# Sleep Disorders

## in Children

18

*Rafael Pelayo, MD   Kin Yuen, MD   James Winde, MD   Maria-Cecilia Lopes, MD*

Sleep disorders in children are relatively common and readily treatable. This chapter will review the various sleep disorders common in children and the management of these sleep disorders. Perhaps nowhere else in this text does modern neurology and psychiatry merge as naturally as in a discussion of sleep disorders. Sleep and dreams are at the core of the mystery (and wonderment) of the relationship between the brain and the mind. Seeking an understanding of sleep has been influential in the development of our culture. In prehistoric societies, attempts to understand the imagery of nighttime dreams and nightmares might have given rise to concepts of the spiritual world and religion. In medieval times, the phenomena of sleep paralysis, night terrors, and sleepwalking may have been interpreted as manifestations of demons.

Three hundred years ago the recurring nighttime afflictions of restless leg syndrome were thought to be a curse until Willis (of Circle of Willis fame) accurately described it as a neurological disease. In the late 19th century, sleep was viewed as a passive state that occurred in the absence of brain stimulation. Thomas Edison thought that the invention of the light bulb would allow us to avoid sleeping. The interest of a young neurologist named Sigmund Freud in sleep and dreams opened a new chapter in psychiatry. Years later a medical student, William Dement, became interested in finding a neurological basis to understand Freud's dream theories (1). In 1952, he helped discover the relationship between electroencephalographically measured rapid eye movements in sleep and dream recall. Infants and small children were an early part of Dement's research into rapid eye movement (REM) sleep. This research led to worldwide studies of the basic physiology of sleep.

Dement became a psychiatrist and initially studied the relationship of sleep and dreams to mental illness. In 1972,

he hired a young neurologist, Christian Guilleminault, and together they established the first medical clinic devoted exclusively to the treatment of patients with sleep disorders within the department of psychiatry at Stanford University. Guilleminault, as a student, had studied child development with Jean Piaget in France. Not surprisingly, children were among the first patients seen at the new clinic. This landmark clinic served as a model for the comprehensive multidisciplinary care of patients with sleep disorders. It also contributed to the recognition of sleep disorders medicine as a recognized medical specialty. The synergy of neurology and psychiatry, which was essential in establishing this new field, should continue for it to progress. The study of normal sleep and sleep disorders in children is an integral part of the development of modern sleep medicine.

It was probably not a coincidence that these researchers were relatively young when they embarked on their studies on sleep. The young seem to be particularly curious about sleep and dreams. Listening to children talk about their sleep can be fascinating. The REMs associated with dreaming are more easily seen in infants and young children than in adults and do not require sophisticated instrumentation. Dement has speculated that perhaps the discovery of REM sleep would have been made earlier if we had only paid closer attention to children when they were asleep (1). This tendency to not pay attention to children while sleeping has persisted. The author (RP) recalls being told as a pediatric intern to advise his patients' parents not to watch their children sleep as they would only return with too many unanswerable questions! Current knowledge of sleep disorders in children has not been incorporated into most medical training programs. This reality is hard to reconcile with the high prevalence of sleep disorders in children. Infant's sleep problems represent one of the most frequent

complaints of parents consulting a pediatrician (2). The National Commission on Sleep Disorders concluded that 25% of parents had some concerns about their children's sleep. One survey estimated that 38% of children had experienced parasomnias such as sleep walking or night terrors, 14% had excessive daytime sleepiness, and 11% had sleep disordered breathing (3). When a child comes in for an evaluation of a possible sleep problem, the first concern of the parents or caretakers is whether the problem is due to a behavioral or physical cause. Often, the sleep problem is neither purely behavioral nor purely physical, but rather represents a combination of these factors.

The most common question asked about a child's normal sleep is, "how much time does my child need to sleep?" When a child has trouble sleeping, parents will often turn to a variety of paperback advice books on the market. The quality of advice offered is quite variable and conflicting. Clinicians should be aware of the advice put forth by the more popular of these books since parents may quote or have specific questions about the material as it applies to their child. Also parents are unlikely to seek a clinician's opinion if the advice book has solved the problem, so the questions that do arise are sometimes the result of frustration or confusion about what the parents have read. Often these books do not provide any long-term longitudinal data about the amount of time that a normal child spends sleeping at different ages.

## NORMAL SLEEP

The basic principles of normal sleep are the same for children and adults. Normal sleep can be simply described as the ability to fall asleep easily, sleep through the night, and wake up feeling refreshed. What does this require? When adults with chronic insomnia describe their sleep difficulty, they initially say it has been a lifelong pattern. However, if you ask them specifically if they had insomnia when they were 8 or 9 years old they will often answer either "no" or "I don't remember." The insomnia problems often emerge in adolescence or even later. When insomnia is present at an early age, fear of sleeping alone is often a component.

Long-term longitudinal data has been published by Iglowstein and colleagues to illustrate the developmental course and age-specific variability of sleep patterns (4). As part of the Zurich Longitudinal Studies, they followed 493 children for 16 years. The study used structured sleep related questionnaires at 1, 3, 6, 9, 12, 18, and 24 months after birth and then at annual intervals until 16 years of age. Total sleep duration decreased from an average of 14.2 hours (SD: 1.9 hours) at 6 months of age to an average of 8.1 hours (SD: 0.8 hours) at 16 years of age. Total sleep duration decreased across the studied cohorts (1974–1993) as a result of later bedtime, but wake time remained essentially unchanged. Between 1.5 years and 4 years of age, there was a prominent decline in napping habits. At age 1.5

years, 96.4% of children had naps; by 4 years of age, only 35.4% napped. This is consistent with a prior study of napping patterns by Weissbluth (5).

Napping patterns were monitored in a cohort of 172 children followed from 6 months to 7 years of age. There were no differences in the number of naps at 6 months of age or the pattern of napping based on gender, birth order, and whether naps disappeared spontaneously or were stopped by the parents. Total daytime sleep remained a stable individual characteristic between 6 and 18 months of age. A pattern of two naps per day was well established by 9 to 12 months of age and one afternoon nap by 15 to 24 months. The duration of naps from 2 to 6 years was 2 hours. During the third and fourth years, napping occurred in the majority of children, but at decreasing rates. A minority of children were napping by 5 to 6 years and naps usually disappeared by age 7. If a child continues to nap by the age of 7 years, it is possible that a sleep disorder may be present. In 2004, Watamuran and colleagues showed changes in cortisol activity in infants who took frequent short naps (6). However, nap behavior can be put into a cultural context; it would be less of a concern if napping or "siestas" are part of the cultural environment. However, it is important to ask about the child's behavior in the afternoon. Naps may not be called naps but rather reported as falling asleep while riding home from school. This overall normative data can serve as a guide to determine if a problem is due to an inadequate amount of sleep.

To determine if a problem is due to an inadequate quality of sleep, more detailed measurements of sleep and the underlying physiology may be needed. Sleep physiology begins with an understanding that sleep is not a homogeneous state, but is instead a mixture of rhythms associated with different states and stages. The brain seems to have three basic states or modes: awake, dreaming, or sleeping without dreaming. Evaluating these states and stages requires three electrophysiological measurements: the electrical activity of the brain during the sleep states, the muscle tone, and eye movements. These parameters are measured with an electroencephalogram (EEG), a chin electromyogram (EMG), and an electrooculogram (EOG), respectively. The patterning of these measures (electrical activity of the brain, muscle tone, and eye movements) divides sleep into two broad categories: REM sleep and non-REM sleep. REM sleep is referred to as paradoxical sleep because the brain waves are similar to those of the awake state but the body seemed paralyzed. REM sleep accounts for approximately 20% of total sleep time after age 3 years. At birth, REM sleep takes up 50% of the total sleep time. Dreaming is associated closely with REM sleep. REM sleep is characterized by loss of muscle tone (atonia), which results in absent or greatly diminished deep tendon reflexes. When a person is awakened from REM sleep, wakefulness returns quickly. REM periods occur in cycles of approximately 90 minutes throughout the night, with the longest and most intense REM periods occurring just after the body

temperature reaches a minimum (approximately 2 hours before waking up). At the end of every REM cycle, there is usually an arousal or brief awakening. In infants, REM cycles are shorter (approximately 40 to 60 minutes). Parents may be concerned that their infant seems to “wake up every hour.” These brief awakenings may be part of the child’s normal rhythm, but an overly attentive parent may inadvertently reinforce and prolong the awakenings. On the other hand, it is possible that the awakenings are due to a condition that is exacerbated by REM sleep, such as obstructive sleep apnea.

NonREM sleep is subdivided into stages 1, 2, 3, and 4. Stage 1 is the lightest sleep and is typically a transition from awake to drowsiness to sleep. Stage 1 occupies less than 10% of the total sleep time. In stage 1, people may not realize they are asleep and think they were awake. They may also have fragments of auditory or dreamlike imagery called *hypnagogic* hallucinations. Similar episodes upon awakening are called *hypnopompic* hallucinations. These episodes occur more commonly with sleep deprivation and in conditions such as narcolepsy. They should not be confused with psychosis. Stage 2 is an intermediate state that can be over half of the total sleep time. Stages 3 and 4 (also called delta or slow-wave sleep) represent the deepest sleep as measured by the amount of stimulation needed to wake up. This stimulation is called the arousal threshold. It is called delta sleep because the EEG is dominated by slow waves in the delta range (<4 Hz). Delta sleep has homeostatic properties: it increases in duration and intensity in response to sleep deprivation. The amount of delta sleep is at least 10% of the total sleep time in children and decreases after adolescence. Delta sleep clusters in the first third of the night. During delta, it is extremely difficult to arouse children. If aroused, they often appear disoriented and cognitively slowed. Parasomnias, such as sleepwalking and sleep terrors, usually emerge from slow-wave sleep and are common in the first third of the night.

A discussion of normal sleep would be incomplete without reviewing the role of circadian rhythm and the biological clock (7–11). The circadian modulation of alertness and sleepiness is an important part of sleep physiology. A successful terrestrial animal must be able to predict dawn and dusk and anticipate the change in seasons. Humans are, in general, diurnal. We have excellent color vision in the daytime but our night vision is not as good as that of many of our potential predators. Part of our circadian physiology is our tendency to have decreased alertness in the afternoon and to have a surge of alertness (“second wind”) in the evenings. This process is modulated by the suprachiasmatic nucleus and is referred to as clock-dependent alerting (12, 13). If a person is having trouble falling asleep, then an earlier bedtime may make the problem worse by creating greater frustration. Dramatic shifts in wake-up times on school days compared to nonschool days can alter the circadian patterns and lead to sleep problems.

## GENERAL CLINICAL GUIDELINES

Sleep disorders should be considered whenever a child is being evaluated for a behavioral problem. Insufficient quality or quantity of sleep may be associated with learning difficulties and attention problems. When a child does not sleep well, it can disrupt the entire household and lead to significant stress for the family. Unrecognized and undertreated sleep disturbances can carry over into adulthood.

In pediatrics, a medical history usually starts with the history of the pregnancy and delivery. However, an adequate history of a child’s sleep disorder should begin with a history of the sleep patterns of the parents/caretakers before the child was born. For example, if an infant sleeps continuously for 7 hours at night and the mother was in the habit of sleeping 6.5 hours before the pregnancy she might be pleased with the way the child is sleeping. However, if the mother usually slept 8 or 9 hours she might complain that the child is not sleeping enough at night. The family’s cultural background must also be taken into account when evaluating a complaint of poor sleep. Also, the influence of other family members, such as grandparents, in shaping the family’s views should be considered. The parents need to be in agreement about their expectations of the child’s sleep, especially if the parents come from different cultural backgrounds. The parent’s own experience in childhood should be explored. The mother and father may view the infant’s sleep pattern from quite different perspectives. However, studies have included both parents to analyze parent-child interactions (14). Particularly in the early years, a child’s life is centered at home. If a parent had a history of occasional insomnia before the infant was born, he or she might be overly sensitized to interruptions of sleep by the infant, whereas the other parent might find the disruption more tolerable. A parent who has a history of snoring or mild obstructive sleep apnea might be less able to tolerate what would otherwise be considered normal interruptions of sleep.

When taking a history it is important to keep in mind that the need for sleep is biological; however, the way someone sleeps is learned. Sleep clearly fulfills some biological needs and has homeostatic properties (15), and the longer you stay awake, the more intense the desire to sleep; the better you sleep, the better you are able to stay awake. At the same time, in theory, a person is more vulnerable and could be attacked while sleeping, so there must be mechanisms present that allow us to sleep and be safe at the same time. Like other animals, we sleep differently depending on the particular circumstances in which we find ourselves. A woman late in her pregnancy will have very fragmented sleep due to multiple factors. Will she then be able to regularly sleep soundly for 8 hours in a row after she becomes a mother? Certainly not, if she has to nurse her newborn every 2 to 4 hours! All of us sleep best when we go to sleep feeling safe and comfortable. We learn to feel this way by forming associations with our sleeping envi-

ronment and these associations are formed starting from infancy. Infant and children, like adults, may develop maladaptive associations that result in sleep difficulties. When evaluating school age children for a sleep problem, it is important to ask the child directly if he is scared of the dark or of being alone. The parents may minimize these concerns and the children may be too embarrassed to volunteer the information. In any evaluation, it is crucial to keep in mind the interaction between the physiological need for sleep and the psychology of sleep.

When evaluating a sleep problem, it is important to recognize that what awakens the patient may not be what keeps the patient awake. For example, you could be awakened at night because of the sudden loud noise coming from a party next door. The fact that you were not invited to the party could bother you and keep you awake! It is not uncommon in a clinical situation to have two or more sleep disorders interacting in the same patient. A child may have an awakening due to difficulty breathing from sleep apnea, but then be unable to return to sleep because she has not learned to settle back down without the parents' intervention. Since patients can not provide us with information about their sleep once they are asleep, it is important to get as much information as possible from other members of the household.

## PHARMACOLOGICAL GUIDELINES

There is relatively little information available on the pharmacological management of sleep disorders in children. Most pharmacological guidelines were developed for sleep disorders in adults and must be empirically extrapolated to children. The medications are typically neither US Food and Drug Administration (FDA) approved for the specific sleep disorder nor for the pediatric age range. The physician is often forced to prescribe medications as an "off label" indication. This may result in frustrating insurance reimbursement delays or denials for the family. These reimbursement problems may affect the availability of a specific medication, the family's compliance with the medication, or force the physician to prescribe a less desirable alternative medication. The medication may not be available commercially in an easily administered format. Young children may not be able to swallow pills or ingest chewable tablets, requiring the local pharmacist to compound the medication into a suspension. In addition, due to the natural aversion among both parents and physicians to use medications for pediatric sleep disorders, medications are usually prescribed as a last resort or in the most refractory situations.

At times, a decision to use medication in a child may be made not necessarily to assist the child as much as to help the parents or other family members sleep better. It is not unusual for parents to finally seek help for a child's long-standing sleep problem when they feel they can no longer

put up with interruptions to their own sleep. Further complicating the pharmacological treatment of sleep disorders in children is the general lack of specialized training in sleep disorders available to the health care providers who are working with these children. Failure to consider or properly apply nondrug treatments as part of the comprehensive management of the child may also lead to unsatisfactory results for the patient and the family. Children with sleep disorders may not be properly managed due to either underdosing or overdosing of medication or incorrect medication selection.

There maybe an overreliance on the effects of the medication by both the parents and health care provider without adequate application of behavioral techniques to help improve the child's sleep. A common scenario in clinical practice is a parent's complaint of a child's paradoxical reaction to a hypnotic medication. "It made it worse" or "he became hyper" may be the parent's complaint. This may occur because the timing or the dose provided was incorrect. The parents may expect that once a medication has been finally prescribed to help their child sleep that it will "knockout" the child. It is important that the health care provider advising this family take into account the circadian modulation of alertness. Humans will typically experience enhanced alertness in the evening, which is often referred to as a "second wind." During this circadian phase, it is harder to fall asleep. If the hypnotic medication is given during this circadian time window, the medication may not work or the child may be frightened by hypnagogic hallucinations. If a medication has been shown to shorten sleep latency by only 20 or 30 minutes, giving this medication 2 or 3 hours before the usual falling asleep time could elicit this common scenario. This same medication given at a more appropriate circadian time could be effective. A similar lack of efficacy or paradoxical reaction could occur if the medication dose is inadequate.

This lack of proper management of the sleep problem may be particularly common among children with neurological or psychiatric disabilities. If the child cannot communicate what she feels is causing the sleep difficulty, incorrect assumptions may be made by the family or health care provider. In a case of insomnia, this can result in an escalating cycle of progressively more sedating agents with increasing likelihood of adverse effects. Concomitant daytime sedation may occur, which may interfere with the child's therapeutic program and exacerbate the child's disabilities. In some situations, the fear of addiction may deter the physician or the family from using pharmacotherapy adequately to improve the child's sleep.

## SLEEP DISORDERS

There are over 80 recognized sleep disorders, encompassing a wide range of disturbances including parasomnias, sleep-related disordered breathing, (obstructive sleep

apnea), restless leg syndrome, and disorders of initiating and maintaining sleep. However, we lack sufficient normative and epidemiological data in the field of pediatric sleep disorders and much more research is needed. There is a paucity of therapeutic clinical trials and health policy outcomes research.

### Sleep-Disordered Breathing

Sleep-disordered breathing is a clinical syndrome ranging from simple snoring to potentially life-threatening obstructive sleep apnea syndrome. This clinical spectrum can occur at any age. Charles Dickens provided a classical description of “Pickwickian” snoring with arousals and excessive daytime sleepiness in a boy named Joe (16). The first medical description in English of children with abnormal breathing in sleep is attributed to William Osler in 1892 in his textbook (17).

In the modern medical literature, Guilleminault reported the first series of children with obstructive sleep apnea in 1976 (18). That report describes the essential clinical features of this condition. More recently there has been a realization that patients may be symptomatic in the absence of frank apneas (19, 20). This has led to use of the terms “sleep-disordered breathing” and “sleep-related breathing disorders” to better describe the clinical spectrum, which includes obstructive sleep apnea syndrome, upper airway resistance syndrome, and obstructive hypopnea syndrome.

The most obvious nocturnal symptom is snoring. Snoring is very common in the pediatric population. It can indicate turbulent airflow and is not normal (21–23). While awake, breathing is silent. If a sleeping animal is vulnerable to attack by a predator, why would it make breathing noise when its guard is down? Indeed animals in the wild do not seem to snore; only domestic animals snore. Not all snoring is due to obstructive sleep apnea. It may be due to other forms of obstruction such as nasal allergies or a cold (24, 25). Chervin et al. assessed the frequency of childhood sleep problems in two general pediatric clinics. Parents of 1,038 unselected children (554 boys) aged 2.0 to 13.9 years completed a validated Pediatric Sleep Questionnaire. Habitual snoring was reported in 176 (17%) of the children (26).

While sleep-disordered breathing in children has many important similarities to the adult version of this disorder, there are also marked differences in presentation, diagnosis, and management. Abnormal daytime sleepiness may be recognized more often by school teachers than by parents. Some parents may consider an increase in total sleep time or an extra long nap as normal. Nonspecific behavioral difficulties in children with sleep disorders may be reported to the pediatrician such as abnormal shyness, depression, hyperactivity, developmental delays, or rebellious or aggressive behavior (27). Chervin and associates found conduct problems and hyperactivity are frequently described in children referred for sleep-disordered breath-

ing. They surveyed parents of children aged 2 to 14 years at two general clinics between 1998 and 2000. Parents of 872 children completed the surveys. Bullying and other specific aggressive behaviors were two to three times more frequent among children at high risk for sleep-disordered breathing (28). Other daytime symptoms may include speech defects, poor appetite, or swallowing difficulties (19, 29). Bedwetting accidents should raise suspicion of sleep-disordered breathing. Crabtree et al. found more impairments in quality of life and depressive symptoms in children who snored (30).

Many of these children breathe through their mouths, and regular mouth breathing should always lead to suspicion of sleep-disordered breathing (31). Children with disordered breathing may avoid going to bed at night due to hypnagogic hallucinations. Upon awakening, these children may report morning headaches, dry mouth, confusion, or irritability. As mentioned, depending on the child’s age, daytime sleepiness may not be obvious. It may present only as a complaint of daytime tiredness or as a tendency to take naps easily anywhere.

A study from Israel found that children with sleep-disordered breathing had lower scores on neurocognitive testing compared to controls; test performance improved after treatment (32). In this prospective study, 39 children aged 5 to 9 years underwent a battery of neurocognitive tests containing process-oriented intelligence scales. Children with sleep-disordered breathing had lower scores compared with healthy children in some of the Kaufman Assessment Battery for Children (K-ABC) subtests and in the general scale Mental Processing Composite, indicating impaired neurocognitive function. Six to 10 months after adenotonsillectomy, the children with obstructive sleep apnea syndrome demonstrated significant improvement in sleep characteristics, as well as in daytime behavior. Their neurocognitive performance improved considerably, reaching the level of the control group in the following subtests: Gestalt Closure, Triangles, Word Order, and Matrix analogies, as well as in the K-ABC general scales, Sequential and Simultaneous Processing scales, and the Mental Processing Composite scale. The magnitude of the change expressed as effect sizes showed medium and large improvements in all three general scales of the K-ABC tests. The authors concluded that neurocognitive function is impaired in otherwise healthy children with sleep-disordered breathing. Most functions improve to the level of the control group, indicating that the impaired neurocognitive functions are mostly reversible, at least 3 to 10 months following adenotonsillectomy (32). An abrupt and persistent deterioration in grades must also raise the question of abnormal sleep and sleep-disordered breathing (23, 33–36).

In schools, tiredness and sleepiness may be labeled as “inattentive in class,” “daydreaming,” or “not being there” (37, 38). Concerns about school performance were raised in the original description of obstructive sleep apnea syndrome in children (14). More recently, a number of

studies have addressed the possible association between sleep-disordered breathing and attention deficit hyperactivity disorder (ADHD) (39–45). O'Brien et al. examined the hypothesis that certain domains of neurobehavioral function would be selectively affected by sleep-disordered breathing. They conducted a survey of 5,728 children, aged 5 to 7 years old, asking questions about the frequency of various sleep-related problem behaviors, including snoring. The parents were also asked if the child was hyperactive. Children with reported symptoms of hyperactivity were then randomly selected for an overnight polysomnographic assessment and a battery of neurocognitive tests. Controls were selected from the group of children whose parents did not endorse hyperactive symptoms. Parents completed standardized rating scales relating to ADHD. Frequent and loud snoring was reported in 11.7% of the children; 7.3% of the parents viewed their children as being hyperactive or as having received a diagnosis of ADHD. The majority (76.5%) were boys. Eighty-three children with parentally reported symptoms of ADHD had sleep studies together with 34 control children. The Conners' Parent Rating Scale was administered to identify the degree of hyperactivity. Overnight polysomnography revealed that obstructive sleep apnea was present in 5% of those with significant ADHD symptoms, 26% with mild symptoms, and 5% of the nonhyperactive control group. REM latency and the proportion of REM sleep were more likely to be affected in the group with significant symptoms of ADHD. The groups did not differ in any other objective sleep measure. The authors concluded that an unusually high prevalence of snoring was identified among of the children who had mild symptoms of ADHD. Thus, sleep-disordered breathing is associated with mild ADHD-like behaviors that can be misdiagnosed as ADHD and potentially delay diagnosis and appropriate treatment (31).

Clinical signs of sleep-disordered breathing include increased respiratory efforts with nasal flaring, suprasternal or intercostal retractions, abnormal paradoxical inward motion of the chest during inspiration, along with sweating during sleep. Sweating may be limited to only the nuchal region, particularly in infants; it may be severe enough to necessitate changing clothes during the night. The parents may mention the child feeling warm at night or preferring to sleep without a blanket. Parents may also observe that the child stops breathing, then gasps for breath. It is surprising to note how often parents have observed abnormal breathing patterns during sleep but were never questioned about it by pediatricians during regular visits. Information regarding the sleep position is also helpful. Typically, the neck is hyperextended and the mouth is open. Another typical sleeping position is prone with the knee tucked under the chest with the head turned to the side and hyperextended. Rarely the child with sleep-disordered breathing prefers to sleep propped up on several pillows (19).

Ohayon has found that individuals identified with sleep-disordered breathing have a much higher incidence

of nightmares, with reports of "drowning," "being buried alive," and "choking" (46). Night-terrors may lead to escape behavior and sleepwalking. If sleep fragmentation induced by the breathing events occurs during slow-wave sleep, night-terrors and sleepwalking may be triggered (47). A physical finding that may be overlooked in a child with sleep-disordered breathing is a narrow and high arched palate (19). Interestingly, the DSM-IV's description of ADHD mentions that minor physical anomalies such as high arched palates may be present (48). The possibility of a sleep disorder being present should be considered in any child being evaluated for ADHD. This is particularly important because treatment of sleep-disordered breathing may improve behavior and academic performance (49, 50).

The diagnostic criteria used for adults with obstructive sleep apnea syndrome cannot be used reliably in children (51–53). The diagnosis of sleep-disordered breathing is based on the history, physical findings, and supportive data. Laboratory testing should be, ideally, tailored to the clinical question. For example, if there are concerns about excessive daytime sleepiness, a multiple sleep latency test (MSLT) may be indicated (54). The MSLT is ideally performed in subjects who are at least 8 years old. The polysomnogram in a child uses the same technology and the same type of information as in adults. Airflow, respiratory effort, and pulse oximetry are the breathing measurements usually monitored. The respiratory effort is measured most accurately in a clinical sleep study using esophageal pressure measurements with a water-filled catheter.

Esophageal pressure measurements are not yet part of the routine polysomnogram in most sleep laboratories. An alternative measurement can be obtained using end-tidal CO<sub>2</sub> monitoring, which can detect important transient episodes of hypercarbia. A more recent technique to measure air flow using a nasal cannula has been introduced. This technique has been replacing nasal thermistors and is less invasive than esophageal manometry (55–58).

In addition to the absence of controlled studies of sleep-disordered breathing in the pediatric age group, there is also a lack of consensus in the definitional criteria. In adults, obstructive sleep apneas are defined as lasting at least 10 seconds. However, because children have faster respiratory rates, the duration is less for clinically significant apneas. Apneas as brief as 3 or 4 seconds may result in oxygen desaturation. There is also no uniform measure of hypopneas in children. The clinician needs to know how apneas and hypopneas are defined and scored when interpreting a polysomnogram report.

The upper airway resistance syndrome is present in individuals with symptoms of sleep-disordered breathing, who on the polysomnogram have evidence of sleep disruption associated with increased work of breathing, without a significant degree of apneas or hypopneas. In children, the work of breathing can be measured by recording

esophageal pressure. Calibration is conducted by measuring esophageal pressure while the child is awake. The baseline pressure usually ranges from  $-10$  to  $-5$  cm of water. A repetitive breathing pattern can be identified with increasingly more negative esophageal pressure culminating in a brief arousal (59, 60). Controversy exists over whether a diagnosis of obstructive sleep apnea, or the larger spectrum of sleep-disordered breathing, should routinely be made without a formal polysomnogram. While some have suggested that this diagnosis can be made in patients using either the history and physical, or the history, physical, and an audio or videotape, others have found that the clinical history alone does not distinguish primary snoring from obstructive sleep apnea syndrome in children (61). The situation is further complicated by the description of upper airway resistance syndrome in children, which may have been missed in the studies cited previously. Therefore, a sleep study is the most definitive test for sleep-disordered breathing (62, 63). Currently, some otolaryngologists who treat children with sleep-disordered breathing may make the surgical recommendation based on clinical findings of airway obstruction, sometimes reviewing an audio or videotape (64, 65). Clinicians must be aware of the potential pitfalls of this practice. Certainly, there are individual cases in which a diagnostic sleep study is not available, but ideally, this should be the exception. The challenge we face in sleep medicine is providing easily accessible and cost-effective care working within a multidisciplinary model. We do not know, for certain, how accurate clinical diagnosis is without objective testing. Until we have a better answer, the diagnostic gold standard should not be disregarded particularly in a tertiary care setting. The American Thoracic Society and American Academy of Sleep Medicine and the American Academy of Pediatrics all support the use of sleep studies (66, 67).

Sleep-disordered breathing is not the only sleep disorder a child may have. Clinical impression may have both false-negative and false-positive results, leading to possible misdiagnosis or unnecessary surgery. For example, without confirmatory testing, a child with only "simple snoring" and symptomatic periodic limb movements will inevitably be misdiagnosed with sleep-disordered breathing and may have unnecessary surgery. Periodic limb movements of sleep and restless leg syndrome may not be rare in children (68). However, the history may be vague or hard to elicit.

Sleep-disordered breathing may occur more frequently in special populations. Any condition or syndrome associated with craniofacial anomalies may be associated with sleep-disordered breathing. Pierre-Robin, Apert's, and Crouzon's are among these syndromes. Approximately half of all children with Down syndrome have sleep-disordered breathing (69). Symptoms of daytime sleepiness and sleep disruptions at night may be due to nonneurological factors such as maxillofacial abnormalities, large tonsils or adenoids, hypoglossus, large tongues, or other abnormalities.

Such factors often lead to sleep fragmentation and daytime sleepiness. Sleep disorders often occur in patients with neuromuscular disorder associated with weakness in respiratory muscles, which is further exacerbated by hypotonia during sleep. In disorders such as Duchenne's muscular dystrophy, daytime pulmonary function studies do not predict the severity of apneic events during sleep. These patients can have nocturnal oxygen desaturation, significant sleep fragmentation, recurrent hypoventilation, and reduced REM sleep, and are also at risk for aspiration during sleep. Diagnosis and treatment of sleep-disordered breathing in these patients can be an important part of comprehensive management.

There are four treatment options for sleep-disordered breathing in adults. These treatments may be combined. The most common treatment is continuous positive airway pressure (CPAP) to help splint open the upper airway. When CPAP is used correctly, snoring should be absent during sleep. There are several surgical options with a wide range of success. In adults, oral appliances that help re-position the mandible have improved breathing during sleep in selected patients. As a conservative measure, adults with sleep-disordered breathing are advised to sleep off their backs, lose weight, and avoid alcohol before sleeping.

In children, adenotonsillectomy is the most common initial treatment for sleep-disordered breathing; however it does not always cure the sleep disorder. The true cure rate of adenotonsillectomy for sleep-disordered breathing is unknown (70-71). Suen and colleagues designed a prospective study of 69 children, age 1 to 14 years, who were referred to an otolaryngologist. Thirty-five (51%) had a respiratory disturbance index greater than 5 on polysomnography. Of these, 30 underwent adenotonsillectomy and 26 of these children then had follow-up polysomnography. Although all 26 children had a lower respiratory disturbance index after surgery, four still had an index greater than 5. Using a respiratory disturbance index cut-off of 5, the cure rate of the surgery would be 85%. However, three children with a post-operative respiratory disturbance index less than 5 continued to snore. If these children were considered to have residual sleep-disordered breathing, then the cure rate of surgery would only be 73%. All patients improved with adenotonsillectomy but the true cure rate was not clear. The possibility of residual sleep-disordered breathing should always be considered after surgery if the child is symptomatic. Suen and associates concluded history and physical findings were not useful in predicting outcome (72). Different surgical techniques may improve the success of surgery in these children (73).

Some may argue that in clear-cut cases of sleep disordered breathing the sleep study may be skipped. However, the adult experience teaches us that it is precisely these obviously more severe or "clear-cut" cases that will have residual disease. Adenotonsillectomy will not change the relationship of tongue size and shape to the palate. The

parents may report that the child is “100 % better”; however, these children can still have residual obstruction. If the child still has trouble paying attention in school, a sleep problem may be overlooked and no longer be considered a possibility. The child may end up labeled as having attention deficit disorder because there was no postoperative sleep test done (74).

If surgery is not a option for the child, then CPAP therapy should be considered (75–77). CPAP uses a small air compressor attached to a mask via a hose. The mask usually only covers the nose but masks are available that cover the nose and mouth. By forcing positive pressure into the airway, the negative pressure of inspiration can be countered to avoid airway narrowing or collapse. CPAP is effective but can be cumbersome to use. Over time, the CPAP devices have become smaller and quieter. The masks have also improved with many more styles and sizes available. Despite these advances, it remains a second choice over surgery in most children, because of the advantage of the surgical option. The main drawbacks of using CPAP are related to getting a properly fitting CPAP mask. If the mask is not fitted correctly, the air pressure may not be maintained causing discomfort and disrupting sleep. If the mask is on too tight, it can cause facial abrasions or bruising. In small children, the possibility of sleeping with the CPAP mask interfering with growth of the maxilla should be considered. As the child grows, the CPAP may require adjustments both in terms of mask size and the amount of pressure delivered to the airway. In addition to a continuous pressure delivery mode, a bi-level mode is available. In this mode, the pressure on expiration is lower than the inspiratory pressure. This may allow the device to be more comfortable and may be preferred in patients with neuromuscular weakness. The most recent advance in positive airway pressure has been the development of machines that can adjust the pressure required to keep the airway open on a breath-by-breath basis. These so-called “smart CPAP” units are promising but are not part of the mainstream treatment of children at this time (75,78).

In summary, it is important for clinicians to be aware that sleep-disordered breathing and snoring are not normal. Difficulty breathing while asleep may impact the daytime behavior of children. Sleep-disordered breathing is readily treatable.

### Narcolepsy

Narcolepsy is a chronic neurological disorder in which the boundaries between the awake, sleeping, and dreaming brain are blurred. The awake narcoleptic will feel sleepy. The sleeping narcoleptic will have disturbed sleep due to arousals. Historically, the word “narcolepsy” was first coined by Gélinau in 1880 to designate a pathological condition characterized by irresistible episodes of sleep of short duration recurring at close intervals. In the same article, he noted that the attacks were sometimes accompanied

by falls or “astacias.” The cardinal features of narcolepsy are daytime somnolence, cataplexy, sleep paralysis, and hypnagogic hallucinations (79). These symptoms were called the “tetrad” of narcolepsy by Yoss and Daly (80,81). The abnormal sleep onset REM sleep periods in narcolepsy were described by Rechtschaffen et al. (82). Since 1975, narcolepsy has been described as a “pentad” of symptoms due to prominent sleep fragmentation in several patients (83).

Narcolepsy is a rare condition; the prevalence of narcolepsy has been calculated at about 1 per 2,000 of the general population (84). Age at onset varies from early childhood to the fifth decade, with a peak in the second decade. It is important to consider narcolepsy, especially in young patients, because it can take up to 20 years between the appearance of the first symptom, commonly sleepiness, and the emergence of the full clinical syndrome. During this time, the patient may be mislabeled with a variety of diagnoses. The patient may be considered lazy or depressed. Before being correctly diagnosed, the patient may turn to illegal drugs, such as “crank” amphetamine, to combat the sleepiness.

### Clinical Presentation

Narcolepsy is characterized by abnormal sleep, including excessive daytime sleepiness with often-disturbed nocturnal sleep later in life and pathological manifestations related to REM sleep. REM sleep-related abnormalities include early REM sleep onset and cataplexy (79).

Cataplexy is an abrupt and reversible decrease or loss of muscle tone, most frequently provoked by emotion, particularly laughter. Consciousness typically remains intact. It may involve only certain muscles or the entire voluntary musculature. Most typically, the jaw sags, the head falls forward, the arms drop to the side, and the knees buckle. The severity and extent of cataplectic attacks can range from a state of absolute powerlessness, which seems to involve the entire body, to no more than a fleeting sensation of weakness. Severe cataleptic attacks can involve a complete loss of muscle tone, resulting in a fall with risk of serious injuries, including skull and other bone fractures, but can consist only of a slight buckling of the knees. Patients may perceive this abrupt and short-lasting weakness and may simply sit or stand against a wall. The attacks may be so subtle as not to be noticed by an observer. Although the extraocular muscles are supposedly not involved, the patient may complain of blurred vision. Speech may be slurred owing to intermittent weakness affecting the arytenoid muscles. Respiration may become irregular during an attack, which may be related to weakness of the abdominal muscles.

As seen during nocturnal REM sleep, the abrupt muscle inhibition is interrupted by sudden bursts of returning muscle tone, which at times even seems enhanced. If the weakness involves only the jaw or speech, the subject may present with wide masticatory movement or odd attacks of stuttering. If it involves the upper limbs, the patient

will complain of “clumsiness,” and may describe dropping cups or plates or spilling liquids when surprised or laughing. These attacks are short and do not resemble the “classic” full-blown attack of cataplexy; that is, with a complete fall. In early childhood, cataplexy attacks are more often the complete fall type. The child may present with repetitive falls that cannot be easily explained. Atonic seizures or drop attacks are the most common initial misdiagnosis for children less than 5 years old (85). The duration of each cataplectic attack, partial or total, is highly variable. They usually range from a few seconds to 2 minutes and rarely up to 30 minutes. Attacks can be elicited by emotion, stress, fatigue, or heavy meals. Laughter and anger seem to be the most common triggers, but the attacks can also be induced by a feeling of elation while listening to music, reading a book, or watching a movie. Cataplexy may be induced merely by remembering a funny situation, and this may also occur without obvious precipitating acts or emotions. In children, it often occurs while playing with others.

A pathway similar to the one leading to REM atonia is used in cataplexy (86–89). Cataplexy is associated with inhibition of monosynaptic H-reflexes and multi-synaptic tendon reflexes. H-reflex activity is fully suppressed physiologically during REM sleep, emphasizing the relationship between the motor inhibition of REM sleep and the sudden atonia and areflexia seen during a cataplectic attack.

Apart from overwhelming sleepiness, patients may feel abnormally drowsy. They may spend the day at a low level of alertness resulting in poor performance at school, memory lapses, and even gestural, or speech automatisms. This low alertness may persist despite the use of stimulant medication.

Daytime sleepiness may not be obvious to parents in very young children and may be missed before kindergarten. Sleepy behavior is more often recognized by teachers who may complain of apathy in the child while the parents may misinterpret the behavior as normal napping. Prolonged nocturnal sleep, difficulty waking up in the morning, and aggressiveness before being awakened are commonly seen. However, sleepiness can be hidden behind other abnormal behavior such as hyperactivity, or social withdrawal and shyness (89).

Sleep paralysis can be a terrifying experience that occurs when the narcoleptic falls asleep or wakes up (90). Children find themselves suddenly unable to move their limbs, to speak, or even to breathe deeply. This state can be frequently accompanied by hallucinations. During episodes of sleep paralysis, particularly the first occurrence, the patient may experience extreme anxiety and fear of dying. This anxiety is often greatly intensified by the hallucinations, sometimes terrifying, that may accompany the sleep paralysis. Children are often reluctant to talk about these events. These experiences are so frightening that the child may resist going to bed to sleep.

Visual hypnagogic hallucinations usually consist of simple forms (colored circles, parts of objects, and so forth) that are constant or changing in size. The image of an animal or a person may present itself abruptly, in black and white but more often in color. Auditory hallucinations are also common. The auditory hallucinations can range from simple sounds to an elaborate melody. The patient may also be menaced by threatening sentences or harsh invectives. Hypnagogic hallucinations and sleep paralysis do not affect all subjects and can be transitory (91). Disturbed nocturnal sleep seldom occurs early in the course of the disorder and generally worsens during adulthood.

### Diagnosis

Unless cataplexy is unequivocally witnessed by the examiner, an objective sleep study will be necessary to obtain an accurate diagnosis of narcolepsy. Unfortunately in children younger than 8 years of age, no objective test has been developed to confirm the diagnosis. In these younger children the diagnosis is made by a process of elimination when there is an otherwise clear history. Clinical EEG and MRI studies are normal. A key finding in this age group is the absence of another sleep disorder such as periodic limb movement disorder as demonstrated on a complete overnight polysomnogram. The polysomnogram should be normal with the possible exception of a short REM sleep latency. Polysomnogram monitoring should include either a nasal cannula or esophageal pressure (PES) in order not to miss a more subtle condition such as upper airway resistance syndrome (30).

In children 8 years or older, objective testing is available to diagnose narcolepsy. After completing a full nocturnal polysomnogram, a multiple sleep latency test (MSLT) is necessary (92). The MSLT was designed to measure physiological sleep tendencies in the absence of alerting factors. The time or latency between lights-out time and sleep onset is calculated for each nap. The type of sleep, REM or nonREM, is also noted. After each nap, the patient must stay awake until the following scheduled nap. The MSLT records the sleep latency for each nap, the mean sleep latency, and the presence or absence of REM sleep in any of the naps. REM sleep that occurs within 15 minutes of sleep onset is considered a sleep onset REM period.

In normal populations, MSLT scores vary with age, puberty being the critical landmark, with prepubertal children between the ages of 8 and 11 years appearing relatively hyperalert. The maximum mean MSLT score obtainable is 20 minutes, which corresponds to a subject staying awake during all naps. Mean MSLT scores under 8 minutes are generally considered to be in the pathological sleepiness range; those over 10 minutes are considered normal in adults. Before puberty, as mentioned above, children are very alert in the daytime and the normal adult MSLT cut off value of 10 minutes may be too low. Even a 12-minute latency in a prepubertal child may be abnormal. In children undergoing an MSLT, the presence

of two or more sleep-onset REM periods is always abnormal and consistent with narcolepsy.

Histocompatibility leukocyte antigen (HLA) typing had been recommended as a test for narcolepsy when it was found to have an association with the DR-2 marker in Japan. However, this marker is neither sufficient nor necessary for the diagnosis because it is present in 10 to 15% of the general population. Determination of HLA haplotypes in children suspected of having narcolepsy is usually not helpful in making the diagnosis (79).

An animal model for narcolepsy has been studied using dogs. Recently, using positional cloning, an autosomal recessive mutation responsible for narcolepsy was discovered in this canine model (92, 93). Canine narcolepsy is caused by disruption of the hypocretin (orexin) receptor 2 gene (*Hcrtr2*). Hypocretins appear to be major sleep-modulating neurotransmitters (93,94). Absence of hypocretins is now thought to be critical in the pathophysiology of most human narcoleptics. In the canine model, the receptor is lacking, but in humans, the actual neurotransmitter is usually lacking. The possibility that an autoimmune mechanism is damaging the hypocretin-producing cells in the lateral hypothalamus has been raised (95). Hypocretin can be measured in cerebrospinal fluid. This research tool is useful in diagnostic situations when the diagnosis is uncertain (96, 97). The absence of hypocretin in cerebrospinal fluid is diagnostic of narcolepsy; however this assay is not widely available. A blood serum equivalent test is not yet available. Future treatment of narcoleptic humans may involve hypocretin analogs.

