those with long-standing kidney failure on dialysis for more than 2 years, and those with diabetes mellitus [50,353,382]. For the remainder of the dialysis and CKD populations, reliable simple measures are available that have been shown in clinical trials to identify most individuals with significant vascular calcification. Sophisticated approaches using computed tomography technology have been developed [390–393] and validated for the general and dialysis populations [60,394–403]. Potentially of greater broad clinical applicability are those techniques that have been developed and validated that utilize X-ray or ultrasound to identify the presence of vascular calcification [404–406].

Meta-analyses comparing sevelamer and other binders

Meta-analyses on the effectiveness of sevelamer as a PO_4 binder have been performed. It should be noted that because most of the clinical trials used either PO_4 levels or the $Ca–PO_4$ product to titrate the dose of the binders, substantial differences in end-of-trial PO_4 levels should not be expected. Any differences might reasonably be assumed to be due to potential protocol failure. On the other hand, meta-analyses could reasonably evaluate differences in control of hyperparathyroidism, frequency of hypercalcemic events, changes in coronary artery calcification, mortality, and morbidities such as hospitalization rates. Attempts at compiling such comprehensive summaries have been limited by the availability of robust RCT evidence of long-term hard outcomes in CKD and ESRD patients and the significant important differences in trial design including duration of follow-up, resulting in significant between-study heterogeneity.

Burke *et al.* conducted a systematic review of the literature on sevelamer-HCl reported through October 2002 (68 published reports, 46 abstracts evaluated, and 17 included in the final analysis) to evaluate the question of the effect of ingestion of sevelamer as a phosphate binder on lipid profiles and on the biochemical parameter of MBD in ESRD, specifically, on serum PO_4, Ca, Ca–PO_4 product, and iPTH [407]. They did not evaluate the literature for comparisons of sevelamer with any other phosphate binder. Burke *et al.* demonstrated a significant fall in serum PO_4 (average

reduction of 2.1 mg/dL; 95% CI, 3.1–1.2), in the Ca–PO_4 product (15.9 mg^2/dL; 95% CI, 121.4–10.4), in iPTH (36.0 mg/dL; 95% CI, 67.7–4.28) and in triglycerides (22.0 mg/dL) and total and LDL cholesterol (30.6 mg/dL [95% CI, 35.4–25.8] and 31.4 mg/dL [95% CI, 35.5–27.3], respectively), and a concomitant rise in HDL cholesterol (4.1 mg/dL). Serum calcium levels did not change (0.09 mg/dL; 95% CI, −0.10 to 0.14).

Nadin conducted a similar evaluation in 2005 but also included an assessment of morbidity and mortality outcomes and cost-effectiveness in comparison to other binders. She included studies identified through January 21, 2005, evaluated 177 reports, and included 53 in the final analysis [408]. She concluded that the evidence demonstrates that sevelamer is as effective as calcium salts in lowering PO_4 and product, with a lower risk of hypercalcemia. She also noted substantial evidence on vascular calcification and more limited evidence on patient-oriented outcomes related to morbidity and mortality.

Most recently, Tonelli and coworkers evaluated the clinical efficacy and safety of sevelamer versus calcium-based phosphate binders [209]. This review represents an update of a prior report from the same investigators [210]. Tonelli *et al.* reported that hypercalcemia was more likely in patients treated with calcium-based phosphate binders, with an absolute risk reduction of 21% (95% CI, 13–29%) with sevelamer for a number needed to harm with the use of calcium-based phosphate binders of 5. Hypercalcemia was the only significant risk difference that emerged from this meta-analysis. These findings reiterate findings reported in the analysis by Nadin and others [208]. Tonelli *et al.* also reported an effect of binder choice on end-of-study phosphorus levels that favored calcium-based binders. They combined studies that used the calcium–phosphorus product as the end point for titration of binder dose with studies that used a serum PO_4 target as the dosing determinant. The former dosing protocol if successful would require lower serum PO_4 levels in those patients allocated to calcium-based PO_4 binders, given the nearly universal observation of higher calcium levels in these patients, and this difference in protocol dosing targets might account for the large heterogeneity reported by Tonelli and could account for the difference in PO_4 levels achieved rather than any difference in intrinsic efficacy of the binders. Indeed, when the DCOR results were eliminated from the meta-analysis, the observed effect of binder class on end-of-study PO_4 levels achieved was magnified.

Tonelli and coworkers also reported an absence of benefit in patient-oriented outcomes when sevelamer was used in place of calcium-based binders. Their finding of an equivalency of survival benefits with either calcium-based phosphate binders or sevelamer is based on their meta-analysis of five RCTs [60,372,378,411,412]. Only two of these studies had mortality as a primary [378] or secondary [60] outcome of the trial and were sufficiently long in duration to observe potential effects of a "vascular sparing" intervention on mortality. Results from the largest study were only available in abstract form at the time of the analysis. Tonelli *et al.* included results from an 8-week crossover study in which no deaths were reported in 20 subjects [412] and results from a

5-month study in which multiple interventions were performed simultaneously (including changes in dialysate calcium content and vitamin D) [411]. Some of the limitations of this analysis have been reviewed recently by Frazao and others [413].

Hyper- and hypoparathyroidism

Evidence that hyper- and hypothyroidism result in increased mortality and morbidity

The clinical benefits that arise from vitamin D therapies and from the management of the dysregulation of phosphorus and calcium metabolism in CKD may be due, in part, to prevention or correction of hyperparathyroidism. Evidence supporting the view that hyperparathyroidism itself leads to increased mortality and morbidity has arisen from epidemiologic studies in "normal" populations with hyperparathyroidism due to vitamin D deficiency [414–422], in cohorts of CKD patients [74], and in prevalent dialysis cohorts and from observational studies and RCTs comparing the long-term outcomes of surgical treatment versus conservative management of primary hyperparathyroidism 423–434].

Epidemiological studies in populations of chronic dialysis patients and of patients with CKD not yet on dialysis have identified an independent association of both hyperparathyroidism and oversuppression of PTH secretion with an increase in mortality. The largest of such studies are included in Table 34.3. This association is most evident in those studies where sensitive and stable PTH assays were employed [86]. Block and coworkers analyzed a large data set of prevalent hemodialysis patients and demonstrated that patients with an initial iPTH level of >300 pg/mL experienced a significant "dose-dependent" increase in mortality over the subsequent 2 years of follow-up [207,210]. Similar observations have emerged from the DOPPS and other large dialysis cohorts [211–220]. Kalantar-Zadeh and coworkers, examining a large data set of prevalent dialysis patients in the USA, demonstrated a similar relationship between PTH and mortality. In their fully adjusted model, adjusted for significant comorbidities, age, gender, and nutritional status, PTH levels of >600 pg/mL were independently associated with increased mortality [44]. The analyses of Kalantar-Zadeh and others have also identified an increase in mortality with achievement of low PTH in dialysis patients, most commonly with levels of iPTH of <100–150 pg/mL. Both high and low PTH levels are also associated with increased risk of fracture in CKD patients [432,433], and primary hyperparathyroidism is associated with increased mortality risk in the general population [414–422].

Studies that have included bone biopsy have identified that a significant number of patients with low iPTH levels have adynamic bone disease. The potential causes of adynamic bone disease have been reviewed elsewhere [85,87,92,349,434]. It is relevant to the optimal management of MBD of CKD that adynamic bone disease may occur in the setting of oversuppression of PTH potentially from vitamin D therapies and excess calcium loads and theoretically with calcimimetics. Kalantar-Zadeh provided evidence that adynamic bone disease occurs principally in patients who demonstrate clinical or laboratory measures of malnutrition [60]. The relative contribution of malnutrition versus pharmacologic oversuppression of PTH on the development of adynamic bone disease awaits clarification by further study.

Adynamic bone disease may increase mortality risk or, as shown recently by London and others, may accentuate the mortality and cardiovascular disease risks associated with an increased calcium intake [51,436,437]. Given the importance of properly identifying patients with adynamic bone disease when determining optimal therapy for an individual patient, it should be noted that Malluche and others reported that conventional iPTH assays may lead to the misclassification of bone disease in a significant number of patients, particularly those with low-turnover disease [63,83,352]. The potential for misclassification is further complicated by the finding that PTH assays vary significantly from one reference laboratory to the next [84]. Nonetheless, at the present time the iPTH assay remains a standard for directing therapy of MBD.