### Treatment Strategies

Successful treatment for narcolepsy includes both behavioral and pharmacological treatments. The situation is analogous to juvenile diabetes mellitus where a combination of diet with medication can control the condition. With the recent discovery of a gene responsible for narcolepsy, novel potential therapeutic approaches may be discovered.

Treatment strategies must include conservative behavioral treatment such as short naps, emotional support to parents and child, and education of school authorities. Repetitive 15- to 20-minute naps at 3-hour intervals are helpful in restoring alertness. Behavioral and emotional disturbances are reported in adolescents with narcolepsy (98). Subjects and families should be referred to narcolepsy support groups led by a therapist who can address issues created by this chronic condition.

Narcolepsy is a lifelong illness, and drug therapy must take this into account when considering possible side effects, because patients will have to take medication for years. Tolerance or addiction may occur with some drugs, and it is importance to balance medication side effects with maintenance of an active life. Hypertension, abnormal liver function, depression, irritability, anorexia, insomnia, or psychosis are associated with some medications (79).

No double-blind placebo controlled trials of medication have been specifically conducted for children with narcolepsy. Central nervous system stimulants have been the drugs most widely used (99). Amphetamines were first proposed in 1935. The alerting effect of a single oral dose of amphetamine is at its maximum 2 to 4 hours after administration, and many patients require a single or twice-daily dose. However, a number of side effects, including irritability, anxiety, nervousness, headache, psychosis, tachycardia, hypertension, nocturnal sleep disturbances, tolerance and drug dependence, may arise. The use of methylphenidate was later encouraged because of a shorter half-life and lower incidence of similar side effects. Pemoline, an oxazolidine derivative with a longer half-life and a slower onset of action, is less efficient but well tolerated. Pemoline, previously the first stimulant used in children, should now be discouraged because of the possibility of severe liver damage. The manufacturer has recommended that baseline liver function tests be obtained before starting pemoline and every 2 weeks thereafter.

There are two drugs with different mode of action that have changed our first-line treatment for narcolepsy. The first one, modafinil, is considered more as a "somnolytic" than a non-specific stimulant. The drug, which has been approved in the United States, has been reported to bring substantial improvement in adults (100). The mechanism of action of modafinil is not entirely clear but it is not dopamine mediated in the same way amphetamines are thought to work (101). The neuronal targets for modafinil in the brain include nuclei of the hypothalamus and amygdala. Modafinil should be considered the initial pharmacological agent used to treat the excessive daytime sleepiness of narcolepsy in children (100). Modafinil does not have the typical side effects of amphetamine. Headaches are the most common side effect of modafinil and may be avoided or minimized by gradually increasing the dose (100). The initial dose should be relatively low, 50 to 100 mg, to avoid headaches. The dosage can later be increased to 200 to 400 mg/day divided twice daily. The second dose should ideally be given before 2 PM because of the long half-life.

The second drug is gamma-hydroxybutyrate (GHB), which, after much difficulty was approved for use in the United States by the FDA in July 2002 (101-103). It is the first substance ever approved specifically for cataplexy. The generic name is sodium oxybate (Xyrem). In the media, it has the infamous name of the "date rape drug" (93). Illegal use of this substance for recreational purposes has been of great concern. Important CNS adverse events associated with abuse of sodium oxybate include seizure, respiratory depression, and profound decreases in level of consciousness, with instances of coma and death. When used outside of clinical trials, for recreational purposes, the circumstances surrounding these adverse events are often unclear (e.g., dose of sodium oxybate taken, the nature and amount of alcohol or any concomitant drugs ingested).

Sodium oxybate has powerful CNS depressant effects and can increase slow-wave sleep (103). When given at bedtime, this medication may reduce cataplexy (101). Patients may prefer this medication over other medications used for cataplexy, particularly if insomnia is also present. Sodium oxybate is rapidly but incompletely absorbed after oral administration; absorption is delayed and decreased by a high fat meal. It is eliminated mainly by metabolism with a half-life of 0.5 to 1 hour. Pharmacokinetics are non-linear with blood levels increasing 3.7-fold as the dose is doubled from 4.5 to 9 g. The pharmacokinetics are not altered with repeat dosing. Sodium oxybate should be taken at bedtime while in bed and again 2.5 to 4 hours later. The recommended starting dose in adults is 4.5 g/day divided into two equal doses of 2.25 g. The starting dosage can then be increased to a maximum of 9 g/day in increments of 1.5 g/day (0.75 g per dose). Two weeks are recommended between dosage increases to evaluate clinical response and minimize adverse effects. Sodium oxybate is effective at doses of 6 to 9 g/day. The efficacy and safety of sodium oxybate at doses higher than 9 g/day has not been investigated, and doses greater than 9 g/day should not ordinarily be administered. The product's package insert does not recommend using the medication in patients younger than age 16 years and dosing guidelines for patients younger than 16 years old have not been established (104). Ironically, unlike most other medications discussed in this text, sodium oxybate is sold as a liquid, thus making it possible to treat young children if clinically indicated.

Cataplexy seems to respond best to medications with noradrenergic reuptake blocking properties (105). There are no systematic trials of anticataplexy drugs on children. Postpubertal teenagers are usually treated as young adults. In this group, two medications have been more commonly used, clomipramine and fluoxetine. Both of these drugs have active noradrenergic reuptake blocking metabolites (desmethylclomipramine and norfluoxetine). It is through these metabolites that the therapeutic effect may be mediated (106). Other compounds have been found to be effective in children with cataplexy, particularly imipramine and desipramine. The anticholinergic side effects of clomipramine and imipramine may be problematic. Treatment with fluoxetine or viloxazine may avoid these side effects (100).

### Restless Legs Syndrome/Periodic Limb Movements of Sleep

Restless legs syndrome (RLS) is a chronic autosomal dominant neurological disorder (107, 108). It is characterized by leg discomfort, most common in the evening, that makes the patients want to move their legs. Discomfort is relieved with movement. The sensation may also be present when the patient is sitting still, such as seated on an airplane or in a movie theater. The leg discomfort may be hard to describe and in children may be characterized as

“growing pains.” In patients with restless legs syndrome, sleep may be disrupted by hundreds of involuntary kicking movements of the legs during sleep, called *periodic limb movements of sleep* (PLMS). The movement in the leg is the extension of the big toe, while at the same time the ankle, knee, and sometimes the hip are partly flexed. These repetitive episodes of muscle contraction last from half a second to 5 seconds with an interval of about 20 to 40 seconds, and may occur in the absence of RLS (108).

The diagnosis of periodic leg movements of sleep requires an overnight sleep study, which demonstrates a PLMS index of over five episodes per hour. Restless legs syndrome/periodic limb movements of sleep can result in significant daytime drowsiness as a result of poor sleep quality, which may lead to daytime behavior that mimics ADHD (109–112). PLMS has also been described in children. However, the clinical presentation differs from that of adults with PLMS. Chervin reported an even higher prevalence rate in a small referred population of children (26%), half of whom also had evidence of sleep-disordered breathing (115). Picchetti and associates reported a retrospective review of 129 children and adolescents who were found to have PLMS in excess of five per hour (115). Sixty-five (50%) had PLMS in the 5 to 10 per hour range, 48 (37%) in the 10 to 25 per hour range, and 16 (12%) had periodic limb movements exceeding 25 per hour. Of the original 129 children, 117 (91%) had been previously diagnosed as having ADHD. Stimulant medication did not seem to play a role in the production of PLMS. In only 25 of the 129 cases did parents note the presence of PLMS of sleep before being specifically asked to look, and in some case, the leg movements of sleep were initially misdiagnosed as seizures. Daytime symptoms improved with dopaminergic medications. Other studies have been confirmed these associations between PLMS and ADHD (112, 113). Children with RLS may present with nonspecific symptom such as growing pains, restless sleep, insomnia, and daytime sleepiness, but most often these issues go unnoticed by their parents. A family history of RLS or PLMS is common (114–117).

A dysregulation of iron metabolism may play a role in the pathophysiology of RLS. Iron is a cofactor in the production of dopamine. Allen reported that decreases in iron concentration in nigrostriatal areas correlated with the severity of RLS (118). Other investigators reported that in individuals with RLS, transferrin receptor expression in neuromelanin cells of the substantia nigra was decreased, suggesting that RLS may result from a defect in iron regulatory protein (119).

Nondrug treatments may temporarily help counteract the sensations of RLS. Patients may find that walking, stretching, taking a hot or cold bath, massaging the affected limb, applying hot or cold packs, using vibration, performing acupressure, and practicing relaxation techniques (such as biofeedback, meditation, or yoga) may help reduce or relieve the symptoms. In addition some find that keeping their mind actively engaged through activities such as reading an interesting novel, or playing video games helps

during times that they must be stay seated, such as when traveling.

Dopamine precursors and agonists have been effective in relieving both RLS and PLMS (120). They have been endorsed by the American Academy of Sleep Medicine however specific guidelines for children were not reviewed (121).

Levodopa (L-DOPA), the metabolic precursor of dopamine, is used for treating Parkinson's disease. It is also used to treat RLS/PLMS in both adults and children (122). Levodopa in itself is largely inert. Its therapeutic as well as adverse effects result from the decarboxylation of levodopa to dopamine in the brain (123). Levodopa is almost always administered in combination with a peripherally acting inhibitor of aromatic L-amino acid decarboxylase such as carbidopa. If levodopa is administered alone, the drug is largely decarboxylated by enzymes in the intestinal mucosa and other peripheral sites so that relatively little unchanged drug reaches the cerebral circulation. In addition, dopamine released into the circulation by peripheral conversion of levodopa produces undesirable effects particularly nausea. Inhibition of peripheral decarboxylase markedly increases the fraction of administered levodopa that remains unmetabolized and available to cross the blood-brain barrier and reduces the incidence of gastrointestinal side effects such as nausea (123). The main complication of levodopa therapy for RLS/PLMS is the development of worsening symptoms during the afternoon or early evening, despite adequate control later at night. This phenomenon which has been termed "restless legs augmentation," may occur frequently, sometimes within months after therapy has been instituted. Once augmentation has occurred, levodopa therapy should be discontinued and, if possible, a different agent should be used. Administering additional doses of levodopa earlier during the day usually results in further exacerbation of the augmentation phenomenon. (124, 125). In addition to motor fluctuations and nausea, other adverse effects observed with levodopa therapy include hallucinations, confusion, and orthostatic hypotension.

These other side effects are more typically seen in adult patients with Parkinson's disease using higher dosages than are used in the treatment of PLMS and RLS. In children, nausea is by far the most common side effect. Sensitivity to side effects makes it necessary to initiate therapy at very low doses (one half of a 25/100 levodopa/carbidopa tablet daily) and increase as tolerated every few days. The therapeutic dose for relief of PLMS and RLS symptoms will be lower than that used in Parkinson's disease. The maximal dose is determined by side effects but most adolescents require at least 75 mg carbidopa and up to 1.5 g of L-DOPA. (126). Levodopa is valuable in the treatment of RLS/PLMS, but the mode of action of the drug is unknown. It seems likely that dopaminergic pathways are involved. Walters and Hening have suggested that the site of action is the postsynaptic dopamine receptor, whereas Guillemainault et al. propose a spinal dopaminergic mechanism as

the site of action (128). There may be differences in the mechanism of action of these medications between patients with RLS and those with only PLMS.

Based on the hypothesis that there is a disturbance of iron regulation in the pathophysiology of idiopathic RLS, a trial of iron supplementation was found to result in improvement in these patients (128–132). Some of the most important findings are that children with PLMS have relatively low serum iron and ferritin levels. In addition, most of these patients will respond favorably to a 3-month course of oral iron therapy, as evidenced by a decrease in PLMS index and an improvement in clinical symptoms (133).

Selective dopamine agonists are potent treatments for PLMS and RLS. They tend to have fewer side effects than carbidopa/levodopa. Pramipexole, ropinirole, and pergolide are the most commonly used medications in this category (134). Selective dopaminergic agonists have similar side effects to carbidopa/levodopa but at a lower frequency. These agents are more potent and allow for lower dosages than with carbidopa/levodopa. Of these agents, pramipexole has been particularly effective in our experience.

Montplaisir and colleagues have found pramipexole to be effective in a double-blind placebo-controlled study in adults (135). The starting dose in adults in this study was 0.375 mg. In children, the lowest dose available is an empirical starting dose. Pramipexole is available in a 0.125-mg scored tablet, which can be halved if an even lower starting dosage is desired. It is important to make medication changes slowly because the symptoms of PLMS and RLS both seem to fluctuate independently of the medication. In addition, if the dosage is too high, significant side effects may occur. We advise parents to only adjust the medication once a week at most when they first start the medication. Once an effective dose is found it does not typically have to be adjusted except to allow for the child's growth. In adults, the dosage of pramipexole for restless legs syndrome usually does not exceed 1.5 mg, and is often effective at a much lower dose.

### Childhood Insomnia

Insomnia in adults is defined as the subjective complaint of nonrestorative sleep associated with difficulty initiating and or maintaining sleep (107). The nonrestorative sleep of insomnia requires a perception of impaired awake function as result of the sleep difficulty. In children, the parents' perception of impairment is just as important as the child's. If an infant does not sleep well at night, the infant may compensate with more naps.

Insomnia characteristics fluctuate with age. With infants, the problem usually involves trouble settling to sleep without the parents' assistance. In toddlers, the problem may also involve inconsistent limit setting with regard to bedtime expectations. By the time children are 8 or 9 years old, they seem to have fewer problems with insomnia. When problems with sleep are present at this age, there may be

some unresolved fear of being alone at night. This might be expressed as a “fear of the dark.” This fear may not be initially volunteered during the clinical interview but a description of the sleep routine and environment may reveal a need for nightlights or hallway lights to be left on at night. Adolescents have a characteristic insomnia pattern called delayed sleep phase syndrome (DSPS) (107). DSPS will be discussed subsequently. All of these insomnia types may merge in different ways in a given individual. In addition, with clinical heterogeneity, there are children who are described as being lifelong poor sleepers without any apparent cause. This condition is referred to, for lack of a better term, as idiopathic insomnia, and fortunately is rare (107).

### **Sleep-Onset Association Disorder and Limit-Setting Sleep Disorder**

These two disorders are related to the inconsistent enforcement of bedtime routines. In normal infants, brief awakenings throughout the night are common. The child and the parent are unaware of most of these, and unbeknownst to the parents, the child may simply drift back to sleep. It is only when these awakenings become associated with external events that a problem arises. If a brief awakening is followed by a full arousal in an active, alert child, and the child is unable to fall asleep, the child may simply become agitated. The child can return to sleep after being comforted by the caregiver.

Sleep-onset association problems seem to be common. Although the need for sleep has a biological basis, the way we sleep is learned and influenced by the cultural environment. This is analogous to eating. All newborns first drink milk, but the diet of older children is different throughout the world. The child will learn or form associations with regard to sleep. As the child is readied for bed, the child may associate sleep onset with particular events, and may associate this process with increased attention and activity rather than getting ready for bed. If continued, the child may then develop an association with parental activity that requires continuous parental involvement to fall asleep. The awakenings in the middle of night often necessitate similar actions. What initially were brief awakenings may develop into lengthy struggles. What wakes up the child may not be what is keeping the child awake. Now the parental actions became the focus of the problem. If returning the child to sleep requires frequent parental assistance, the parents’ sleep may be very disturbed. The entire family may start to dread the nighttime instead of looking forward to going to sleep. The nighttime routines are no longer pleasurable but become a source of frustration. A vicious cycle may form, which is exacerbated by middle-of-the-night awakenings. Parents may report that the infant wakes up crying every hour. The normal sleep cycle length in an infant is approximately 1 hour and is followed by a brief arousal before initiating the next sleep cycle. Therefore, when a parent complains of hourly awakenings with prompt return to sleep with the parents’ intervention, the

possibility of a sleep-onset association disorder should be considered.

Limit-setting sleep disorder is term used to describe stalling behaviors or refusal to go to bed at the desired time associated with inadequate limit-setting for a child’s behaviors. This sleep disorder is usually seen in a child who is sleeping apart from the parents and is old enough to get out of bed or climb out of the crib, go to the parents’ bedroom and disrupt their sleep. Usually there is no enforcement of consistent bedtime rules. The same behaviors may occur after nighttime awakenings. When the child does sleep, it is usually of normal quality and duration. The parents may lack an understanding of the importance of setting limits and inadequate knowledge of limit-setting techniques. There may be underlying psychosocial factors limiting the parents’ ability to set limits. The limit-setting difficulties may also be manifest in the child’s daytime behavior such as tantrums.

These insomnia patterns are of a behavioral nature and usually do not need to be treated with medication (136). Antihistamines and clonidine may be tried in some of these children but there is little evidence to suggest that these preparations provide anything but short-term sedation (137). In particularly difficult situations, medication can be used as part of a comprehensive treatment program with behavior modification at its core. Behavioral techniques have been helpful and applied to a variety of clinical situations (138, 139). The first issue to be addressed in the evaluation of a behavioral sleep problem in an infant or small child is, where do the parents want the child to sleep? The child will typically prefer to sleep with the parents; the question is what the parents prefer. Many variations are possible with regard to such sleeping arrangements. The child might sleep in a crib in a separate room, a crib in the parents’ room, in the same bed with the parents, or in the same bed or bedroom with another member of the family. The sleep situation may change based on multiple factors such as new siblings or the size of the home. Cultural issues will also play a part in this situation. Once the parents and caretakers agree, then a plan to teach the child what to expect can be developed.

Perhaps the best known behavioral approach is that popularized by Dr. Richard Ferber at Harvard (140). This approach has not been without some controversy and the clinician needs to be familiar with it since undoubtedly the parents will be. In essence, a “progressive” approach to helping the child fall asleep and stay asleep is advocated. After a bedtime routine such as singing, rocking, or reading a book, the child is put to bed while still awake. Putting the child in bed awake is thought to teach the child to go to sleep on his own. Parents are advised that once the child is in bed, they should leave the room. If the child cries, wait a while before checking in on the child. The suggested waiting time should be based on how comfortable the family is with the situation and can be charted to help track the progress. When

the parent returns to the child's room, the child should be soothed verbally but the parents should avoid picking up, rocking, or feeding the child. The time between parental interventions should be gradually increased. The time should be predetermined and not shortened during the night. Ideally within a week, the child will learn to sleep without the parents' help.

This method is not desirable or effective for all families. Alternatives have been published by various authors some that seem diametrically opposed to the above method (141–143). A discussion of different approaches and counter arguments about helping a child sleep at night are beyond the scope of this chapter. Suffice it to say that parents will typically seek professional help only after they have tried one or more of the different popular approaches. The relationship between the parents may suffer due to frustration and sleep deprivation. Given this situation, a pragmatic approach that takes into account the individual situation is appreciated by the family. A judgmental or patronizing attitude from the health care provider will not be appreciated.

The parents may need additional direction to be able to implement firm limits for the child. For example, reassure the parents they have not abandoned the child if they decide to sleep separately or that they are spoiling the infant if they decide to share their bed with the infant. If the child has learned to sleep in the parents' bed and the parents want to change this arrangement, they need to realize the infant has no incentive to change. One approach is for the parents to start the night sleeping in the child's room. The amount of time that the parent spends with the child in bed could be decreased gradually until the child learns to sleep alone. These gradual interventions are not meant to be punitive, and require patience, persistence, and reassurance for both the parents and the child.

A food allergy may occasionally play a role in a child's insomnia (144, 145). This usually occurs between birth and about 2 years of age. The insomnia is often initiated by food allergens causing somatic manifestations after ingestion of food or formula. Manifestations of an allergy, such as a skin rash, would be expected to be present. A young child fed formula may become fussy and irritable shortly after being fed. In a case of cow's milk allergy, IgE levels may be elevated and a radioallergosorbent test positive for cow's milk protein. A change in formula may be curative and a cow's milk challenge would induce the reappearance of insomnia.

### **Delayed Sleep Phase Syndrome**

The sleep patterns of adolescents seem different from those of other children and adults. This may be due to a combination of physiological changes and external societal influences. In the United States, Dr. Mary Carskadon has done extensive research on adolescent sleep (146–148). The most common form of insomnia in adolescents may be delayed sleep phase. Delayed sleep phase syndrome is a circadian disorder characterized by chronic sleep-onset insomnia

and an inability to arise at an appropriate time in the morning. Once the major sleep episode has been initiated, the individual has the ability to sleep soundly and for a normal duration (149). When not required to maintain a strict sleep schedule (e.g., weekends, vacations, and holiday periods) patients will awaken spontaneously, albeit at a late morning or early afternoon hour. They will have a normal nocturnal total sleep time.

Delayed sleep phase syndrome is associated with depression and should be considered when evaluating adolescents with depression (150–152). A study in Japan attempted to define the psychological features of patients with delayed sleep phase syndrome (153). They administered a series of neuropsychiatric tests including the Minnesota Multiphasic Personality Inventory (MMPI) and Rorschach. Compared to the controls they found that patients with delayed sleep phase syndrome manifested increased nervousness, depression, and difficulty regulating emotional displays. They were defensive, introspective, overly abstract in their thinking, compulsive, and tended to set high standards for intellectual achievement, despite questionable cognitive ability, which made them vulnerable to disappointment. However, they were also impulsive, and sought immediate gratification. The investigators described them as neurotic, hypochondriacal, depressed, and prone to conversion symptomatology. They suggested that these characteristics might increase social withdrawal, decreasing the social cues that might entrain circadian rhythm. Finally, they concluded the phase shift becomes more difficult and a vicious circle is constituted.

Patients with delayed sleep phase syndrome describe themselves as "night owls" and the preference for "eveningness" appears to run in families (154, 155). Several genes have been identified that may play a role in delayed sleep phase syndrome. Mammalian circadian rhythmicity has been shown to be regulated at the genetic level by transcription-translation feedback loops. Key molecular components are proteins, among which are called Clock, Timeless, and Period (Per). A single nucleotide polymorphism of the human *CLOCK* gene has been shown to be related to diurnal preference. Individuals carrying one of the two *CLOCK* alleles showed a strong preference for "eveningness" (154). There are three subtypes of the Per protein. Researchers in the United Kingdom reported that the shorter allele of the Per 3 polymorphism was strongly associated with "eveningness" (75% of the subjects were homozygous for this polymorphism), whereas the longer allele was associated with "morningness" (156–159). A different molecular mechanism for delayed sleep phase syndrome has been reported by investigators in Japan who identified a polymorphism in the gene for a rate-limiting enzyme used in the synthesis of melatonin, arylalkylamine N-acetyltransferase (155). They suggested this could be a susceptibility gene for delayed sleep phase syndrome (156). In general, it may be intrinsically easier for people to go to sleep later than usual (delay) than to go to sleep

earlier than usual (advance). People susceptible to delayed sleep phase syndrome may have more difficulty adjusting to an earlier sleep time than others (160–162).

Delayed sleep phase syndrome is not difficult to diagnosis once the clinical suspicion is raised but obtaining satisfactory response to treatment is more difficult. Attempts to correct the sleep schedule will be fruitless unless the adolescent is motivated to alter the lifestyle factors that influenced the late bedtime, particularly on weekends (163). The original treatment for delayed sleep phase was called chronotherapy by Weitzman (149). Chronotherapy resets the patient's sleep cycle by a series of consecutive delayed adjustments of the bedtime, which are made over several days. To maintain the readjusted sleep pattern, the patient is encouraged to keep strictly to the new sleep onset and wake times. This treatment can be impractical because the progressive forward bed time shifts will have the child at one point temporally sleeping in the daytime. The child must be constantly supervised to avoid falling asleep at the wrong time. This treatment, although physiologically sound, has been impractical.

Another treatment technique resets the sleep-wake rhythm by using bright morning light combined with evening light restriction to phase-shift the patient's sleep time (164–166). The term *phototherapy* is used for this treatment (163). The essential principals of phototherapy are that bright light in the morning can phase advance sleep onset and bright light in the evening can phase delay sleep onset. Different phototherapy protocols have been used with various success rates. A pragmatic approach for the individual patient needs to be developed. Our practice is to use light intensity 10,000 lux for 30 to 45 minutes within a few minutes of awakening for several weeks. In addition, bright lights should be minimized in the last 2 hours before the expected sleep time. This includes the use of computer monitors. A practical compromise in adolescents may be to minimize or restrict watching television or using a computer before bedtime but allow their use promptly after awakening. This might serve as an incentive for the adolescent to get up on time or early if this time is available for recreational computer use. Phototherapy should not be used in patients who are bipolar because it may aggravate mania (163).

Treatment with melatonin has been described (151–154). Melatonin is a hormone secreted by the pineal gland and its primary function seems to be to convey information about the changing length of the night in the course of the year. This information is used by photoperiodic animals to ensure the correct timing of seasonally variable functions such as reproduction, coat growth, and probably the duration and organization of sleep. The clinical use of melatonin may be difficult and perhaps its use by the nonspecialist discouraged. Melatonin has been used to treat poor sleep in a variety of conditions including Asperger syndrome (167–169). Melatonin is not regulated as a pharmaceutical in the United States, but rather is classi-

fied as a food additive (170). This lack of regulation may make the quality of over-the-counter melatonin highly variable. The timing of the dose must be individually determined based on the subject's core body temperature rhythm. The patient's motivation to modify their lifestyle is essential for successful treatment. Adolescents may have a variety of social and academic reasons to avoid going to bed at an earlier time. A large difference between the bedtimes and wake-up times from school nights compared to weekends can reinforce the delayed sleep phase.

### Parasomnias

According to the International Classification of Sleep Disorders, parasomnias are clinical disorders that are not abnormalities of the processes responsible for sleep and wake states per se but, rather, are undesirable physical phenomena that occur predominantly during sleep (107). This nosology describes over 20 different parasomnias, the majority of which can occur in children. These are divided into four groups: arousal parasomnias, sleep-wake transition parasomnias, parasomnias associated with REM sleep, and other parasomnias.

The arousal parasomnias are more common in children and include the clinical spectrum of confusional arousals, sleep terrors, and sleepwalking. These conditions are thought to arise from impaired arousal from sleep, typically slow-wave sleep. Since slow-wave sleep (stages 3 and 4) dominates in the first third of the night, the arousal parasomnias also occur at that time. Anything that increases the amount of slow-wave sleep, such as recovery from sleep deprivation, may increase the likelihood of these parasomnias occurring in susceptible individuals. If necessary, clonazepam may help decrease these arousal parasomnias but should be avoided in the presence of sleep-disordered breathing (136).

Confusional arousals may be partial manifestations of sleep terrors and sleepwalking events. As the name implies, confusion occurs during and following arousals, usually in the first third of night. The individual is disoriented, speech and mentation are slowed, and response to questioning is confused (107). These behaviors usually last only a few minutes in children and can be precipitated by forced awakenings out of slow-wave sleep. The condition is benign and tends to decrease over time. However, a child with a tendency to have these events may also be at risk for sleepwalking, and parents/caretakers should be warned of this possibility. The events can be minimized by avoiding situations that can increase slow-wave sleep or sleep disruption.

Sleep terrors are characterized by a sudden arousal from slow-wave sleep with a characteristic "blood-curdling" scream accompanied by intense fear. Pronounced autonomic nervous system discharge may occur with tachycardia and sweating. The child may be described as wide-eyed with an intense look of fear staring past the parents. The prevalence of sleep terrors in children is 3% in children and

decreases with age to about 2% in adults (46). Arousal is difficult, and if successful, the patient may be confused and disoriented. The child may try to describe fragments of images with poor coherence. These images will not have the rich detail of a nightmare. Waking the child 15 minutes after they have fallen asleep has been a popular treatment. Awakening the child at the point that they would be expected to be entering slow-wave sleep seems somehow to decrease the tendency for these parasomnias to occur. When the child returns to sleep, the homeostatic mechanism driving slow-wave sleep may raise the arousal threshold and decrease the likelihood of the recurrence of the sleep terror. The parents should be warned that the child with sleep terrors might also sleepwalk.

Sleepwalking is also called somnambulism (107). The term sleepwalking may be a misnomer, perhaps "sleep fleeing" would better characterize the dramatic behaviors. The range of behaviors witnessed may range from simply sitting up in bed to running out of the home and driving an automobile. During the sleepwalking episode, pain thresholds are elevated (171). The child will be hard to awaken and may be confused and disoriented. Motor activity may terminate spontaneously or the child may simply return to bed without reaching alertness. Sleepwalking may occur during this event. The treatments mentioned previously for the other arousal parasomnias may be helpful. Safety precautions should always be taken. Specifically the child should sleep on a ground floor if possible to avoid injury while negotiating stairs. If the child has a bunk bed, he should use the lower bunk. Drapery should be kept over the bedroom windows to protect the hands of the child in case the child tries to punch a window. A door alarm is helpful to warn the parents if the child walks out of the home. Weapons should be kept away from adults who may sleepwalk. It is helpful to keep precipitants of sleepwalking at a minimum. Thus, sleep deprivation should be avoided. Obstructive sleep apnea may be an occult aggravator, and should be treated if present (47).

Parasomnias such as sleepwalking and sleep terrors need to be distinguished from nocturnal seizures. The timing of seizures is different from sleepwalking and sleep terrors. Nocturnal seizures do not cluster during slow-wave sleep in the first third of the night. The motor activity of generalized tonic-clonic seizures is very different from these parasomnias. Tongue biting and urinary incontinence are not characteristically seen in sleepwalking and night terrors. Patients with generalized nocturnal seizures have a low risk of daytime seizures (172). The motor activity of a partial complex seizure may be more difficult to distinguish from parasomnias and may resemble a confusional arousal (173). Usually the overall clinical picture can help with the diagnosis. If a patient has been injured during an apparent parasomnia, a comprehensive neurological evaluation should be considered including a sleep-deprived electroencephalogram.

Some forms of epilepsy may be misidentified as a benign parasomnia (174) or as narcolepsy in children (159). Frontal lobe epilepsy is poorly understood and often unrecognized by health care workers dealing with children. Age of onset varies from infancy to adolescence. Seizures are typically brief (30 seconds to 2 minutes), stereotypic, nocturnal, and can occur several times during the night. They have an explosive onset, characterized by screaming, agitation, stiffening, kicking or bicycling of the legs, and incontinence. The interictal electroencephalogram is usually normal. Longterm video electroencephalographic monitoring is required to demonstrate the frontal epileptic discharges. This condition may be misdiagnosed as a sleep disorder or psychiatric problem. Nocturnal paroxysmal dystonia is a sleep disturbance that may be misidentified as a pseudo-seizure (176–178). It appears to be a form of frontal lobe epilepsy with motor attacks characterized by complex behavior, with dystonic–dyskinetic or ballistic movements arising from non-REM sleep. The movements are not symmetrical. Seizure control is difficult and may require epilepsy surgery (179).

## CONCLUSION

---

Sleep disorders are very common in children and are often associated with daytime behavioral problems. Most sleep disorders will improve when correctly addressed. It is important for children and their caretakers to give sleep the same priority as exercise and nutrition. We cannot continue to punish our children by sending them to bed early and reward them by permitting them to go to bed late and expecting them to grow up valuing a full night of sleep. There is a need for greater information on the pharmacological management of sleep disorders in children. Health care providers need to have a comprehensive understanding of clinical sleep disorders in children. Training programs should play a lead role in enhancing knowledge of sleep disorders in children.

# Ischemic Stroke in Childhood

19

**Peter E. Anderson, PhD**    **Gabrielle A. deVeber, MD, MSc**

A stroke is the result of a sudden occlusion or rupture of cerebral arteries or veins, with consequent focal cerebral damage and neurological deficits. A stroke can be either ischemic (i.e., secondary to an occlusion, termed a cerebral infarction) or hemorrhagic (i.e., intraparenchymal or resulting from subarachnoid bleeding). This chapter focuses on ischemic strokes.

There are two types of ischemic stroke: arterial ischemic stroke and sinovenous thrombosis. An arterial ischemic stroke occurs when there is an obstruction in the arterial system of the central nervous system. Sinovenous thrombosis, sometimes referred to as cerebrosinovenous thrombosis, occurs when there is an obstruction to the venous system of the brain. In both cases, blood flow to a specific brain area is interrupted, with resulting cerebral damage and neurological deficit(s). The ratio of arterial ischemic strokes to sinovenous thromboses is on the order of three to one (1).

Awareness of stroke in childhood continues to increase. The publication in the year 2000 of the special issues on cerebrovascular disorders by the *Journal of Child Neurology* and *Seminars in Pediatric Neurology* as well as the work of those involved in the clinical care and research of children with stroke have led to an increase in the reporting of child-

hood stroke and to a more complete understanding of the etiological factors and outcomes of childhood stroke. In addition, the development and availability of more effective forms of diagnostic technology has increased our understanding (2). Advances in other areas of medicine, which have made it possible for children who would not have survived earlier to survive, have also broadened the clinical spectrum of children who are at risk for stroke (e.g., premature births, severe cardiac disease, cardiac surgery, extracorporeal membrane oxygenation [ECMO], and trauma).

A note regarding the approach to this chapter—given the excellent review provided in the previous edition of this text, this chapter will emphasize the literature that has emerged since its publication (i.e., late 1990s).

## EPIDEMIOLOGY

The first systematic epidemiological study of cerebrovascular disease in infants and children involved a review of the records of the Mayo Clinic (Rochester, Minnesota) from 1965 to 1974 (3). This population-based study produced an incidence rate of 2.52 cases per 100,000 children; that is, four cases of stroke over a 10-year period. The authors noted that neonatal strokes were not included and that the incidence of sickle cell anemia, a significant risk factor for stroke, was not seen in any of the hospitals in Rochester and that, therefore, the “true” incidence might be higher. Moreover, this study was completed before computerized tomography (CT) scans were developed so that this effective means of diagnosing stroke was not available. In a subsequent study by Broderick et al. involving infants and children residing in Greater Cincinnati, which took place in 1988–1989 (a period when CT/MRI was standard in the workup of a child

### Acknowledgments:

This work was supported by Heart and Stroke Foundation of Ontario (NA4107, G.dV) and the Hospital for Sick Children Foundation (G.dV.). Dr deVeber is also supported with a Stroke Investigator award from the Heart and Stroke Foundation of Canada.

We thank Sarah Reiss and Maartje Salden for assistance with manuscript preparation, the members of the Children’s Stroke Program at the Hospital for Sick Children, and our colleagues Drs. Michael Balthazor, Simone Kortstee, and Maureen Lovett for their support and critical review of the manuscript.

referred for stroke-like phenomena), the incidence rate was similar to that of the Rochester study, namely 2.7 strokes per 100,000. The study population was much larger than that of Rochester (295,577 children versus 15,834 children) (4). An incidence of 1.5 per 100,000 for intracerebral hemorrhage and subarachnoid hemorrhage and 1.2 per 100,000 for cerebral infarction was reported in this study.

A series of papers by Giroud and colleagues (5, 6) regarding the incidence of cerebrovascular disease in children in Dijon, France, reported far higher numbers of strokes in infants and children: 7.91 per 100,000 for ischemic stroke and 5.11 per 100,000 for hemorrhagic stroke. This series also reports a preponderance of ischemic stroke, differing with the findings of the Cincinnati study reported by Broderick. The authors noted that these differences might be explained by several factors. The data were gathered outside the main University Hospital, death certificates were reviewed for “unknown” causes of death, and “mild” stroke and strokes induced by trauma were included.

The Canadian Pediatric Ischemic Stroke Registry was conceived to obtain comprehensive and prospective epidemiological data on arterial ischemic stroke and cerebral sinovenous thrombosis in children. Given the participation of all 16 pediatric tertiary care centers in Canada, this is truly a national registry, encompassing a general population of approximately 31,000,000 citizens. The most recent figures from this registry report an incidence of 2.6 per 100,000 per year for arterial ischemic stroke (7) and 0.7 per 100,000 per year for sinovenous thrombosis (8), resulting in a total of 3.3 per 100,000 per year. A 60% male preponderance was also reported for ischemic stroke at all ages (7, 8).

## ETIOLOGY

Stroke in infants and children can occur for a myriad of reasons. A thorough workup will typically result in identifying at least one etiologic factor, although in approximately 20% of cases, the cause will remain cryptogenic despite the most complete of investigations. It has often been reported that the most common cause of stroke in infants and children is cardiac disease, which is thought to account for approximately 15% of childhood stroke (9). For example, a series of 59 consecutive cases of childhood stroke reported a total of seven children with cardiac or transcerebral embolic strokes, a rate of 12% (10). Cardiac disease was listed as the primary risk factor for stroke in 19% of patients enrolled in the Canadian Pediatric Ischemic Stroke Registry, followed by coagulation disorders (14%), dehydration (11%), vasculitis (7%), infection (6%), dissection (5%), neoplasm (4%), metabolic disorder (3%), Moyamoya disease (2%), sickle cell anemia (2%), and perinatal complications (2%), with miscellaneous factors accounting for 4%. A risk factor could not be identified in 21% of participants in this registry (11, 12).

The search for a putative cause(s) of a stroke is of great importance and should extend beyond the obvious cause

(e.g., an arterial dissection or congenital heart disease), as multiple risk factors are often found in ischemic strokes and the presence of multiple risk factors has been linked with both stroke recurrence and stroke outcome (12). There is frequently a preceding or concomitant condition, which by itself or in combination with its treatment results in cerebral insult, in addition to the stroke itself. It is sometimes difficult to separate out the primary and secondary causes of the cerebral insult. The adult literature, often used as a jumping off point for the treatment of children, is of limited use as the causes of stroke in adults can be quite different (e.g., although atherosclerosis and atrial fibrillation are common risk factors in adults, they are not listed as common in stroke in children).

## CLINICAL PRESENTATION

Presentation of stroke varies with the age at which the lesion occurs, as well as the location and type of lesion. Infants with arterial ischemic strokes and sinovenous thrombosis often present with lethargy and seizures, while in older infants and toddlers symptoms may present with an abrupt onset and with focal neurological signs, such as facial droop or hemiparesis. If a stroke occurs in the prenatal or perinatal stroke period, motor signs may not emerge until several months later—between 4 to 8 months of age (13). A school-age or teenage child may describe more subtle symptoms, such as word finding difficulty or visual disturbance, headache, or a focal sensory deficit. There is some thought that transient ischemic attacks precede arterial ischemic strokes in up to one third of cases, although they are rarely diagnosed (7). In some cases, the symptoms of these transient ischemic attacks may be thought to be hysterical in nature, or a conversion disorder, given that the symptoms appear and then fade away, possibly to return again if there is another attack.

Seizures and lethargy are the most typical presentations of sinovenous thrombosis in the neonatal period (8). Older infants and children typically present with more varied symptomatology, related to increased intracranial pressure, with headache, visual disturbance papilledema, and, occasionally, sixth-cranial nerve palsy. Hemiparesis and seizures are common occurring in 35 to 45 and 48%, respectively (8).

As is the case with stroke in adult patients, there are a great number of etiologies for a stroke in the neonatal period or in childhood, which can be broken down into major categories) with several examples under each category, some of which will be described in the text (see Table 19.1).

## SICKLE CELL DISEASE

Sickle cell disease is one of the numerous medical conditions that can precede a stroke. Cerebrovascular accidents are a frequent and major complication in patients with sickle cell disease. Sickle cell disease is the result of an abnormal

**TABLE 19.1**  
**RISK FACTORS FOR STROKE IN CHILDREN**

### Hematologic Disorders

Hemoglobinopathies (e.g., sickle cell anemia)  
Immune thrombocytopenic purpura  
Thrombotic thrombocytopenic purpura  
Thrombocytosis  
Polycythemia  
Leukemia or other neoplasm  
Disseminated intravascular coagulation

### Vasculopathies

Postvaricella angiopathy  
Ehlers-Danlos syndrome  
Early atherosclerosis  
Diabetes  
Systemic hypertension  
Hypernatremia  
Superior vena cava syndrome  
Homocystinuria  
Pseudoxanthoma elasticum  
Fabry disease  
Arterial fibromuscular dysplasia  
Moyamoya syndrome  
Moyamoya disease  
Postradiation vasculopathy  
NADH-CoQ reductase deficiency  
Williams syndrome

### Vasculitis

Meningitis  
Systemic lupus erythematosis  
Systemic infection  
Polyarteritis nodosa  
Granulomatous angiitis  
Takayasu's arteritis  
Rheumatoid arthritis  
Dermatomyositis  
Inflammatory bowel disease  
Drug abuse (cocaine, amphetamines)  
Hemolytic-uremic syndrome

### Vasospastic Disorders

Migraine  
Ergot poisoning  
Vasospasm with subarachnoid hemorrhage

### Cardiac Disorders

Complex congenital heart defect  
Ventricular/atrial septal defects  
Patent ductus arteriosus  
Patent foramen ovale  
Aortic or mitral stenosis  
Coarctation  
Cardiac rhabdomyoma or myxoma  
Rheumatic heart disease  
Prosthetic heart valve  
Bacterial endocarditis  
Libman-Sacks endocarditis  
Cardiomyopathy and myocarditis  
Arrhythmias

### Coagulation Disorders

Congenital coagulation defects  
Prothrombotic medications (oral contraceptives, L-asparaginase)  
Pregnancy/postpartum period  
Lupus anticoagulant  
Antithrombin III deficiency  
Anticardiolipin antibodies  
Lipoprotein abnormalities  
Factor V Leiden  
Protein S deficiency  
Protein C deficiency  
Liver dysfunction with coagulopathy  
Vitamin K deficiency  
Plasminogen deficiency  
Hyperhomocystinemia  
Hyperlipidemia

### Trauma

Amniotic fluid/placental embolism  
Child abuse  
Fat or air embolism  
Foreign body embolism  
Cardiac catheterization  
Carotid ligation (e.g., ECMO)  
Vertebral trauma due to cervical rotation  
Posttraumatic arterial dissection  
Brain herniation and arterial compression  
Intra-oral trauma  
Arteriography  
Carotid cavernous fistula

hemoglobin, which causes red blood cells to form a sickle shape. As the hemoglobin is deoxygenated, the stiff, inflexible sickle cells occlude small vessels and deprive the brain and other organs of oxygenated blood and result in infarction. Sickle cell anemia is the most common form of sickle cell disease in the United States, accounting for 60 to 70% of the cases, and the most likely to cause stroke is the HbSS genotype (14). This autosomal recessive disorder results from a mutation in the hemoglobin beta (HBB) gene. Other forms

of sickle cell disease result from co-inheritance of Hb S with other abnormal globin beta chain variants. These include sickle-hemoglobin C disease (Hb SC) and two types of sickle- $\beta$ -thalassemia (Hb  $S\beta^+$ -thalassemia and Hb  $S\beta^0$ -thalassemia). Other globin beta chain variants such as D-Punjab and O-Arab also result in sickle cell disease when co-inherited with Hb S. In a Jamaican cohort of 310 patients of all genotypes ranging in age from 9 to 17 years, the overall estimate of incidence of stroke was 7.8%, a very high number (15).