In the absence of overt kidney disease, both primary hyperparathyroidism and secondary hyperparathyroidism that is the result of 25(OH)-vitamin D deficiency are associated with increased cardiovascular mortality. Outcomes data from a prospectively followed Swedish cohort demonstrate that individuals newly identified with primary hyperparathyroidism have a significantly increased risk of death over the next 14 years compared to healthy individuals in the population [422]. These findings have been reproduced in other populations that have included subjects with symptomatic hyperparathyroidism as a consequence of hypercalcemia as well as those who are entirely "asymptomatic" [422]. Sambrook *et al.* observed an increased mortality associated with elevations in serum PTH levels in a cohort of elderly frail Australian men and women that was independent of vitamin D status, bone mass, or renal function [417].

These studies do not permit an unambiguous separation of the causal influence of a high PTH on mortality from other potential confounders, such as renal insufficiency and mineral dysregulation, in CKD patients. However, preliminary evidence from an RCT does support the view that has emerged from observational studies that PTH in excess can lead directly to an increase in mortality, principally from cardiovascular causes [423,424,426]. Patients with "asymptomatic" primary hyperparathyroidism were randomized to undergo minimally invasive parathyroidectomy versus medical management without surgery. Those with parathyroidectomy demonstrated an improvement in cognitive function and quality of life and improved survival [423,424].

Targets for PTH levels

On the basis of the observational data from dialysis populations, K/DOQI guidelines recommend that therapies be initiated to maintain iPTH levels in dialysis-dependent patients of 150–300 pg/mL, in CKD stage 3 patients of 35–70 pg/mL, and in CKD stage 4 patients of 70–110 pg/mL [22]. The recommendations for target PTH levels in CKD stages 3 and 4 are based principally on expert opinion. To date, there is no evidence from RCTs that provides definitive proof for the recommended PTH target levels in

patients with CKD stages 3 and 4, nor are there any RCTs that demonstrate that treatment of patients with CKD stage 3 or 4 with hyperparathyroidism to the recommended PTH target for each stage improves survival.

Treatments for secondary hyperparathyroidism of CKD

There are five modalities of treatment (four of which have practical clinical application) that have been demonstrated with either observational studies or clinical RCTs to help prevent or manage secondary hyperparathyroidism. Vitamin D and phosphate reduction therapies, which may have other important therapeutic benefits in patients with CKD beyond their effect on PTH, are reviewed above. Other modalities that will suppress PTH include induction of hypercalcemia, surgical parathyroidectomy, and calcimimetic administration. The latter is sometimes referred to as a medical parathyroidectomy.

It was recognized more than 4 decades ago that elevations in serum calcium levels in dialysis-dependent patients result in reductions in PTH levels. This led to adoption of higher dialysate calcium concentrations as the standard of care and facilitated the widespread adoption of vitamin D therapies and oral calcium supplementation. More recently, attention has been directed towards the risks associated with increased calcium burdens, including the oversuppression of parathyroid function and the development of low-turnover bone disease. This led to a major shift in the choice of dialysate composition; currently, lower bath ionized calcium concentrations are the standard [1]. Thus, although PTH secretion remains somewhat responsive to serum calcium levels in patients with secondary hyperparathyroidism of CKD, strategies to intentionally increase serum ionized calcium concentrations to hypercalcemic levels are no longer considered safe or prudent. Intentional calcium loading as a means of controlling PTH will not be considered further in this chapter as a practical therapy for secondary hyperparathyroidism. The clinical trial evidence for the two remaining therapies for reduction of hyperparathyroidism, namely, surgical parathyroidectomy and cinacalcet administration, are considered.

Surgical parathyroidectomy

Numerous case series and cohort studies have demonstrated that surgical parathyroidectomy does reduce PTH levels in dialysis patients with secondary hyperparathyroidism. Prospective surgical cohorts have also described the rate of complications, the "optimal" surgical technique to increase the probability of maintaining target PTH levels postoperatively, and the effects of parathyroidectomy on the bone component of MBD, on postoperative serum calcium levels, and the need for vitamin D supplementation [425426,431,438–440]. Surgical parathyroidectomy has been advocated principally as a means of controlling severe hyperparathyroidism in dialysis patients who are refractory to medical management. There have been, to date, no long-term RCTs

comparing parathyroidectomy to other modalities of controlling PTH in ESRD patients with respect to mortality and significant morbidities, including pathologic fractures and cardiovascular events [427–434,441–443]. Parathyroidectomy has not been evaluated either with observational studies or with an RCT as a modality of treatment for secondary hyperparathyroidism in patients not yet on dialysis. Surgical parathyroidectomy has not been evaluated in comparison to medical approaches such as the use of calcimimetics. The latter medical approach has displaced surgical parathyroidectomy in many areas of the world.