Ohene-Frempong and colleagues (16) initiated the Cooperative Study of Sickle Cell Disease, a prospective longitudinal study that enrolled more than 4,000 patients between 1978 and 1988. Among all of these genotypes, the investigators found that the HbSS patients had the highest prevalence rate for stroke (4.01%) and an incidence rate for stroke of 0.61 per 100 patient years, although they emphasized that stroke occurred in all common genotypes. It should be noted that these findings included both ischemic and hemorrhagic stroke. In this study, a history of transient ischemic attack was a strong risk factor for a completed infarctive stroke, indicating that an aggressive stance toward the prevention of stroke should be adopted if evidence of a transient ischemic attack is present. A low steady-state hemoglobin concentration, elevated systolic blood pressure, and recent episode of acute chest syndrome or crisis were also considered as risk factors for an ischemic stroke. Finally, it was noted that sickle cell patients who had a stroke had a high risk of recurrent stroke, a risk that can be attenuated, but not eliminated, by chronic transfusion therapy (17).

### MOYAMOYA DISEASE/SYNDROME

Another medical condition that predisposes one to stroke is Moyamoya disease. When Takeuchi and Shimizu first described Moyamoya disease in 1957, they used the technical term “hypoplasia of the bilateral internal carotid arteries” (18). In this report, they presented a case study of a 29-year-old man. Following the publication of this case study, many more reports followed, and in 1967, Suzuki and Takaku coined the phrase “Moyamoya disease” to describe the neuroradiological characteristics (19). Moyamoya, as the disease has been called since this time, is a Japanese expression meaning “something hazy, just like a puff of cigarette smoke drifting in the air” and refers to the cerebral angiogram of an individual with this rare disease.

Although the fine network of vessels at the base of the brain or the basal ganglia is the aspect of the disease that initially attracted the attention of neurosurgeons, the formation of these vessels is thought to be a secondary process of the disease induced by chronic ischemia (20). More specifically, the development of these Moyamoya disease vessels is seen as the brain’s reaction to occlusion (blockage of a vessel or artery) or stenosis (narrowing of vessel or artery) as it tries to compensate for the decrease in cerebral blood flow to the areas distal to the sites of occlusion or stenosis by making collateral vessels (21). This specific response of the brain is unique to Moyamoya disease and is not seen in other cerebrovascular diseases (22).

The main feature of Moyamoya disease is the progressive occlusion or stenosis of one or more of the main arteries of the circle of Willis; namely, the terminal portion of the internal carotid artery, the proximal portion of the anterior, or the middle cerebral arteries, the result of which is

chronic ischemia. Both stenosis or occlusion next to the Moyamoya vessels should be found bilaterally, according to the official diagnostic criteria (23). Of note to this review, the diagnostic criteria are based on the observable characteristics of the disease as measured by invasive and noninvasive devices. Alternatively, Moyamoya disease can be diagnosed by medical reports of associated diseases or the conditions of the patient at time of autopsy.

Moyamoya disease is rare, however, prevalence rates vary. In Asian countries such as Japan, China, and Korea, the incidence is higher than in European and American countries (24). For example, the estimated total number of Moyamoya disease patients in Japan in 1994 was 3,800, which represents an incidence of 1/1,000,000 each year (23). A questionnaire study provided an estimate of the incidence of Moyamoya disease across Europe as being one tenth of the Japanese incidence (25). A somewhat different picture is seen if one uses a pediatric stroke sample as the population of interest. A study of 59 pediatric stroke patients in France (10) found that four (7%) patients presented with Moyamoya symptomatology. The study also reported that the patients with Moyamoya disease had the highest risk of stroke recurrence (75%) relative to the other identified mechanisms causing stroke in childhood (10).

In a nationwide study of Moyamoya disease in Japan, four subtypes were identified: hemorrhagic (occurring in 33% of participants), infarctive (22%), transient ischemic attack (20%), and epileptic (12%) (26). The incidence of these subtypes varies depending on gender and age. The infarct subtype is more common among males as opposed to the hemorrhagic subtype, which is more common in females (26). Different studies show that hemorrhagic strokes are more common among adults than children (23, 27–29).

### HUMAN IMMUNODEFICIENCY VIRUS

As the number of persons with human immunodeficiency virus (HIV) continues to grow, so the number of HIV-infected children grows. Approximately 20% of HIV-infected infants will develop acquired immunodeficiency syndrome (AIDS) in the first year of life, and approximately 90% will develop AIDS by 18 months of age. This progression to AIDS is important for pediatric stroke, as an estimated 1.3% of these children will go on to experience stroke (30), a combination of ischemic and hemorrhagic strokes. For example, in the case of a young lady with known AIDS who presented with new-onset seizures and a right hemiparesis, a combination of subacute hemorrhage and a complete occlusion of the left middle cerebral artery was diagnosed (31). These authors speculated that the cause of stroke in this case was a vasculopathy caused by the human immunodeficiency virus, an etiology similar to postvaricella vasculopathy (32). Interestingly, this patient returned after her hemiparetic symptoms worsened, at

which time a new left frontal ischemic infarction was noted, with occlusion of both anterior cerebral arteries. The angiographic characteristics of this vasculopathy were described as “Moyamoya disease-like.” Other authors stress that stroke and seizures can represent the presenting symptoms of pediatric HIV infection or AIDS, describing two such cases (33) and emphasizing that testing for HIV should be included in the investigation of stroke in a child who is at risk for HIV infection. A follow-up letter to this article proposed a cause for the vasculopathy and ischemic stroke, that being an “HIV-1-associated vasculitis-vasculopathy-hypoxia/ischemia sequence” (34). The supposition of these authors that cytotoxic T lymphocytes are responsible for the cascade of events culminating in ischemic stroke led to suggestions for therapeutic approaches in children with HIV infection, including those related to the HIV infection (e.g., antiretroviral medications, prophylactic immunomodulators) and to the cerebrovascular system (e.g., vasodilators, calcium-channel blockers).

## PROTHROMBOTIC DISORDERS

Many genetic syndromes not only predispose a child to stroke (e.g., hyperhomocysteinemia (35) but exert their own influence on the neuropsychological, behavioral, or psychiatric profile (e.g., Down syndrome (36)). Arterial ischemic strokes and sinovenous thrombosis can both be caused by thrombotic vascular occlusion. While vascular occlusive strokes in adults are typically the result of atherosclerosis, in children, they are often the result of another disease or risk factor, including prothrombotic disorders. Prothrombotic disorders are thought to be present in anywhere from 20 to 50% of childhood arterial ischemic strokes and from 33 to 99% in childhood sinovenous thrombosis. The fact that these disorders can be both a cause for the initial stroke but can also be a cause for recurrent strokes highlights the need for a thorough workup and evaluation when a child strokes. Relatively common prothrombotic disorders include deficiencies of antithrombin, protein C, protein S, plasminogen, the presence of Factor V Leiden, Prothrombin gene G20210A, dysfibrinogenemia, antiphospholipid antibodies, hyperhomocysteinemia, and elevated lipoprotein (37). Of note in this review is the approach provided by Chan and deVeber to suggested laboratory tests when faced with a child suspected of having or having a stroke (37).

## DIFFERENTIAL DIAGNOSIS

When a child presents with a hemiparesis or seizure, there are, of course, many diagnostic options, one of which is stroke. Other causes for a hemiparesis could include the pressure exerted on brain structures by a brain tumor or an arteriovenous malformation, acute disseminated

encephalomyelitis, or a progressive epileptic condition, such as Rasmussen’s encephalitis, of which a progressive hemiparesis is a symptom. Todd’s paralysis (a transient hemiparesis that can follow a seizure) should also be considered. Finally, a migraine may present with a hemiplegia, in addition to other symptoms (38).

The diagnosis of stroke is best confirmed by neuroimaging. Cranial ultrasound, which has unquestionable value in the diagnosis of periventricular and intraventricular hemorrhage in premature infants, has been shown to be too insensitive for the diagnosis of ischemic stroke in term newborns (39). Advances in other areas of neuroimaging, including magnetic resonance imaging (MRI) techniques such as diffusion weighted imaging and perfusion MRI, as well as magnetic resonance angiography, have enhanced the ability to identify and characterize ischemic strokes in children (2). Conventional angiography continues to be the gold standard for children with stroke; however, as magnetic resonance angiography images flow signal rather than vascular anatomy and has been shown to miss abnormalities that would be identified with conventional angiography (40).

When considering the consequences of stroke, there are many factors other than stroke to consider. For example, those children who develop a seizure disorder secondary to their stroke will most likely be prescribed an anticonvulsant medication(s), which are well known to have effects on cognitive functioning (41–44). Migraine headaches can precede stroke or result from a stroke, and, if severe, can have a debilitating effect on many aspects of functioning (45). The functioning of a child and family can also be significantly disrupted by the medical sequelae of a stroke (e.g., investigations for stroke etiology, such as phlebotomies, CT, or MRI scans), or the concern about stroke recurrence. Finally, it is not uncommon for children who are not walking or talking as other children do to be ostracized in their schools and neighborhoods secondary to the visible aftereffects of stroke. Keeping these additional factors in mind, the neurological, neuropsychological, behavioral, and psychiatric sequelae of stroke are considered.

## NEUROLOGICAL SEQUALAE

In the adult population, 85% of patients with sinovenous thrombosis have been reported to have a good longterm (mean 6.5 years) outcome, based on the absence of neurologic signs and symptoms (46). However, in a study of 57 adults with sinovenous thrombosis, significant cognitive morbidity was reported at a mean 1.5-year follow-up (47).

Some information has been reported regarding the neurological outcome of sinovenous thrombosis in infants and children. In a literature review, neurologic sequelae were present in 27% of 124 survivors of childhood sinovenous thrombosis untreated with anticoagulant therapy (49). A prospective study utilizing a standardized neurological

assessment found that 18% of 38 infants and children surviving sinovenous thrombosis had poor outcome, based on the presence of moderate or severe neurologic deficits (49). In the Canadian Registry, the neurologic outcomes in 61 neonates and 91 nonneonates at a mean interval from thrombosis of 1.6 years were as follows: 54% were normal, 38% had neurologic deficits, and 8% had died. The neurologic deficits (based on neurological examination only) included motor impairment in 80% of cases, cognitive impairment in 10%, developmental delay in 9%, speech impairment in 6%, visual impairment in 6%, and other impairments in 26% (8).

In children with ischemic arterial stroke, an altered level of consciousness, or seizures, and a completed or cortical completed middle cerebral artery stroke were significant risk factors for poor outcome, measured by both the presence of recurrent stroke and neurological impairment (50).

### **COGNITIVE/INTELLECTUAL/ NEUROPSYCHOLOGICAL SEQUALAE**

---

Most investigations of intellectual outcome after childhood stroke focus on the effect of unilateral lesions. Coupled with this emphasis on unilateral lesions has been a focus on the perceived plasticity of the immature central nervous system, more specifically, a search for the age at which the traditional functional specialization of the left hemisphere for speech and language and the right hemisphere for visuospatial functioning emerges (51–54). Part and parcel of this approach has been the investigation of whether either hemisphere of the immature brain can take over for any cognitive functions if the lesion occurs early enough. For example, evidence has been presented suggesting that prenatally and perinatally acquired lesions in the left periventricular white matter shift the organization of speech to the right hemisphere, documented as right-hemisphere fMRI activation with left facial motor tract involvement (55).

Intellectual outcome after unilateral lesions that have taken place in infancy and childhood is typically reported as being within the average range, but below that of normal population means, and that of matched controls (54, 56–59). Hogan and colleagues (59) as well as Bates and colleagues (57) have summarized this body of research, examining the impact that a number of factors may have on poststroke outcome. For example, given the evidence to date, there does not appear to be a consistent significant effect for side of lesion, a result that is consistent across a number of studies (57, 60, 61). A lack of consistent results has also been found for variables including etiology of stroke and associated neurological disorders, in particular, seizures; lesion variables including extent of lesion, hemispheric lateralization of lesion, and location of lesion within the hemisphere; and variables related to the child, such as sex, age at onset, time since onset, and age at test; and socioeconomic status.

Children with focal stroke often appear to demonstrate a remarkable recovery from the insult (62). However, detailed studies of children with severe brain injuries do identify deficiencies in the area of discourse (connected language) (63–66). Chapman et al. found that the children with stroke performed more poorly than orthopedic controls when examined for language-structure (e.g., the length of utterance) as well as information-structure (the content and organization of the episodic structure, including being able to relay the core propositions, the gist propositions, and a macrolevel interpretation). This pattern of recovery in children, that is, the recovery of lexical and grammatical ability in the context of weakness in discourse macrolevel skills, is opposite to the pattern that typically found in adult stroke patients (67). These investigators also noted that there was a poorer outcome for discourse in those who had a stroke at an early age (up to 12 months of age) compared to those who had a stroke at 12 months of age or later. Moreover, the site- and size-of-lesion effects found in adult stroke populations were not observed. The implications of these findings for how these children will perform in an academic environment are clearly concerning and should be the focus of continuing investigation.

### **BEHAVIORAL SEQUALAE**

---

As is the case with research into the cognitive or intellectual outcome of pediatric stroke, most of the research into the behavioral sequelae of pediatric stroke has focused on the discrepancy between lesions of the left or the right hemispheres. More specifically, left-sided lesions in adults tend to result in disturbances of language, calculations, and praxis, while right-sided lesions tend to result in the alteration of functions that are reliant on directed attention and visuospatial skills, modulation of affect, and the paralinguistic aspects of communication (68). Previous research into the “right hemisphere deficit syndrome” in children (68–72) generally supported these findings and suggested the presence of a fairly specific pattern of social and personality deficits, with difficulties being noted in social interaction/social withdrawal, attention, and arithmetic. The latter difficulty has also been described as a “nonverbal learning disability” (73).

In keeping with this line of research, children with early focal right-hemisphere lesions have been documented to have greater difficulties recognizing and identifying facial affect than both normal controls and children with early focal left-hemisphere lesions (74). Precursors of this social difficulty may also be seen in investigations of early temperament by Nass and Koch, who described babies with right-hemisphere lesions as consistently showing more negative temperament and mood than babies with left-hemisphere lesions (75).

While the number of investigations into the behavioral sequelae of strokes in infancy and childhood does not rival

that of investigations into the intellectual outcome, some have been reported. Trauner and colleagues (76) found that children with early focal lesions differed from control children in the areas of general adjustment (i.e., cognitive and academic development), social skills, and social adjustment. These children were subdivided into those with left- and right-hemisphere lesions, with the resulting discrepancies failing to reach significance. The overall conclusion of these authors was that any early onset and focal brain lesion predisposes one to social and cognitive deficits. A subsequent study, reporting on the behavioral profile of children with prenatal or perinatal onset unilateral brain damage, found little difference between these children and controls (77). In fact, when the effect of IQ was removed from the analysis, there was no difference between the groups on any of the scales or subscales of the questionnaire used (78). These authors were careful, however, to avoid stating that such lesions do not have an impact on the behavioral profile of a child. They noted that their group of children with unilateral brain damage was mixed, with some lesions being left hemisphere, some right hemisphere, some frontal and some nonfrontal, and so on, and that the behavioral profiles of these subgroups may have “balanced out” across the other groups. They also stated that patients with bilateral or more extensive damage than that of the children in their study may be at a greater risk for behavioral dysfunction than their subjects were.

## PSYCHIATRIC SEQUALAE

Changes in the psychiatric functioning of adults who have suffered a stroke have been widely reported, including personality changes, impaired social behaviors, decision-making deficiencies, and other executive functions following damage to the frontal lobes (79–81). The impact of side of lesion has also figured prominently in this literature, with left-hemisphere lesions commonly being associated with depression (82–85). Right-hemisphere lesions have been associated with difficulties comprehending or expressing emotion (79, 86, 87), as well as mania or hypomania (86, 88, 89). More recently, depression has been associated with stroke severity (i.e., a major hemispherical stroke syndrome, reflecting the severity of the neurological impairment), infarcts affecting the limbic system of the brain, presence of dementia, and female gender (90). Other investigators have also found that greater degrees of physical disability are related to depression and poor emotional outcome (91).

Adults who have suffered a stroke have been reported to have difficulty controlling their emotional responses, in some cases resulting in significant problems controlling anger and aggression (92, 93). Kim and colleagues have looked at the inability to control anger and aggression in adult stroke, comparing the ratings of close relatives or caretakers of adults poststroke to their estimates of the ability to control anger and aggression prior to the stroke

(92). They reported that 32% of those sampled were unable to control their anger or aggression, with some of these behaviors being spontaneous and some being environmentally triggered.

Poststroke changes in aggression and anger control, while observed clinically in pediatric populations, have not been formally reported in the pediatric stroke literature. We completed a pilot study, asking the parents of children with stroke to complete the aggression subscale of the Behavior Assessment System for Children Parent Rating Scales (BASC) (94) as well as a 5-point Likert scale to indicate whether there was a poststroke difference in their child’s level of aggression or expression of anger, and whether this behavior interfered with family functioning (95). Of 26 completed questionnaires, 6 (23%) yielded a T-score equal to or greater than one standard deviation above the mean on the BASC aggression subscale, with two ratings exceeding a T-score of 65 (i.e., within the defined clinical range). More than one quarter of respondents reported that their child’s current level of aggression or expression of anger disrupted the functioning of their family. These early data suggest that aggression and expression of anger is of clinical concern in a subset of children with stroke, to the point that families have stopped or changed their involvement in various activities as a result of concern about their child’s ability to control his or her emotions.

In some case studies, lesions in specific areas have resulted in tic-like behaviors (96). Two boys who suffered subcortical strokes involving the right basal ganglia at the age of 8 years were described. In the case of one boy, the right caudate and putamen were affected, while in the other case, the head of the right caudate nucleus was lesioned. In both cases, the boys developed a left hemidystonia 2 weeks after the stroke, with the later emergence of tic-like behavior. Difficulties in the realm of focusing and attending were also noted.

A number of investigations have focused specifically on the psychiatric sequelae following a stroke in childhood. Max and colleagues have explored the prevalence of psychiatric morbidity in children with stroke relative to orthopedic controls (i.e., the subjects with stroke were matched individually to subjects with clubfoot or scoliosis). This group has also explored groups of children with stroke and similar controls for the presence of a psychiatric disorder that was not present prior to the child experiencing the stroke. When they considered general categories of psychiatric disorder, they found that 46% of their sample had poststroke ADHD, 31% had a poststroke anxiety disorder, 21% had a poststroke mood disorder, and 17% had a poststroke personality change (97). Strongly correlated with the development of a poststroke psychiatric disorder was an abnormal neurological exam (assessment of neurological severity was rated by seizure history, head circumference, degree of hemiplegia, and function of the unaffected side of the body), lower full-scale IQ (FSIQ) and verbal IQ (VIQ), socialization deficits (noted on the Socialization Domain

of the Vineland Adaptive Behavior Scales), and increased family psychopathology (in first-degree relatives).

The children with attention deficit hyperactivity disorder (ADHD) were followed up in an accompanying study, designed to determine whether a commonality in lesion characteristics was present (98). Of 25 children with focal stroke lesions, 15 were noted to have ADHD or ADHD traits (that is, cases with symptoms that fell at a subsyndromal level or cases in which there was disagreement between raters). Lesion volume was not associated with the presence of ADHD traits. When the MRI scans of the 13 children with the largest lesions (greater than 10<sup>3</sup> cm were examined, it was found that ADHD traits were present in six of seven patients with lesions of the putamen compared to two of six patients with lesions that did not involve the putamen (Fisher exact test  $p = .1$ ). These authors stress that the putamen is a part of dopamine-rich ventral or limbic striatum, and that this area of the brain has been related to ADHD in previous studies (99, 100), especially ADHD dominated by symptoms of inattention.

Max and colleagues have also reported that lifetime ADHD traits were significantly more common in children with stroke and no prior ADHD symptomatology than in orthopedic controls (46 versus 17%) (101). Inattention and apathy were identified as “core features” of the presence of ADHD traits in children with stroke, secondary to their performance across several neurocognitive measures.

## REMEDIATION

As is apparent from the preceding review of the various types of outcome of stroke in infancy or childhood, it is clear that early views of the plasticity of the immature brain (i.e., that the earlier the insult to the brain, the more complete recovery) were overly optimistic (102–104). Indeed, it is clear that there are considerable and lasting changes and areas of deficit that these children and their families, as well as those working with them, will have to keep in mind. Effort must be directed toward the development of remediation and rehabilitation techniques to help these children if improvement in their functioning is to be seen. A major part of this effort to help these children is being able to provide an accurate assessment of their strengths and weaknesses in order (1) to document that they are in need of assistance and (2) to better guide and direct that assistance. We have found that providing them with a neuropsychological assessment is often ideal in determining the best way to approach helping these children.

The purpose of a neuropsychological assessment is to promote the development of independence, competence, and well-being for the child being assessed. In addition to careful consideration of the developmental and physical context that the child is in, it is important to assess a sufficient number of domains of functioning to be able to provide specific recommendations for the child and those

working with him or her. More specifically, determining the IQ of a child will not translate into specific recommendations for the development of language or visual-spatial functioning, for example. A typical neuropsychological assessment, therefore, includes the assessment of general cognitive/intellectual functioning, verbal or language functioning, visual-spatial functioning, attention/concentration, memory, sensory-perceptual, motor, academic achievement, executive functioning, and socioemotional functioning (see the following for cogent reviews of neuropsychological assessment (105–107)). Translating the assessment results into a form that is real to those involved, and that includes practical implications and treatment recommendations, is extremely important. For example, a 3-year-old with frontal infarcts would not be expected to differ much from another child that is 3 years old, as the functioning of the frontal lobes begins to become more important for the overall functioning of a child later in life, say when she or he is entering school. Therefore, from a practical perspective, the neuropsychologist may be able to point out subtle areas of current deficit and translate them as indicators of the difficulties yet to come (i.e., how attentional and organizational issues will play a greater role as the child ages) and provide recommendations about how to best work with the child to encourage the development of these skills and abilities.

Numerous resources are available for parents and those working with children with stroke that address specific areas of functioning, such as difficulties with academic subjects (e.g., reading or math) and difficulties with the development of executive functioning or social skills. For example, Stephen Nowicki and Marshall Duke have written an excellent series of books designed to promote the development of social skills (108–110).

## CONCLUSION

It is important to realize that the pediatric stroke field is in its infancy, with the vast majority of the stroke literature coming from the adult/geriatric end of the age spectrum. However, definitive steps have been taken to move the field forward, including the aforementioned special issues (*Journal of Child Neurology*, *Seminars in Pediatric Neurology*), a text devoted to the field (111), conferences dedicated to pediatric stroke, such as the First International Conference on Cerebrovascular Disease in Children in 1998, and several multisite research initiatives, such as the Canadian Pediatric Ischemic Stroke Registry and a project directed toward the establishment of standards of practice and the initiation of further multicenter, multinational clinical trials for neonates and children with stroke, sponsored by the Child Neurology Society/Child Neurology Foundation.

It is also important to note that some steps have been taken in assessing outcome in some areas of functioning in children with stroke. For example, investigators are now

exploring specific aspects of language functioning and finding areas of weakness, rather than relying on global measures of verbal functioning and concluding that performance based on this global measure was age appropriate. Early studies of behavioral or psychiatric outcome also often focused on generalities and found few or no differences between children with stroke and controls. More recent studies, such as those of Max and colleagues (97, 98, 101) have focused on specific areas of functioning (e.g., ADHD, anxiety disorders) and on more specific methods of assessment, again with the result of identifying areas of need that were previously masked by (imprecise) measures of global functioning. Continued developments along these lines will more clearly demarcate areas of need in children with stroke, which will, in turn, allow for the fine-tuning of efforts toward the development of specific methods of rehabilitation/remediation.

Over the coming years, it will be the goal of those working in the field of pediatric stroke to continue to inform the medical and lay world of the magnitude of childhood stroke and to emphasize the importance of early and accurate diagnosis, as well as early and effective intervention to improve the outcome for these children.

Aspects of Blindness

and Severe Visual Impairment,

and Deafness and Severe

Hearing Loss in Children

*Bryan H. King, MD*

*Peter C. Hauser, PhD*

*Peter K. Isquith, PhD*

#### **DEFINITION OF BLINDNESS/SEVERE VISUAL IMPAIRMENT**

The population of children with blindness or severe visual impairment is a heterogeneous one. Visual impairment is measured on a continuum, and there is therefore no universally accepted criterion for defining "blindness." Consequently, in many parts of the world, definitions fall to those applied for legal purposes. In the United States, the first of these definitions was that of "economic blindness" (Schloss 1963; Jan, Freeman and Scott 1977). This definition has since been adopted by most of the Western cultures and defines blindness as the visual acuity in the best eye with correction of less than 20/200 or a defect in the visual field so that the widest visual diameter is less than 20 degrees. This legal definition of blindness was not developed for children but rather for determining the disability status of adults and thus there are distinct disadvantages in the assessment of youngsters. Moreover, until the age of 3 or 4 years, a child may satisfy criteria for legal blindness but nonetheless be quite able to function in

society. Indeed even among children whose visual acuity satisfies criteria for legal blindness there remains extreme heterogeneity; congenitally blind children may be grouped together with those who retain some perception of light as well as children with some intact vision (Jan et al. 1977). Currently, the International Classification of Diseases (World Health Organization 1992) designates six categories to describe significant visual impairment with category 1 corresponding to the best possible corrected visual acuity being between 20/70 and 20/200; category 2 is between 20/200 and 20/400; category 3 is between 20/400 and 20/1200, which corresponds to finger counting at 1 meter; category 4, is between finger counting at 1 meter and mere light perception, and category 5, is "no light perception." A sixth category is reserved for "unspecified or undetermined degrees of visual impairment". Persons in categories 1 and 2 are also referred to as having "low-vision" and those in categories 3, 4, and 5 are referred to as having "blindness." Regarding visual field defects, if the field is no greater than 10 degrees but greater than 5 degrees around central fixation, individuals are

placed in category 3. Persons with a field no greater than 5 degrees around central fixation are placed in category 4 even if their acuity is not impaired.

### Incidence and Prevalence of Blindness in Children and Adolescents

In their landmark studies, Jan and colleagues (Jan, et al. 1977) surveyed the entire population of children born in British Columbia in the cohort 1944 through 1973 utilizing a questionnaire to record the etiology, sight, and type of lesion and associated handicaps. The legal definition of blindness was used and cortical blindness was excluded because of the commonly associated profound mental retardation in that context and the attendant difficulty in assessing visual function in those individuals. Four hundred fifty-four children were included in the study, the majority of whom, 382, had a congenital etiology for their blindness while the remaining 72 acquired their visual impairment in childhood. Of the total, one third were characterized as having no sight or light perception only and the remainder had some useful vision with the percentages being similar when the subgroups with congenital versus acquired blindness were compared. While the male–female ratio was essentially 1:1 in children with the congenital etiologies for their blindness, there was a relative preponderance of males among those with acquired visual impairment (60%). Among the children with visual impairment, the children with congenital etiologies were typically referred at less than 1 year of age and for those referred in the second year of age, the vast majority had suspected visual impairment at less than 1 year. Overall, looking at the annual incidence of congenital blindness in British Columbia during the 30-year study period, the investigators noted a figure of between one and eight per 10,000 population. The incidence rates increased during the late 1940s and early 1950s secondary to retrolental fibroplasia, prior to its identification as a side effect of exposure to high oxygen saturation in premature infants. The authors further observed that while the incidence generally stabilized over the latter part of their study to about two per 10,000 live births, the prevalence of blindness was clearly increasing, perhaps secondary to advances in pediatric care enabling more children with blindness to survive. More recent epidemiological studies have been reported from other groups of investigators.

Frick and Foster (2003) applied epidemiologic modeling to World Health Organization estimates for blindness and projected that there will be 2 million blind children (0 to 14-year olds) in 2010 and 2020. Causes of blindness in childhood, as for any disability, may be divided into genetic factors and those that operate in the neonatal, perinatal, or early childhood period. Molecular genetic aspects of blindness are reviewed in Black and Craig (1994); an example of a prenatal cause of blindness is an intrauterine in-

fection like rubella. Retinopathy of prematurity would represent an early acquired cause, and vitamin A deficiency would contribute to blindness later in childhood. The differences in prevalence of blindness in children, which range from 0.3 per thousand population in developed countries, to 0.9 to 1.1 in developing countries, is largely accounted for by an increase in acquired (and preventable) causes of blindness including xerophthalmia, or vitamin A deficiency, in the context of protein malnutrition or malabsorption due to diarrhea. Together with xerophthalmia, trachoma, a chronic infection of the conjunctiva and cornea, and onchocerciasis, an infection due to a roundworm transmitted by black fly bites, are recognized as the main causes of blindness in developing countries (Vader 1992). Measles is the single leading cause of blindness among children in low-income countries and accounts for up to 60,000 cases per year (Semba and Bloem 2004). Frick and Foster (2003) estimate that the projected number of blind children in the world could be cut in half with implementation of the VISION 2020 initiative of the World Health Organization and the International Agency for the Prevention of Blindness, which specifically targets cataract, trachoma, onchocerciasis, vitamin A deficiency, and refractive errors. The application of traditional eye remedies with resultant corneal scarring and neonatal bacterial infections are also significant contributors to blindness in Africa and many parts of Asia (WHO 1992; Gilbert et al. 1995; Alemayehu et al. 1995).

### Development of the Primate Visual System

The visual system in the primate is composed of the retina, optic nerves, optic chiasm, optic tracts, lateral geniculate nuclei, geniculostriate radiations, striate cortex (area 17), visual association cortex, and related interhemispheric connections (areas 18 to 21). All together, over one million axons comprise the optic nerve, an order of magnitude greater than comparable afferent neurons in the aural system (Glaser and Sadun 1990).

The first evidence of eye development in humans occurs at approximately the third week of gestation when the primordial optic bulbs extend from the prosencephalon. The “torus opticus” is the primitive optic chiasm and appears as a thickening between optic bulbs. Cup-shaped evaginations induce lens growth on contact with overlying surface ectoderm. By approximately 5 weeks, retinal development has begun, and cells in the retinal ganglion differentiate to send optic nerve fibers through the optic stalk into the chiasm, which is reached 2 weeks later. By seven weeks, a full complement of axons is contained in the optic nerve, and the optic disc and scleral openings are well defined (Glaser and Sadun 1990).

Neural connections in the visual system begin diffusely as the axons from the retinal ganglion cells terminate in the lateral geniculate nucleus (LGN) and form synapses throughout this structure. Through selective retraction and

more directed growth, refinement of the network is achieved so that within the lateral geniculate nucleus, the retinotopic organization of the optic tract is maintained in vertical columns of cells called "projection lines," which have been described in all mammals studied to date. This refinement of connections is dependent upon signaling emanating from retinal ganglion cells, and recent studies reveal that synchronous bursts of action potentials from these cells can be detected long before photoreceptors have matured (Meister et al. 1991; Masland 1977; Galli and Maffei 1988).

Six distinct cellular laminae can be identified within the LGN. Ventrally, layers one and two receive contralateral and ipsilateral retinal projections, respectively, and are termed "magnocellular" because of their relatively larger neuron size. The remaining layers are termed "parvocellular." Functional studies of retinal ganglion cells which project to the magnocellular or parvocellular LGN ("M" or "P" pathways, respectively) reveal that the former are cells that detect motion, direction, speed, coarse stereopsis (depth perception), and pursuit (Tychsen 1994). The latter cells respond to color, shape, fine acuity, and fine stereopsis. Thus M-retinal ganglion cells transmit the "where" of visual stimuli, and P ganglion cells transmit the "what" (Tychsen 1994). From the LGN, magnocellular laminae project to area 4B of the striate cortex and then primarily to parietooccipital association cortex. Parvocellular laminae project to area 4A of the striate cortex, and then primarily to temporooccipital association cortex. These distinct occipitoparietal and occipitotemporal visual pathways are also described as the dorsal and ventral stream, respectively.

The maturation of M and P projections to the striate and extrastriate cortices occurs significantly after birth and this maturation is dependent upon visual stimulation. In their landmark studies, Hubel and Wiesel (Wiesel and Hubel 1963, 1965) demonstrated that periods of critical sensitivity exist in the developing visual system during which the deprivation of adequate stimulation will prevent the progression toward normal adult characteristics. In their early work, kittens and adult cats were subjected to unilateral eye closure for varying durations. Susceptibility to the effects of eye closure, as determined by the number of cells in the striate cortex responding to visual stimulation from the previously closed eye, peaked over a period of 2 weeks. Eye closure for as little as 6 days during this interval effectively reduced the proportion of cells the eye could influence by over 90%. In the adult, eye closure for over 1 year produced no detectable effects (Hubel and Wiesel 1970). The finding of sensitive periods of development has been extended to the barn owl (Knudsen and Knudsen 1990), mouse (Gordon and Stryker 1996), rat (Stafford 1984), and nonhuman primates (Sloper 1993). In humans, stimulation in advance of a critical period does not hasten or enhance vision. In their comparative study of preterm infants and those delivered at term, van Hof-van Duin and colleagues (1992)

found that visual experience before the expected term date had no measurable effect upon the development of visual acuity or in terms of accelerating the development of peripheral vision.

It has also become clear that multiple, partially overlapping sensitive periods exist for various functions of the primate visual system (Harwerth et al. 1986). The critical period for the rod system to respond to different light wavelengths differs from that for cone information processing, and different sensitive periods also exist for both spatial vision and for binocular vision (Harwerth et al.).

When sensory input from a given modality is disrupted during a critical period, significant changes in the distribution of the cortical map may occur. Rauschecker and colleagues (1993, 1994) have shown that auditory spatial discrimination is enhanced in cats deprived of visual stimulation associated with an enlargement of the cortical representation for auditory processing. Similar findings have been revealed in neuroimaging and electrophysiological studies in humans which demonstrate recruitment of occipital cortex for tactile manipulation and even tactile imagery, for example, imagining the "feel" of textures on the fingertips in early blind subjects, or even simply performing a Braille reading task (Theoret et al. 2004). Occipital recruitment has also been demonstrated for auditory tasks in subjects with congenital blindness.

Recently, Theoret and colleagues (2004) reviewed evidence to support the occurrence of neurophysiological changes that occur with blindness. Studies demonstrating better sound localization abilities for blind subjects in comparison to sighted controls not only demonstrate that vision is not critical to placing the origin of sounds in three-dimensional space, but also support the longstanding notion that compensatory enhancement of audition occurs in blindness. Moreover, the same compensatory advantage is evident in studies of tactile discrimination in blind and control subjects, and within the blind population, sensory thresholds are lower for the Braille-reading finger than for other fingers in a gratings orientation task (the ability to detect the direction of grooves cut into a metal surface).

Kauffman and colleagues (2002) conducted an elegant study in which sighted subjects were compared to blindfolded subjects with respect to the speed with which they learned to recognize Braille characters. Interestingly, blindfolding conferred a significant advantage (as measured by error rate of character recognition), after just 5 days. Thus, some plastic changes in the brain in response to sensory deprivation appear to occur quickly, and not to be exclusively confined to specific critical developmental windows. On the other hand, Sadato and colleagues (2002), have observed differences in activation of primary visual cortex with a tactile discrimination task in blind subjects as a function of the timing of their loss of sight (before or after 16 years of age). Consequently, they

conclude that the first 16 years of life may be a critical period for cross-modal plasticity in primary visual cortex (e.g., from processing visual stimuli to processing tactile stimuli).

In human infants, the development of M-pathway visual functions precedes that for those mediated by the P-pathway. The former can be detected by motion-evoked visual evoked potential studies, as well as by examining optokinetic nystagmus pursuit and vergence eye movements and large disparity stereoscopic vision, all of which are evident at 3 to 5 months of age (Tychsen 1991). P-neurons in the lateral geniculate nucleus do not achieve adult-like dendritic morphology until 8 or 9 months (de Courten et al. 1982). The refinement of spatial contrast and color sensitivity which occur after 1 year of age are attributed to the ongoing development of P-neuron-mediated vision. Milestones in the development of vision are summarized in Table 20.1, where it can be seen that interrelationships between vision, motor development, and praxis become particularly apparent in later childhood.

The clinical principle that derives from the observations above is that early intervention is essential to the ultimate correction of visual disturbance. Surgery for congenital cataracts is now performed within days of diagnosis with optical correction and occlusion therapies instituted shortly thereafter, and outcomes from this aggressive approach have been characterized as “astounding” (Tyschen 1994). Studies with regard to the timing of intervention for strabismus or esotropia are also clear in suggesting that intervention after two years of age is significantly less successful in restoring binocularity in comparison to early treatment (6 to 18 months) (Sarniguet-Badoche 1984; Rethy and Rethy-Gal 1984; Ing 1984). Based upon these studies, one might also conclude that a role exists for early and frequent exposure to visual stimuli among children with severe visual impairment. Brodsky, Baker, and Hamed (1996) observe that visual stimulation as a therapeutic modality is somewhat controversial in terms of its usefulness owing to the largely anecdotal nature of reported outcomes. Such “visual stimulation therapy” follows from the premise that vision is in some respects a learned skill, and, either by recruiting neurons, increasing synaptic density or by some other means, such stimulation may help a child to maximize his or her rudimentary sight (Sonksen et al. 1991). Preliminary but certainly compelling results of tachistoscopic visual stimulation (presenting flashes of light repetitively for 1 to 2 hours daily for 6 months) in three adult patients with partial cortical blindness were reported by Pleger and colleagues (2003). Color and pattern recognition improved significantly and in a clinically meaningful way in two of the subjects, all of whom had sustained their occipital injuries fully two years prior to this therapeutic intervention; an interval that argues strongly against mere spontaneous recovery.

### Circadian Rhythms

A number of studies have examined the effect of blindness on circadian rhythms, but few have involved children. Many groups have demonstrated that circadian rhythms including temperature, cortisol, melatonin, and sleep are free-running in blind individuals (Sack et al. 1992, Miles and Wilson 1977, Nakagawa et al. 1992). Since the free-running diurnal cycle approximates 25 hours, persons with sleep-wake cycle disorders will have periods in which they awaken during the night and sleep during daytime hours. Okawa and colleagues (1987) studied four congenitally blind children and observed free-running sleep-wake cycles in three and an irregular sleep-wake rhythm in the fourth child. Despite attempts to entrain the sleep-wake cycles in these patients to a 24-hour rhythm by the use of forced awakening, playing musical instruments, and tactile stimulation, only two of the children could maintain such a rhythm. The authors concluded that concurrent severe mental retardation in these children diluted the effectiveness of environmental manipulation to serve as a synchronizer. Nevertheless, exposure to bright light may have an effect on neuroendocrine function and mood even in the context of blindness. Czeisler and colleagues (1995) measured melatonin suppression by bright light in 11 blind patients without light perception in comparison to sighted controls. All of the subjects were blind in both eyes due to retinal pathology, congenital glaucoma, or acquired eye injury. In three of the 11 blind subjects, melatonin secretion was reduced by nearly 70% following light exposure just as for control subjects. Since these subjects were also unique in that they did not report periodic insomnia, the authors concluded that the visual subsystem by which melatonin secretion is suppressed may be functionally intact in some blind subjects despite the absence of conscious light perception. Effects of light exposure in blind subjects were also documented by Partonen and associates (1995), who observed that subjective sleepiness was reduced, and mood improved, in both controls and blind subjects after exposure to 3300 lux of bright light for 2 weeks. Differences did emerge, however, between sighted controls and blind subjects with respect to the body temperature response to light exposure.

There is a growing body of literature examining the effects of melatonin for sleep disturbance in persons with blindness. A recent double-masked, randomized trial of placebo, a physiological (0.14 mg) dose, and a pharmacological dose (2.2 mg) in a 7-year-old child with blindness associated with birth asphyxia and septo-optic dysplasia was noteworthy for significant improvement on the high dose of melatonin only (Cavallo et al. 2002).

### Behavioral and Developmental Consequences of Blindness

The etiology and the timing of blindness or severe visual impairment is of tremendous importance in terms of predicting its developmental consequences, but few studies

**TABLE 20.1**  
**MILESTONES IN DEVELOPMENT OF SIGHT**

Age	Visual Responses and Capabilities
30–34 wk gestation	Pupillary light reaction present, lid closure in response to bright light; vestibular eye rotations well developed.
0–1 mos	Attends to light and forms, limited fixation ability (visual acuity approx. 20/400), can discriminate color red from achromatic background; optokinetic nystagmus well developed, horizontal gaze. Beginning oculomotor coordination.
1–2 mos	Limited imitation of facial expression (tongue protrusion; open mouth). Can follow moving objects and light, attend to novelty and complex patterns, stare at faces.
2–3 mos	Beginning binocular coordination. Eyes can fixate, converge, and focus. Discriminate from among faces. Color discrimination includes blue, green, yellow, orange, red. Conjugate vertical gaze.
3–4 mos	Smoother eye movements and improved acuity. Can manipulate and examine objects. Blink response to visual threat.
4–5 mos	May shift focus from objects to body parts, attempt to reach for and approach objects. Explores the environment visually, tracks objects across entire field of vision. Development of binocularity (fusion and stereopsis). Accommodation well developed, differentiation of fovea completed.
5–6 mos	Can reach and grasp objects demonstrating eye-hand coordination.
6–7 mos	Visual attention can shift from object to object, can reach for and retrieve dropped objects. Eye movements become more fluid. Stereoaucuity at near adult level; iris stromal pigment well developed.
7–8 mos	Can manipulate objects and look at results. Can follow movements.
9–10 mos	Excellent visual acuity, smooth accommodation. Can hunt for hidden objects around corners and play looking games.
11–18 mos	Ongoing refinement of optical skills and sharpening of acuity. Can put objects together. Cornea 95% of adult diameter.
1½–2 yrs	Can match objects, point to objects in a book, imitate strokes and actions with writing instrument.
2–2½ yrs	Can inspect objects at distance, imitate movements of others, match colors and like forms. Visual memory span is increased. Objects can be ordered by color. Snellen letter acuity at adult level.
2½–3 yrs	Can match geometric forms, draw crude circles, insert objects in proper holes and assemble two puzzle pieces. Eyeball 95% of adult diameter.
3–4 yrs	Can match identically shaped objects by size. Demonstrates good depth perception. Discriminates line lengths, can copy an X, discriminate most basic forms.
4–5 yrs	Eye-hand coordination is further refined. Can color, cut and paste, draw a square, and perceive detail in objects and pictures.
5–6 yrs	Can perceive relationships in pictures, abstract figures and symbols. Can copy symbols and match letters and words.
6–7 yrs	Can identify and reproduce abstract symbols. Perceive the constancy of letter and word styles. Associate words with pictures and read words on sight.

have looked specifically at developmental issues in children with a homogeneous etiology for their visual impairment.

### Motor Development

In terms of its effect on behavior and early development, the absence of sight exerts profound influences on motor and adaptive function. In their early studies of preschool-

ers, Nesker and colleagues (Nesker Simmons, & Davidson 1985) were overwhelmed by the stark contrast of the motor activity of blind children in comparison to children with sight in a nursery setting. The nursery was described as extraordinarily quiet and sterile-looking, with everything remaining in its place even after the children had left. On balance, the blind children were characterized as less mobile, less verbal, and less socially aware than their 2- and

3-year-old sighted counterparts. Moreover, the investigators were also impressed with the degree of intervention required on the part of mothers or staff to encourage blind children to participate in activities other than stereotyped rocking, eye rubbing, or meaningless repetitive speech. These observations were interpreted to underscore the particularly important role that a blind child's care providers and the surrounding environment must play in facilitating developmental progress. Gross motor function appears to be uniformly delayed in blind children (Davidson 1983; Levtzion-Korach et al. 2000). The greatest delays are evident early, including precrawling, sitting, pulling to standing, and walking. Nearly all blind children reviewed by Davidson (1983) had substantial lags in the onset of walking that did not appear until a median age of 20 months. Levtzion-Korach and colleagues (2000) suggest that environmental enrichment may be helpful in hastening motor development, but caution that motor delays should be expected in children with blindness.

### Social Development and Adaptive Function

In part, stereotyped and other self-stimulatory or maladaptive behaviors may be more frequently observed in visually impaired children because of the differences observed in how they bond to caregivers and form social attachments. For example, blind infants smiled at a caregiver's face only inconsistently, even at the age of 12 months and reacted to separation between 11 and 20 months of age. This represents a delay of approximately 6 months compared to their sighted peers (Davidson 1983). Warren (1994) notes that development of attachment is dependent not only upon the visually impaired child's construct of parents as distinguished from other persons, but also the parents' responsiveness to a child having a disability. In combination with other factors, such as extended hospitalization as a result of prematurity, effects upon the existing family structure, or financial strains, parents may be faced with numerous unanticipated difficulties in bonding with their disabled child. Compounding these stresses is the emotional readjustment associated with the "imperfection" of their infant. Observation of mother-infant interactions indicates that blind children receive less positive and more negative vocalization and affect from their mothers than sighted controls (Rogers and Puchalski 1984; Warren 1994).

Generally, the social maturity scores of children with visual impairments are lower than their age-matched sighted peers (Warren 1994). In a study comparing the social skills of visually impaired adolescents to sighted peers through the use of role plays, interviews, and rating scales, Van Haselt, Hersen, and Kazdin (1985) found that, as a group, adolescents with visual impairment asked fewer open-ended questions, spoke for longer durations in social interactions, had greater speech disturbances, and experienced greater difficulty being assertive. Cole, Jenkins, and Shott

(1989) found that congenitally blind children were just as able to mask disappointment as their sighted peers. They had a greater tendency to make neutral comments or change the topic, and paid less attention to the quality of their facial expressions or awareness that others might "read" their expressions. Thus, some specific differences in social behavior are likely a product of the loss of visual information. Unfortunately, social development and adjustment have been inconsistently assessed in young blind children, despite evidence that problems presenting later are rooted during these formative years. Child and parent interviews, observations in naturalistic settings (home, school), and role play tests should all be considered for any visually impaired child who evidences deficits in social functioning.

### Language Development

Preisler (1993) examined the development of communication in a cohort of blind children in comparison to children with deafness. She found that the development of communication was delayed in the blind infants and concluded that visual stimulation in infancy probably plays a more critical role in comparison to auditory stimulation in terms of its promotion of mother-infant interactions (Preisler 1995). Preisler further observed that in the period of early infancy (up to age 18 months) blind children did not use gestures like pointing or showing, gestures that would facilitate for caregivers the ability to understand preference and interest. The absence of these eye, finger, or hand-pointing gestures in blind infants challenges the ability for parents to elaborate on the expressed interests of their children by referring to mutually discernible external events. Although blind children may "point" with their head or upper torso in response to sounds, such gestures may frequently be lost or not understood by parents, resulting in the recommendation for specific education of caregivers with the use of video (Preisler and Palmer 1989; Preisler 1990). McConachie and Moore (1994) found delays in early language development in children with severe visual impairments. The ages at which children with severe visual impairment or blindness spoke their first word was at 15 and 18 months, respectively, with the first ten words being spoken at approximately 20 months of age for both groups. The latter compares to a 10-word vocabulary emerging at 15 months in a control group of sighted children. These authors also noted that the content of blind children's initial vocabulary differs subtly in quality in comparison to sighted children. There is reported to be a relative increase in the use of verbs, particularly to those referring to the children's own actions as well as an increased use of specific names instead of generalized labels for classes of objects or functions. In his review of the development of language in blind children, Hodapp (1998) elaborates on this point illustrating that "doggie," for example, may refer only to the blind child's pet, and not to dogs in general. While these

observed differences in language could logically follow from the unique ways in which blind children must experience the world (Bigelow 1987), there may also be differences in cognitive abilities which may further influence the acquisition of language. Although it was once believed that blindness predisposed to the late acquisition of personal pronouns and other personal reference terms as well as frequent pronominal reversal, recent work has called this notion into question (Perez-Pereira 1999).

### Cognitive Development

While blind children may progress through Piagetian stages of development in the same sequence as do sighted children, their development appears to be relatively slowed in comparison to sighted children particularly insofar as tasks involving classification and conservation are concerned (Hodapp 1998). Between 3 and 15% of the blind population are believed to function at or below the range of mild mental retardation, and intellectual disability is particularly common among children with blindness secondary to retinitis of prematurity and deaf-blindness due to rubella (Davidson 1983).

In terms of measuring intellectual functioning however, there are many problems that come with attempting to adapt intelligence quotient (IQ) tests to the population with severe visual impairment. Because of the inability to use subtests that rely on performance, many IQ instruments are simply inappropriate for persons with severe visual impairment. Some investigators have long cautioned against the widespread use of the Wechsler verbal scales to assess visually impaired children (Ammerman et al. 1986; Bauman and Kropf 1979; Margach and Kern 1969), and more recently Warren (1994) notes that use of verbal IQ tests, while common, is inappropriate for testing the intelligence of visually impaired children. In doing so, examiners ignore the existence of certain aspects of intelligence that cannot be captured by purely verbal means. The Perkins-Binet, a modification of the original Stanford-Binet, has items specifically selected for their appropriateness with children with visual impairment. Two versions have been developed: Form N for blind children and Form U for the partially sighted (Ammerman et al. 1986). The need for different versions is highlighted by Hull and Mason (1995), who found that congenitally blind children who had no better than light perception consistently did better on verbal memory tasks than did children with acquired blindness. Finally, some investigators have advocated using a “functional-ecological” or “behavior-analytic” approach as opposed to using test measures that have been insufficiently normed on visually impaired populations, particularly in the assessment of educational and social skills (Downing and Perino 1992, Van Hasselt 1985).

Beelman and Brambring (1998) described a home-based early intervention program for ten children (average age of 12 months) with congenital blindness and their parents

that addressed blindness-specific issues like tactile and auditory object perception, and spatial orientation and mobility. Approaches were individualized based on assessment of the children’s developmental level. Parents were also offered problem-oriented counseling as well as guidance and training on parent–child interactions like remaining in calling distance, verbal accompaniment of activities performed with the child, intensive body contact with the child, and guiding hands from behind when carrying out exercises or playing games. The intervention team visited families every 2 weeks for an average of 2 years. Results were quite mixed. Children who were born prematurely did not seem to benefit, but others showed significant acceleration of development, particularly with respect to orientation and mobility and cognitive and socioemotional development.

### Neuroanatomy of Blindness and Behavior

It is possible to distinguish different behavioral presentations among children blind from damage to the retina, the anterior visual pathways, visual cortex, visual fields, and disorders of oculomotor control (Good and Hoyt 1989). Eye pressing is a behavior associated with retinal disease which is common in blindness (Williams 1969). Jan and colleagues (1983) examined a large cohort of blind children and found that eye pressing occurred exclusively in the context of retinal damage; specifically, Leber congenital amaurosis, retinitis of prematurity, retinal dysplasia, or retinal infections in utero. Children who engage in chronic eye pressing behavior may develop orbital fat atrophy or the orbits may in fact enlarge from the sustained pressure resulting in the appearance of sunken eyes. Jan and colleagues (1983, 1994) suggested that children engage in eye pressing behavior to stimulate visual cortex and took support for this assertion from the observation that children with defects in the visual pathways or with cortical atrophy do not engage in eye pressing. Additional support may be taken from the recent report of electrical stimulation of the retinal surface in patients blind from retinitis pigmentosa, which yielded light perception (a spot of light) localizing to the area stimulated (Humayun et al. 1996).

“Overlooking” behavior is the term given to describe the position a child with macular disease might adopt in lifting the chin up and appearing to look above the object of interest. This behavior occurs in the absence of nystagmus and has been interpreted by Taylor and colleagues (1983) as a compensatory response to the presence of some residual vision in the inferior fields. Some behaviors in blind children have also been linked to diseases of the anterior visual pathways and roving eye movements are one example. Typically these slow drifting movements are present from birth and indicate a lack of central fixation (Good and Hoyt 1989). The slow drifting nature of these movements makes them readily distinguishable from nystagmus, and roving movements and nystagmus do not coexist. Among children with visual impairment from cortical defects specific behaviors

that may be observed are influenced in part by the frequently coexisting generalized brain damage and attendant neurologic abnormalities. Children with cortical impairment seem to prefer colors over shapes (Jan et al. 1987), and this preference is taken to derive from the bilateral representation of color vision, that is, color vision would be spared except when a very large cortical lesion is present. Children with visual impairment from cortical pathology also typically turn their heads away from an object when reaching to grab it, seeming to prefer peripheral vision over central. The anterior striate cortex is the cortical area that typically represents the peripheral visual field (Benton et al. 1980) and because it is often spared in cases of even severe cortical visual impairment, this may account for the head-turning by some children with cortical visual defects. "Blindsight" is the term given to explain the observation that cortically impaired children can sometimes ambulate and avoid objects even in the absence of detectable cortical vision (Campion et al. 1983). It is suggested that such blindsight might derive from the presence of an extrageniculostriate visual system, and while its specific function is debated, it has been suggested that such a system could mediate the unconscious awareness of motion in the peripheral field, spatial localization, and visuospatial orientation (Good et al. 1994; Brodsky, Baker, and Hamed, 1996).

### Blindness, Stereotypy, and Autism

Stereotyped behavioral traits occur in the majority of children with blindness (Fazzi et al. 1999). Janson (1993) reviewed the link between retinal pathology and abnormal and stereotyped movements in children with blindness secondary to the retinitis of prematurity. Indeed, others have noted that children with congenital blindness are often at risk for behavioral and emotional disturbances including withdrawal, isolation, and even symptoms of autism. One survey of 24 congenitally blind children drawn from special schools found that nearly half of the sample of 3- to 9-year olds met criteria for autism (Brown et al. 1997). Some symptoms of autism in such populations occasionally are referred to as blindisms and include repetitive stereotyped behaviors and echolalia-like imitations as well as pronoun reversal, social withdrawal, and frequent self-stimulatory behaviors. As noted by Good and Hoyt (1989), and more recently by Fazzi and colleagues (1999), eye pressing and finger waving may actually heighten the sensitivity of retinal ganglion cells, appear to offer sensory input, and should not be viewed as inherently pathological. Janson (1993), too, suggests that such behaviors are normative in the blind population. Developmentally, eye rubbing, rocking, swaying, head turning and stereotyped hand gestures usually appear at the end of the first or during the second year of life. In comparison to children with autism, in blind children diagnosed with retinitis of prematurity, general development is frequently delayed and occasionally experienced as deviant. But while blind children may have difficulties in initiating interaction, they may

respond normally when contacted. The lack of functional communication in some children with autism and their stereotyped manipulation of certain objects is not characteristic of children with retinitis of prematurity or blindness from other causes (Sakuma 1975). That said, the incidence of autism in the context of blindness appears to be much greater than that in the general population (Hobson and Bishop 2003), and specific causes, such as retinitis of prematurity and Leber congenital amaurosis, may also be predisposing factors for autism (Rogers and Newhart-Larson, 1989).

The specific topography, rate of occurrence of stereotypy, and even the degree to which it interferes with attention and learning is generally not a good diagnostic indicator to determine whether a visually impaired child also has autism. That said, Hobson and Bishop (2003) studied the relationship between blindness and autism and suggested that the many sources of social impairment that come with blindness, both physical and environmental, may lead to impoverished interpersonal experiences that could predispose to autism. These investigators are nonetheless clear, however, that there are blind children who do not have autism, but who still have marked impairment in interpersonal engagement. Other factors, then, such as (1) echolalic and/or repetitive verbal behavior; (2) significant delays in social development, especially cooperative play and use of symbolism in toy play; (3) excessive need for sameness in activities, routine, or physical environment; (4) extreme tantrum behavior when attempts are made to change routine or redirect while engaged in ritualistic or stereotypic behavior; (5) excessive avoidance of physical contact and/or extreme clinginess with primary caregivers; and (6) unusual posturing or mannerisms are more significant determining criteria in the differential diagnosis of autism than the presence of stereotypic behaviors alone.

### Blindness and Maladaptive Behaviors

In addition to stereotyped behaviors noted previously, maladaptive behaviors may occur in the context of blindness. Concurrent mental retardation increases the likelihood for self-injurious behavior, for example, which may be expressed as hand and arm biting; head-banging; hits to the head or body; dropping to the ground; skin picking, scratching, and excessive hand mouthing causing skin breakdown. Blind children are sometimes highly reactive to the sudden presence of others around them and may startle by headbutting or lashing out with their arms or hands (Van Hasselt 1987). Hitting, scratching, and pinching others has also been reported (Vollmer et al. 1992). Such behaviors place those around the child at risk for any number of injuries. Children with visual impairment may also reject objects presented to them by throwing the objects indiscriminately. Other impulsive behaviors may occur; for example, staff and parents working with visually impaired children have reported being struck in the face, nose, or chin as children jerk their heads quickly backward,

striking the unprepared. In beginning orientation and mobility training with children and adolescents, especially individuals with concurrent language deficits who may not be able to perceive where others are in space, caregivers face the risk of being struck by a walking cane.

### Psychopathology in Blindness

Blindness appears to be a risk factor for the development of behavioral and psychiatric disorders in children and adolescents but studies of psychopathology in blind children are few. Blacher and colleagues (1992), examining the factors that result in out-of-home placement for children with mental retardation, found that blindness alone was not highly contributory. Age (older children were more often placed), degree of retardation, reduced adaptive behavior, and increased maladaptive behaviors were much more significant factors resulting in placement. These data support Williams' (1969) inferences drawn from placements out of home and in hospital among children in England and Wales with severe visual defects, that upwards of 30% probably had some behavioral "maladjustment." Fine (1968, in Williams 1969) also observed similar percentages. Williams (1969) was clear in suggesting that there are no symptoms of psychiatric disorder unique to the child with blindness. Neurotic disorders, conduct disorders, autism, and hyperactivity could all be diagnosed in blind children. Reviewing the diagnoses associated with blind children between 7 and 13 years of age referred for psychiatric consultation (N = 17), Williams recounted nine cases of "free floating anxiety," aggressiveness (N = 8), irritability and distractibility (N = 8), and overactivity (N = 5). Although five of the children were said to exhibit autistic behavior, the diagnosis of autism was made in only one.

In their classic study, Jan and colleagues (1977) examined children and adolescents in British Columbia who met criteria for legal blindness. No exclusions were made in the presence of additional handicapping conditions and while these children were compared with a gender and age matched control group, they were not matched for IQ. The study also predated current diagnostic criteria for mental disorders, but global psychiatric assessments are listed in Table 21.2.

In addition to the previous distribution, 7% of the sample were judged to have abnormalities in thought process as judged by loose associations, another 7% were found to be pathologically preoccupied with certain topics, and 23% of the children were said to lack a sense of humor, being characterized as excessively serious. Nearly one third of the children examined had received some tranquilizing drug (unspecified), and one fifth of the sample continued to receive a psychoactive medication at the time of the study (excluding anticonvulsants) in comparison to 1% of controls. This study was also important in suggesting that the degree of visual impairment tended to impact on the likelihood of psychopathology, with the totally blind experiencing more

dysfunction than their partially sighted peers. Ammerman and colleagues (1986) made the important point that some characteristics of blind children identified as pathologic, such as high scores on indices of anxiety, may in fact be appropriate responses to blindness when, for example, the fear in question includes a worry about running into things. Similarly, elevated measures of dependence may also be artifacts of the reality that finds children and young adults with blindness frequently dependent on supports from others in the environment to make their way in the world.

Indeed, because many parents may feel ill-equipped to adapt to the special needs of their visually impaired infants, they may unintentionally foster social dependence and inhibit haptic exploratory search in their children as they develop. Clinicians working with blind children should anticipate parents having difficulty leaving their child alone for the testing session, wanting to hold their child's hand during an interview, and having difficulty not answering for their child. While these protective behaviors are by no means universal, they underscore the importance of early intervention programs to teach parents how to permit their children to develop competence and independence.

### Assessing the Need for Treatment

Treatment of the child with blindness should always follow from a comprehensive evaluation. In the context of developmental disabilities, and blindness in particular, a multidisciplinary approach is essential. Medical problems may present as behavioral difficulties, and the latter may occur as side effects of medical treatment. It does little good to bring a visually impaired, developmentally delayed child to a psychiatrist's or internist's office for medication evaluation, unless the purpose of the visit is to observe how the child reacts in novel, unfamiliar environments or to examine the child for particular medication side effects. A

treating clinician will receive far more useful data by arranging for involved persons to collect observational data on selected target symptoms. To this end, teachers and parents, occupational therapists, nurses, social workers, psychologists, pediatricians, ophthalmologists, and child psychiatrists best function as a team in their approach to the child with blindness.

In determining whether children with visual impairments exhibit behavior that requires the attention and intervention of mental health professionals, it is necessary to determine how the observed symptoms interfere with the child’s development or ability to achieve greater independence. Clinicians may wish to ask themselves the questions summarized in Table 21.3 regarding a presenting symptom.

If the behavior does appear to meet criteria for intervention, several factors must be considered initially: Is the behavior a symptom that may be treated medically? In children lacking effective language skills, self-injury may reflect their underlying physical discomfort, such as an ear infection. Clinicians should look for recent changes in the child’s sleep, health, diet, or general level of functioning. Recent significant environmental or social changes (i.e., parents divorced, move to new home, arrival of new sibling, etc.) may also affect adaptive functioning. “Setting events” may also be an influencing factor. Such events refer to antecedent social or environmental conditions that alter the probability of behavior in the child’s repertoire occurring (Durand 1990; Twardosz 1985). Increased problems may occur with students if their favorite staff happens to have the day off. Sometimes poor sleep is a problem, particularly in totally blind individuals. Insomnia may predispose them to irritability, poor attention span, and other behaviors, that may again increase the likelihood of maladaptive behaviors occurring.

Often children with both developmental delay and visual impairment develop fears associated with transitions between settings or activities. This difficulty can be com-

pounded by the fact that different caregivers may be teaching the child at any given point in time and may not be sufficiently consistent in how they transition the child from one activity or place to another. In examining why transitions are difficult for students, it may be helpful to consider the following factors (Wright et al. 1994): (1) What is the child’s tolerance for noise, physical crowding, changes in routine (Environment). (2) How do staff or peer interactions affect them? Does having different caregivers around make a difference? (Social). (3) What is the child’s ability to communicate when frustrated? Are they ever with individuals who cannot understand how they communicate? (Communication). (4) What is their frustration tolerance level, how well do they control impulses, how do they respond when confronted with sudden changes? (Emotional). (5) How do they explore their environment, how long can they pay attention? What are the best ways to help them stay focused and motivated? (Cognitive). (6) How are transitions handled? What does waiting do to them? Do they understand where they are going and why? (Task-related).

### Psychotherapeutic Interventions

There has been considerable growth and sophistication in the types and breadth of methods used in behavioral treatment. What began as consequence-driven, behavior reduction techniques involving punishment, aversive stimulation, or time-out has evolved into a multifaceted, highly positive, treatment approach. Behavioral treatment approaches should be a standard part of any treatment plan designed for the amelioration of stereotypic, self-injurious, and disruptive behaviors in children, and a growing literature attests to successful applications in treating children with visual impairment (Van Hasselt 1987). These treatments are derived from theories of social learning, classical and operant conditioning, and cognitive restructuring, and detailed reviews can be found elsewhere (Martin and Pear 1996; Thorpe and Olson 1990; Bellack and Hersen 1985). Contingent positive reinforcement is the most widely researched and effective tool available to caregivers working with visually impaired children. Review of treatment approaches for managing self-injury, stereotypic, and disruptive behaviors (Van Hasselt 1987) indicated over two thirds of the studies from 1970 on used positive reinforcement as part of the treatment of persons with visual impairment. For reinforcement to be effective, it must immediately follow the behavior to be increased. Having a child sign “eat” then taking him or her across the hall to receive food might be effective for a well-established behavior, but would be much less likely to teach the child to make the connection initially, resulting in an increase in spontaneous signing. To maximize the effectiveness of positive reinforcement, it is important to: (1) specify the exact behavior targeted for reward; (2) provide reward or signal the availability of reward immediately following emission of the target behavior; (3) vary the availability of reinforcing stimuli

**TABLE 20.3**  
**ASSESSMENT OF NEED FOR BEHAVIORAL INTERVENTIONS**

Behavior	Example
Potentially of harm to the child?	Eye poking; darting into traffic; self-injurious behavior
Dangerous to others?	Startle-induced aggression; throwing objects; head-butting; scratching; pinching
Impairs acquisition of new skills or behaviors?	Stereotypies; noncompliance
Limits independence?	Difficulty with transitions; fear of separation
Distress to the individual?	Sleep disturbance; excessive fears
Disruptive to others?	Screaming; public masturbation
Socially inappropriate?	Taking others’ food

and activities; (4) replace contrived rewards with naturally occurring rewards as the behavior becomes more frequent; (5) reduce the number of times the behavior is rewarded as it becomes more firmly established in the child's repertoire.

For children with sufficiently developed language skills, cognitive functioning, and the ability to form social attachments, supportive psychotherapy may be a useful addition to behavior therapy (Anders and Walton 1983). Often, it is necessary to work with families who may be reacting to the stress of having a handicapped child to help them cope more effectively with feelings that may prevent them from effectively participating in their child's behavioral treatment.

As with sighted individuals, exercise may be of benefit for visually impaired and blind individuals. Hanna (1986) reported that blind school children exhibit significant differences in lateral posture, biological functioning, and cardiovascular endurance relative to their sighted peers, and recommended recreational activities that make moderate demands on the cardiovascular system. Gleser and colleagues (1992) found that judo practice, in combination with group psychotherapy, occupational therapy, and physiotherapy, benefited school-aged mentally retarded blind children who exhibited improvement in developmental and motor skills as well as their social attitude. O'Cleirigh and colleagues (1994) also endorsed noncontingent exercise as an intervention warranting further attention.

### Social Skills Training

Next to self-injurious and stereotypic behaviors, Van Hasselt (1987) found that the majority of studies in his review of behavioral treatments for blind children focused on disruptive behaviors. It is thus necessary to be sure that children and adolescents learn what is considered socially offensive behavior and learn how to suppress such behaviors in certain settings. Otherwise, others in the community will be less likely to interact with these individuals, increasing their sense of isolation and withdrawal. As reported by Van Hasselt (1987), maladaptive behaviors do not usually disappear on their own, but continue to interfere with interactions with others and with learning.

Treatment to improve social skills does not need to be burdensome or complicated. Providing increased opportunities for social interaction through prompting by teachers or parents is likely to result in the initiation of peer interaction and, once it begins, it is more likely to be sustained through continued positive feedback. Breaking certain activities down and providing assistance that is gradually reduced may also be helpful. Van Hasselt (1987) indicated that improvement in assertiveness skills could be accomplished with visually impaired female adolescents in less than a month. Sessions occurred five times weekly for 15 to 30 minutes and included modeling, direct instructions, behavioral rehearsal, performance feedback, and manual guidance. Targeted behaviors evidencing change included direction of gaze, posture, voice tone, and requests for behavior

change. A one-month follow-up evaluation showed a retreat toward baseline in some responses; however, once "booster" treatment sessions were implemented, further follow-up indicated these behaviors had returned to posttreatment levels. This experience highlights some of the primary considerations in improving prosocial behaviors: (1) Assessment is critical and specific behaviors to be changed must be targeted; (2) A single approach is less likely to be effective than a treatment package; (3) The techniques are not time-consuming or complex and may be implemented in a variety of situations; (4) Maintenance of treatment gains may require booster sessions; (5) Once social behaviors are established, naturally occurring consequences are likely to maintain such behaviors, but only if the child has sufficient opportunity to interact in a social environment.

### Psychopharmacology

Little has been written about the use of psychotropic medications in children with blindness or severe visual impairment. It is well known, however, that there are ophthalmic effects of medications commonly used to treat mental disorders and, in particular, in the context of severe visual impairment, medications which impair accommodation have the potential of exerting significantly greater impact than would the same drugs administered to children with more in the way of visual reserve. Medications well known for such anticholinergic side effects include the tricyclic antidepressants, but the mood stabilizers, lithium carbonate and carbamazepine, as well as the neuroleptic drugs all have the potential to impair visual acuity through this mechanism. Sanabria-Bohorquez and colleagues (2001) have observed decreased cerebellar benzodiazepine receptor density in early blind subjects. There did not appear to be cortical differences in receptor density as assessed by flumazenil binding. The clinical implications of these observations are unclear, but may suggest a potential for differential sensitivity to therapeutic and motor or other side effects of benzodiazepines in persons who became blind early in life.

Geringer (1994) has reviewed psychiatric considerations in ophthalmology and noted a variety of potentially significant ophthalmic effects associated with commonly used psychotropic agents. While most of these effects have greater implications for adults with visual impairment, for example concerns about the use of agents with anticholinergic effects in the context of narrow angle glaucoma, it is worth noting that a variety of side effects with regard to the visual system have been described. These include for the antidepressants bilateral internuclear ophthalmoplegia (doxepin and amitriptyline), palinopsia (trazodone), impaired smooth pursuit eye movements, divergence paralysis and decrease in saccadic velocity associated with benzodiazepines in general, and glaucoma and allergic conjunctivitis associated with diazepam in particular (Donhowe 1984; Hughes and Lessel, 1990; Arai and Fujii 1990; Hyams and Keroub 1977).

Downbeat nystagmus, saccadic dysmetria, oculogyric crisis, opsoclonus, unilateral gaze palsy, papilledema and eye irritation all have been associated with lithium administration (Corbett et al. 1989; Deleu and Ebinger 1989; Sandyk 1984; Levine and Puchalski 1990). The use of carbamazepine has been associated with downbeat nystagmus, retinopathy and oculogyric crisis (Chrousos et al. 1987; Nielson and Syversen 1986). Among the neuroleptic drugs, oculogyric crises, corneal and lenticular deposits, pigmentary retinopathy and blinking blepharospasm, perhaps a tardive dyskinesia variant, have been reported (Hamilton 1985; Miller et al. 1982; Sachdev 1989).

In addition to particular issues with regard to the use of psychotropic medications in children with blindness, there are also considerations that need to be kept in mind with regard to the use of ophthalmic drugs and their possible psychiatric consequences. Among these drugs, the medications most likely to cause psychiatric symptoms include anticholinergic agents used for pupillary dilation, and beta-blockers, which may be used in the treatment of glaucoma. Among the anticholinergic eyedrops widely used are preparations of atropine, scopolamine, homatropine and cyclopentolate hydrochloride. The latter is most often associated with symptoms of irritability, restlessness, agitation, insomnia, and confusion, as well as occasionally more severe symptoms of depersonalization, delirium, paranoid thoughts, memory loss, and visual hallucinations (Geringer 1994). Among patients treated with beta-blockers, typically timolol for glaucoma, approximately 10% may report psychiatric symptoms, which include light-headedness, depression, fatigue, dissociative states, and loss of memory.

## Conclusion

Research in the neurobiology of vision has contributed much to our understanding of basic brain function. Arguably, vision is the dominant sense in humans, and impairment of this modality can significantly alter cortical maps, sleep-wake cycles, and motor, language, and personality development. Blind children are at risk for psychiatric disorder. Advances in knowledge of the visual system have informed therapeutic approaches, but considerable work remains to advance our understanding of how best to prevent and remediate blindness and its attendant developmental consequences in children.

## DEAF AND HARD-OF-HEARING CHILDREN AND ADOLESCENTS

### Definition of Hearing Loss

Deafness can at once be simple and quite difficult to define, and choice of terminology can have important connotations for individuals with varying degrees of hearing

loss. At the simplest level, "deaf" refers to the mechanical characteristics of hearing loss, with individuals exhibiting thresholds for sound detection sufficient to interfere with ability to detect and decipher speech (approximately 60 dB or greater), while "hard-of-hearing" individuals have lesser degrees of hearing loss such that they can still understand at least some speech, particularly with the benefit of hearing aids. Beyond level of hearing, however, hearing loss and associated terms such as deaf and hard of hearing can be defined by additional mechanical features including not only amount but also quality of residual hearing, timing of onset, etiology, whether or not the hearing loss occurs in isolation (nonsyndromic) or with other symptoms (syndromic), educational experience, linguistic choices, and cultural identification. In this discussion, hearing loss refers to the mechanical aspects of audition, "deaf" or "deafness" refers to hearing loss sufficient to prevent access to auditory inputs, "hard of hearing" refers to a more modest hearing loss that allows for auditory input, and "Deaf" refers to a cultural identification of oneself with the deaf community, a recognized cultural and linguistic minority. We avoid, however, the term "hearing impaired," as this has long been considered by many deaf and hard-of-hearing individuals to be an attempt by hearing professionals to concatenate two ends of the spectrum of hearing loss for simplicity and to medicalize a "disorder" or "disability"; a premise with which many such individuals disagree. The term can be considered offensive and clinicians are forewarned to remove "hearing impaired" from their lexicon.

Mechanical features of hearing loss include degree of loss measured in decibels (dB) and is described as normal when thresholds are between 0 and 26 dB, mild 27 to 40 dB, moderate 41 to 55 dB, moderately severe 56 to 70 dB, severe 71 to 90 dB, and profound for thresholds greater than 90 dB. The pattern of hearing loss across the frequency spectrum also plays an important role in the degree to which a child has access to spoken language via auditory channels. With primary speech frequencies ranging from 500 to 4,000 Hz, losses outside of that range have less impact on ability to detect and understand speech than losses within these speech frequencies. Hearing loss is also characterized as either conductive, sensorineural, or mixed. Conductive hearing loss stems from defects or disruption in the external or, more likely, middle ear components that conduct sound to the sensory organ (cochlea) within the inner ear. Sensorineural hearing loss stems from deficits in the inner ear or auditory (VIII) nerve. The majority of children with clinically significant hearing loss have sensorineural losses.

Stability of hearing thresholds over time has important implications for a child's access to, and development of, spoken language. Early intact hearing or only mild to moderate loss is more likely to provide the child with access to, and experience with, spoken language that can serve as a basis for spoken language development, even when the hearing loss progresses to a more severe degree once basic

language abilities are developed. Quality of residual hearing also impacts ability to detect and discriminate sounds. It is possible to have a severe or profound hearing loss but with good discrimination such that the child benefits well from amplification, while it is also possible to have only a moderate to severe loss with poor discrimination such that amplification is unhelpful to the child in comprehending speech via aural channels. Hearing loss can be further defined by timing of onset, or as congenital, acquired prelingual, or postlingual. Congenital and acquired prelingual hearing loss is more likely to interfere with acquisition of spoken language, while postlingual, as the term implies, occurs after the child has developed spoken language. Postlingually, or adventitiously, deafened children have sufficient experience with their spoken language (e.g., English) to enable continued speech and knowledge of the language of their hearing peers.

Hearing loss can further be described as occurring in isolation (nonsyndromic) or with other symptoms (syndromic), and can be hereditary or acquired via a number of mechanisms, including intrauterine or neonatal infections such as cytomegalovirus or Rubella, later infections such as meningitis, or events such as anoxia. Certain hereditary forms of hearing loss, particularly those that are syndromic, are more often associated with other neurological deficits. Intrauterine and postnatal infectious causes of hearing loss are also often associated with neurological, behavioral or psychiatric deficits.

### Epidemiology of Hearing Loss in Children and Adolescents

The epidemiology of hearing loss is based on fragmentary information (Nadol and Merchant 2001), but estimates suggest that both the incidence and prevalence of deafness are approximately 1 in 1,000. Although approximately 1 in 1,000 children are born with severe or profound deafness (Fraser 1964; Kitson and Fry 1990), as many as one in 300 children are born with at least some degree of hearing loss (Thiringer et al. 1984). Another 1 in 1,000 children become deaf before adulthood (Petit and Weil 2001).

### Etiology of Hearing Loss

Hearing loss has many causes, including hereditary factors, anoxia, congenital and postnatal infections, and ototoxic drugs. Although etiologies have historically been difficult to determine and estimates vary widely across the few extant studies, substantial strides have been made in the past decade in the identification of genetic causes. This, in combination with interventions for prenatal infections such as rubella and alternatives for ototoxic drugs, has led to a marked increase in the incidence of known genetic causes of hearing loss in children. Etiology of hearing loss is an important historical factor in the clinical evaluation of deaf and hard-of-hearing children, as certain etiologies are likely

to carry additional neurological complications such as visual, motor, or cognitive deficits.

### Hereditary Deafness

The number of genes involved in development and functioning of the hearing system are unknown, but is estimated to number in the hundreds or as many as 1,000 (Nance, 1980). Over 350 different genetic conditions associated with hearing loss are described in the literature (Martini, Mazzoli, and Kimberling 1997). These can be broken down further into syndromic, comprising some 30% of cases, and nonsyndromic, accounting for 70% of cases (Petit 1996). At least 50% of children born deaf have genetic bases for their hearing loss, and 70 to 80% of these are autosomal recessive, 15 to 20% are autosomal dominant, and 2 to 3% are X-linked or mitochondrial in origin (Morton 1991, Bussoli and Steel 1998). At least 30% of the causative genes have been identified.

#### Syndromic Hereditary Deafness

There are several hereditary syndromes that feature sensorineural hearing loss as a primary symptom, among them Waardenburg's and Usher's syndromes. Although there are a few recognizable syndromes involving hearing loss associated with in utero infection (e.g., rubella, cytomegalovirus), the majority of cases of syndromic deafness are genetically mediated.

Waardenburg's syndrome is an autosomal dominant genetic syndrome with four known subtypes (Nadol and Merchant 2001). Hearing loss in Waardenburg's syndrome varies, ranging from unilateral to bilateral and across the hearing spectrum, with a characteristic low frequency loss. Type I is associated with dystopia canthorum and heterochromia iridis along with sensorineural hearing loss and is attributed to a mutation of the PAX-3 gene at 2q35. Type II is similar in presentation but without dystopia canthorum and is attributed to mutation of the microphthalmia gene. Type III is referred to as Klein-Waardenburg and is similar to Type I with added abnormalities of upper limbs and is attributed to the PAX-3 gene at 2q35. Type IV, or Waardenburg-Shah, is akin to Type II but with Hirschsprung disease. The mechanism for Waardenburg's syndrome is thought to be genetically induced abnormal migration of melanocytes from the neural crest, leading to defective development of the stria vascularis and other cochlear structures (Merchant, McKenna, Baldwin, Milunsky, and Nadol, 2001).

Usher's syndrome is an autosomal recessive syndrome categorized into three subtypes, each with congenital hearing loss and onset of visual impairment later in life. Type I is characterized by congenital profound sensorineural hearing loss and onset of retinitis pigmentosa by age 10 years. Type II includes a sensorineural congenital hearing loss with a downsloping audiogram, no vestibular abnormalities and retinitis pigmentosa by age 10 to 20 years. Type III

is characterized by progressive sensorineural hearing loss, some involvement of the vestibular system, and variable onset of retinitis pigmentosa. Nadol and Merchant (2001) describe several genetic mutations responsible for each type of Usher's syndrome.

There are many syndromic disorders attributed to inherited mitochondrial DNA mutations that involve hearing loss including MELAS syndrome (metabolic encephalopathy, lactic acidosis, and stroke-like episodes), MIDD syndrome (maternally inherited diabetes and deafness), MERRF syndrome (myoclonic epilepsy associated with ragged red fibers), and Kearns-Sayre syndrome.

### **Nonsyndromic Hereditary Deafness**

Autosomal-recessive inheritance characterizes 80% of cases of nonsyndromic inherited deafness. Autosomal dominant inheritance occurs in nearly all of remaining cases, with X-linked and mitochondrial inheritance patterns comprising approximately 1% of cases (Petersen 2002). Some 53 loci for nonsyndromic recessive forms have been reported (Petit and Weil 2001), including a mutation in the GJB2 gene, which may account for hearing loss in as many as 50% of cases in some populations (McGuirt and Smith 1999). With respect to dominant patterns of transmission, 38 genes, consecutively numbered DFNA1-38 (autosomal dominant sensorineural deafness) have been mapped to 15 different chromosomes, whose functions relate to hair cell formation, potassium recycling into endolymph, several connexin (gap junction) proteins, and others (Petersen 2002). Autosomal recessive forms of deafness tend to be more severe, and sensorineural in etiology in comparison to the conductive loss that typifies most syndromic forms of deafness. Nonsyndromic causes of deafness are, almost by definition, less likely to be associated with other neurological, cognitive, behavioral, or psychiatric concerns.

### **Nonhereditary Causes**

Although the incidence of non-hereditary forms of deafness continues to decrease, these are important etiologies as they are often associated with other, sometimes severe, neurological sequelae that affect behavioral, cognitive, and psychiatric functioning in children. Hearing loss can result from hyperbilirubinemia congenital infections such as cytomegalovirus and rubella, postnatal infections such as bacterial meningitis, prenatal, perinatal, or postnatal anoxia, ototoxic drugs such as aminoglycosides during pregnancy, or use of ototoxic drugs postnatally.

### **Congenital Infections**

Select pathogens can infect the placenta and damage the developing fetal central nervous system resulting in neurological disorders including sensorineural hearing loss. Of the so-called TORCH infections (toxoplasmosis, others,

rubella, cytomegalovirus and herpes; Nahmias 1974), cytomegalovirus (CMV) and rubella are the primary culprits.

### **Cytomegalovirus**

CMV may be the most common cause of nonhereditary deafness. The incidence of acquired CMV infection in the population is 1 to 2% per year, with nearly 100% of adults infected at some point (Bale and Jordan 1989). The majority of healthy individuals with acquired CMV infections do not exhibit symptoms, and most infected neonates have no signs of infection at birth. Some 10% of neonates exhibit symptoms including jaundice, hepatomegaly, splenomegaly, rash, intrauterine growth retardation, and respiratory distress. Over 90% of these infants have neurological sequela, including microcephaly, chorioretinitis, seizures, hypo/hypertonia, cerebral palsy, mental retardation, and behavioral disorders (Boppana et al. 1992; Noyola et al. 2001; Pass et al. 1980). Sensorineural hearing loss occurs in approximately 40% of infants with congenital CMV infection (Istas, Demmler, Dobbins, and Stewart 1995). Imaging studies have shown periventricular calcifications in approximately 50% of infants with intrauterine infection and may also show periventricular leukomalacia, polymicrogyria, pachygyria, or lissencephaly (Bale 2002).

### **Rubella**

Until the introduction of the rubella vaccine in 1969, rubella epidemics occurred at 6- to 9-year intervals and resulted in thousands of cases of congenital rubella syndrome (Bale 2002). This was the most common cause of hearing loss in children born in the early 1960s during a rubella pandemic. Since the vaccine, however, the incidence of congenital rubella syndrome has declined in the United States to less than 0.1 per 100,000 births (Schluter, Reer, Redd, and Dykewicz 1998). Unfortunately, rubella prevalence in central and eastern Europe, particularly in the former Soviet Union, has increased dramatically (Banatvala and Brown 2004). Moreover, recent concerns in the United Kingdom and United States regarding the safety of the measles-mumps-rubella vaccine have substantially reduced the uptake rate of the vaccine.