Calcimimetic therapy

The fourth modality of treatment for MBD in ESRD that is gaining in usage in many countries is the suppression of excess PTH secretion with a calcimimetic [444]. Currently the only calcimimetic that has been approved for use in the USA and elsewhere is cinacalcet. Cinacalcet has been approved by the US Food and Drug Administration for treatment of secondary hyperparathyroidism in ESRD only. Therapy with cinacalcet is not currently included in any of the major national guidelines, most of which were written prior to its clinical introduction. Clinicians have investigated cinacalcet's actions with prospective cohorts [445,446] and RCTs [447–451] and have demonstrated its efficacy in lowering elevated PTH levels in patients with secondary hyperparathyroidism. With the reduction in PTH levels, serum calcium, and to a lesser degree PO_4, levels fall as calcium moves into bone. A number of these clinical trials have demonstrated that patients treated with cinacalcet as part of their MBD therapy are much more likely to achieve K/DOQI targets than patients receiving more conventional therapy [447,448,450]. Attainment of target biochemical parameters may be specifically enhanced by a dose optimization algorithm that adjusts doses of vitamin D and cinacalcet simultaneously [450,452].

The short-term clinical trials address, only partially, patient-centered outcomes such as any mortality benefit from cinacalcet and long-term safety of its use. Ongoing clinical trials are currently addressing the former issue [453]. To address the latter question, Cunningham combined the results from four trials of 6–12 months in duration [454]. The majority of study subjects were observed for 6 months. Cunningham reported that patients assigned to cinacalcet treatment were less likely to be hospitalized for a cardiovascular event (RR, 0.61; 95% CI, 0.43–0.86) or sustain a fracture (RR, 0.46; 95% CI, 0.22–0.95) compared to control study subjects. Furthermore, cinacalcet-treated patients reported improvements in their quality of life as measured by the SF-36 and KDQOL-CF. No difference in mortality was noted.

These studies did not address the potential risk of low-turnover bone disease from excess suppression of PTH with cinacalcet. Lien *et al.* evaluated the effects of cinacalcet on BMD over 26 weeks in 14 patients randomly assigned to conventional therapy ($n = 6$) or cinacalcet ($n = 8$) [448]. They reported an improvement in BMD of the proximal femur with cinacalcet from a pooled analysis using

Student's *t* test rather than more conservative nonparametric methods. Although their conclusion that cinacalcet reverses bone loss cannot be supported with their small sample size, their observation that the changes in bone mineral density if present with cinacalcet are much smaller than those following surgical parathyroidectomy does suggest that medical parathyroidectomy with cinacalcet might be quite different from its surgical counterpart.

Recently, Strippoli and coworkers completed a meta-analysis of high-quality studies examining calcimimetic use in CKD and ESRD [455,456]. Garside *et al.* have conducted a similar analysis as part of their Health Technology Assessment 2007 [457]. Both groups reported similar findings. Both groups reported that the studies included in their final meta-analyses were conducted principally in patients with ESRD on dialysis. They concluded that cinacalcet when administered with standard therapy was more effective at achieving PTH target levels than placebo (40 vs. 5% in the pooled analysis by Garside; $P < 0.001$) and was more effective than standard therapy for patients with moderate to severe hyperparathyroidism. Among study subjects that achieved the PTH target, 90% of those treated with cinacalcet exhibited a fall in the $Ca–PO_4$ product, versus 1% of those treated with placebo. Pooled incidences of serious adverse effects for cinacalcet versus placebo were not different [455,457]. Significantly more episodes of nausea (31 vs. 19%; $P < 0.001$) and vomiting (27 vs. 15%; $P < 0.001$) were reported for patients treated with cinacalcet and these increases were dose dependent [457]. Strippoli noted in a meta-analysis that no significant effects on patient-oriented outcomes such as mortality were demonstrated [455].