Infants born with congenital rubella syndrome exhibit a broad spectrum of symptoms including sensorineural hearing loss, cataracts, retinopathy, micro-ophthalmia, microcephaly, cardiac defects (myocarditis, patent ductus arteriosus, valvular stenosis, and septal defects). Neurological symptoms can include autistic features and mental retardation. Abnormalities are related to timing of infection during gestation (Ueda, Nishida, Oshmia, and Shepard 1979): cataracts and cardiac defects result from infection during the first 8 weeks and hearing loss results from infection during the first 16 weeks. Infections after the 16th week have few known sequelae, although hearing loss can occur. Although the incidence of congenital rubella syndrome in the United States has declined, it is more likely to occur in immigrants from countries without compulsory immunization (Schluter et al. 1998).

### Herpes Simplex Virus

Neonatal herpes simplex infection occurs in 1 in 3,000 to 20,000 live births (American Academy of Pediatrics 2000) and is typically a result of viral exposure during birth. Sensorineural hearing loss results in most cases where the infection presents in disseminated fashion, in some 40% of children with encephalitis, and 25% of children with only localized infections (Whitley and Hutto 1985). Hearing loss in these cases is often accompanied by other neurological symptoms, including mental retardation, visual impairment, and seizures (Roizen 2003).

### Other Etiologies

#### Bacterial Meningitis

Before vaccination programs, bacterial meningitis accounted for the majority of hearing loss in infants and children (Anderson and Taylor, 2000). While the incidence of specific forms of the illness has markedly decreased since introduction of vaccination for *Haemophilus influenzae* type b meningitis, there are as yet no vaccines for other forms of the disease, including pneumococcal meningitis, meningococcal meningitis, and group B streptococcal infections, the most common form of neonatal meningitis. While each form tends to affect children at different ages (e.g., group B streptococcal infections are often neonatal, while other forms occur between 1 month and 4 years), the majority of childhood infections occur during the critical language development period. For young children who contract meningitis, mortality rates are between 4 and 10% (Grimwood, Nolan, Bond, Anderson, Catroppa, and Keir 1996). Of the survivors, some 40% exhibit acute neurological complications (Grimwood et al. 1996, Taylor et al. 1990), although the majority have no residual effects (Taylor, Schatschneider, and Rich 1992). Hearing loss is the most common residual sequelae of bacterial meningitis. Baraff, Lee, and Schriger (1993) found that 16% of bacterial meningitis survivors had severe or profound hearing loss. This may be accompanied, however, by other neurological sequelae including mental retardation (6%), spasticity or paresis (4%), and seizure disorders (4%). Cognitive, language, behavioral and academic difficulties are seen in many children with histories of meningitis, with acute phase neurological symptoms and persistent hearing loss increasing risks for these difficulties. Longterm deficits have been documented in language, fine and gross motor function, perception, memory, executive function, and academic skills in postmeningitic children. Although language deficits may be associated with hearing loss itself, they are also seen in postmeningitic children without hearing loss, suggesting that language deficits may be a result of meningitis infection that are further compounded by hearing loss (Anderson and Taylor 2000). Anderson and Taylor also note that deficits may change over time, such that gross motor difficulties may be more apparent in the acute phase, but fine motor, language, perceptual and behavioral difficulties may emerge and persist in later years as environmental demands increase.

### Prematurity

The incidence of sensorineural hearing loss as a result of perinatal/neonatal complications has increased substantially over the past 30 years, accounting for only some 2% of children with hearing loss in the 1960s but some 27% in the 1990s (Kile 1993). This is thought related in part to the increased survival of high-risk infants. In a study of etiological factors resulting in deafness in prematures less than 33 weeks gestational age, duration of intubation, ventilation, oxygen exposure, and acidosis contribute significantly to later hearing loss. Although bilirubin levels and aminoglycoside levels were not in themselves associated with later hearing loss, the risk of later hearing loss increased significantly when acidosis and/or aminoglycoside use occurred during peak bilirubin levels (Marlow, Hunt, and Marlow 2000). (See also Chapter 23.)

### Anatomy of the Hearing System

The human hearing system is composed of three distinct components: the external, middle, and inner ear. The external ear includes the auricle and external auditory canal, bringing sound from the external environment up to the tympanic membrane. The middle ear begins at the tympanic membrane, which transduces sound vibrations, or airwave pressure oscillations, into mechanical energy, transmitted from the membrane through the three ossicles (malleus, incus, and stapes) to the oval window. The oval window is the entry point of sound to the inner ear. At the oval window, the mechanical energy is again transduced to fluid vibrations in the endolymph, a potassium-rich fluid that fills the cochlea and the vestibule. The vestibule is responsible for balance and includes the saccule and utricle, which respond to linear acceleration, and three semicircular canals, which respond to rotational movements. The cochlea and vestibule contain sensory receptors termed hair cells or stereocilia. The hair cells are covered by acellular membranes: the tectorial membrane within the cochlea, otoconial membranes for the saccule and utricle, and cupulae for the semicircular canals. The hair cells and membranes move in response to endolymph vibrations within the cochlea and vestibule, resulting in depolarization and neurotransmitter release into synapses corresponding to the hair cells. This process generates signals that are transmitted along the auditory nerve (VIII). Sound intensity or amplitude and frequency or pitch are encoded via the hair cells in the cochlea, which are arranged *tonotopically* with hair cells near the base of the cochlea responding to high frequencies and those near the apex of the cochlea responding to low frequencies. This tonotopic organization is maintained throughout most of the auditory perceptual system.

Once signals enter the central auditory system via the auditory (VIII) nerve, they bifurcate at the cochlear nuclei and superior olivary complex, or brainstem auditory nuclei, into several separate monaural and binaural pathways. Monaural pathways capture spectral features (amplitude, frequency) of sound from one cochlea and arise

from the cochlear nucleus, projecting via the acoustic stria to the contralateral inferior colliculus. Binaural pathways compare and contrast signals from both cochlea and are responsible for localization of sound and discrimination of sound in noise via two mechanisms: interaural timing and interaural level differences. Lower frequency sounds below 3,000 Hz are localized in space via timing differences from sound waves reaching the closer or more proximal ear in an earlier phase than the distal ear, while higher frequency sounds are loudest in the proximal ear and attenuated slightly by an auditory “shadow” created by the head. From a functional standpoint, binaural inputs are essential for sound localization and discrimination of foreground sounds from background noise. Thus, while frequency and volume of sound may be preserved in unilateral hearing loss, localization and discrimination is affected.

Binaural processing begins in the superior olivary complex, which receives ipsilateral excitatory input and contralateral inhibitory input from the cochlea. This information projects ipsilaterally to the lateral lemnisci where it is projected to both the ipsilateral inferior colliculus and to the contralateral lemnisci and on to the contralateral inferior colliculus. At the inferior colliculus, binaural and monaural pathways are combined and integrated and passed to the medial geniculate nucleus in the thalamus, which serves as a relay to the primary auditory cortex (Brodmann’s area 41) in the posterior area of the superior temporal gyrus. Tonotopic organization is maintained within the auditory cortex, with low frequencies processed rostrally and high frequencies processed caudally.

The inferior colliculus also has several projections to the superior colliculus. This provides for integration of spatial sensory information from somatosensory, visual and auditory inputs. The auditory projections form an auditory map of space that parallels that of the visual map.

Descending auditory pathways provide control of auditory inputs and processing from the cortex down to the cochlear nuclei and directly to the hair cells within the cochlea. There are two primary pathways; one arising from the lateral division of the superior olivary complex whose function is not yet known, and one arising from the medial division of the superior olivary complex that is involved in modulating or attenuating sound from the cochlea.

### Behavioral and Developmental Consequences of Deafness

Hearing loss, by itself, does not have any direct behavioral or developmental consequences. If a deaf or hard-of-hearing child is brought up in a visual sociolinguistic environment at home and school that compensates for their hearing loss, the child’s development would be within normal limits. However, there are often indirect behavioral and developmental consequences of growing up with hearing loss in a world that relies heavily on audition such as environ-

mental factors that hinder their language, academic, and psychosocial development. There are negative consequences when parents, teachers, and professionals have on these children when they do not know how to deal with a child or adolescent with hearing loss. These factors are discussed in depth in the following sections.

### Motor Development

There is widespread agreement that deaf children’s early gross and fine motor development is quantitatively and qualitatively similar to that of hearing children (Paul and Jackson 1993). In a study that focused on various aspects of motor skill development in 201 deaf (mean hearing loss = 96.94 dB) children and adolescents (ages 4 to 18), it was found that they had similar motor skills acquisition compared to hearing peers (Dummer, Haubenstricker, and Stewart 1996). Deaf children with sign language fluency have been found to perform better on tasks that require rapid manual speed compared to non-signers (Braden 1985, 1987). Deaf children of deaf parents are faster than deaf children of hearing parents, who in turn are faster than hearing children on these types of tasks (Braden 1988).

### Language Development

Language access is perhaps the primary concern when dealing with hard-of-hearing or deaf children and adolescents. Some hard-of-hearing children are able to have full access to spoken language when fitted with hearing aids. Other hard-of-hearing individuals cannot understand speech from hearing alone but with hearing aids or cochlear implants they can lip read better; for example, the hearing aid or cochlear implant can help them identify the differences between the voiceless /s/ and voiced /z/ phonemes while lip reading. There remain to be some who receive no obvious benefits from hearing aids or cochlear implants. Those who do not attain normal hearing with hearing aids and those with cochlear implants often do not have the benefits of language acquisition in the periphery and they have only limited access to language when they are watching someone’s lips.

Lip reading requires more attention and effort than passive listening and often requires guesswork. For example, one study demonstrated that deaf adolescents were able to guess pseudosyllables correctly with 30% accuracy through lip reading alone. The same subjects were able to correctly identify key words in sentences with low predictability with 25.5% accuracy and in highly predictable sentences with 49.2% accuracy (Nicholls and Ling 1982). Hearing aids and cochlear implants have been shown in a number of studies to improve the accuracy of lip reading in some children and adolescents (Geers and Brenner 1994). The intelligibility of deaf and hard-of-hearing individuals’ speech varies widely depending on degree of hearing loss, age of onset of hearing loss, and how much the individual benefits from speech therapy (Ellis and Pakulski 2003; Monsen 1983).

Visual languages have emerged and visual codes have been developed because of the difficulties of providing adequate access to language through lip reading. American Sign Language (ASL) is the language of North American deaf communities (Padden and Humphries 1988). It evolved almost 200 years ago from its original pidgin form that included French Sign Language (*Langue des Signes Francaise*), a sign language that used to exist in Martha's Vineyard, Massachusetts, and Native American Indian sign languages (Lane 1984). Over the time, it creolized into a natural language that has a different grammatical structure than spoken English (Liddell 1980, 1995) and is different from sign languages in other countries, for example, British Sign Language.

The benefit of using ASL is that a child is able to learn a visual language as their primary language and later learn English as their second language (Hoffmeister 2000). When deaf and hard-of-hearing children are in a signing environment, they are able to passively acquire more language skills when watching others communicate with each other that they would otherwise miss in an auditory environment. Deaf and hard-of-hearing children who are born to deaf parents develop native fluency in ASL; however, less than 5% of deaf and hard-of-hearing individuals have at least one deaf parent (Mitchell and Karchmer 2002). They achieve the same language development milestones in ASL as children with no hearing loss (Caselli and Volterra 1994). Literature has shown that deaf children of deaf parents often develop better English literacy skills than those with hearing parents (Padden and Ramsey 2000) and it is believed that having fluency in one language (ASL) helps these children acquire a second language (English) at a faster rate compared to deaf children who attempt to acquire English as their first language.

There are visual codes that have been created to follow a similar word order as spoken English but involve different phonological and morphosyntactical structures such as Manually Coded English and Signing Exact English (Lucas and Valli 1989). They have been created to remove the need for bilingual education although English sign systems cannot achieve the exact same grammatical structure as English. There is also another coding system that minimizes the grammatical differences between its visual form and spoken English; that is, the cued English or cued Speech system (Cornett 1967, Fleetwood and Metzger 1998). The cued English system provides visual phonemes in the form of hand shapes, hand placements, and mouth shapes. While it is phonologically different from spoken English, it follows English's phonemic sequence and it shares the same morphological and syntactical structure. Deaf adolescents who use cued English have been shown to guess pseudosyllables and key words in low predictable and high predictable sentences with 83.5%, 96.2%, and 96.6% accuracy, respectively (Nicholls and Ling 1982). Similar results were found in a study with deaf children from Belgium who used cued French (Périer, Charlier, Hage, and Alergia 1990).

It is important for early detection of hearing loss and immediate accommodations in the home to provide language access and early educational intervention to treat their language delay. Deaf children who are born to a household that does not use a visual language almost always have a delay in their language development. The average age that hearing loss is detected is approximately 18 months (Mertens, Sass-Lehrer, and Scott-Olson 2000). The child's need for visual access to language usually is not addressed in the first 2 years of their lives. Often after diagnosis, professionals attempt to correct their hearing rather than focusing on providing visual access to language (with or without hearing aids or cochlear implants), which further hinders their language development.

The delay of deaf and hard-of-hearing children's English development includes their literacy development. The most recent national survey of 17- to 18-year-old deaf and hard-of-hearing students' reading achievement found the average reading level to be at the 4th grade equivalent (Holt, Traxler, and Allen 1997). If a psychiatric (i.e., lower intelligence) or neurological (i.e., cerebral palsy, epilepsy) disorder is also present, it can exacerbate the language delay. Often deaf and hard-of-hearing children are given a primary diagnosis of a learning disability and/or attentional disorder that is actually secondary to language delay. Deaf and hard-of-hearing children with limited access to language and a language delay often have difficulty paying attention or sitting still in class. Their academic development is often below their cognitive potential. Differential diagnosis is very difficult and many deaf and hard-of-hearing children are misdiagnosed with these types of disorders.

### Cognitive Development

Myklebust (1964) proposed that the lack of auditory stimulation experienced by deaf individuals shifts the cognitive organization within the individual. Event-related potential (ERP), functional magnetic resonance imaging (fMRI), and cognitive behavioral studies have confirmed this hypothesis (e.g., Bavelier, Tomann, and Hutton 2000; Neville and Lawson 1987a, 1987b, 1987c; Prosch and Bavelier 2002). The cognitive reorganization of some functions does not seem to have an impact on intellectual functioning. Deaf and hard-of-hearing individuals' intellectual functioning has a similar distribution to that of hearing individuals (Braden 1994; Maller 1999).

The compensatory theory states that the loss of one sense may be met by a greater reliance upon, and therefore an enhancement of, the remaining senses (Grafman 2000; Neville 1990). Psychophysical studies within the visual domain in deaf individuals, compared to hearing individuals, have failed to validate this theory. Both groups have similar thresholds for brightness discrimination (Bross 1979), contrast sensitivity (Finney and Dobkins 2001), motion sensitivity (Bosworth and Dobkins 1999), and temporal discrimination (Bross and Sauerwein 1980; Poizner and

Tallal 1987). The cognitive differences found in deaf individuals are at the higher level perceptual processing rather than an enhancement of visual sensory thresholds.

Within the domain of executive functions, deaf children and adolescents demonstrate similar cognitive flexibility in nonverbal problem solving compared to age-matched hearing peers (Kelly 1995; Rosenstein 1960); however, a study of nonverbal problem solving involving multiple steps demonstrated that deaf and hard-of-hearing children and adolescents (ages 6 to 19) lagged behind their age-matched hearing peers (Luckner and McNeill 1994). Deaf and hard-of-hearing children have demonstrated similar executive abilities compared to age-matched peers in their ability to initiate behaviors and responses, plan, organize, self-monitor, and control their emotions (Rhine 2002). The area of executive functions that has been documented to be different between deaf and hearing individuals is within the area of impulse and attention control.

Earlier studies have claimed that deaf children are more impulsive than hearing children (Altshuler, Deming, Voltenweider, Rainer, and Tendler 1976; Chess and Fernandez 1980; Quellette 1988); however, these conclusions are not based on well-controlled experimental measures of impulse control; rather they are based on personality measures. Deaf children of deaf parents have impulsivity rates that are lower than those of deaf children of hearing parents (Harris 1978). Current psychological inventories on deaf and hard-of-hearing children's impulsivity, inattention, and ability to shift attention continue to illustrate higher incidences of impulsivity and difficulty shifting attention but not within clinical ranges (Rhine 2002). Similar results are found in continuous performance tasks that are often used by psychologists for ruling out attentional disorders (Parasnis, Samar, and Berent 2003).

The results of psychological assessment tests of attention contradict current cognitive neuroscience literature. Cognitive neuroscience literature has demonstrated that deaf individuals' attention and ability to inhibit distractors is better in some areas and different than that of hearing individuals. Deaf individuals have been shown to have an enhanced capacity to distribute attention over the whole visual field (Sireteanu and Rettenbach 2000) and are able to terminate their search faster when no target was present, without compromising their accuracy as compared with hearing subjects (Rettenbach, Diller, and Sireteanu 1999; Stivalet, Moreno, Richard, Barraud, and Raphel 1998). In studies that required deaf adults to attend to peripheral stimuli while ignoring centrally presented distractors, they did not demonstrate difficulty inhibiting these distractors. Instead, they demonstrated a superior ability, compared to hearing subjects, to selectively attend to the peripheral stimuli while ignoring the centrally presented distractors (Parasnis and Samar 1985; Reynolds 1993).

Other studies have demonstrated that deaf adults are faster and more accurate than hearing adults at detecting (Loke and Song 1991) and discriminating (Neville and

Lawson 1987c) shapes presented in the periphery compared to the center of the visual field suggesting enhanced attention and increased vigilance in the periphery. Proksch and Bavelier (2002) report that deaf adults (native signers) allocate more attentional resources to the periphery compared to the center of the visual field. The allocation of attentional resources to the periphery seems to bring with it reduced resources at the center of the visual field. A similar allocation of attention was not found in hearing subjects who were native ASL signers, suggesting that sign language alone could not be responsible for this change. These results suggest that auditory deprivation from birth enhances the speed of orientating visual attention and attentional processing of the peripheral visual field. Deaf individuals' enhancement of visual attention in the periphery has been supported by ERP (Neville and Lawson 1987b) and fMRI studies (Bavelier et al. 2000).

Sign language experience has been shown to improve some cognitive functions. Deaf signers were found to have a longer spatial memory span than hearing nonsigners (Wilson, Bettger, Niculae, and Klima 1997), but deaf children with no exposure to sign language and hearing children were found to have a similar spatial memory span (Parasnis, Samar, Bettger, and Sathe 1996). Deaf signers are more accurate (McKee 1988) and faster (Emmorey, Kosslyn, and Bellugi 1993) in performing mental rotation skills than hearing nonsigners while deaf nonsigners performed similarly to hearing nonsigners (Chamberlain and Mayberry 1994). Deaf signers between the ages of 6 and 9 years old performed better at every age level than hearing children on a test that involves matching the frontal view of a target face with other views of the same person (Bellugi et al. 1990). Similar results were found in hearing adult signers (Bettger 1992) but not in deaf adult nonsigners (Parasnis et al. 1996). Deaf signers are more accurate than hearing nonsigners in discriminating between faces that were identical except for a change in a single facial feature (McCullough & Emmorey, 1999). Deaf and hearing signers are more accurate than hearing non-signers at remembering locations of faces in a matching pairs task but both groups did not differ in remembering locations of objects (Arnold and Murray 1998).

Psychological tests are designed to be used with hearing individuals and often when they are used with deaf individuals, they measure something other than what the test is intended to measure. This might be why the psychological literature that is based on psychological assessment instruments has shown deaf individuals to have attention and impulse control abilities lower than the norm. Well-controlled experiments have demonstrated that deaf individuals do not necessarily have attentional and impulse control difficulties but their upper level visual perceptual processing is different than that of hearing individuals. Auditory deprivation alone is responsible for some of these changes. As illustrated previously, sign language fluency can cause enhanced attentional, memory, and visual perceptual abilities.

### Psychosocial Factors of Parent–Child Attachment

The diagnosis of a permanent medical condition often is difficult for any parents to accept without emotional distress. The diagnosis of hearing loss is no exception especially since communication difficulties are inherent in the diagnosis. Parents often go through a grieving process (Harvey 2003; Mertens et al. 2000; Schirmer 2001) and their attachment with their child is often different from the norm. There is substantial literature demonstrating that interactions between hearing mothers and their deaf or hard-of-hearing children are less than optimal. The mothers of deaf and hard-of-hearing children tend to be more involved in their childrearing than fathers. This usually includes learning how to communicate with the child. Azar (1995) demonstrated that there are marked differences in 20- to 40-month-old deaf children's relationships with their mothers compared to their fathers. It is crucial for fathers to realize the importance of their active participation in early intervention programs. Azar's study also demonstrated the more parents have a negative attitude toward deafness, the weaker the child's security of attachment.

Hearing mothers of deaf or hard-of-hearing children have been described as more rigid, intrusive, and negative; deaf or hard-of-hearing children of hearing mothers are less active, responsive, and involved compared to dyads in which both members are hearing (Meadow-Orleans 1990; Spencer and Gutfreund 1990). Hearing mother–hearing child dyads have shown more maternal structuring and hearing mother–hearing child nonhostility when compared to hearing mother and deaf or hard-of-hearing child dyads (Pipp-Siegel, Blair, Deas, Pressman, and Yoshinaga-Itano 1998).

Maternal sensitivity is related to gains in language competence in young deaf and hard-of-hearing children (Pressman, Pipp-Siegel, Yoshinaga-Itano, and Deas 1999) and to more broad indices of the affective climate between mothers and deaf and hard-of-hearing children (Greenstein, Greenstein, McConville, and Stellini 1975). Deaf and hard-of-hearing children who have mothers that are sensitive to their needs learn more vocabulary between the ages of 2 and 3 years compared to mothers who were less sensitive to their deaf or hard-of-hearing children's needs (Pressman, Pipp-Siegel, Yoshinaga-Itano, Kubicek, and Erode, 1998). Samuel (1996) found that maternal sign language skills and attitude toward deafness is positively correlated to deaf 15- to 18-year-old adolescents' positive sense of attachment to their mothers. Samuel's study also demonstrated that the deaf adolescents' attachment to parents and close peers predicted the adolescents' self-concept and social adjustment.

Deaf parents' relationship with their deaf or hard-of-hearing children is often dramatically different from that of hearing parents. Many deaf individuals consider being deaf

as a part of their cultural identity rather than as a disability. Genetically deafened parents often go through a similar grieving process and have similar parent–child attachment issues when they have hearing children. In a study of 12- to 40-month-old deaf children of deaf parents, it was found that their ability to develop secure attachment and independence from their parents is the same as that of hearing children (Meadow, Greenberg, and Erting 1984).

### Psychosocial Development

It has long been believed that deafness itself does not necessarily lead to lower self-esteem; it is the quality and quantity of communication the child receives that is positively correlated with self-esteem development (Schlesinger and Meadow 1972). Meadow (1980) claimed that the language delay of children with hearing loss who have hearing parents has a negative impact on their self-esteem and self-concept. Earlier studies have shown that if parents treated the child's hearing loss as a family issue it has a positive effect on the child's self-esteem (Bat-Chava 2002; Schlesinger 1978; Schlesinger and Meadow 1972). This means that the whole family plays an active role in communicating with the child rather than viewing the hearing loss as a deficient characteristic of the child.

In a meta-analytic review of 42 studies on self-esteem in deaf and hard-of-hearing individuals, it was found that deaf children with hearing parents who use sign language have better self-esteem than deaf children who have parents who do not sign (Bat-Chava 1993). A study conducted on adolescents from residential schools for the deaf found a significant positive correlation between the students' self-esteem and parents' signing skills. The students who had parents who did not sign had the lowest self-esteem whereas parents with some signing skills had children with higher self-esteem and those with the best signing skills had children with the highest self-esteem (Desselle 1994). A recent study with a sample of over 1,000 deaf students from Turkey found similar results (Polat 2003). Desselle (1994) found a significant positive relationship between deaf children's self-esteem and their reading achievement.

This meta-analysis (Bat-Chava) also found that deaf individuals have a response similar to that of other minority groups wherein the negative attitudes toward minorities is internalized and hinders development of self-esteem. Cocker and Major (1989) claimed that members of minority groups who identified with their minority group have higher self-esteem than those who do not. In Bat-Chava's (1993) meta-analysis, it was found that this was also true for deaf children; those who identified with deaf adults have higher self-esteem and deaf children born to deaf parents experience a similar upbringing to that of minority children with minority parents. Deaf children of deaf parents were found to have a higher self-esteem than deaf children of hearing parents (Bat-Chava 1993; Hilburn, Marini,

and Slate 1997). However, the meta-analysis revealed that overall, deaf individuals have lower self-esteem compared to hearing individuals. Similar results have been found in studies of the self-esteem of deaf adults who have deaf parents compared to those who have hearing parents (Yachnik 1986).

Later onset of hearing loss has been associated with poor psychosocial adjustment and earlier onset has been associated with greater degree of satisfaction with self (Loeb and Sarigani 1986; Polat 2003). Some studies have found that higher degrees of hearing loss have been associated with higher degree of adjustment problems (Polat 2003), while others have found no differences (Frustenberg and Doyal 1994; Sinkkonen 1994). Literature has shown that the existence of additional disabilities has consistently been associated with more psychosocial and adjustment problems (Mertens 1993 et al; Polat 2003).

### Psychopathology

In the past, many deaf people with poor written, spoken, or signed language skills were in psychiatric institutional care, often with no appropriate communication or formal diagnosis (Denmark 1985, 1994). Studies of adult deaf and hard-of-hearing psychiatric inpatients from the United States and other countries have shown a greater overall prevalence of mental illnesses than the hearing population and longer hospital stays (Vernon and Diagle-King 1999). Deaf children, particularly those from hearing families, may be exposed to an excess of the risk factors that can affect all children and lead to adjustment disorders in adolescence. These factors include academic failure, low self-esteem, inconsistent discipline, failure of age-appropriate development, and sexual and physical abuse. Most of these are secondary to negative attitudes to deafness and failure to develop age-appropriate language fluency (du Feu and Fergusson 2003).

Schlesinger and Meadow (1972) found that 31% of deaf children had mild to severe psychiatric disturbances while the hearing control group had an incidence rate of 9.7%. In a sample of 117 deaf children from ages 5 to 16 years old, Freeman, Malkin, and Hastings (1975) found a prevalence rate of 22% for moderate to severe psychiatric disturbances. They found that those who had psychiatric disturbances also had a higher prevalence of neurological disorders. Based on a study of 62 deaf children 11 to 16 years of age in the United Kingdom, the prevalence of psychiatric disorders was found to be as high as 50.3%. The prevalence was even higher in children in mainstream educational settings than in those attending schools for the deaf (Hindley, Hill, McGuigan, and Kitson 1994).

Fundudis, Kolvin, and Garside (1979) compared deaf, hard-of-hearing, and hearing children and found prevalence rates of psychiatric disturbances to be 54%, 28%, and 18%, respectively. However, Hindley (2000) stated that the degree of hearing loss generally does not appear to be a risk

factor for psychiatric illnesses. Other studies have shown that the deaf and hard-of-hearing groups with higher prevalence of psychiatric disturbances come from dysfunctional families that involved substance abuse, physical abuse, verbal abuse, parent psychiatric difficulties, parent refusal to learn the child's language or communication (Goldberg, Lobb, and Kroll 1975; Powers, Elliott, Patterson, and Shaw 1995) and lower intelligence quotients (Schlesinger and Meadow 1972). Neurological problems associated with the cause of deafness can have disproportionately adverse effects for deaf children; for example, cerebral palsy can limit speech, signing and writing and epilepsy may reduce confidence and increase overprotectiveness from others (du Feu and Fergusson 2003).

Meadow (1980) claimed that behavioral disorders in deaf children occur at a rate three times higher than in hearing children. However, Bond (2000) has stressed that any problem behaviors are not a result of hearing loss per se; but the consequences of other factors such as the environment and the factors mentioned in the psychosocial development section of this chapter. Additionally, there is a higher prevalence of sexual and physical abuse perpetrated upon deaf and hard-of-hearing children and adolescents (Hindley 2000).

A recent large-scale survey of school administrators and teachers of deaf children estimated that approximately 8 to 11% of the deaf population is affected by learning disabilities (Schildroth and Hotto 1996). The actual incidence of learning disabilities might be lower since many deaf and hard-of-hearing children's learning difficulties are secondary to their hearing loss and language delay. It is difficult to differentiate a primary diagnosis of a learning disability from those that are secondary to hearing loss. Such evaluation needs to be conducted by a skilled psychologist who is familiar with and experienced in working with this population. Studies on the incidence of learning disabilities in this population have historically relied on teacher and parent reports rather than comprehensive psychological evaluations by qualified professionals.

There is no evidence for genetic aggregation of hearing loss and attention-deficit/hyperactivity disorder (ADHD), nor is there any evidence that auditory deprivation itself causes ADHD (Parasnis, Samar, and Berent 2003). However, some of the recognized causes of ADHD, such as anoxia and drug toxicity, are also causes of hearing loss (Mauk and Mauk 1992; Samar, Parasnis, and Berent 1998). The incidence of ADHD in hearing individuals has been estimated to be between 3 and 7% (Barkley 1997) and in deaf and hard-of-hearing individuals the incidence ranges from 3.5 to 38.7% with the highest rates of ADHD occurring in children with acquired hearing loss as opposed to hereditary hearing loss (Kelly, Forney, Parker-Fisher, and Jones 1993). The actual incidence of ADHD most likely is lower. It is difficult to survey the actual incidence because the frequent language delays found in this population can cause

restlessness and difficulty following language dialogue in the classroom.

### Psychological Assessment

There is an inherent ethical dilemma involved in the psychological evaluation of a deaf or hard-of-hearing patient (Maller 2003). Test instructions often need to be given in a visual mode (e.g., signing, cueing, or lip reading) or a combination of verbal and visual modalities, depending on which communication mode is most readily accessible to the patient. Almost every time a test is administered to this population, the standard administration procedures are modified and therefore violated (Braden 1994). The use of psychological tests with verbal content has been strongly discouraged when evaluating a patient from this population (Braden 1994; Maller 2003; Vernon and Brown 1964). Psychologists must realize that some non-verbal psychological tests continue to be a problem because they require verbal mediation strategies for correct or rapid responses and many require verbal instructions (Simeonsson, Wax, and White 2001).

Verbal items are often omitted from intelligence batteries and thus the only tests remaining are the non-verbal subtests (Blennerhassett 1990; Moores 1987). This poses a problem because subtests are not equally effective at measuring all aspects of intelligence, and cannot function alone as an appropriate representation of intelligence. The most widely used test with deaf children, the Wechsler Intelligence Scale for Children (WISC-III; Wechsler 1991, Braden and Hannah 1998; Gibbins 1989) has been reported to measure the construct of intelligence differently at the item and factor structure levels with deaf children (Maller 1999; Maller and Ferron 1997). Other intelligence batteries also have some validity issues (Maller 2003, Simeonsson, Wax, and White 2001). Deaf children are often misdiagnosed as mentally retarded or learning disabled when assessed by psychologists unfamiliar with the issues of intelligence testing in this population (Vernon and Andrews 1990).

There are not enough validated tests designed for the deaf and hard-of-hearing client that can be administered without modification. This ethical dilemma forces the psychologist to leave the safety of relying on each test's psychometric soundness and to rely more on clinical skills and judgment while taking into consideration the factors that might be affecting clients and their test scores. The psychological assessment of deaf and hard-of-hearing clients requires relatively more reliance on knowledge and qualitative data obtained through observations, to support clinical hypotheses, diagnoses, and recommendations. Psychiatrists who refer their patients for a psychological evaluation should seek psychologists who are familiar with the empirical literature and test modifications that are necessary to provide a valid evaluation of deaf and hard-of-hearing children and adolescents' psychological functioning.

### Psychopharmacologic Interventions

There is surprisingly little literature reporting pharmacotherapy of mental disorders in children with deafness. Case reports exist for the use of various medications to treat maladaptive behaviors, for example, self-injury and aggression, in individuals with developmental disorders such as congenital rubella syndrome.

As is the case for children with blindness, concerns about medication side effects need to be firmly on the radar screen of the prescriber. Drugs that may affect visual acuity, for example, may be particularly disconcerting in persons who must rely on their vision for communication (Roberts and Hindley 1999). Similarly, medication-induced extrapyramidal symptoms carry obvious additional significance.

For those individuals whose deafness was the result of ototoxic drugs, the clinician may have to take extra care to explore a family's willingness to consider medication treatment given a likely bias against such intervention.

### Psychotherapeutic Interventions

After the initial diagnosis of hearing loss, hearing parents of deaf and hard-of-hearing children often would benefit from psychotherapy to avoid psychopathological changes in the parent-child attachment. Family therapy is often beneficial because having a deaf or hard-of-hearing child frequently changes the family dynamics. In family therapy, it may be necessary to use an interpreter if the deaf or hard-of-hearing child or adolescent is most fluent in a signed language and the patient's family is not fluent in that language (ASL) or communication mode (cued or signed English) (Harvey 1984, 2003). The family therapist should also be knowledgeable about the family dynamics of having a deaf or hard-of-hearing child. In the case where a deaf or hard-of-hearing patient needs therapeutic intervention, it is necessary to seek a mental health professional who specializes in working with this unique population (Harvey 2003; Leigh, Corbett, Gutman, and Morere 1996; Sussman and Brauer 1999).

The use of mental health professionals who are not familiar with this population could lead to misdiagnosis and mistreatment. As previously mentioned, there are psychosocial, language, and cognitive factors that make this population different from hearing children and adolescents. It is also important for the patient to work with a mental health professional who can communicate directly with the patient. The use of sign language interpreters has a direct impact on the individual therapeutic process (Leigh et al. 1996). Therapists who have used interpreters acknowledge that it dilutes and distorts the patient-therapist relationship (Wohl 1995). There is an additional challenge of using interpreters with deaf or hard-of-hearing children because the patient would be looking at the interpreter, not the therapist (Sussman and Brauer 1999). There are

additional problems when working with younger children who are not familiar with using interpreters.

The literature has shown that various psychotherapeutic approaches can be used to successfully treat deaf or hard-of-hearing children. These include psychoanalytic and insight-oriented therapies (Levin 1981; Rayson 1985) as well as humanistic oriented therapies, Adlerian therapy, cognitive therapy, and rational-emotive therapy (Anderson and Watson 1985; Gough 1990; Sussman 1988). The type of approach that would be best for any patient (hearing, hard-of-hearing, or deaf) would depend on their psychopathology, not their hearing status. Psychiatrists and parents usually do not have the flexibility to choose between a variety of approaches and professionals. Instead, they usually have to choose the mental health professional who specializes in working with this population. Sometimes, this means traveling long distances for such treatment.

If there are no professionals that specialize in this population, then it is necessary to accept the second best alternative which would be working with a mental health professional (with interpreting services if necessary) who does not have any experience working with this population. One common mistake made by therapists who are not familiar with treating deaf and hard-of-hearing children is that they often automatically assume that the core problem with the patient's psychopathology has something to do with their hearing loss. It is possible that a patient's hearing loss might be exacerbating their psychopathology but the patient's hearing loss often is not the primary problem.

It is important for professionals who work with deaf and hard-of-hearing individuals to realize that they are not only dealing with a disability group, but also a group that has a different lifestyle. There is a continuum within the deaf and hard-of-hearing community between those who identify with deaf culture and those who do not. Regardless of their cultural identification, there are similar psychosocial issues shared by members of this community. Literature on psychotherapy with cultural minorities is more relevant to this community than literature on disability groups. It is necessary for mental health professionals to provide culturally affirmative psychotherapy (Glickman 1996) when treating individuals from this community.

## Conclusions

As with visual impairment, research in the neurobiology of hearing loss has contributed much to our understanding of basic brain function. Significant advances in molecular genetics have informed our understanding of the physiology of hearing. Neuropsychological studies will continue to look to individuals with deafness to better understand language and personality development. Deafness does not protect from psychiatric disorders, but recent work may place the prevalence closer to that for the general population than once believed. Considerable work remains with respect to characterizing specific psychiatric treatments in

this population, but individualized treatment approaches that are culturally sensitive are always indicated.

## **BASAL GANGLIA**

The basal ganglia are a group of gray matter structures symmetrically placed in a deep paracentral location within the brain. The chief nuclei of the basal ganglia are the striatum and the pallidum (1, 2). The terms “striatum” and “neostriatum” refer to the caudate and putamen. The term “dorsal striatum” refers to most of the caudate and putamen, while the term “ventral striatum” refers to the ventral parts of the caudate and putamen, the nucleus accumbens septi, and the striatal part of the olfactory tubercle. The terms “pallidum” and “paleostriatum” refer to globus pallidus (composed of the globus pallidus interna and globus pallidus externa). The term “corpus striatum” refers to the caudate, putamen, and globus pallidus. The putamen and globus pallidus together compose the “lentiform nucleus.” The term “extrapyramidal system” refers to the basal ganglia and an array of subcortical structures and brainstem nuclei (red nucleus, subthalamic nucleus, substantia nigra pars compacta, and substantia nigra pars reticulata, reticular formation, and portions of the ventral tier thalamic nuclei) to which they are connected (Fig. 21.1).

### **Neurotransmitters in the Basal Ganglia**

Dopamine is widely distributed throughout the brain, but over 80% of this neurotransmitter located in the brain is concentrated in the striatum (3). Besides the nigrostriatal pathway, other dopamine-containing pathways include the mesolimbic (from the medial portion of the substantia nigra pars compacta and ventral tegmental area to the ventral striatum, rostral caudate nucleus, the olfactory tubercle, and the amygdaloid nucleus), the mesocortical (from the medial portion of the substantia nigra pars compacta and ventral tegmental area to the prefrontal and the cingulate cortex), the tuberoinfundibular, and the hypothalamo-spinal pathways.

Five distinct receptors for dopamine (D1 to D5) have been cloned (3). The D1 family is composed of D1 and D5 receptors, and the D2 family of D2, D3, and D4 receptors. The various dopamine receptor subtypes are distributed in different parts of the brain and subserve distinct functions (Table 21.1). The D1 and D2 receptors are found mainly in the striatum and mediate dopamine signals involved in motor control. Presynaptic dopamine receptors, known as autoreceptors, are of the D2 subtype and provide feedback inhibition of dopamine synthesis and dopaminergic neuron firing when stimulated by the release of the neurotransmitter from the presynaptic nerve terminal. The D3 receptors are abundant in limbic connections. The D4 receptors are also found in the frontal cortex and seem to play a role in behavior. The atypical antipsychotic clozapine blocks D4 receptors but has low affinity for D2 receptors, accounting for its very low potential to cause parkinsonism. D5 receptors are located throughout the cortex, thalamus, and striatum.

Glutamate is the predominant excitatory neurotransmitter of the basal ganglia. The main output pathways of the basal ganglia involve gamma-aminobutyric acid (GABA). Acetylcholine is present in the striatal interneurons. There are also noradrenergic inputs from the locus coeruleus and serotonergic inputs from the raphe nucleus to the basal ganglia. Many more neuropeptides and neuromodulators, whose functions are largely unknown, are found in the basal ganglia (3).

### **Functional Anatomy**

Frontal-subcortical circuits mediate motor activity, eye movements, cognition, behavior, and limbic function (4). Their interconnections represent parallel reentrant circuits that convey information from different regions of the cortex, through the basal ganglia and then via the thalamus back to the cortex. These circuits have been named according to their

function or cortical site of origin: the motor circuit, the oculomotor circuit originating in the frontal eye fields, the dorsolateral prefrontal and lateral orbitofrontal (cognition and behavior), and anterior cingulate (limbic) circuits (Fig. 21.2). Within these circuits, information flows through two parallel (direct and indirect) pathways whose balance of

activity is critical for normal function. The putamen is the predominant striatal structure for the motor circuit; caudate for the oculomotor, dorsolateral prefrontal, and lateral orbitofrontal circuits; and the ventral striatum for the limbic circuit. The striatum can be further subdivided into neurochemically distinct compartments known as striosomes and

matrix (1, 2). Striosomes form branched three-dimensional labyrinths that constitute only 10 to 20% of the striatum and are mainly present in the head of the caudate. They stain for acetylcholinesterase and have higher levels of mu opioid receptors, D<sub>1</sub> dopamine receptors, and the neuropeptides Substance P and dynorphin. Striosomal neurons communicate with substantia nigra pars compacta and the limbic regions. The matrix, on the other hand, gives rise to the direct and indirect striatal output pathways and receives corticostriatal inputs from sensory cortices, motor and premotor areas, and association cortex as well as thalamic input.

The frontal-subcortical motor circuit (Fig. 21.3) originates in primary motor, supplementary motor, and primary sensory cortices. The excitatory glutamatergic corticostriatal pathway mainly terminates on the heads of the dendritic spines of the medium spiny neurons, whereas the dense dopaminergic input from the substantia nigra pars compacta terminates principally on the shafts of the spines, thus modulating the effect of cortical inputs. The medium spiny neurons constitute about 95% of the striatal neurons and send GABAergic projections to globus pallidus externa and globus pallidus interna/substantia nigra pars reticulata. The remaining striatal neurons (interneurons) are restricted to the striatum and include large aspiny cholinergic cells, among others. The cholinergic interneurons in the striatum synapse on the soma and the shafts of the dendrites of the medium spiny neurons and exert an opposite effect to dopamine in terms of modulation of the glutamatergic corticostriatal input, which probably constitutes the basis of anticholinergic treatment in Parkinson's disease. The neurons projecting to the globus pallidus interna/substantia nigra pars reticulata (*direct*

pathway) express Substance P and dynorphin and predominantly have D<sub>1</sub> receptors, which activate the synthesis of cyclic adenosine monophosphate when stimulated by dopamine. Thus, stimulation of D<sub>1</sub> receptors is "excitatory" and increases the inhibitory output to the globus pallidus interna/substantia nigra pars reticulata. The *indirect* pathway originates from the medium spiny neurons that express the neuropeptide enkephalin and have a preponderance of D<sub>2</sub> receptors, which are "inhibitory." This pathway is completed by an inhibitory GABAergic projection from the globus pallidus externa to the subthalamic nucleus, and an excitatory, glutamatergic projection from the subthalamic nucleus to the globus pallidus interna/substantia nigra pars reticulata. Thus, dopamine stimulation of the indirect pathway leads to a reduction in the excitatory drive from the subthalamic nucleus to the globus pallidus interna/substantia nigra pars reticulata through double inhibition. Dopaminergic stimulation provides a positive feedback for cortically initiated movements via the direct pathway and a negative feedback for undesired movement. The relative balance of activity in the direct and indirect pathways regulates the inhibitory output from globus pallidus interna/substantia nigra pars reticulata to the ventral thalamus. Thus, one important mechanism by which the basal ganglia exert motor control is by determining the level of excitatory activity of the thalamus on the motor cortex at the origin of the pyramidal (corticospinal) system.

Despite its highly simplified nature and its serious shortcomings, this model of basal ganglia function (5) has fostered the formulation of hypotheses for the study of movement disorders and provided an important rationale

## FRONTAL-SUBCORTICAL CIRCUITS (BASAL GANGLIA LOOPS)

**Figure 21.3** Basal ganglia loops. DA, dopamine; SNC(R), substantia nigra pars compacta (reticulata); GPE(I), globus pallidus externa (interna); STN, subthalamic nucleus; CM, centromedian; PF, parafascicular; VL(A), ventral lateral (anterior) nuclei of thalamus; SC, superior colliculus; s, striosome; m, matrix; DA, dopamine; 5HT, serotonin; NA, noradrenaline; LC, locus ceruleus; RN, Raphe nucleus; VTA, ventral tegmental area; Cing, cingulate; cx, cortex. for the successful revival of surgical treatment for Parkinson's disease. In Parkinson's disease, loss of dopaminergic innervation of the striatum decreases the activity of the direct pathway, reducing the inhibition of the globus pallidus pars interna and substantia nigra pars reticulata. At the same time, activity in the indirect pathway is augmented, leading to increased excitatory input to the globus pallidus pars interna/substantia nigra pars reticulata from subthalamic nucleus. Together, these effects produce strong inhibition of the ventral thalamus and reduced excitation of motor cortex. As predicted by this model, surgical procedures that impair the function of globus pallidus pars interna and subthalamic nucleus improve parkinsonian symptoms such as bradykinesia and rigidity. Pathologic lesions of the subthalamic nucleus such as an infarction markedly increase motor activity, leading to ballismus, while surgical intervention in this structure utilizing deep brain stimulation seldom results in this abnormal movement. In adult-onset Huntington's disease, the enkephalinergic striatal projection neurons are more vulnerable to degeneration, causing severe impairment of the indirect pathway, with relative preservation of the direct pathway. This leads to unopposed inhibition of globus pallidus pars

interna/substantia nigra pars reticulata and increased motor output, a possible basis for chorea.

With regard to psychiatric disorders, such as Tourette's syndrome, obsessive-compulsive disorder (OCD), schizophrenia, and attention deficit hyperactivity disorder (ADHD) (6), dysfunction of the basal ganglia leads to a disruption of cognitive control and impaired inhibition of competing inappropriate thoughts and behaviors. OCD is thought to be associated with abnormal activation of striosomes, the compartment that is preferentially connected with the orbitofrontal and anterior cingulate cortex (7).

## HYPOKINETIC MOVEMENT DISORDERS

### Juvenile Parkinsonism

Juvenile parkinsonism, a heterogeneous entity, is clinically and pathologically distinct from young-onset Parkinson's disease (8). In addition to cardinal features of parkinsonism (rest tremor, bradykinesia, rigidity), many patients with juvenile parkinsonism have one or more atypical features including ophthalmoparesis, seizures, and dementia leading

to a diagnosis of one of the childhood encephalopathies. Some have identifiable causes such as drug toxicity, encephalitis, or tumors leading to the diagnosis of secondary parkinsonism. The secondary and hereditary/metabolic causes of juvenile parkinsonism show great overlap with childhood dystonias (Table 21.2).

Mutations of the parkin gene on chromosome 6q25–27, which codes for a ubiquitin ligase, are the most common cause of autosomal recessive juvenile parkinsonism across many different ethnic groups (9). In autosomal recessive juvenile parkinsonism related to the parkin mutations, classic parkinsonism is usually accompanied by foot dystonia, hyperreflexia, a good response to levodopa, and the early appearance of levodopa-induced dyskinesias (9). Lewy bodies are generally absent in this disorder. In chil-

dren and adolescents, autosomal recessive juvenile parkinsonism associated with the parkin mutation, self-mutilation, anorexia nervosa, depression, and suicidality has been described (13).

A mutation on the DJ-1 gene has been identified as another cause of autosomal recessive parkinsonism, albeit with a slightly older age of onset (10). Anxiety disorder is commonly associated with this form of parkinsonism (11).

The treatment of juvenile parkinsonism, similar to that used for idiopathic Parkinson's disease, is predominantly centered on preparations of levodopa combined with a peripheral DOPA decarboxylase inhibitor such as carbidopa or benzeraside to increase bioavailability and decrease peripheral side effects. Adjunctive therapies include catecholamine-O-methyl transferase (COMT) inhibitors

**TABLE 21.2**  
**ETIOLOGIC CLASSIFICATION OF DYSTONIA**

### 1. Primary (Idiopathic)

- a. *DYT1 dystonia*: Oppenheim's dystonia, dystonia musculorum deformans
- b. *Other DYT dystonias*
- c. *Sporadic*: Usually adult-onset and focal

### 2. Dystonia Plus

- a. Dystonia with parkinsonism
  - i. Dopa-responsive dystonia (DYT5)
  - ii. Dopamine agonist-responsive dystonia
  - iii. Rapid-onset dystonia-parkinsonism (DYT12)
- b. Myoclonus-dystonia syndrome (DYT11)

### 3. Secondary Dystonia

- a. *Drug-induced*: Neuroleptic induced (acute, tardive), anticonvulsants, levodopa
- b. *Toxic*: Manganese, carbon monoxide, carbon disulfide, cyanide, methanol, 3-nitropropionic acid
- c. *Infectious*: Viral encephalitis, postinfectious, Reye's syndrome, subacute sclerosing leukoencephalopathy, wasp sting encephalopathy, HIV
- d. *Focal central nervous system lesions*: Trauma, stroke, arteriovenous malformation, tumor affecting the basal ganglia, thalamus, cortex, brainstem or spinal cord
- e. *Physical causes*: Hypoxia, perinatal cerebral injury, electric shock, peripheral injury
- f. *Autoimmune*: Multiple sclerosis, antiphospholipid syndrome, Sjogren syndrome
- g. *Metabolic*: Hypoparathyroidism
- h. *Psychogenic*

### 4. Heredodegenerative Disorders

- a. *Autosomal dominant*: Juvenile Parkinson's disease, Huntington's disease (Westfahl variant), Machado-Joseph disease (SCA3), Dentatorubro-pallidoluysian atrophy, other spinocerebellar degenerations
- b. *Autosomal recessive*: Wilson's disease, Niemann-Pick type C, juvenile neuronal ceroid-lipofuscinosis (Batten's disease), GM1 and GM2 gangliosidosis, metachromatic leukodystrophy, Lesch-Nyhan syndrome, homocystinuria, glutaric acidemia, Hartnup's disease, ataxia telangiectasia, aeuodegeneration with iron accumulation (formerly Hallervorden-Spatz syndrome), neuroacanthocytosis
- c. *X-linked recessive*: Lubag (dystonia-parkinsonism), deafness-dystonia syndrome (Mohr-Tranebjaerg syndrome)
- d. *X-linked dominant*: Rett's syndrome
- e. *Mitochondrial*: Leigh's disease, Leber's disease, deafness-dystonia-retardation-blindness syndrome

such as entacapone to prolong the effect of levodopa, dopamine agonists such as pramipexole, ropinirole, pergolide, or bromocriptine, anticholinergics (benztropine mesylate or trihexyphenidil) MAO-B inhibitors such as selegiline, and amantadine, an adenosine 2B type glutamate receptor inhibitor. In many instances, initial therapy with an agonist rather than levodopa is used in this patient group to forestall the development of dyskinesias and offer the putative benefit of neuroprotection (12). Some patients with parkin-related juvenile parkinsonism are remarkably responsive to anticholinergic drugs (13).

## HYPERKINETIC MOVEMENT DISORDERS

### Tremor

*Tremor* is a rhythmic, alternating movement of a body part. It can be described by its frequency and amplitude, as well as by the circumstances under which it occurs. Resting tremor (e.g., Parkinson's disease) occurs in a body part in complete repose, postural tremor when the involved body part is being maintained in position against gravity (e.g., essential tremor, enhanced physiologic tremor), and kinetic tremor when the affected limb or body part is in motion (e.g., essential tremor, cerebellar tremor). When a single position or a specific activity causes tremor, the terms "position-specific" and "task-specific" tremor are used.

### Physiologic Tremor

Physiologic tremor is present in all individuals at all ages but under normal circumstances it is not apparent and is not associated with disability. Circumstances such as anxiety, fatigue, hypoglycemia, hyperthyroidism, alcohol withdrawal, or drug effects (e.g., adrenergic agents, stimulants) can result in enhanced physiologic tremor, which is clearly visible and potentially disabling.

### Essential Tremor

Essential tremor, an autosomal dominant trait, is the most common movement disorder seen in clinical practice. No structural or cellular abnormalities responsible for essential tremor have been identified, but functional imaging studies suggest increased reverberations in the olivocerebellar circuits that can be enhanced or suppressed by reflex pathways. Approximately 5% of all new essential tremor cases arise during the first two decades of life, as early as age 2 years. Most cases emerge during late childhood and adolescence with a male predominance (14). It virtually always presents with a gradual onset, postural, distal upper extremity 4 to 12 Hz tremor and may occasionally affect the head or the voice.

Essential tremor should be treated when it results in functional disability or social embarrassment. In most cases of childhood essential tremor, no pharmacologic

therapy is recommended (14), in part because of the side effect profile of antitremor medications and their modest efficacy in most cases. Primidone and propranolol are the two first-line drugs in the treatment of essential tremor. Benzodiazepines and gabapentin offer a modest benefit, and topiramate has shown some promise for this condition (15). Drug-resistant essential tremor in adults can be treated with surgical interventions including thalamotomy and thalamic deep brain stimulation of the ventral intermediate nucleus of the thalamus. Thalamic deep brain stimulation has been successfully performed in children for indications such as severe chorea or dystonia, but to our knowledge it has not been performed in the pediatric age group for essential tremor.

### Dystonia

*Dystonia* is a sustained abnormal movement that is much slower than chorea and often has a twisting appearance due to abnormal cocontraction of agonist and antagonist muscles. When severe or chronic, dystonia may lead to a relatively fixed position of the involved body parts, resulting in a characteristic posture. When patients voluntarily attempt to move the involved part in the direction opposite to a dystonic movement, a rhythmic or arrhythmic oscillation may develop during this "tug of war" resulting in a dystonic tremor. Dystonia that is worsened during attempted voluntary movement is referred to as action dystonia. Dystonia can be described by the body parts or regions that are involved. Focal dystonia refers to the involvement of an isolated body part such as a hand, while segmental dystonia implies that adjacent body parts such as the neck and arm are affected, and generalized dystonia indicates involvement of limbs bilaterally or one limb and a nonadjacent body part.

Dystonic movements increase with fatigue and stress and improve with relaxation, hypnosis, and sleep. Most patients discover that they can reduce dystonic muscle contractions by using tactile or proprioceptive stimuli such as touching the involved or an adjacent body part. These maneuvers are known as "sensory tricks."

Some children and adolescents may experience a sudden marked increase in the severity of dystonia, which can lead to rhabdomyolysis and myoglobinuria. These episodes are known as a dystonic storm or status dystonicus and require treatment in an intensive care unit due to the risk of renal failure and death (16).

A detailed etiological classification of dystonia is presented in Table 21.2. In primary (idiopathic) dystonia, there are no other systemic and neurologic abnormalities except for tremor, and there is no identifiable exogenous cause or other inherited/degenerative disease. In dystonia-plus, other neurologic signs such as parkinsonism or myoclonus may occur; however, these disorders are of neurochemical nature and unassociated with apparent neurodegeneration. Secondary dystonia is due to acquired/exogenous causes. Heredodegenerative disorders are caused by a genetic

abnormality and are typically associated with morphological brain changes.

Primary dystonia results from a functional disturbance of the basal ganglia, particularly in the striatal control of the globus pallidus (and substantia nigra pars reticulata), causing altered thalamic control of cortical motor planning and executive function, as well as abnormal regulation of brainstem and spinal cord inhibitory interneuronal mechanisms (17).

In a child with typical primary dystonia, diagnostic evaluation can be started with DYT1 DNA testing after genetic counseling is obtained, followed by a levodopa trial if DYT1 is ruled out. If the patient does not respond to levodopa, serum ceruloplasmin and slit-lamp examination for Keyser-Fleischer ring should be obtained to rule out Wilson's disease. If history and examination suggest a structural lesion, neuroimaging with brain magnetic resonance imaging (MRI) should be obtained. If history and examination suggest other metabolic or inherited disorders, genetic testing, lactate/pyruvate, serum and urinary amino acids in, urine organic acids, cerebrospinal fluid analysis, electromyography/nerve conduction velocities, electroencephalogram, red blood cell smear for acanthocytes, antiphospholipid antibody, lysosomal analysis, alpha-fetoprotein, biopsies of skin, muscle, nerve, or bone marrow should be considered as guided by the clinical clues.

### **DYT1 Dystonia**

DYT1 dystonia (primary torsion dystonia, dystonia musculorum deformans, Oppenheim's dystonia) is an autosomal dominant disease with a penetrance rate of 30 to 40%. A guanine-adenine-guanine (GAG) deletion in the gene coding for Torsin A, a protein of unknown function, on chromosome 9q34, accounts for ~90% of childhood-onset limb dystonia in those of Ashkenazi Jewish descent and approximately 40 to 60% of early-onset limb dystonia in the non-Jewish population (18).

DYT1 dystonia starts at a relatively young age, with an average age of onset around 12 years. In the great majority of cases, the disorder affects a limb first, but craniocervical or axial onset may also be the initial sign. Cases with lower extremity onset usually present at a younger age and, over time, tend to generalize (16). Psychiatric disorders have been reported to be associated with DYT1, particularly major depressive disorder. Heiman et al. reported on a large sample of individuals with the DYT1 mutation, contrasting manifesting carriers, symptomatic carriers, and noncarriers. In comparison to noncarriers (who shared many of the same environmental and psychosocial factors) the risk for recurrent major depression was three times as high in carriers, regardless of whether they had motor signs or not. The increased risk was quite specific for recurrent major depressive disorder, and did not include other affective disorders such as bipolar disorder, single episode major depressive disorder, or any combination of mood disorders (16a). Carriers of the DYT1 gene also have subtle deficits in learn-

ing sequences, although they do not differ from controls in terms of motor accuracy or timing. Positron emission tomography (PET) study revealed increased activation in the left premotor cortex and right supplementary motor area, with reduction in the posterior medial cerebellum (16b).

### **Dystonia-Plus Syndromes**

#### **Dopa-Responsive Dystonia (DYT5)**

Dopa-responsive dystonia presents in mid-childhood with dystonia affecting the gait, hyperreflexia, and parkinsonism signs (19) that show a dramatic and sustained response to low-dosage levodopa without emergence of motor fluctuations (16). Patients progressively worsen throughout the day, becoming more dystonic and parkinsonian by evening, but improve the next morning after overnight sleep. Dopa-responsive dystonia is an autosomal disorder with marked phenotypic heterogeneity (20), affecting females more than males with gender-related incomplete penetrance.

Mutations in the guanosine triphosphate (GTP) cyclohydrolase I gene on chromosome 14q22.1–q22.2 that codes for a cofactor of tyrosine hydroxylase account for many cases of dopa-responsive dystonia (21). These mutations are heterogeneous and may also affect other genes involved in dopamine synthesis (22). Approximately 40 to 50% of patients with Dopa-responsive dystonia have no known mutations (23).

Aromatic L-amino acid decarboxylase deficiency, also known as dopamine agonist-responsive dystonia, is characterized by reduced metabolism of 3,4-dihydroxyphenylalanine (DOPA) to dopamine and 5-hydroxytryptophan to serotonin (24). This autosomal recessive disorder begins in infancy with dystonia-parkinsonism, hypotonia, hyperhidrosis, miosis, and ptosis, as well as episodes of oculogyria and paroxysmal movements. Diurnal fluctuations with sleep benefit is present in 50% of cases.

#### **Myoclonus-Dystonia Syndrome (DYT11)**

Autosomal dominant myoclonus-dystonia syndrome, perhaps the same disorder as essential myoclonus (25), is caused by mutations in the  $\epsilon$ -sarcoglycan gene on chromosome 7q21 (26). It may start at any age and primarily affects the upper body with alcohol-responsive myoclonus. It progresses slowly and then tends to plateau (25). There is also a sporadic form of this condition that is not associated with mutations in the  $\epsilon$ -sarcoglycan gene (27).

#### **Rapid-Onset Dystonia-Parkinsonism (DYT12)**

Rapid-onset dystonia-parkinsonism is an autosomal dominant disorder mapped to chromosome 19q13 (28) and characterized by sudden onset of dystonia and parkinsonism during adolescence or early adulthood. The symptoms evolve over hours or days and generally stabilize within a few weeks, with slow or no subsequent progression. There is little or no response to levodopa. The concentration of homovanillic acid in the cerebrospinal fluid is low in patients with rapid-onset dystonia-parkinsonism and in some

carriers (29), but PET studies indicate no loss of presynaptic dopaminergic nerve terminals (30).

### **Heredodegenerative Dystonia**

#### **Niemann-Pick Type C**

Niemann-Pick type C (juvenile dystonic lipidosis) is a rare neurovisceral disorder that is clinically and genetically heterogeneous (31). The disorder typically presents in late childhood and culminates in death in the second decade, but some cases start in the neonatal period and some with adult-onset have been reported. Characteristic clinical signs are hepatosplenomegaly and vertical supranuclear gaze palsy, usually accompanied by neonatal jaundice, dystonia, ataxia, or seizures. Foam cells in the bone marrow are characteristic but not pathognomonic. A decreased rate of cholesterol esterification in skin fibroblasts and abundant staining of free, lysosomal cholesterol by filipin are diagnostic (32). The translocation of low-density lipoprotein-derived cholesterol from lysosomes to the endoplasmic reticulum and the Golgi apparatus is impaired due to mutations in the Niemann-Pick type C1 gene on chromosome 18q11–12, which codes for a transmembrane pump (33) in the vast majority of cases. Mutations in the Niemann-Pick type C2 gene encoding for a lysosomal protein (HE2) with cholesterol-binding properties (34) account for the rest. Niemann-Pick type C1 and Niemann-Pick type C2 cannot be differentiated clinically or histochemically.

#### **Mitochondrial Disorders**

Leigh syndrome is caused by defects in mitochondrial respiratory chain enzymes such as cytochrome C oxidase (COX), pyruvate dehydrogenase complex, Complex I, Complex II, and biotinidase (35, 36). It presents during childhood or early adolescence and causes widespread neurological dysfunction, including ataxia, spasticity, optic atrophy, developmental delay, psychomotor retardation, and psychiatric manifestations. Dystonia, although rarely a presenting sign, is the most common (86%) movement disorder, followed by parkinsonism, tremor, chorea, athetosis, myoclonus, and tics (37, 38). The diagnosis is supported by serum lactic acidosis and necrotic lesions in the basal ganglia on neuroimaging studies (38). Ragged red fibers on muscle biopsy, mutations on mitochondrial DNA analysis, defective oxidative phosphorylation on phosphorus magnetic resonance spectroscopy of muscle, and elevated cerebrospinal fluid lactate are useful ancillary tests. There is no specific treatment.

#### **Amino Acid Disorders**

Glutaric acidemia, type I (39), is an autosomal recessive condition caused by deficiency of glutaryl-CoA dehydrogenase (GCDH). The gene, glutaryl-CoA dehydrogenase has been mapped to 19p13.2 (39a).

It usually presents at some point between age 6 and 18 months with hypotonia and associated loss of head control, followed by progressive dystonia (opisthotonic posturing, facial grimacing, tongue thrusting, and limb dys-

tonia) with relative preservation of intellect. Macrocephaly is a common finding. Metabolic stress such as fever and viral illness may lead to a dystonic storm that may be accompanied by encephalopathy and ketosis. The encephalopathy results in striatal necrosis primarily affecting medium spiny neurons (39b). Glutaric acid concentration is increased in the blood, urine, and CSF. The presence of 3-hydroxyglutaric acid in urine is a unique finding. Deficient glutaryl-CoA dehydrogenase activity in cultured skin fibroblasts confirms the diagnosis. Dietary restriction of glutarigenic amino acids (lysine, tryptophan, and hydroxylysine), L-carnitine, and riboflavin is recommended as a therapeutic measure. Propionic acidemia (40) and methylmalonic acidemia may also cause similar basal ganglia dysfunction and dystonia or chorea (41).

### **Secondary Dystonia**

#### **Acute Dystonic Reactions**

Acute dystonic reactions typically involve the muscles of the mouth, face, eyes, and neck with resultant combinations of retrocollis, trismus, tongue protrusion, and upward or lateral deviation of the eyes. They occur after exposure to dopamine receptor blocking agents including neuroleptic agents such as haloperidol and antiemetic agents such as prochlorperazine. Acute dystonic reactions occur in over 50% of cases within the first day after exposure to dopamine receptor blocking agents and approximately 90% within 5 days (42). The atypical neuroleptic agents are generally associated with a lower incidence of acute dystonic reactions. Risk factors include young age, male gender, a primary psychotic disorder, and prior dystonic reactions. The risk of acute dystonic reactions may be greater after administration of very potent dopamine receptor blocking agents such as haloperidol or discontinuance of a concurrently administered anticholinergic drug.

The treatment of acute dystonic reactions is parenteral intravenous diphenhydramine or benztropine. A second-line, but usually effective therapy is intravenous diazepam. The impressive immediate response to these therapies helps confirm the diagnosis as well. After acute resolution of symptoms, it is wise to continue oral anticholinergic agents for 2 weeks, especially if a long-acting dopamine receptor blocking agent was used or if dopamine receptor blocking agent therapy will need to be continued.

#### **Posttraumatic Dystonia**

Dystonia can occur after significant craniocerebral trauma resulting in thalamic or basal ganglia lesions (16, 43). Dystonia can appear after head trauma within a few days of the insult, but is more commonly delayed, sometimes as long as several years. Once established, the dystonic movements may progress over a period of years. Injury at a young age is associated with a longer latency to onset of subsequent movement disorder, a greater tendency to development of generalized dystonia, and a greater probability of altered handedness, perhaps due to age-related neuroplasticity

(43). The delayed appearance of dystonia can be due to resolution of hemiparesis or aberrant neural connections. Focal dystonia and hemidystonia are the most common clinical patterns seen in these patients.

### Treatment of Dystonia

The symptomatic treatment of dystonia is often difficult and characterized by incomplete responses. Dystonia may be greatly improved by the treatment of specific underlying causes such as the dramatic response of dopamine responsive dystonia to low doses of levodopa. In this regard, a trial of levodopa is recommended for all children with primary dystonia. The anticholinergic medication trihexyphenidyl has been used with good success in some patients with dystonia, but high doses (30 to 60 mg/day or more) are often required to obtain maximum benefit (44). The most common side effects are dry mouth, constipation, decreased concentration, and blurred vision. If there is inadequate benefit from levodopa or trihexyphenidyl, baclofen alone or in combination with trihexyphenidyl may be beneficial (45). The most common side effect of baclofen is sedation. Benzodiazepines may also be beneficial, but often the benefit is limited by side effects or tolerance. Botulinum toxin injections may be highly effective, especially if impairment or disability is attributable to a few muscle groups. An intrathecal baclofen pump can be tried for severe primary or secondary dystonia that is refractory to medications. However, success is not universal, there are potentially serious side effects, and maintenance can be difficult (46). Stereotaxic surgery (pallidotomy or pallidal deep brain stimulation) has been used with increasing success for a select group of patients, especially those with primary dystonia (47–49), but it should still be considered investigational (50). Some patients with secondary dystonia may be more responsive to thalamic stimulation (51).

### Chorea

*Chorea* is characterized by arrhythmic, nonstereotypic, rapid and distally predominant flinging movements that randomly flow from one body part to another. In pure chorea, there is no sustained quality to any of these rapid movements, as is usually the case in Sydenham's chorea. In other forms of chorea, such as that often seen in Huntington's disease or levodopa-induced dyskinesia, there is a slower, slightly sustained component to the movement, described as choreoathetosis. When this slowing results in still more prominent sustained postures superimposed on chorea, the term "choreodystonia" is used. Ballism is considered by most authorities to be a severe form of chorea in which larger amplitude movements are seen with a predilection for proximal portions of the limbs. When chorea or ballism involve only one side of the body, the terms "hemichorea" and "hemiballism" are used. Chorea can be caused by disorders of the basal ganglia that are inherited, autoimmune, infectious, metabolic, toxic, traumatic, or neoplastic.

### Huntington's Disease

Huntington's disease is an autosomal dominant condition caused by a cytosine-adenine-guanine (CAG) trinucleotide expansion mutation on chromosome 4 in the gene coding for huntington, a protein of unknown function. The Huntington's disease phenotype is not always penetrant for repeat sizes of 36 to 39, but is fully penetrant for alleles with repeats of 40 or more (52). Although Huntington's disease can begin in adolescence or even earlier in childhood, or as late as age 70, most affected individuals begin to manifest clinical signs of the illness during the third or fourth decade of life. Longer repeat lengths appear to correlate with earlier onset and more rapid disease progression (53). The phenomenon of progressively earlier onset in successive generations of affected individuals, known as anticipation, is felt to be due to a further increase in CAG repeat length during meiosis, especially when the gene has been paternally inherited (54), as seen in up to 80% of juvenile-onset Huntington's disease (55).

In addition to chorea, motor impersistence (inability to sustain tongue protrusion or apply a continuous grip to the examiner's fingers) and a dancing-type gait with poor balance are common. With progression of the illness, chorea may become less prominent and be replaced by rigidity and dystonia. Abnormalities of ocular motility including slowed saccades, jerky pursuit, and impaired ability to initiate rapid refixation saccades may also be among the early findings.

Cognitive, behavioral, and psychiatric symptoms including executive dysfunction, irritability, depression, impulsiveness, mania, and psychosis typically appear after the development of motor abnormalities, but on occasion can be the presenting signs (56). CT or MRI scans of the brain typically reveal prominent atrophy of the head of the caudate. The duration of the illness from clinical onset to death is usually between 15 and 20 years.

The earliest cognitive manifestations of Huntington's disease in asymptomatic carriers occurs in deficits in attention, working memory, verbal learning, verbal longterm memory and learning of random associations (56a).

Juvenile Huntington's disease is characterized by the onset of clinical symptoms prior to the age of 20 years. Affected individuals in this age group differ from the adult phenotype in that they more commonly present with an akinetic-rigid syndrome (Westphal variant), have an increased risk of seizures, suffer from learning disabilities, and have rapid progression of disease (57). A child who presented with major depression at age 10 years, which then evolved into severe motor dysfunction at age 14, has been described (57a).

The identification of presymptomatic Huntington's disease carriers by genetic testing is a complex issue with many ethical ramifications. Pre- and posttest psychological and genetic counseling is required for asymptomatic individuals (58). Predictive testing in children under the age of 18 years is almost never recommended.

There is not yet any curative therapy for Huntington's disease. Both the irritability and depression associated with

Huntington's disease are responsive to treatment with selective serotonin reuptake inhibitors. Benzodiazepines may also be useful for irritability. Symptoms of psychosis can be improved with standard neuroleptic agents, but the chronic use of these agents can result in development of tardive dyskinesia or parkinsonism. Atypical neuroleptic drugs with a lower potential for extrapyramidal side effects such as olanzapine (59) or clozapine (60) can also be used. Clozapine must be used with great caution because of its potentially serious complication of agranulocytosis. Mild chorea does not require therapy, but more severe chorea that interferes with motor skills or socialization should be treated using neuroleptics or dopamine-depleting agents. Levodopa or dopamine agonists are useful in treating akinesia and rigidity, but they may exacerbate or uncover chorea. Supportive treatment using physical and speech therapy may help with the management of dysphagia, speech, and gait disorders (61).

Fetal striatal transplantation has not provided clear benefit despite survival of transplanted cells and has been associated with a high incidence of serious complications (62). Coenzyme Q10 demonstrated a trend toward slowing the functional decline in Huntington's disease (63). Caspase inhibitors to prevent the development of the neuronal toxicity associated with the mutant protein are being evaluated (64).

### **Sydenham's Chorea**

Sydenham's chorea typically occurs within 4 to 8 weeks after an episode of Group A beta-hemolytic streptococcal infection. Some have drawn an analogy between this condition and the childhood neurobehavioral disorders collectively termed PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection) (65). Although an autoimmune etiology has not been unequivocally proven, the presence of serum antineuronal antibodies in Sydenham's chorea (66) and the reported success of immunomodulating therapies such as plasma exchange support this notion (67). With the advent of effective antibiotic therapy for streptococcal infections, the incidence of Sydenham's chorea in the United States has declined markedly. Sydenham's chorea typically develops in early childhood with a mean age at onset of 9 years. Carditis is present in a large majority of patients (68), its detection is enhanced by echocardiography (69). The chorea itself is usually bilateral, although asymmetric, and in up to 20% of cases it appears as hemichorea. Other neurologic signs and symptoms include dysarthria, hypotonia, and hypometric saccades. Behavioral abnormalities such as obsessive compulsive symptoms, emotional lability, and personality changes are common and often appear weeks before and occasionally after the onset of chorea. One survey found that 82% of children with Sydenham's chorea met diagnostic criteria for OCD (70). The behavioral and motoric symptoms usually resolve within 9 months, sometimes leaving behind subtle signs of chorea. Up to 50% of

patients experience recurrent episodes of chorea, sometimes precipitated by subsequent streptococcal infections, therapy with oral contraceptives, or pregnancy. The reappearance or persistence of the original chorea suggests that an acute attack of Sydenham's chorea can result in irreversible changes in the basal ganglia in some patients (71).

Diagnostic studies are of limited use in evaluating Sydenham's chorea. Evidence of Group A beta-hemolytic streptococcal infection, such as a positive throat culture or an elevated antistreptolysin titer, is not consistently present by the time chorea appears, often several months after the acute infection. Although 10% of patients gave a history of sore throat, group A streptococci were isolated in only 1.4% of patients at the time of chorea onset (72). Anti-DNAse B titers remain elevated for as long as a year and are therefore more likely to be abnormal at the onset of chorea. MRI scans of the brain in Sydenham's chorea demonstrate increased size of the caudate, putamen, and globus pallidus (73) and occasionally show increased signal in the basal ganglia (74). The specificity of antineuronal antibodies for Sydenham's chorea is not proven (75).

No specific therapy is required for mild chorea in this self-limited condition. Valproic acid (76) or carbamazepine (77) may help moderately severe or persistent chorea. For still more severe or refractory chorea, neuroleptic therapy may be required. Pimozide may be the agent of choice because of its more favorable side effect profile in children. When other therapies fail, oral or intravenous corticosteroids, or rarely other immunomodulating therapies such as plasma exchange and intravenous immunoglobulin, have been used (67). Penicillin remains the most appropriate primary and secondary prophylaxis for recurrent streptococcal infection (78).

### **Tardive Dyskinesia**

Tardive dyskinesia consists of a variety of involuntary movements appearing in a patient currently or recently exposed (usually greater than 3 months) to chronic neuroleptic therapy or another dopamine receptor blocking agent. In addition to classic tardive dyskinesia, children are prone to develop withdrawal dyskinesias when dopamine receptor blocking agent therapy is discontinued. In one of the largest recent series, 5.9% of children receiving antipsychotic therapy with neuroleptics had tardive dyskinesia, and 14.5% of those whose treatment was stopped developed withdrawal dyskinesias (79). Risk factors for developing tardive dyskinesia or withdrawal dyskinesias in children, other than exposure to typical neuroleptics (80), include a high drug dosage, underlying CNS dysfunction, history of extrapyramidal side effects, concurrent anticholinergic use, and rapid antipsychotic dose taper, as well as presence of autism or a history of perinatal complications (81). Withdrawal dyskinesias can appear within a few days to 2 months after dopamine receptor blocking agent withdrawal but most commonly is seen after about 2 weeks. The value of slow dopamine receptor blocking agent taper in avoiding

withdrawal dyskinesias is not well established (80, 81). Tardive dyskinesia seems to be rare in patients receiving antipsychotic agents for Tourette's syndrome (82).

The vast majority of children with tardive dyskinesia have involuntary, choreiform movements of the face, lips, tongue, and jaw, often resulting in a typical masticatory pattern, while the extremities or the trunk are involved in less than half of the cases (79, 81). The differential diagnosis of the classical choreic tardive syndrome in children includes Wilson's disease, Sydenham's chorea and chorea gravidarum, systemic lupus, Huntington's disease, hyperthyroidism, and lesion of the subthalamic nucleus or its efferent or afferent connections.

Dopamine receptor hypersensitivity or a shift in the balance of dopamine receptor subtype function (83, 84), as well as a complementary mechanism involving GABA insufficiency in the basal ganglia (85) has been postulated to explain the pathophysiologic basis of tardive dyskinesia.

Early discontinuance of the neuroleptic or reduction to the lowest required dosage is thought to improve the chances for permanent remission and diminished clinical disability (86), but the benefit of this approach has not been proven in controlled trials (87). The chances for improvement after discontinuance of the dopamine receptor blocking agent may be higher in younger patients and in those with a shorter duration of therapy. Total withdrawal of neuroleptics must be balanced against the risk of reemergence of the underlying psychiatric disorder. One option is to change therapy to an atypical neuroleptic such as clozapine or olanzapine that is less likely to induce tardive dyskinesia. These agents can be used either to replace the more typical antipsychotic agent that is required for continued therapy or, in a patient who no longer requires neuroleptic therapy, can be used to simply suppress the dyskinetic movements. In adult patients, suppressive medical therapy with dopamine-depleting agents such as reserpine (88) and tetrabenazine (89) has been tried with some success. Preliminary clinical studies have suggested that thiamine (90), gabapentin (91), branched chain amino acids (92), or vitamin E (93, 94) may be helpful. Although various benzodiazepines have been proposed as therapy for tardive dyskinesia, an extensive literature review indicated that benzodiazepines were not better than placebo (95). Tardive dystonia may respond to anticholinergic therapy; when the cervical muscles are involved, botulinum toxin injections are very effective (96).

### Neuroacanthocytosis

Neuroacanthocytosis, previously referred to as choreoacanthocytosis, presents during childhood or any time during adult life, most commonly in the fourth decade, and has an average survival of 10 years after disease onset (97). The gene (*VPS13A*) has been mapped to chromosome 9q21 (98) and encodes chorein, an evolutionarily conserved protein that is involved in protein sorting. In addition to chorea, dystonia, tics, and parkinsonism can be seen. A

characteristic orofaciolingual movement, "feeding dystonia," can sometimes be so profound as to lead to mutilation of the lips and tongue. Other neurologic abnormalities include seizures and a variety of neuropsychiatric symptoms including personality change, impulsivity, executive dysfunction (99), and peripheral neuropathy (100). Peripheral smear reveals spiculated erythrocytes known as acanthocytes, sometimes only seen by scanning electron microscopy (101). Creatine kinase levels are typically elevated and correlate with the generalized muscle atrophy seen in this condition. MRI shows caudate and cortical atrophy, as well as striatal hyperintensity on T2-weighted sequences (102).

### Other Genetic Causes of Chorea

Benign hereditary chorea presents in the first decade of life is an isolated, nonprogressive autosomal dominant chorea that is mapped to chromosome 14q (103). Chorea can occasionally be seen in patients with trinucleotide repeat expansion disorders other than Huntington's disease. A subtype of dentatorubropallidolusian atrophy, an autosomal dominant condition common in Japan but only infrequently observed in the Western Hemisphere, may mimic Huntington's disease (104). Chorea seen in autosomal dominant spinocerebellar ataxia types 1 (105) and 2 (106) is not the predominant neurologic finding. Several conditions, clinically similar to Huntington's disease but genetically distinct, have been identified, consistent with the observation that approximately 1 to 7% of patients with phenotypically classical Huntington's disease do not have expanded CAG repeats in the IT15 gene on chromosome 4p (107).

### Chorea Associated With Systematic Illness

Chorea can occur in patients with systematic lupus erythematosus or the antiphospholipid syndrome (108). Although chorea associated with antiphospholipid syndrome can occur at any time in life, it is somewhat more likely to appear in childhood. Once thought to be due entirely to vasculitis and ischemia, the finding of striatal hypermetabolism in patients with antiphospholipid syndrome-related chorea and the response of the symptoms to immunosuppressive therapy suggest that this syndrome may be the result of an immune-mediated striatal excitatory effect instead (109).

Hyperthyroidism occasionally causes chorea (110), or even less commonly paroxysmal chorea (111). AIDS can be associated with chorea or hemichorea through a variety of mechanisms, including basal ganglia abscess, HIV encephalopathy, and progressive multifocal leukoencephalopathy (112). Children undergoing cardiac surgery with deep hypothermia and extracorporeal circulation are at risk for developing postoperative chorea that may resolve within a few weeks or persist indefinitely (113).

### Ballism

The large amplitude, proximally predominant flinging movements that are characteristic of ballism are felt to exist

on a clinical continuum with the smaller amplitude, more distally predominant movements of chorea. The fact that these two different types of abnormal involuntary movements are pathophysiologically related is strengthened by the observation that both may exist in the same individual at the same time, and ballism, as it improves, may evolve into chorea. Structural causes of hemiballism include stroke, multiple sclerosis, abscess, neoplasm, Moyamoya disease, or arteriovenous malformation that affect subthalamic nucleus, or less commonly striatum, thalamus, and cerebral cortex. A host of other pathologies including encephalitis, systemic lupus erythematosus, basal ganglia calcification, nonketotic hyperglycemia, or minor systemic infection in children with static encephalopathy can also result in hemiballism (114, 115). Hemiballism should be treated aggressively using dopamine blocking or depleting drugs, valproic acid, or even thalamic deep brain stimulation (116) to prevent physical injury, extreme exhaustion, or cardiac symptoms.

### Myoclonus

Myoclonus is a lightning-like movement produced by a sudden and brief muscle contraction (positive myoclonus) or a muscle inhibition (negative myoclonus) (117). Asterixis is an example of negative myoclonus. Myoclonus can be classified according to its distribution (focal, multifocal, segmental, or generalized), activation characteristics (spontaneous, reflex, or action), temporal profile (continuous or intermittent, rhythmic or arrhythmic), site of origin (cortical, subcortical [brainstem, reticular], spinal, or peripheral), and etiology (physiologic, essential, epileptic, or symptomatic).

Posthypoxic myoclonus, reflex myoclonus seen in neurodegenerative diseases such as neuronal ceroid lipofuscinosis, and *epilepsia partialis continua* are examples of cortical myoclonus. Subcortical myoclonus is usually generalized and may be associated with an exaggerated startle response (hyperekplexia). Examples of subcortical myoclonus include reticular reflex myoclonus, essential myoclonus, palatal myoclonus, and uremic myoclonus (118). Symptomatic palatal myoclonus usually persists during sleep, whereas essential palatal myoclonus disappears with sleep (119). Essential palatal myoclonus frequently is associated with an ear-clicking sound. Symptomatic palatal myoclonus is often associated with hypertrophy of the inferior olive that develops subsequent to a lesion involving the dentate-olivary pathway in the Guillain-Mollaret triangle (118) with accompanying impairment of cerebellar or brainstem function (119). The differential diagnosis of startle syndromes also includes reticular reflex myoclonus, startle epilepsy, exaggerated startle in Tourette's syndrome, and hereditary hyperekplexia. This latter syndrome is an autosomal dominant disorder of childhood, caused by disinhibition of motor neurons resulting from mutations on chromosome 5 in the gene for the glycine receptor (120),

leading to impaired glycine- and GABA (A)-receptor transmission. Clonazepam is the treatment of choice (121). In essential myoclonus, there are no other significant neurological signs or symptoms.

Generalized myoclonus is believed to reflect discharges arising from the brainstem reticular formation. Segmental myoclonus consists of spontaneous and rhythmic (1 to 3 Hz) contractions of several contiguous muscle groups due to discharges from the brainstem or the spinal cord (122). Segmental myoclonus, usually, is symptomatic due to a tumor, demyelinating process, spondylosis, infection, or a degenerative condition (122). An irritative lesion affecting a nerve root or a peripheral nerve may give rise to peripheral myoclonus (123). Hemifacial spasm, an example of this condition, is most frequently attributed to compression of the facial nerve at the root exit zone by an ectatic blood vessel, possibly resulting in ephaptic transmission. It is characterized by involuntary, irregular, clonic, or tonic movements of muscles innervated by the seventh cranial nerve on one side of the face (124).

Physiologic myoclonus (sleep myoclonus, anxiety or exercise-induced muscle jerks, hiccups, and benign infantile myoclonus) is a normal phenomenon that is not associated with disability (125).

The most common causes of *epilepsia partialis continua* include cortical stroke and Rasmussen's encephalitis, a disorder of childhood or adolescence caused by focal cortical lesion or inflammation, possibly from viral infection (126). Other epileptic myoclonias include childhood myoclonic epilepsies such as juvenile myoclonic epilepsy of Janz, benign familial myoclonic epilepsy, and progressive myoclonic epilepsy (117). The progressive forms of epileptic myoclonus, seizures, and myoclonus may ultimately be accompanied by encephalopathy after time (117).