These two meta-analyses did not address the use of calcimimetics in CKD stages 3 and 4 prior to the initiation of renal replacement therapy. To date there has been only one 18-week RCT exclusively in pre-ESRD patients treated with calcimimetics compared to other modalities of secondary hyperparathyroidism management. Charytan *et al.* reported that cinacalcet improved PTH levels without producing significant changes in serum PO_4 and Ca levels [449]. They reported modest GI side effects. Lien *et al.* included four CKD stage 4 patients in their RCT on bone mineral density [448]. Neither of these studies permits firm conclusions about the possible benefits or harms of cinacalcet in predialysis patients. Trials in CKD stages 3 and 4 are in progress. Trials in pre-ESRD patients should address issues related to the impact of calcimimetics on mortality and on morbidity, including whether suppression of PTH with cinacalcet in this patient population increases the subsequent risk of low-turnover bone disease, especially when these patients progress to ESRD. Although there is potential promise with the use of cinacalcet in pre-ESRD patients, pending the results of the ongoing studies, cinacelcet cannot be recommended as either safe or effective in patients with the CKD stage 3 or 4.

Bisphosphonates

Bisphosphonates are used widely for the treatment and/or prevention of osteoporosis and its complications in the general population. These agents are eliminated importantly via renal excretion [458,459]. The efficacy of these agents in the treatment of osteoporosis in individuals without renal function has been confirmed with robust RCT evidence from multiple trials [460]. Their use in individuals with CKD is less well studied. In multiple large RCTs, elderly individuals with osteoporosis experienced fewer significant fractures when treated with bisphosphonates than those in control groups treated with customary care (typically, calcium supplementation). These RCTs, however, have not included by design significant numbers of individuals with known CKD, and none of these studies stratified subjects by baseline kidney function. Many elderly patients with CKD are identified as at risk for osteoporosis [461]. This risk appears to be much higher than for age- and gender-matched controls [462,463]. Alem *et al.* described a much-increased risk of hip fractures in Caucasian ESRD patients with an overall odds ratio of fracture of 4.44 (95% CI, 4.16–4.75) [464,465]. In patients with CKD the degree of demineralization is directly correlated to the degree (stage) and/or duration of CKD [461,466]. Additionally, demineralization may be accelerated in certain CKDs, such as those typically treated with steroids (e.g. glomerulonephritis, lupus nephritis, etc.) and those with chronic metabolic acidosis associated with renal tubular acidosis [467].

It is likely that the osteoporosis risk in elderly patients with mild to moderate CKD will be recognized by these patients' primary care physician long before they are identified with CKD and referred to a nephrologist [466]. Thus, it is relevant to review the data regarding the use of bisphosphantes in the CKD and ESRD populations. There are five questions that need to be addressed. Because bisphosphonates are principally metabolized via renal excretion, are they safe for use in patients with CKD and ESRD? Do they contribute to low-turnover bone disease in CKD, as suggested by case series arising from the non-CKD population [468]? If used to treat osteoporosis, are they effective in this population in improving bone health and reducing morbidity and/or mortality? If they are to be used in treating osteoporosis, how can patients with osteoporosis best be identified? And if they are useful for treatment of osteoporosis, do they have any role in preventing the bone mineral loss that occurs in transplant patients receiving corticosteroids?

The risk of adynamic bone disease and the effectiveness of these agents in individuals with both osteoporosis and MBD can be determined best by clinical RCTs. No such trials have been conducted that have been specifically designed to address the risk of adynamic bone disease in CKD and/or dialysis-dependent patients. Recently, Miller and coworkers evaluated the safety of bisphosphonates in patients with CKD stages 3 and 4 [469,470]. They reanalyzed and combined by meta-analysis data from nine large RCTs examining the use of the bisphosphonate risedronate (5 mg daily) to treat or prevent osteoporosis or to treat or prevent steroid-induced bone disease. Some subjects were included in these RCTs who had significant levels of CKD that was initially unrecognized because these subjects had near-normal serum creatinine levels but significant CKD when estimated GFRs (eGFRs) were calculated in retrospect. In this post hoc secondary analysis of patients with CKD treated in these RCTs with risedronate compared to control treatment, Miller

and coworkers demonstrated that CKD patients treated with risedronate did not experience an increase in reported adverse events. Furthermore, they did not see an acceleration of decline in renal function or an increase in low-turnover bone disease for patients in any of the three CKD strata evaluated.