Symptomatic myoclonus is frequently associated with an identifiable static or progressive encephalopathy, often one of the dementing syndromes (127). The underlying causes include storage diseases, spinocerebellar degeneration, basal ganglia degeneration, degenerative dementias, spongiform encephalopathy, malabsorption syndromes, focal central nervous system lesions, and encephalopathies due to mitochondrial, viral, metabolic, endocrinologic, toxic, traumatic, hypoxic, or paraneoplastic causes (128). The progressive myoclonus epilepsies belong to the category of symptomatic myoclonus. They are clinically characterized by stimulus sensitive myoclonus, epilepsy, and progressive neurologic deterioration in cognitive, motor, and psychiatric domains depending on the etiology (129). Dentatorubropallidolusian atrophy is a trinucleotide repeat—a CAG repeat expansion in 12p13.31. Mitochondrial encephalomyopathy with ragged red fibers (MERRF) arises from a RNA Lys mutation in mitochondrial DNA. With the exception of these two disorders, the progressive myoclonus epilepsies are mostly autosomal recessive disorders (129). Specific mutations have been identified in Lafora disease (gene for laforin or dual specificity phosphatase on 6q), Unverricht-Lundborg

disease (cystatin B in 21q), Jansky-Bielschowsky ceroid lipofuscinoses (CLN2 gene for tripeptidyl peptidase 1 in 11q15), Finnish variant of late infantile ceroid lipofuscinoses (CLN5 gene in 13q), juvenile ceroid lipofuscinoses or Batten disease (CLN3 gene in 16p), a subtype of Batten disease, and infantile ceroid lipofuscinoses of the Haltia-Santavuori type (both caused by mutations in palmitoyl-protein thioesterase gene at 1p) (129). Ramsay Hunt syndrome (dyssynergia cerebellaris myoclonica, progressive myoclonic ataxia) is characterized by combination of ataxia and myoclonus with infrequent seizures and absence of dementia. Its differential diagnosis overlaps with that of progressive myoclonus epilepsies (130). A variety of drugs and toxins can cause myoclonus (131, 132). The most common of these are listed in Table 21.3.

Valproic acid and clonazepam probably improve myoclonus largely via their GABAergic activity (133). Lev-tiracetam, an agent that increases adenosine metabolism and modulates acetylcholine levels, has shown promising efficacy in the treatment of cortical myoclonus (134) and progressive myoclonus epilepsies (135), possibly by

reducing corticospinal excitability at the motor cortex level (136). Posthypoxic myoclonus may respond dramatically to 5-hydroxytryptophan, a direct precursor of serotonin, supporting the serotonin deficiency hypothesis for its etiology (137). Primidone, phenobarbital, diazepam, carbamazepine, baclofen, and phenytoin have also been used for various types of myoclonus (131).

### Tics and Tourette's Syndrome

Tourette's syndrome, first characterized in 1885 by George Gilles de la Tourette, is a relatively common, but complex hereditary neurobehavioral disorder of unknown cause. It is characterized by motor and vocal tics starting in childhood that often are accompanied by behavioral problems such as OCD, ADHD, and lack of impulse control (138, 139). The clinical expression is often different in various members of the family (140). Tourette's syndrome is the most common cause of tics and affects males approximately three times as frequently as females. Prevalence estimates range from 0.7 to 4.2% (138).

**TABLE 21.3**  
**ETIOLOGICAL CLASSIFICATION OF MYOCLONUS**

#### 1. Physiological Myoclonus

Sleep jerks, exercise-induced, hiccough, benign infantile myoclonus

#### 2. Essential Myoclonus

Hereditary (may include myoclonus dystonia syndrome), sporadic

#### 3. Epileptic Myoclonus

- a. **Component of epilepsy:** Isolated epileptic myoclonic jerks, epilepsy partialis continua, photosensitive myoclonus, myoclonic absence
- b. **Myoclonic epilepsies of childhood and adolescence:** Infantile spasms, Lennox-Gastaut syndrome (myoclonic astatic epilepsy), Aicardi's infantile myoclonus epilepsy, Janz's juvenile myoclonus epilepsy, benign familial myoclonic epilepsy
- c. **Progressive myoclonus epilepsy**

#### 4. Symptomatic Myoclonus

- a. **Hereditary:** Progressive myoclonus epilepsy (Lafora body disease, Unverricht-Lundborg disease, neuronal ceroid lipofuscinosis, dentatorubropallidolusian atrophy), Friedreich's ataxia, ataxia telangiectasia, Wilson's disease, Hallervorden-Spatz disease, Huntington's disease, mitochondrial encephalopathies such as MERRF sialidosis, lipidoses (GM2 gangliosidosis, Tay-Sachs, Krabbe's)
- b. **Neurodegenerative:** Parkinson's disease, Alzheimer's disease, corticobasal ganglionic degeneration, multiple system atrophy, progressive supranuclear palsy, pallidal degenerations
- c. **Acquired:**
  - i. **Drugs:** Selective serotonin reuptake inhibitors, tricyclic antidepressants, lithium, levodopa, valproic acid, carbamazepine, phenytoin, morphine
  - ii. **Metabolic:** Hepatic failure, renal failure, hypoglycemia, hyponatremia, dialysis syndrome, nonketotic hyperglycemia
  - iii. **Toxins:** Bismuth, heavy metals, methyl bromide, DDT
  - iv. **Physical encephalopathies:** Posthypoxic (Lance-Adams), posttraumatic, heat stroke, electric shock, decompression injury
  - v. **Focal CNS lesions:** Stroke, tumor, trauma, multiple sclerosis affecting the cortex, thalamus, brainstem (palatal myoclonus), or spinal cord (segmental or spinal myoclonus)
  - vi. **Infectious:** Viral encephalitis (arbovirus, herpes simplex), subacute sclerosing panencephalitis, Creutzfeldt-Jakob disease, postinfectious
  - vii. **Psychogenic**

DDT, dichlorodiphenyltrichloroethane; MERRF, myoclonic epilepsy and ragged red fibers.

Other tic disorders include transient tic disorder, chronic tic disorder, and secondary tics due to an identifiable cause. Both transient tic disorder and chronic tic disorder are idiopathic and typically start before age 18 years (141). Patients with transient tic disorder have single or multiple motor or vocal tics that occur for at least 4 weeks, but for no longer than 12 consecutive months. Patients with chronic tic disorder have single or multiple motor or vocal tics, but not both, that have been present for more than 1 year, during which time there was never a tic-free period of more than 3 consecutive months.

### Clinical Features

#### Tics and Motor Symptoms

Tics, the clinical hallmark of Tourette's syndrome, are sudden, brief, intermittent, involuntary or semivoluntary movements (motor tics) or sounds (phonic or vocal tics) (138). They typically consist of simple or coordinated, repetitive or sequential movements, gestures, and utterances that mimic fragments of normal behavior. Simple motor tics involve a limited number of muscles and can further be classified as clonic (brief, jerking movements such as blinking, nose twitching, or jerking of the head and limbs), dystonic (slow, briefly sustained abnormal postures such as blepharospasm, oculogyric movements, bruxism, torticollis, and shoulder rotation), or tonic (isometric contractions such as tensing of abdominal or limb muscles). Complex motor tics, a sequence of intense and coordinated movements, may resemble normal, purposeful motor acts or gestures that are incorporated into the flow of movement, but with inappropriate timing. Specific examples of complex motor tics include obscene gestures (copropraxia) or imitation of movements of others (echopraxia). Examples of typical simple vocal tics are sniffing, throat clearing, grunting, screaming, coughing, and blowing. Complex vocal tics may include seemingly meaningful but inappropriate utterances and verbalizations. Specific examples include shouting of obscenities (coprolalia), repetition of someone else's words or phrases (echolalia), and repetition of one's own utterances (palilalia).

Tics are often preceded by premonitory sensations or psychological symptoms that are temporarily relieved after the execution of the tic. These sensations may consist of localizable paresthesias, or discomfort such as a burning feeling in the eye before an eye blink, tension, or sore throat before throat clearing. Premonitory psychologic symptoms include urges, as well as anxiety or a fear of a catastrophic event if tics are not promptly or properly executed. Patients may need to repeat a particular tic until this uncomfortable feeling is relieved, suggesting a compulsive component.

Tourette's syndrome patients can temporarily suppress the frequency and severity of their tics volitionally or by concentrating on mental or physical tasks. Upon relaxation after a period of tic suppression (e.g., coming home from school), the tics may rebound. Suggestibility and exacerbation with stress, excitement, boredom, or fatigue are other distinguish-

ing features (138). Tics can be socially disabling by causing embarrassment and interference in interactions with others or physically disabling by causing pain or discomfort (138).

The definitive criteria for the diagnosis of Tourette's syndrome (142) are (1) onset before the age 21 years; (2) presence of both multiple motor tics and one or more phonic tics at some time during the illness, although not necessarily concurrently; (3) occurrence of tics many times a day, nearly every day, or intermittently throughout a period of more than 1 year; (4) change of the anatomical location, number, frequency, type, complexity, or severity of tics over time; (5) exclusion of other medical conditions that can cause tics; and (6) confirmation of the tics by a reliable examiner at some point during the illness by direct examination or watching an audiovisual recording.

Tourette's syndrome typically begins between ages 3 and 8 years and is manifested by age 11 years in the large majority of cases (143). Tics usually become most severe around 10 years of age and then start declining thereafter. By age 18 years, half of Tourette's syndrome patients are free of tics (144), especially by their own assessment, but careful examination suggests that 50% of them continue to have subtle tics (145). Males demonstrate substantially more variability in improvement but overall tend to improve more than females (146). In females, there has been no consistent correlation between hormonal levels and fluctuations in tics or OCD symptoms (147). In children with developmental stuttering, one should look for clues for Tourette's syndrome, since careful study has suggested that such signs may be present but undiagnosed in almost 50% of cases (148). Except for tics, the neurologic examination in Tourette's syndrome is normal. Tics are evident in all stages of sleep, and sleep abnormalities are observed in Tourette's syndrome (149). Table 21.4 displays the clinical classification and etiology of tic disorders.

#### Behavioral-Cognitive Symptoms

Although intellectual ability is generally normal in Tourette's syndrome, specific cognitive deficits such as visuomotor integration problems, impaired fine motor skill, and executive dysfunction may be present (150). The presence of comorbid conditions, notably ADHD and OCD, appear to significantly increase the likelihood of learning problems or cognitive impairment. Behavioral disorders such as ADHD, OCD, or both, are apparent at some time during the course of Tourette's syndrome in the majority (60 to 80%) of patients (151, 152). Anxiety and mood disorders may also be observed (153). They usually interfere with personal, academic, and professional life more than the tics and may lead to social and emotional maladjustment if untreated. Impaired attention in Tourette's syndrome can result from a number of different factors: comorbid ADHD, the intrusive thoughts associated with OCD, the mental effort required to suppress tics and premonitory urges, and as a result of sedation caused by the drugs used to treat tics.

**TABLE 21.4**  
**ETIOLOGICAL CLASSIFICATION OF TICS**

Primary
<ul style="list-style-type: none"> <li>• Tourette's syndrome</li> <li>• Chronic (&gt;1 year) tic disorder: Similar to Tourette's except that patients have only either motor or vocal tics, but not both</li> <li>• Transient (&lt;1 year) tic disorder: Similar to chronic tic disorder except total duration of the illness</li> <li>• Adult-onset tic</li> </ul>
Secondary Tics
<ul style="list-style-type: none"> <li>• <i>Drugs</i>: Stimulants (amphetamines, methylphenydate, cocaine), levodopa, dopamine blockers (tardive tourettism), carbamazepine, phenytoin, phenobarbital, lamotrigine</li> <li>• <i>Infectious/immunologic</i>: Encephalitis, Sydenham's chorea, neurosyphilis, Creutzfeldt-Jakob disease</li> <li>• <i>Hereditary</i>: Huntington's disease, neuroacanthocytosis, Hallervorden-Spatz disease, Wilson's disease, tuberous sclerosis, primary dystonia, and chromosomal anomalies such as Down syndrome, Klinefelter syndrome, and fragile X syndrome</li> <li>• <i>Others</i>: Developmental disorders with mental retardation and behavioral problems, head trauma, carbon monoxide poisoning, stroke, schizophrenia, neurodegenerative diseases</li> </ul>
Related Disorders
<ul style="list-style-type: none"> <li>• Stereotypies, habits, and mannerisms</li> <li>• Akathisia</li> <li>• Hyperekplexia</li> <li>• Jumping Frenchmen of Maine, latah, myriachit</li> <li>• Obsessive-compulsive disorder</li> </ul>

Additional cognitive, behavioral and neurological abnormalities are seen in patients with Tourette's syndrome who have comorbid ADHD (152). Associated poor impulse and anger control may lead to temper outbursts, rage, inappropriate sexual aggressiveness, and antisocial or oppositional behavior. Episodic rage can cause significant morbidity (154). Self-injurious behavior (139) and migraine headaches (155) are also associated with Tourette's syndrome. A less well appreciated but not unexpected fact is that parents of children with Tourette's syndrome have a markedly increased caregiver burden and are themselves at risk for psychiatric morbidity (156).

### Pathogenesis

Although postmortem neuropathological examinations of Tourette's syndrome brains (157) and standard anatomical neuroimaging studies have not revealed any specific abnormalities, various biochemical, functional imaging, neurophysiological, and genetic studies suggest that it is an inherited, developmental disorder of synaptic neurotransmission resulting in the disinhibition of cortico-striatal-thalamic-cortical circuitry (138, 158, 159). The caudate nucleus and the inferior prefrontal cortex have been implicated in the pathogenesis of Tourette's syndrome, as well as in that of OCD and ADHD (138, 159, 160).

Volumetric MRI studies in Tourette's syndrome show loss of the normal asymmetry of the basal ganglia, which are

usually larger on the right, suggesting a developmental abnormality (160). Functional MRI studies reveal decreased neuronal activity during periods of suppression in the ventral globus pallidus, putamen, and thalamus and increased activity in prefrontal, parietal, temporal, and cingulate cortical areas; areas normally involved in the inhibition of unwanted impulses (160). PET studies show a nonspecific pattern of increased motor cortical activity, as in other hyperkinetic disorders, as well as a specific brain network characterized by a reduction in the activity of limbic basal ganglia (especially caudate) thalamocortical projection systems (161). There is temporally-related aberrant activity in the interrelated sensorimotor, language, executive, and paralimbic circuits during tics that may account for the initiation and execution of diverse motor and vocal behaviors, as well as for the urges that often accompany them (162).

Using back-averaging electroencephalographic techniques, the involuntary nature of tics has been demonstrated in many Tourette's syndrome patients by the absence of the premovement potential (Bereitschafts potential) before the execution of motor tics. Its presence, however, in other patients, suggests evidence of a voluntary component to some tics (163). The shortened cortical silent period and defective intracortical inhibition demonstrated by transcranial magnetic stimulation may explain the decreased motor inhibition and intrusive phenomena seen in Tourette's syndrome and OCD (164, 165). The inability to inactivate

secondary motor areas when no movement is performed possibly explains Tourette's syndrome patients' involuntary urges to move, resulting in interference with accurate planning of voluntary behavior (166).

An alteration of neurotransmitters in Tourette's syndrome has been suggested based on the relatively consistent clinical responses to pharmacologic modulation of the dopaminergic system in patients with the disorder. Increased binding of 3H-mazindol to presynaptic dopamine-uptake-carrier sites indicates dopaminergic hyperinnervation of the ventral striatum and the associated limbic system (167). High [18F] Fluorodopa accumulation in the caudate nucleus and the substantia nigra and ventral tegmental area provides evidence of high presynaptic dopaminergic activity (168). However, the response of some Tourette's syndrome patients to dopamine agonist therapy (169) calls into question the role of dopamine overactivity. In addition to dopamine, other neurotransmitters have been implicated in the pathophysiology of Tourette's syndrome. Low levels of serotonin in the brainstem, low levels of glutamate in the globus pallidus, and low levels of cyclic adenosine monophosphate in the cortex have been demonstrated in the few brains available for postmortem study (157, 167).

Studies of twin have found a ~90% concordance for tics and Tourette's syndrome, providing strong evidence of a genetic etiology (170). Bilineal transmission is present in 25 to 41% of families with Tourette's syndrome (171, 172). Ethnic differences in the nature and frequency of vulnerable alleles for Tourette's syndrome and related disorders are suggested by the finding that the rates of Tourette's syndrome and related disorders in Japan are much lower than those in studies on twin and family studies in the United States and Western Europe (173). Genetic studies suggest a rather complex inheritance pattern with elements of gender-specific penetrance (males are more affected than females) and the possibility of multiple susceptibility genes (174–177). Nongenetic prenatal factors also affect the phenotype since low birth weight (170), maternal life stress, and nausea and vomiting during the first trimester of pregnancy (178) correlate with tic severity.

Some Tourette's syndrome patients have been shown to have elevated titers of antibodies to group A beta-hemolytic streptococcus (179), possess the B-lymphocyte antigen D8/17 (180), or display increased levels of antineuronal antibodies against putamen (181), suggesting an immunologic pathogenesis. The most recent attempts to passively transfer antineuronal antibodies from the serum of Tourette's syndrome patients to animals have been unsuccessful (182). Classification of Tourette's syndrome under the controversial category of pediatric autoimmune neuropsychiatric disorders associated with streptococcus infections (PANDAS) has been proposed (65). However, well-designed and adequately controlled studies will be needed to determine whether there is a true etiologic relation between streptococcal infection and the onset or

exacerbation of childhood neuropsychiatric disorders such as Tourette's syndrome and whether the use of immune-modifying therapies for these conditions is rational (183).

### Treatment

Behavioral therapy, a beneficial ancillary modality (184), and adjustments in the home, school, and classroom environments through education play an important part in the management of patients with Tourette's syndrome and are helpful in improving self-esteem and increasing motivation (185). Pharmaceutical treatment should only be started when symptoms begin to interfere with peer relationships, social interactions, academic or job performance, or activities of daily living and should be tailored to the individual needs of the patient by targeting the most troublesome symptom first (138). Each medication and dosage regimen should be given an adequate trial to avoid unnecessary changes that might be made in response to normal variations in symptoms during the natural course of the disease.

### Treatment of Tics

Neuroleptics are the most effective agents for treating tics. However, given that their side effects include tardive dyskinesia, parkinsonism, sedation, depression, weight gain, school phobia, and hepatotoxicity, they should be used judiciously. The goal should be to relieve tic-related discomfort or embarrassment and to achieve a degree of control of tics that allows the patient to function as normally as possible, rather than elimination of all the tics. Haloperidol and pimozide are the only neuroleptic drugs currently approved by the Food and Drug Administration for the treatment of Tourette's syndrome. Pimozide has been found to be superior to haloperidol for controlling tics at equivalent doses, while causing fewer side effects (186). However, pimozide may prolong the QT interval and requires periodical monitoring with electrocardiography.

Risperidone (187–189) and ziprasidone (190) have been found to be beneficial in placebo-controlled, double-blind studies. Other neuroleptics such as quetiapine (191), fluphenazine, thioridazine, trifluoperazine, molindone, thiothixene, or tiapride are also used. Tetrabenazine, a drug that depletes monoamine and blocks the dopamine receptors, is a powerful antit tic drug that, unlike the conventional neuroleptics, has not been demonstrated to cause tardive dyskinesia (192). However, worsening of hyperkinetic movement disorders while on tetrabenazine has been observed in a small subset of patients (193).

Baclofen (194) and pergolide (169) have also been demonstrated to be modestly useful in Tourette's syndrome by placebo-controlled, double-blind studies. Other drugs found to be useful in the treatment of tics include clonazepam, quetiapine, olanzapine, cannabinoids, nicotine gum, and transdermal nicotine patches, but none of these drugs have been studied in well-designed, placebo-controlled trials (195). Focal motor and vocal tics have also been treated successfully with injections of botulinum

toxin in the affected muscles (196–198). Such local chemical denervation not only ameliorates involuntary movements but may also eliminate the premonitory sensory component. However, tic reduction may not necessarily translate into global subjective improvement (196). Although stereotactic surgery has not generally been found to be useful in the treatment of tics (199), preliminary reports of successful thalamotomy (200) and high-frequency deep-brain stimulation of the thalamus (201) in severe, refractory Tourette's syndrome are encouraging.

### Treatment of Coexisting Behavioral Symptoms

Central nervous system stimulants, such as methylphenidate, controlled-release methylphenidate, dextroamphetamine, a mixture of amphetamine salts, and pemoline, are very effective in the treatment of ADHD (202). Potential side effects include nervousness, irritability, insomnia, anorexia, abdominal pain, headaches, and rare hepatotoxicity (pemoline) (203). Previous concerns over the safety of stimulants used to treat Tourette's syndrome have largely been erased (204). The initial increase of severity and intensity of tics with stimulant use is usually not sustained (205, 206), but if necessary, dopaminergic blockers can be added for exacerbation of tics.

If central nervous system stimulants are not well tolerated or are contraindicated, presynaptic  $\alpha_2$ -adrenergic agonists can be considered. Clonidine, also available as a transdermal patch, and guanfacine (longer acting, less sedative, and better tolerated) reduce the symptoms of ADHD and impulse-control problems and may also ameliorate tics (207–209). The most frequently encountered side effects of clonidine and guanfacine include sedation, dry mouth, itchy eyes, dizziness, headaches, fatigability, and postural hypotension. A randomized, double-blind clinical trial found that methylphenidate and clonidine (particularly in combination) are effective for ADHD in children with comorbid tics (210). Other drugs occasionally used in the treatment of mild cases of ADHD disorder include selegiline (211) and tricyclic antidepressants, such as imipramine, nortriptyline, and desipramine.

The selective serotonin-reuptake inhibitors (SSRIs) are the most effective drugs for OCD (212) and can also help with associated anxiety and social phobias (213). In some refractory cases they may need to be combined with buspirone, clonazepam, lithium, or neuroleptics (214). With such combinations, one should be vigilant to monitor for serotonin syndrome (confusion, hypomania, agitation, myoclonus, hyperreflexia, sweating, tremor, diarrhea, and fever), withdrawal phenomena, and possible extrapyramidal side effects (215). Limbic leucotomy or cingulotomy may be considered as a last resort in extremely severe and refractory OCD (216).

### Paroxysmal Dyskinesias

Paroxysmal dyskinesias manifest as episodic chorea, dystonia, ballism, or a mixture of these abnormal involuntary

movements (217). The patient is generally normal in between the episodes. Although some paroxysmal dyskinesias respond well to therapy, they often go untreated because they are commonly misdiagnosed as being psychogenic. Paroxysmal dyskinesias are classified as "paroxysmal kinesigenic dyskinesia," referring to disorders induced by sudden movement, or "paroxysmal nonkinesigenic dyskinesia," indicating those in which it is not (217). Those cases in which exercise is the precipitating cause are described as paroxysmal exercise-induced dyskinesia. The term "paroxysmal hypnogenic dyskinesia" is used when dyskinesias occur only during sleep. The majority of paroxysmal dyskinesias are idiopathic (primary, familial), while approximately 20% are classified as symptomatic (secondary) due to trauma, vascular lesions, multiple sclerosis, kernicterus, and encephalitis (218).

Paroxysmal kinesigenic dyskinesia starts in childhood and is characterized by a distinct predominance of males (219). Family history is present in about a quarter of cases and usually follows an autosomal dominant pattern of inheritance (219). Typical paroxysmal kinesigenic dyskinesia (220) and the syndrome of benign familial infantile convulsions and paroxysmal choreoathetosis (221) have been linked to the pericentromeric region of chromosome 16 (16p12–q12) and are also referred to as dystonia 10 (DYT10). Rolandic epilepsy with paroxysmal exercise-induced dystonia and writer's cramp has also been mapped to this area (221a).

Attacks in paroxysmal kinesigenic dyskinesia usually consist of episodes of dystonia or choreodystonia precipitated by a sudden change in position such as moving from a sitting to standing position. Startle, hyperventilation, vigorous exercise, or a sudden change in the speed of an ongoing movement can also induce an attack (219). A premonitory phase consisting of tingling or other sensory phenomena that is generalized or felt in the body part that subsequently becomes dyskinetic occurs in most cases (219). Attacks commonly involve the hemibody and rarely generalize. Speech can be affected but there is no change in consciousness. Typically, paroxysmal kinesigenic dyskinesia attacks last from seconds to 1 to 2 minutes and occur up to dozens of times per day with a subsequent refractory period. Some patients can abort or prevent an attack by stopping moving or starting their movement slowly. The large majority of patients with paroxysmal kinesigenic dyskinesia respond dramatically to low doses of anticonvulsants, especially to carbamazepine or phenytoin (219). The attack frequency of paroxysmal kinesigenic dyskinesia diminishes over time with potential remission in adulthood (222).

Paroxysmal nonkinesigenic dyskinesia presents in childhood with intermittent episodes of involuntary movements that are a mixture of dystonia and chorea (222). These episodes are much more infrequent than those in paroxysmal kinesigenic dyskinesia but usually last for a few hours. The attacks can be spontaneous, but more often there are

one or more precipitants such as stress, fatigue, alcohol, or caffeine. It may be possible to abort an attack by going to sleep (223). Similar to paroxysmal kinesigenic dyskinesia, there is a male predominance and a tendency for improvement with age. The pattern of inheritance is autosomal dominant with linkage to chromosome 2q, classified as DYT8 (224). In sporadic cases, adulthood onset and female predominance has been noted (225). Another paroxysmal condition—referred to as choreoathetosis/spasticity, episodic movement disorder, or DYT9—is linked to chromosome 1p. These patients have accompanying perioral paresthesias, diplopia, headache, generalized myoclonus with seizures, and spastic paraparesis (226). Paroxysmal nonkinesigenic dyskinesia is more difficult to treat than paroxysmal kinesigenic dyskinesia (217). Clonazepam is useful in some patients (225). Patients usually do not benefit from anticonvulsants, but occasionally individuals respond to levodopa suggestive of an abnormality of dopamine metabolism in this disorder (227).

Paroxysmal exercise-induced dyskinesia is provoked by ongoing exertion such as walking for at least 10 to 15 minutes. The dyskinetic episode usually lasts 5 to 30 minutes (228). The attacks are usually dystonic and appear in the body part involved in the exercise, such as leg dystonia after prolonged walking or jaw dystonia after chewing gum, and then wane in 10 to 15 minutes after stopping the offending exercise (229). Exposure to cold (230), or passive movements and vibration (231) may also precipitate attacks. Both sporadic and autosomal dominant cases have been described, the latter being more common (228). Anticonvulsants, levodopa, acetazolamide, and trihexiphenidyl have been used with limited success (228).

Paroxysmal hypnogenic dyskinesia is sporadic or familial (232–235). Affected individuals awaken often with a shout or cry and then exhibit dystonic and ballistic movements lasting up to 45 seconds, usually with no detectable concurrent EEG abnormalities. Several attacks can occur each night (232). Most cases, especially the familial ones, have autosomal nocturnal frontal lobe epilepsy, which has been linked to chromosomes 15q24 (236) and 20q13.2 (237), genes coding for the acetylcholine receptor (234, 235). Discharges arise from the mesial frontal lobe explaining the difficulty in detecting EEG abnormalities on surface recordings (235). Carbamazepine is an effective therapy for most cases of paroxysmal hypnogenic dyskinesia (235).

### Stereotypies

A stereotypy is a voluntary repetitive movement. Like tics, the movement may be simple or complex. Typical stereotypies include hand ringing, repetitive lip pursing, and body rocking. This form of excessive movement is common in individuals with moderate or severe mental retardation, autism, or Rett syndrome and can also be seen as a part of the symptom complex of tardive dyskinesia. Such repetitive behaviors can be also induced environmentally in confined settings.

Confinement in adulthood results in a functional disorder that rapidly dissipates when normal conditions are restored, but confinement in infancy may have a more lasting effect (238).

### Rett Syndrome

Rett syndrome is one of the leading causes of mental retardation and developmental regression in girls. The majority of cases of sporadic Rett syndrome are caused by mutations in the gene encoding methyl-CpG-binding protein 2 (*MeCP2*) (239) that likely regulates gene expression and chromatin structure. The type of the specific mutation coupled with possible variation in X-chromosome inactivation appears to determine phenotype–genotype correlations (240). After the first 6 months of life, there is developmental slowing and loss of social interest accompanied by decelerating brain growth. This is followed by a severe dementia and loss of hand skills, development of stereotypies such as frequent hand wringing, apraxia and ataxia, autistic features, irregular breathing with hyperventilation, and seizures. Patients stabilize somewhat during the preschool to school years, associated with more emotional contact but also abnormalities of the autonomic and skeletal systems. After the age of 15 to 20 years, a late motor deterioration occurs with dystonia and spasticity, but seizures become milder (241).

## OTHER MOVEMENT DISORDERS

### Wilson's Disease

Wilson's disease is an autosomal recessive disorder due to mutations in the *ATP7B* gene on chromosome 13q, which encodes for a copper-transporting P-type adenosinetriphosphatase (ATPase) (242). More than 200 mutations of the Wilson's disease gene have been detected, and most patients are compound heterozygotes who carry at least two mutations (243). Correlations between genotype and phenotype are weak. The disease occurs in every ethnic and geographic population, with a worldwide prevalence of ~1 in 30,000 and a heterozygous carrier frequency of ~1 in 90 (243).

The abnormality in copper-transporting P-type ATPase leads to a marked reduction in biliary copper excretion. Initially, copper accumulates in the liver, causing progressive damage, but ultimately it overflows, producing toxic effects in the brain and other sites, including the eye, kidney, bones, and bone marrow. Symptoms usually start between the ages of 11 and 25 years but can occur as early as 4 years of age and rarely as late as in the sixth decade. The clinical features are age dependent (244). In about half of patients, usually children, the clinical onset may be heralded by hepatic disturbances. The initial manifestations of the illness are neurological in about 40% of patients (usually after the age of 12 years) and psychiatric in about 15% (245). Both modes of presentation are almost always accompanied by Kayser-Fleischer rings, golden brown copper depositions in the

cornea. The diagnosis of Wilson's disease may occasionally be made when Kayser-Fleischer rings are observed during routine ophthalmologic examination by slit-lamp (246). Kayser-Fleischer rings may be absent in patients presenting only with hepatic symptoms. In about 5% of patients, the clinical onset reflects neither a hepatic nor a central nervous system disturbance (247) but rather atypical features such as primary or secondary amenorrhea. In about half of Wilson's disease patients, the initial symptoms are misinterpreted resulting in an average delay of the diagnosis by 2 years.

In children, the initial neurologic symptoms usually consist of progressive dystonia, rigidity, and dysarthria. Tremor that typically involves the proximal upper extremity ("wing-beating tremor") is the most common presenting neurological feature in adults. Many patients with neurological signs of Wilson's disease develop prominent disorders of speech, swallowing and facial expression. Dysarthria can be a manifestation of lingual and facial dystonia, parkinsonism with hypophonia, or a result of cerebellar involvement with features of scanning speech. Facial dystonia often results in a peculiar grinning appearance. An akinetic-rigid state resembling Parkinson's disease can be seen, but chorea is uncommon. Rarely, seizures are part of the syndrome.

Psychiatric or behavioral abnormalities occur in the majority of patients with Wilson's disease. Although psychiatric symptoms are the presenting sign in a relatively small percentage, they emerge somewhat later in the course of the disease in the majority of patients. Symptoms range from relatively mild behavioral manifestations in about 45.9%, which include personality change, irritability and emotional lability or aggression. Depression may occur in 27%. Other less frequent psychiatric symptoms include anxiety, psychosis, and catatonia (247a). In one study, depressive symptomatology was shown to be negatively correlated with presynaptic serotonin transporter availability (247b). Dementia and psychosis may also occur. The dopamine blocking drugs used to treat psychiatric symptoms of Wilson's disease may incorrectly be considered the etiology of later-developing extrapyramidal symptoms.

### Diagnosis

Wilson's disease should be considered in any young patient with an unexplained liver disease or a movement disorder, cognitive dysfunction, or psychiatric abnormalities. The most useful laboratory screening test for Wilson's disease is plasma ceruloplasmin, which usually is less than 20 mg/dl. Normal ceruloplasmin levels, however, can be present in up to 5% of Wilson's disease patients (248), and low ceruloplasmin levels can be seen in patients with other forms of severe liver disease. The serum copper level is usually less than 100  $\mu$ g/dl in Wilson's disease, and 24-hour urine excretion of copper is usually above 100  $\mu$ g/24 hours (normal less than 50) (243). Since serum and urine copper levels are influenced by dietary intake of copper, these tests are not entirely reliable in the diagnosis of Wilson's disease. The diagnosis is confirmed by the demonstration of either

a serum ceruloplasmin level  $<20$  mg/dL and Kayser-Fleischer rings, or a serum ceruloplasmin level  $<20$  mg/dL and copper concentration in a liver biopsy sample  $>250$   $\mu$ g/g dry weight (243, 247). Other abnormalities in Wilson's disease include hemolytic anemia, hematuria, abnormalities in liver and renal function, increased excretion of amino acids in the urine, and elevated CSF levels of copper. MRI scans of the brain are usually abnormal (249) and may show decreased signal intensity on T1-weighted scans, and on T2-weighted scans hyperintensity in the striatum and superior colliculi. A characteristic, but rare MRI finding is increased signal intensity in the midbrain tegmentum (except for the red nucleus) and in the lateral substantial nigra pars reticulata, giving the appearance of "face of the giant panda" on T2-weighted images (250). Due to the high number of possible mutations over the entire length of the gene, commercial genetic testing is not feasible. However, genetic testing of full siblings of Wilson's disease patients can be useful in identifying presymptomatic individuals and starting prophylactic treatment (251).

Postmortem examination of the brain shows Alzheimer type II astrocytes in the striatum, and Opalski cells in the gray matter (252, 253) with 10- to 15-fold increased concentration of copper in all brain regions.

### Treatment

Pharmacological treatment is aimed at preventing or reversing the copper deposition. The strategies include a low copper diet, removing copper by the use of chelating agents (D-penicillamine, trientine hydrochloride, British Antilewisite-BAL, and tetrathiomolybdate), and maintenance therapy with zinc salts that compete for intestinal copper absorption and stimulate the production of the copper-sequestering protein metallothionein in the liver (243). Penicillamine therapy can result in initial worsening due to mobilization of copper stores. Symptomatic therapies for the movement disorders associated with Wilson's disease include levodopa for parkinsonism and anticholinergics or botulinum toxin for dystonia.

Liver transplantation is indicated in cases of fulminant hepatitis and Coombs-negative hemolytic anemia or if progressive hepatic insufficiency occurs despite adequate treatment with penicillamine or trientine (254). Although an improvement of the neurologic picture has been seen in almost 80% of cases, the decision to perform liver transplantation in patients with Wilson's disease solely on the basis of neurological impairment must be considered experimental (255).

Wilson's disease treatment must be continued for life. Inadequate treatment or interruption of therapy can be fatal or cause an irreversible relapse.

### Hallervorden-Spatz Syndrome

Hallervorden-Spatz syndrome, now referred to as neurodegeneration with brain iron accumulation (256), is an

autosomal recessive disorder that usually presents in childhood and is characterized by dystonia, parkinsonism, and iron accumulation in the brain (257). Additional features may include spasticity, progressive intellectual impairment, retinitis pigmentosa or optic atrophy (258), tourettism, or hemiballism (259). Many patients with this disease have mutations in the gene encoding pantothenate kinase 2 (*PANK2*); these patients are said to have pantothenate kinase-associated neurodegeneration (257). Hypoprebetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration (HARP syndrome) are part of the pantothenate kinase-associated neurodegeneration disease spectrum (260).

There is considerable clinical variation from patient to patient and even within the same family (261). The disease is progressive. Patients who become symptomatic in early childhood have the most rapid progression. Adults progress more slowly, with the mean survival being 11 years (262). Those who present in late childhood progress at an intermediate rate. In a large series of patients with neurodegeneration with brain iron accumulation, all patients with the classical syndrome (characterized by early onset with rapid progression) and approximately one third of those with atypical disease (later onset with slow progression) had *PANK2* mutations (257). Patients with atypical disease who had *PANK2* mutations were more likely to have prominent speech-related and psychiatric symptoms than patients with classic disease or mutation-negative patients with atypical disease. Predicted levels of *PANK2* protein correlated with the severity of disease (257). On T2-weighted MRI of the brain, all patients with neurodegeneration with brain iron accumulation, whether classic or atypical, have hyperintensity within the hypointense medial globus pallidus ("eye of the tiger" pattern (263)), a pattern not seen in any patients without *PANK2* mutations (257).

The pathology of neurodegeneration with brain iron accumulation/pantothenate kinase-associated neurodegeneration includes iron accumulation, demyelination, and gliosis especially in the globus pallidus and pars reticulata of the substantia nigra. Swollen axons, also known as axonal spheroids, and Lewy-type bodies are present (264, 265). Both the Lewy-like bodies and the axonal spheroids seen in this disorder have been found to contain  $\alpha$ -synuclein, linking this disease to the class of degenerative conditions collectively termed the synucleinopathies, which also includes Parkinson's disease (266).

There is no curative therapy for neurodegeneration with brain iron accumulation or pantothenate kinase-associated neurodegeneration. Iron chelation therapy has not been successful in this condition. Symptomatically, dystonia responds to levodopa, dopamine agonists, or anticholinergic agents in some patients (258). Stereotactic pallidotomy has been reported to be a benefit for relieving painful dystonia and improving limb function in a single case (267). Levodopa may also be useful to treat parkinsonism in late-onset patients (268). Antioxidant therapies have been pro-

posed to treat this disorder, based on histologic evidence of oxidative stress and lipid peroxidation that has been found in autopsy studies (269).

### Psychogenic Movement Disorders

Psychogenic movement disorders are defined as abnormal movements for which no organic cause can be found or is likely. In this respect, they are ultimately considered to be due to a somatoform disorder or a result of overt malingering. The diagnosis is often suggested by abnormal movements that conform to a pattern of onset, intermittency, inconstancy, medication responsiveness, or anatomic distribution that is not seen in any of the recognized organic movement disorder syndromes. In addition to these atypical clinical features, a variety of behavioral or historical risk factors have been associated with the development of psychogenic movement disorders (270), such as a history of psychiatric treatment, suicide attempt, self-injurious behavior, drug or alcohol use, physical or sexual abuse, previous somatization, exposure to a person with an organic movement disorder, or medicolegal conflict over the current or a past illness. Added to these risk factors are accompanying clinical findings such as false weakness or anatomically unlikely sensory loss. Yet the clinician must be aware that 100% accuracy cannot be achieved even when the maximal numbers of predictors are present. Confounding issues include patients with bonafide movement disorders who also manifest concurrent psychogenic movements or bizarre exaggerations of a true underlying abnormal movement, which then dominates the clinical syndrome (271).

Tremor is the most commonly encountered psychogenic movement disorder followed by dystonia (272). Psychogenic tremor often changes frequency or direction within the span of a few minutes and often displays an intermittency that cannot be associated with any apparent precipitating factors such as a specific position or motor activity. A common feature of psychogenic dystonia is abrupt onset, rapid progression, and immediate progression to a fixed dystonic posture.

The treatment of a psychogenic movement disorder involves informing the patient, family members, and caregivers of the diagnosis and the relatively high degree of certainty of its correctness. A confrontational approach must be avoided and commentary on the validity of other physician's opinions should not be central to the discussion, as opposed to the current diagnostic process and conclusions. Referral to a mental health professional with an interest and expertise in these disorders should be suggested as an option. Despite this approach, experience has suggested that these disorders are often relatively refractory to therapy. Poor outcome with respect to resolution of these movements appears to be associated with long duration of symptoms, insidious onset of movements, and psychiatric comorbidity (273).

# Epilepsy Syndromes in Childhood

22

*Rochelle Caplan, MD*    *Erin Lanphier, PhD*

## INTRODUCTION

Epilepsy occurs in 4 per 1,000 children (Hauser and Hesdorffer, 1990) with a lifetime incidence of 4 to 9 /1,000 in 10-year-old children (Murphy et al., 1995). Since epilepsy is a recurrent chronic disorder that involves the brain, child clinicians need to be aware of the neurological and behavioral aspects of this disorder to understand the impact of this illness on the child and his or her family.

The Commission on Classification and Terminology of the International League Against Epilepsy (1989) divided the epileptic syndromes by seizure types (i.e., partial, focal, or localized versus generalized) and by etiology into idiopathic (primary) or symptomatic (secondary) (Table 22.1). Using the Commission classification, this chapter describes the clinical and behavioral aspects of the most common epileptic syndromes in childhood and adolescence. It then reviews the clinical manifestations, associated disorders, diagnosis, and treatment of pseudoseizures in childhood and adolescence. The chapter concludes with a brief discussion on how epilepsy affects school achievement, cognition, and language in children.

## LOCALIZATION-RELATED EPILEPSIES AND SYNDROMES

### Symptomatic

#### *Temporal Lobe Epilepsy (TLE)*

Seizures originating from the temporal lobe can be simple partial, complex partial, secondarily generalized, or a combination of the above (Commission, 1989). As described for adolescents and adults, the etiology of temporal lobe

epilepsy in childhood includes mesial temporal sclerosis, tumors, and cortical dysplasia (Aso et al., 1994; Porter et al., 2003; Wyllie et al., 1993). However, dual pathology involving both mesial temporal sclerosis (hippocampal pathology) and cortical dysplasia is more common in children with temporal lobe epilepsy (Bocti et al., 2003; Mohamed et al., 2001).

Nonetheless, the younger the cohort of children, the more infrequent is mesial temporal (hippocampal) sclerosis. Magnetic resonance imaging (MRI) studies show that only 46% of children and 44% of adolescents with temporal lobe epilepsy have focal atrophy of the hippocampal head or body; whereas the remaining patients in these age groups have asymmetry of total hippocampal volumes (Mohamed et al., 2001). As described for adults, the presence of mesial temporal sclerosis in childhood is associated with a history of febrile convulsions and status epilepticus (Aso et al., 1994; Harvey et al., 1993; Scott et al., 2001; Wyllie et al., 1993).