These findings are limited because the clinical trials were not specifically designed to evaluate the kidney injury outcomes in CKD patients. Furthermore, patients with CKD were not separately randomized. Nonetheless, this analysis supports the view that in patients with eGFRs of greater than 30 mL/min/1.73 m^2 that risedronate is safe and may be safe for patients with even more severely impaired renal function after dose adjustment. In a similar manner, Jamal *et al.* evaluated the effects of alendronate in women in the FIT study who had reduced renal function [471]. They too indentified no differences in reported adverse events. Furthermore, from their post hoc analysis of RCT results, these authors provided some data supporting the efficacy of alendronate in women with CKD. In the women with eGFRs of <45 mL/min/1.73 m^2, bone mineral density increased with treatment by 5.6% (95% CI, 4.8–6.5%) compared to an increase in bone mineral density in treated women with normal or near-normal renal function of 4.8% (95% CI, 4.6–5.0). Each group demonstrated a similar reduction in clinically important fractures with alendronate therapy. These results arise from a retrospective analysis.

Three small prospective trials have provided additional preliminary evidence that oral bisphosphonates might result in beneficial clinical outcomes in patients with CKD and ESRD [472–474]. In a case–control study, Hansen *et al.* reported that the risk of changes in bone mass of the spine, femur, and radius were similar in men in the low versus the normal renal function groups [472]. Nitta followed 35 hemodialysis patients for 15 months, including 6 months on standard therapy and 9 months of etidronate therapy (200 mg/day for 14 days every 3 months for three cycles) and reported that coronary calcification scores were improved and markers of inflammation diminished during etidronate therapy [473]. In a small RCT, Aryoshi *et al.* compared arterial calcification progression in dialysis patients assigned to receive 400 mg/day of etidronic acid versus customary care over 24 weeks [474]. Patients assigned to the bisphosphonate therapy demonstrated no progression of CAC and a decline in aorta calcification, whereas aorta calcification in the control group increased significantly. There was no difference in other biochemical parameters or CAC scores. These latter two studies raise the possibility, yet to be proven, that bisphosphonates might have therapeutic benefits for patients with ESRD. Current guidelines recommend that these agents not be used in individuals with moderate to severe CKD (GFR of <30 mL/ min/1.73 m^2). Furthermore, certain bisphosphonates classically used in patients with the hypercalcemia of malignancy (zoledronate and pamidronate, but not ibandronate) have been reported to cause either acute kidney failure or a focal and segmental glomerulosclerosis-like lesion when given in higher doses acutely to patients with renal insufficiency [475]. From the case reports of acute kidney injury with zoledronate, the kidney failure occurred after some delay and was not always fully reversible

with cessation of the medication. In the posttransplant period, the use of zolendronate has not been associated with acute renal failure in small clinical trials [476,477].

A number of clinical trials have evaluated the use of bisphosphonates in the post-kidney transplant patient. These patients present a mixed picture; they often have secondary hyperparathyroidism and MBD as a consequence of long-term dialysis treatment antecedent to their transplantation and they are at increased risk in the posttransplant period for steroid-induced osteoporosis. This patient population might shed some light on the potential efficacy and safety of bisphosphonates in a kidney failure population. A number of RCTs have examined the effects of bisphosphonates on renal function and on bone mineral density after transplant for up to 2 years [478–480]. These clinical trial results have been summarized by Mitterbauer *et al.* and by Palmer *et al.* [476,477] and will not be addressed further in this chapter. However, it may be significant that even though renal function in transplant patients was substantially restored, adynamic bone disease was identified in the clinical trial that included evaluation of bone histomorphology [480].

Ideally, individuals with CKD without osteoporosis should not be given bisphosphonates, because these agents suppress bone turnover and thereby could potentially complicate in this patient population any adynamic bone disease that has arisen from other causes. Noninvasive methods typically used to identify patients with osteoporosis are problematic. In particular, dual-energy X-ray absorption methodologies do not differentiate well between demineralization due to renal osteodystrophy and osteoporosis. Alternative noninvasive measures, such as peripheral quantitative computed tomography, might better identify individuals with demineralization, but the only reliable method for differentiating osteoporosis from the MBD of CKD is with a bone biopsy [481,482].

At present, bisphosphonates are not approved for use in patients with significant renal impairment. Evidence does suggest that these agents, especially oral agents such as risedronate and alendronate, are safe and may result in improved bone health when used in patients with milder degrees of CKD (eGFR of >30 mL/min/1.73 m^2). The study by Nitta and colleagues raises the possibility that these agents might also benefit patients with ESRD, but these investigators' findings await confirmation in larger RCTs.