In terms of ictal semiology, simple partial seizures of temporal origin present with sensory (e.g., rising unpleasant epigastric sensation, olfactory or auditory hallucinations or illusions), autonomic (e.g., nausea, vomiting), or psychic symptoms (e.g., forced thinking, *déjà vue*, *déjà entendu*) (Commission, 1989). Complex partial seizures last less than 1 minute and present with loss of consciousness, a motor arrest, orolimentary automatisms followed by other automatisms, and postictal confusion or amnesia (Commission, 1989).

In contrast to adults, the clinical manifestations of temporal lobe epilepsy in children are not homogenous and motor phenomena, such as tonic, clonic, hypermotor movements as well as epileptic spasms, occur (see the review in Fogarasi et al., 2002). Other ictal manifestations of temporal lobe seizures in children include shouting, tonic

**TABLE 22.1**  
**CLASSIFICATION OF EPILEPSY AND EPILEPTIC SYNDROMES**

### 1. Localization-Related Epilepsies

- a. **Partial (Focal)**
  - Temporal lobe epilepsy
  - Frontal lobe epilepsy
  - Parietal lobe epilepsy
  - Occipital lobe epilepsy
- b. **Idiopathic**
  - Benign rolandic with centro-temporal spike
  - Childhood epilepsy with occipital paroxysms
  - Primary reading epilepsy
- c. **Symptomatic**
  - Chronic progressive epilepsia partialis continua of childhood (Kojewnikow's syndrome)

### 2. Generalized Epilepsies and Syndromes

- a. **Idiopathic**
  - Benign neonatal familial convulsions
  - Benign neonatal convulsions
  - Benign myoclonic epilepsy in infancy
  - Childhood absence epilepsy
  - Juvenile absence epilepsy
  - Juvenile myoclonic epilepsy
  - Epilepsy with grand mal seizures on awakening
  - Other generalized epilepsies not defined previously
- b. **Cryptogenic or symptomatic**
  - West syndrome (infantile spasms)
  - Lennox-Gastaut syndrome
  - Epilepsy with myoclonic-astatic seizures
  - Epilepsy with myoclonic absences
- c. **Symptomatic**
  - Epilepsies and syndromes undetermined whether focal or generalized
  - Neonatal seizures
  - Severe myoclonic epilepsy in infancy
  - Epilepsy with continuous spike-waves during slow wave sleep
  - Acquired epileptic aphasia (Landau-Kleffner syndrome)

### 3. Special Syndromes

- Febrile convulsions
- Isolated seizures or isolated status epilepticus
- Seizures with acute metabolic or toxic event

Source: Adapted from Commission on Classification and Terminology of the International League Against Epilepsy, 1989.

posturing, versive seizures, vomiting, eye deviation, and laughing, but these are more infrequent in children (Aso et al., 1994; Olbrich et al., 2002).

In terms of auras, like adults, children with temporal lobe epilepsy due to mesial temporal sclerosis have abdominal or gustatory auras (Wyllie et al., 1993) or rising epigastric sensation (Aso et al., 1994); whereas those without mesial temporal sclerosis have more complex auras with somatosensory and visual phenomena, dizziness, or headache (Aso et al., 1994; Wyllie et al., 1993). The automatisms of complex partial seizures are, however, more infrequent and simpler in children compared to adults and are limited to lip smacking and fumbling hand gestures

(Mohammed et al., 2001; Wyllie et al., 1993). Secondary generalization occurs infrequently in 2 to 24% of the seizures of children with temporal lobe epilepsy (Aso et al., 1994; Wyllie et al., 1993).

Whereas the EEG of adolescents with temporal lobe epilepsy present with unilateral anterior temporal interictal spikes, the anterior temporal spikes of children with temporal lobe epilepsy are associated with mid/posterior temporal, bilateral temporal, extratemporal, or generalized spikes in 60% of the cases (Mohammed et al., 2001).

Studies on the course and outcome of pediatric temporal lobe epilepsy indicate that these are difficult-to-control seizures and usually do not remit spontaneously (Aso et al.,

1994). A retrospective chart study of 120 children, ages 1 to 18 years revealed that failure of the first antiepileptic drug (AED) trial accurately predicts refractory pediatric TLE at the 2-year follow-up (Dlugos et al., 2001). Bilateral temporal interictal sharp waves and bilateral hippocampal sclerosis on MRI are associated with a tendency for lower seizure-free outcome at the 2.6 year follow-up (Mohamed et al., 2001).

In terms of long-term outcome, in a prospective study Lindsay et al. (1979a) reported that one third of 100 children with temporal lobe epilepsy were seizure free as adults. However, they might have included cases of benign focal epilepsy of childhood (discussed later), an entity unknown at that time, in their sample (Kotagal et al., 1987). Aso et al. (1994) described a similar course in children with mesial temporal sclerosis and in those with other underlying etiologies. This finding led Aso et al. (1994) to conclude that, irrespective of the underlying pathology, pediatric complex partial seizures originating from the temporal lobe have a bad prognosis.

### Behavioral Aspects of Temporal Lobe Epilepsy

Several older studies suggest that children with temporal lobe epilepsy have characteristic behavioral disturbances (Hoare, 1991; Lindsay et al., 1979a, 1979b, 1984; Rutter et al., 1970; Stores, 1978a; Stores et al., Taylor, 1975), particularly if they have left-sided foci (Lindsay et al., 1979b, 1984; Stores, 1978a). These include hyperactivity, antisocial behavior, and aggression (Hoare, 1991; Rutter et al., 1970; Stores, 1978), and a schizophrenia-like psychosis (Caplan et al., 1991; Lindsay et al., 1979a and b).

Antisocial behavior was related to male sex, poor seizure control, low IQ, and childhood rages (Lindsay et al., 1979a, 1979b; Stores, 1978a, 1978b). Lindsay et al. (1979a) reported that 10% of children with temporal lobe epilepsy developed psychosis by adulthood, in particular, if they had experienced cataclysmic rage attacks and hyperkinetic reactions in childhood. The schizophrenia-like psychosis appeared to be associated with hallucinations, delusions, and illogical thinking but not with loose associations or negative signs of schizophrenia (Caplan et al., 1991, 1992a). Unlike adults with temporal lobe epilepsy and schizophrenia-like psychosis (Dongier, 1959; Kristensen and Sindrup, 1978; Landolt, 1958; Pakalnis et al., 1987; Slater et al., 1963), middle childhood onset of interictal psychosis was not associated with a long latency period, seizure control, or normalization of EEG (Caplan et al., 1991). Despite these behavioral difficulties, a prospective study by Lindsay et al. (1979a, 1979b) demonstrated a significant reduction of behavioral disturbances in adulthood compared to adolescence, particularly if seizures were controlled prior to age 12 years.

In contrast to these findings, Kaminer et al. (1988) were unable to demonstrate increased psychopathology in adolescents with temporal lobe epilepsy compared to adolescents with asthma. Other researchers were unable to

identify differences in measures of psychopathology in children with temporal lobe and generalized epilepsy (Hermann et al., 1988; Whitman et al., 1982). Camfield et al. (1979) found that dysfunction on neuropsychological tests rather than lateralization of the temporal lobe focus was related to differences in the psychopathology profile of children with epilepsy.

Studies indicate high rates of psychopathology in children with complex partial seizures, many of whom have temporal lobe epilepsy. Sixty percent of the children have an axis I diagnosis compared to age- and gender-matched normal control subjects (Caplan et al., 2004). Subtle verbal difficulties, not seizure variables, are a robust predictor of these behavioral problems (Caplan et al., 2004). Of note, this high rate of behavioral problems is not specific for children with TLE and is also found in childhood absence epilepsy (Caplan et al., 1998; Ott et al., 2001, 2003).

Short-term follow-up 3 months after surgery of 21 surgically treated children with intractable epilepsy, 13 of whom had anterior temporal lobectomy, showed significant improvement in parent-based internalizing, externalizing, attention, and thought problems of the Child Behavior Checklist (Achenbach, 1991) compared to presurgical measures and to a control group of medically treated children with comparable psychopathology scores (Lendt et al., 2000). A good seizure outcome predicted these behavioral changes similar to the findings of earlier studies indicating reduced aggression in surgically treated TLE children with seizure control (Green, 1977; Hopkins and Klug, 1991; Lindsay et al., 1984). However, none of these earlier studies used standardized psychiatric instruments to follow the postoperative behavioral changes of a representative sample of children undergoing temporal lobectomy.

In contrast, seizure variables were unrelated to the findings of a follow-up study of 30 children who had anterior temporal lobectomy compared to 21 medically controlled children with intractable TLE. There were no psychosocial differences between the groups 1 year after surgery other than a trend toward promotion of independence and less satisfaction with the family of the surgical patients (Smith et al., 2004).

Lower IQ scores and impaired performance on neuropsychological tests are also found in both new onset (Hermann et al., 2005) and chronic childhood temporal lobe epilepsy (Caplan et al., 2004; Schoenfeld et al., 1999). These neuropsychological deficits have been associated with reduction in total white matter volume in the chronic patients (Hermann et al., 2002) but not in the new onset patients (Hermann et al., 2005). Parent reports support attentional difficulties, particularly in children with left-sided lesions (Duval et al., 2002).

In children who had temporal lobe epilepsy surgery, earlier reports indicated unchanged cognition and memory (Miranda and Smith, 2001; Williams et al., 1998), decline in memory and language (Szabo et al., 1998), or improved

attention and memory (Lendt et al., 1999; Mabbott and Smith, 2003). Smith et al. (2004) found no difference at the 1-year follow-up in cognition and behavior in children who had undergone epilepsy surgery compared to medical control subjects. Compared to children with other epilepsy syndromes (e.g., frontal lobe epilepsy, childhood absence epilepsy), children with temporal lobe epilepsy have significantly worse memory function and reduced performance on most verbal and visual tasks (Nolan et al., 2004).

In addition, these children have significantly impaired linguistic skills when compared to either normal (Caplan et al., 2004) or sibling-control subjects (Schoenfeld et al., 1999). In formulating and organizing their thoughts, they also perform poorly compared to age- and gender-matched normal subjects (Caplan et al., 2002a). Additionally, they monitor and correct communication breakdowns more infrequently than do the normal children (Caplan et al., 2001).

### Diagnosis

A child who presents with abdominal, gustatory, somatosensory, or psychic aura automatisms, such as lip smacking or hand gestures, decreased level of awareness, and postictal amnesia, might have temporal lobe epilepsy. An EEG finding of focal interictal spikes or sharp waves in the temporal area using scalp or depth electrodes will confirm the diagnosis.

The differential diagnosis should include other seizure disorders, such as childhood absence epilepsy if the child presents with absences; frontal lobe epilepsy if the child presents with aura, motor seizures, or tonic versive seizures; benign focal epilepsy if the seizures are nocturnal and involve the orofacial area; and benign occipital epilepsy if the child presents with visual aura. Psychic symptoms, like hallucinations, illusions, and forced thinking, that occur during temporal lobe epilepsy auras need to be differentiated from those that occur in psychoses, such as schizophrenia, manic depressive disorder, psychosis not otherwise specified, or dissociative psychosis associated with posttraumatic stress disorder.

Ictal psychic symptoms are stereotyped and consistent across ictal episodes. In contrast, the form and content of the hallucinations, illusions, and abnormal thoughts of psychotic children vary over time. Furthermore, children with ictal auditory hallucination usually do not recall the content of their hallucinations. Psychotic children describe the content, albeit bizarre, of their auditory hallucinations. Ictal psychic phenomena cause marked subjective distress to children who perceive them as an unreal experience. In the acute phase of psychosis, children might respond with subjective distress and insight as to the unreal nature of the experience. The child with chronic psychosis, however, does not become upset and has poor reality testing when he or she experiences hallucinations, illusions, or forced thinking.

Finally, forced thinking should be differentiated from the obsessions of obsessive-compulsive disorder. Forced thinking and obsessions can both cause subjective distress

in the child. Unlike the epileptic child with stereotyped forced thinking, the child with obsessive-compulsive disorder usually has more than one obsession, and these obsessions change over time.

### Treatment

The drugs commonly used in children with temporal lobe epilepsy include carbamazepine and valproic acid, and more recently lamotrigine, topiramate, oxcarbazepine, and gabapentin (French et al., 2004). Children who fail to respond to the first AED have a high rate of treatment failure (89%) to a subsequent AED trial (Dlugos et al., 2001). Anterior temporal lobectomy (Clusmann et al., 2004; Sinclair et al., 2004) and vagal nerve stimulation have variable success rates. Normal intelligence at baseline and tumor as etiology are associated with better outcome in pediatric epilepsy surgery that also includes anterior temporal lobectomy (Gashlan et al., 1999; Sherman et al., 2003).

### Frontal Lobe Epilepsy

A good understanding of the clinical and behavioral aspects of this epileptic syndrome is important because they often involve bizarre behaviors (Chauvel et al., 1995; Delgado-Escueta et al., 1994) that are labeled as hysteria (Saygi et al., 1992; Stores et al., 1991) or other psychiatric syndromes (Boone et al., 1988; Sinclair et al., 2004). In addition to bizarre behaviors, this syndrome poses diagnostic difficulties because the ictal and interictal scalp EEG is often normal, particularly in patients with mesial or orbital frontal lobe epilepsy (Shigematsu et al., 1992; Van Ness, 1993; Williamson et al., 1985).

Typically, frontal lobe seizures are characterized by auras, bilateral coarse and upper extremity movements, rare oroalimentary automatisms, short duration of less than 1 minute, minimal postictal confusion, and frequent seizures (Kotagal et al., 2003; Laskowitz et al., 1995; Quesney et al., 1992; Salanova et al., 1995; Wieser et al., 1992; Williamson, 1992, 1995). The clinical presentation of frontal lobe seizures depends on the anatomical location of the focus and ipsilateral or bilateral seizure spread.

There are different opinions on the anatomical classification of frontal lobe seizures (Quesney et al., 1992), and in some cases the epileptic zone might be a continuum rather than a discrete focus (Quesney et al., 1990). Penfield and Jasper (1954) originally classified them into focal motor seizures, supplementary motor seizures, and psychomotor seizures, and this classification is supported by Wieser et al.'s (1983) cluster analysis of psychomotor seizures and by more recent studies (Chauvel et al., 1995; Salanova et al., 1995).

Focal motor seizures involve unilateral clonic movements of the face followed by the arm, speech arrest, blinking, version of the head and eyes, but no loss of consciousness (Salanova et al., 1995). Seizures originating in the supplementary motor area occur in clusters at night (Bancaud and Talairach, 1992; Wieser et al., 1992) and

present with somatosensory auras, unilateral or bilateral posturing and tonic movements that spread to the whole body, vocalizations from simple groaning to shouted obscenities, laughing, crying, and version of the head and eyes (Laskowitz et al., 1995; Salanova et al., 1995; Williamson et al., 1985). Patients with supplementary motor seizures maintain consciousness prior to generalization of the seizure and spread to the other side (Bancaud and Talairach, 1992; Morris et al., 1988; Wieser et al., 1992).

Complex partial seizures occur if the seizure focus is in the frontal opercular convexity or the anterofrontal region (Quesney et al., 1992). Complex partial seizures of frontal origin have a sensory aura with a feeling of pins and needles, tingling, or sensation of heaviness or light headedness on the contralateral side (Quesney et al., 1992). The patient can also experience whole body dizziness, fear, or visual phenomena. During a seizure, the patient stares ahead with partial or complete unresponsiveness, vocalizes, has bilateral tonic arm movements, laughs, cries, makes pedaling bicycle movements, or turns the head and eyes contralateral to the seizure focus (Salanova et al., 1995).

Seizures from the mesial frontal cortex produce emotional and autonomic manifestations, such as aura with panic or fear and changes in sympathetic tone. Seizures of orbitofrontal origin are silent until they spread to the adjacent cingulate or insular regions and then produce autonomic signs (i.e., facial reddening, tachycardia), olfactory hallucinations, or oroalimentary automatisms (Laskowitz et al., 1995). The presence of sexual automatisms reflects involvement of the anterior cingulate gyrus (Stoeffels et al., 1980). Finally, frontal lobe seizures from the frontal pole present with a motionless stare, loss of postural tone, and secondary generalization (Laskowitz et al., 1995).

Preschool children with frontal lobe epilepsy have frequent short seizures that occur at night or during sleep with motor manifestations and automatisms, such as moaning, groaning, and crying, but rare secondary generalization and laughing or pedal movements (Fogarasi et al., 2002). In older children asymmetric tonic posturing, contralateral head/eye deviation, and unilateral clonic jerking were associated with reduced blood flow in dorsolateral, front central, and medial frontal regions while vocalization, hyperventilation, truncal flexion, and complex gestural automatisms were found in children with reduced blood flow in orbital and polar frontal regions (Harvey et al., 1993). Seizures occur mainly in sleep and are associated with bilateral ictal and interictal epileptiform EEG findings (Lawson et al., 2002).

### Behavioral Aspects of Frontal Lobe Epilepsy

There have been no studies on the psychiatric aspects of frontal lobe seizures in children to date. Children with complex partial seizures with EEG evidence for frontal involvement have more severe formal thought disorder (Caplan et al., 1992) and discourse deficits (Caplan et al., 1994) than those with temporal involvement. Two case re-

ports (Boone et al., 1988; Stores et al., 1991) describe sexual disinhibition, pressured and tangential speech, screaming, aggression, disorganized behavior, and nightmares in children with frontal lobe epilepsy. Children with frontal lobe epilepsy appear to have more deficits in planning and executive function (Culhane-Shelburne et al., 2002), but no difference in language scores (Blanchette and Smith, 2002) compared to those with temporal lobe epilepsy.

### Diagnosis

This is a difficult disorder to diagnose (Bass et al., 1995; Riggio and Harner, 1992). One should entertain a diagnosis of frontal lobe epilepsy in a child if he or she presents with brief sudden unresponsiveness without loss of consciousness and continued understanding of spoken language during the episode with either clonic or tonic motor phenomena that involve the face and arms and become bilateral. The presence of vocalizations, laughing, crying, or rarely pedaling movements could be suggestive of this diagnosis. A normal EEG with scalp electrodes does not rule out the diagnosis of frontal lobe epilepsy.

The two main disorders to consider in the differential diagnosis are complex partial seizures of temporal origin and pseudoseizures. The aura, stare, and automatisms of frontal lobe epilepsy might resemble the complex partial seizures of temporal lobe origin. Unlike complex partial seizures of temporal lobe origin, the amnesia of complex partial seizures of frontal origin is more pronounced than the degree of loss of consciousness (Chauvel et al., 1995). Furthermore, frontal complex partial seizures have associated unilateral or bilateral tonic posturing and bicycling movements, partial rather than complete loss of consciousness, and contralateral head and eye deviation. In contrast, patients with complex partial seizures of temporal lobe origin have more oroalimentary and repetitive hand automatisms and looking around (Salanova et al., 1995).

Among the similarities of pseudoseizures and frontal lobe seizures, children with both disorders present with unresponsiveness or partial loss of consciousness and no EEG correlates during continuous video-EEG monitoring of these episodes. In addition, the vocalizations of children with frontal lobe seizures can be interpreted as emotional lability or dissociative phenomena in children with pseudoseizures. Among the differences between these two disorders, pseudoseizures have a prolonged onset and duration and usually do not occur during sleep, whereas frontal lobe seizures start suddenly, last less than 1 minute, and are nocturnal. The motor phenomena of pseudoseizures involve thrusting or rolling rather than the rhythmic flexion and extension of clonic movements in frontal lobe epilepsy. Children with pseudoseizures, in contrast to frontal lobe epilepsy, have a primary conflict that involves difficulty expressing negative affect and a secondary gain that reinforces their pseudoseizures. In some cases, however, it is difficult to differentiate between these disorders, particularly when a child has both disorders. Continued

video-EEG monitoring with depth electrodes is helpful in providing a definitive diagnosis of frontal lobe epilepsy in these children (Bass et al., 1995).

Finally, the presence of sensory, gustatory, or olfactory hallucinations underscore the importance of ruling out psychotic disorders, such as schizophrenia, psychosis not otherwise specified, manic psychosis, or another organic psychosis as previously described in the section on temporal lobe epilepsy.

### Treatment

Typically this is a difficult disorder to treat medically or surgically (Fish et al., 1993; Kral et al., 2001).

### Benign Rolandic Epilepsy

Benign rolandic epilepsy begins in childhood between ages 3 and 10 years and remits by age 16 years (Blom and Heijbel, 1992; Lerman and Kivity, 1975; Loiseau et al., 1988; Kramer and Lerman, 2001). This form of epilepsy is frequent in childhood and accounts for 15 to 25% of all epileptic syndromes in children under age 12 years (Astradsson et al., 1998; Cavazutti, 1980). Benign rolandic epilepsy occurs more frequently in children with a history of febrile seizures (Degen and Degen, 1990; Gregory and Wong, 1984; Kajitani et al., 1992; Lerman and Kivity, 1975), a family history of febrile seizures (Kajitani et al., 1992), or benign rolandic epilepsy (Heijbel et al., 1975). It is also frequent in children with fragile X syndrome (Berry-Kravis, 2002). MRI studies might reveal hippocampal asymmetries and white matter abnormalities (Lundberg et al., 1999).

Benign rolandic seizures usually occur nocturnally during sleep (Drury and Beydoun, 1991). The children have brief and mild tonic-clonic seizures of the face, lips, tongue, pharyngeal and laryngeal muscles, speech arrest, saliva pooling and drooling, and no loss of consciousness (de Weerd and Arts, 1993; Iannetti et al., 1994; Lerman and Kivity, 1991). Although partial, these seizures tend to generalize (de Weerd and Arts, 1993; Iannetti et al., 1994; Kajitani et al., 1992). Daytime seizures that are simple/partial, involving the face and tongue, occur in one third of the children (Camfield and Camfield, 2002).

The EEG findings include normal background, as well as interictal spikes or blunted monomorphic sharp waves (Drury and Bedoun, 1991; Lüders et al., 1989). Similar EEG findings occurring in 1.3 to 2.4% of normal children (Cavazutti, 1980) are thought to reflect central nervous system immaturity in terms of brain excitability and inhibition (Ferri et al., 2000). The cortical generators for rolandic discharges are localized in the sulcal or gyral cortices on either side of the central sulcus of the precentral motor cortex, closer to hand secondary somatosensory cortex than to primary cortex (Jung et al., 2003; Lin et al., 2003). Spike propagation involves spreading across the central sulcus (Jung et al., 2003). Spikes in the high central region are associated with hand involvement, whereas those in the low

central region are associated with oromotor phenomena and drooling (Legarda et al., 1994). Studies demonstrate rare or no association between this syndrome and childhood absence epilepsy (Dimova and Daskalova, 2002; Gellisse et al., 1999).

Most children with benign rolandic epilepsy have few seizures, 15% have one seizure, 56% have two to six seizures, and 29% have more than six seizures (Ambrosetto et al., 1987). The children who present with a generalized convulsive seizure and with a long interval between the first and second seizure have the best prognosis (Ambrosetto et al., 1987). The course is benign in 95 to 100% of the children.

### Behavioral Aspects of Benign Rolandic Epilepsy

Although these children were thought to have normal psychomotor development and functioning, parents recognize difficulties with concentration, temperament, and impulsiveness (Croona et al., 1999). In addition, neuropsychological testing reveal significantly lower scores on immediate and delayed recall of auditory-verbal and visual material, verbal fluency, problem-solving ability, visuospatial constructional ability, and Raven's Coloured-Progressive Matrices compared to age- and gender-matched normal control subjects (Croona et al., 1999; Deonna et al., 2000). The findings of some investigators, however, imply preferential impairment of executive function in these children (Chevalier et al., 2000), cognitive impairment and attentional difficulties in children with EEG evidence of a prolonged slow focus, and strong activation of spike and wave discharges at night (Saint-Martin et al., 2001). Given the small sample size of these studies, the possible role of carbamazepine on these findings needs to be considered (Seidel and Mitchell, 1999).

### Diagnosis

A diagnosis of benign rolandic epilepsy should be considered when a child presents with a history of hemifacial nocturnal seizures with normal EEG background activity and midtemporal spikes. From the clinical perspective, these seizures differ from complex partial seizures of temporal origin because they are partial motor seizures and do not involve loss of consciousness. Like benign rolandic epilepsy, frontal lobe epilepsy that involves the supplementary motor area also occurs during sleep. However, children with benign rolandic seizures do not have posturing and tonic movement, vocalizations, laughing, crying, and version of the head and eyes. The possibility of facial and eye movements during REM sleep should also be ruled out.

Regarding midtemporal spikes, these are not pathognomonic for benign rolandic epilepsy (van der Meij et al., 1992) and, as previously mentioned, occur in children who have no clinical epileptic manifestations (de Weerd and Arts, 1993; Ferri et al., 2000). Midtemporal spikes are also found in children with neurological disorders, such as cerebral palsy, epilepsy, developmental delays, and attention deficit hyperactivity disorder (van der Meij et al., 1992).

Finally, parental anxiety and misinterpretation of children's myoclonic movements during sleep can be easily differentiated from benign rolandic epilepsy. Myoclonic jerks involve large groups of muscles other than the face and do not present with a consistent pattern.

### Treatment

Although carbamazepine, valproic acid, and levetiracetam have been successfully used in these children, randomized trials have been conducted only with gabapentin (Bourgeois et al., 1998) and sulthiame (Rating et al., 2000).

### Benign Occipital Epilepsy

This form of epilepsy presents with visual, motor, and migrainous symptoms with unilateral or bilateral spike-wave complexes in the occipital regions that are inhibited by eye-opening (Lerman and Kivity, 1991). In 25% of cases the seizures are precipitated by going from light to dark or vice versa (Gastaut, 1985). Benign occipital epilepsy has greater morbidity than benign rolandic epilepsy. Antiepileptic drugs control about 60% of the cases of benign occipital seizures, and seizures stop between ages 13 and 19 years (Lerman and Kivity, 1991; Oguni et al., 2001).

The benign form of the disease, most frequent in 4- to 8-year-old boys (Beaumanoir and Nahory, 1983; Lerman and Kivity, 1989), involves nocturnal motor seizures with tonic deviation of the head and eyes, clonic (i.e., nystagmoid) eye movements, and loss of consciousness, which can be prolonged (Lerman and Kivity, 1991). In Panayiotopoulos syndrome, autonomic symptoms (e.g., ictal vomiting), lateral eye deviation, and impairment of consciousness, followed by hemi- or generalized seizures occur more frequently in girls (Lada et al., 2003).

Children older than 8 years have the Gastaut type with a more protracted course of illness with diurnal seizures, visual symptoms, migrainous symptoms, and preserved or impaired consciousness (Lerman and Kivity, 1991; Martinovic, 2001; Tsai et al., 2001). The visual symptoms include partial or complete loss of vision, elementary or complex visual hallucinations, and visual illusions (i.e., micropsia, macropsia, metamorphosia) (Gastaut, 1982; Gastaut and Zifkin, 1984; Lerman and Kivity, 1991; Panayiotopoulos, 1989). The symptoms of migraine can be ictal or postictal and include a diffuse nonpulsatile headache and vomiting (Gastaut, 1985; Lerman and Kivity, 1991).

The EEG findings typically entail unilateral or bilateral spikes or sharp waves in posterior head regions. Non-REM sleep, closed eyes, or lack of visual fixation activate, and REM sleep and eye opening inhibit the epileptic discharges (Lerman and Kivity, 1991). Among children with early onset occipital seizures (e.g., Panayiotopoulos syndrome), occipital spike focus is seen in younger children, ages 2 to 5 years; whereas independent frontopolar, occipital, and centroparietotemporal spike foci appear between ages 6 to 10 years (Ohtsu et al., 2003). These EEG patterns are unrelated to the prognosis.

### Behavioral Aspects of Benign Occipital Epilepsy

To date, the single study that examined neuropsychological functioning in 21 children with this disorder found lower attention, memory, and intellectual functioning compared to 21 children without epilepsy with whom they were matched by age, gender, and socioeconomic status (Gulonen et al., 2000).

### Diagnosis

A diagnosis of benign occipital epilepsy should be considered in children who have nocturnal adverse seizures with loss of consciousness, diurnal seizures with visual, autonomic, and migrainous symptoms, but preserved or somewhat impaired consciousness, and EEG evidence of posterior epileptic discharges that disappear with eye opening. Based on the clinical symptoms, this syndrome should be differentiated from supplementary motor epilepsy, temporal lobe epilepsy with autonomic manifestations (e.g., abdominal epilepsy), migraine, occipital lobe tumor, and psychotic disorders.

Unlike occipital epilepsy, the nocturnal tonic deviation of the head and eyes in supplementary motor epilepsy is associated with somatosensory auras, posturing and tonic movement, vocalizations, laughing, and crying. Children with temporal lobe epilepsy with autonomic symptoms do not have tonic deviation of the eyes. Compared to migraine, children with benign occipital epilepsy have visual hallucinations and illusions, not scotomata. Their headache is diffuse, not pulsatile.

If unilateral, the EEG findings of benign occipital epilepsy could mimic those of a cortical lesion in the occipital lobe. During an attack of migraine, there might be slowing rather than posterior sharp waves or spikes on the EEG. Activation of the epileptic discharges on EEG by closed eyes and nonREM sleep do not occur in other conditions.

Finally, the visual hallucinations of psychotic disorders are complex, variable, and associated with auditory hallucinations, not with symptoms of migraine.

### Treatment

Most patients respond well to classic AEDs (Oguni et al., 2001).

### Chronic Progressive Epilepsia Partialis Continua of Childhood (Rasmussen's Syndrome)

Rasmussen encephalitis, a progressive disorder of unproven viral or autoimmune etiology (Park and Vinters, 2003; Pardo et al., 2004; Watson et al., 2004), presents with increasingly intractable unilateral seizures, emerging hemiparesis that sometimes progresses to hemiplegia, and a downhill cognitive course (Granata et al., 2003a; Honavar et al., 1992; Oguni et al., 1991; Rasmussen and Andermann, 1989; Vining et al., 1993). The onset occurs in childhood, adolescence, or adulthood (Honavar et al., 1992; McLachlan et al., 1993; Rasmussen and Andermann), but in 85% of cases the illness begins before age 10 years (Rasmussen and Andermann).

There is a characteristic progression observed in both the MRI scan and EEG. By 4 months after the onset of symptoms, the MRI reveals focal contralateral white matter hyperintensity with cortical atrophy that always involves the insula and in most cases, the head of the caudate (Granata et al., 2003a). As the disorder progresses, there is increasing MRI signal intensity. Subsequently, signal intensity decreases, with or without progressive unilateral cortical atrophy (Kim et al., 2002). Initially the EEG reveals focal slowing and ictal and interictal multifocal spikes. Over the next few months there is progressive slowing and voltage attenuation, with unilateral multifocal independent spikes. Contralateral asynchronous slow waves were often noted.

#### Behavioral Aspects of Rasmussen Syndrome

Despite earlier normal development, children with Rasmussen's syndrome have impaired cognitive (Honavar et al., 1992; Vining et al., 1993) and linguistic function (Caplan et al., 1999; Vargha-Khadem et al., 1991).

#### Diagnosis

Diagnosis is based on the evolving clinical picture of intractable unilateral motor seizures with *epilepsia partialis continua*, contralateral increased signal intensity with or without cortical atrophy on MRI, and brain biopsy. The histological hallmarks of Rasmussen encephalitis include chronic inflammation, microglial nodules, and focal patchy gliosis.

#### Treatment

AEDs usually do not control the seizures. Treatment with hemispherectomy (Jonas et al., 2004; Rasmussen and Andermann, 1989) and immunomodulatory treatments (Granata et al., 2003b) appear to stop progression of the disorder (Honavar et al., 1992). Postsurgical improvement in the communication deficits of children with Rasmussen encephalitis is associated with later age of onset and shorter duration of illness prior to surgery (Caplan et al., 1999).

#### Generalized Epilepsies and Syndromes Idiopathic (With Age-Related Onset) Childhood Absence Epilepsy

An absence is a brief change in the state of consciousness during which the child suddenly stops ongoing activity and stares vacantly (Lockman, 1989). Typical absence seizures (also known as *petit mal*) occur frequently and are associated with automatisms of the eyes (i.e., eyelid fluttering) and face (i.e., twitching of the perioral muscles), unchanged tone, and generalized spike and wave discharges at a rate of three per second on a normal EEG background (Holmes et al., 1987; Lockman). Atypical absence seizures last longer, are associated with a decrease in postural tone or tonic activity, greater than three per second spike and wave ictal recordings, abnormal interictal EEGs, and multiple seizure types (Holmes et al., 1987). Hyperventilation can induce typical absence seizures, but not atypical ab-

sence seizures. Both typical and atypical absence seizures start and stop suddenly without postictal symptoms (Erba and Browne, 1983; Holmes et al., 1987). During a typical or atypical absence, the child maintains receptive and expressive speech (Holmes et al., 1987). In *petit mal* status, however, the child might experience cognitive clouding and difficulties with comprehension and expression of language.

Typical absence seizures are found in school-age children, more frequently in girls than boys (Camfield et al., 1996). They remit in 64 to 90% of the cases if therapy is adequate and given for at least 2 years (Bouma et al., 1996; Camfield and Camfield, 2002; Siren et al., 2002; Wirrell et al., 1996, 2001). Predictors of good remission include the absence of generalized tonic clonic seizures, absence status, cognitive problems, myoclonic seizures, abnormal background, and a family history of generalized tonic clonic seizures.

#### Behavioral Aspects of Absence Seizures

Children with absence seizures have high rates of psychopathology including disruptive disorders (i.e., attention-deficit hyperactivity disorder, oppositional defiant disorder, conduct disorder), anxiety/affective disorders, and comorbid disruptive and anxiety/affective disorders (Caplan et al., 1998). They have difficulties using language to organize and formulate their thinking (Caplan et al., 2001, 2002a), as well as problems with general cognition (Mandelbaum and Burack, 1997; Pavone et al., 2001), attention (Levav et al., 2002), memory, particularly nonverbal memory (Nolan et al., 2004; Pavone et al.), and performance IQ (Caplan et al., 2004). As previously mentioned, children with atypical absence seizures usually have mental retardation or developmental delay (Holmes et al., 1987).

#### Diagnosis

A child who presents with brief staring spells during middle childhood, eyelid fluttering or twitching of the perioral muscles, no loss of tone, generalized three per second spike and wave on EEG, and induction of episodes by hyperventilation has typical absence seizures. From the neurological perspective, typical absence seizures should be differentiated from the absences of complex partial seizures. In contrast to children with typical absence seizures, hyperventilation will not induce the absence episodes of children with complex partial seizures. In addition, children with complex partial absences also have lip smacking and hand fumbling automatisms, postictal amnesia or tiredness, and focal interictal spikes rather than generalized 3 Hz spike and wave complexes. EEG findings of 3 Hz spike and wave together with eye opening and eyelid flutter differentiate typical absence seizures from hyperventilation-induced high-amplitude rhythmic slowing also associated with loss of awareness but with automatisms, such as yawning, smiling, and fidgeting (Lum et al., 2002).

From a behavioral perspective, children with typical absence seizures might first be noticed by the teacher who will

complain that the child is inattentive or has lost ground in his or her studies. Unlike the child with attention-deficit hyperactivity disorder (ADHD), children with typical absence seizures do not have a history of hyperactivity, impulsiveness, and distractibility since the toddler period, and they are unaware of their attentional difficulties. Children with a learning disorder will report specific learning difficulties; whereas the child with typical absence seizures will be unaware of why he or she is having learning difficulties.

Finally, the stares of autistic children that precede or occur together with their stereotyped behaviors, such as hand flapping, could be misinterpreted as absences. Children with typical absences do not have stereotyped behaviors other than the stare, eyelid fluttering, or twitching of lip muscles. Unlike autistic children, they do not have impaired communication skills and poor social relationships. Children with atypical absence seizures might have developmental delays like autistic children; however, unlike the brief staring associated with the stereotypies of autistic children, the staring spells of children with atypical absence seizures are long and associated with some loss of tone.

### Treatment

Monotherapy ethosuximide, valproic acid, and lamotrigine control typical absences in 70%, 75%, and 50 to 60% of the cases, respectively (see the review in Panayiotopoulos, 2001; Coppola et al., 2004; Henriksen and Johannessen, 1982; Wirrell et al., 2001) with no cognitive or behavioral adverse effects (Mandelbaum and Burack, 1997). In contrast, atypical absence seizures are more difficult to control, particularly in children with early onset or with late onset and lower intelligence, necessitating antiepileptic drug polytherapy.

### Juvenile Myoclonic Epilepsy

Juvenile myoclonic epilepsy affects 7% of adolescents with epilepsy; 3 to 8% of whom had childhood absence epilepsy (see the review in Renganathan and Delanty, 2003). The clinical seizures and/or the EEG abnormalities may be observed in relatives (Delgado-Escueta et al., 1994; Obeid, 1994). Juvenile myoclonic epilepsy is an inherited disorder that is genetically heterogeneous, and is associated with mutations in a number of genes, including the short arm of chromosome 6 (Greenberg et al., 2000; Sander et al., 1997). Relatively few cases can be linked to single genes and most cases appear to be the result of the interaction of complex genetic and environmental factors (Zifkin, Andermann, Andermann, 2005).

All cases have myoclonic jerks that occur shortly after awakening in the neck and upper extremities without loss of consciousness. In addition to sudden awakening, sleep deprivation, photic stimulation, alcohol consumption, menses, and stress precipitate the jerks (Dreifuss, 1989). Usually these jerks are undiagnosed because adolescents interpret them as clumsiness or nervousness (Gordon, 1994). The jerks are usually bilateral but can be unilateral, arrhythmic, and repetitive. A massive myoclonic jerk can

make the patient fall to the ground with brief loss of consciousness and no postictal phenomena (Lockman, 1989).

The disorder becomes progressive with onset of clonic seizures and generalized tonic-clonic seizures in 90 to 95% of the cases. The symmetric and violent generalized tonic-clonic seizures have a long tonic component (see the review in Renganathan and Delanty, 2003). Absences occur in 40% of the cases.

Ictal EEGs reveal bilateral diffuse spikes at a rate of 16 to 24 Hz (Delgado-Escueta et al., 1994) that can be preceded by asymptomatic spike and wave complexes and followed by 1 to 3 Hz spike and slow wave complexes. The interictal EEG is also abnormal with 4 to 6 Hz multiple spike and slow wave complexes. Photic stimulation leads to a generalized paroxysmal EEG discharge in about 30 to 40% of the cases. Some of these patients also have absence seizures, which often are undiagnosed because they are unaccompanied by behavioral phenomena (Voeller, 1995).

The prognosis is excellent with AED treatment (Gordon, 1994) in 80 to 90% of the cases. Intractability occurs in patients who have all three seizure types and behavior problems (see the review in Renganathan and Delanty, 2003).

### Behavioral Aspects of Juvenile Myoclonic Epilepsy

Other than clumsiness, nervousness, or ill-defined attentional difficulties prior to the onset of generalized tonic-clonic convulsions, there have been no studies to date on the behavioral aspects in adolescents with juvenile myoclonic epilepsy.

### Diagnosis

Several studies emphasize the long lag time between onset of the syndrome and correct diagnosis (Asconape and Penry, 1984; Gordon, 1994; Obeid, 1994). When presented with an adolescent with poorly defined complaints about clumsiness, nervousness, and difficulties concentrating, one should ascertain if the clumsiness is precipitated by sleep deprivation, photic stimulation, or alcohol consumption. A positive family history and characteristic ictal and interictal EEG findings will help confirm the diagnosis of juvenile myoclonic epilepsy.

Among the neurological disorders, one needs to rule out nonepileptic myoclonus and movement disorders. Unlike myoclonic seizures, myoclonus is not precipitated by sensory stimuli, continues during sleep, has no EEG correlates, and does not remit in response to AEDs. The jerks of movement disorders, such as Tourette's disorder, dystonia, or chorea, involve repetitive involuntary movements of parts of the body rather than isolated movements of large muscle groups. In addition, tics, dystonia, and chorea usually disappear during sleep. Finally, complaints of poor self-esteem (associated with clumsiness and poor concentration) can present in adolescents with psychiatric disorders, such as depression, schizophrenia, or adjustment disorder. The early stages of juvenile myoclonic epilepsy might suggest the prodrome of one of these psychiatric disorders.

**Treatment**

The treatment response to valproic acid is excellent (Gordon, 1994; Dreifuss, 1989; Obeid, 1994). Topiramate and vagal nerve stimulation have been used in intractable patients with success (see the review in Renganathan and Delanty, 2003).

**Cryptogenic or Symptomatic Infantile Spasms (West Syndrome)**

Infantile spasm is a generalized seizure disorder with clusters of flexion, extension, or brief tonic seizures often associated with hypsarrhythmia, high voltage slowing, and multifocal spikes on EEG (Commission, 1989). This syndrome usually begins by age 4 to 8 months (Glaze et al., 1988; Jeavons and Bower, 1964; Riikonen, 1982) and is cryptogenic (e.g., normal prior development, no known causative factors, normal neuroimaging) in 20% and symptomatic in 80% of the cases associated with a variety of etiological causes (see Hrachovy and Frost, 2003 for a review).

Although regarded as a generalized seizure disorder (Commission, 1989), focal cortical abnormalities due to cortical dysplasia (Alvarez et al., 1987; Cusmai et al., 1988), tumors (Branch and Dyken, 1979; Mimaki et al., 1983), or other etiologies underlie the symptomatic form of infantile spasms. The origin of the pathology, whether interaction of focal cortical and brainstem pathology, brainstem, or basal ganglia pathology (Avazini et al., 2002; Chugani, 2002; Hrachovy and Frost, 1989), increased proconvulsant activity in both cortical and brainstem regions (Lado and Moshe, 2002), or abnormal release of corticotrophin release hormone (Brunson et al., 2002) continue to be debated.

The rate of spontaneous remission is 25% and occurs from 1 to 12 months after the onset of infantile spasms (Hrachovy et al., 1991). Although 51% of the children continue to have seizures (see the review in Frost and Hrachovy, 2003), infantile spasms and hypsarrhythmia are age-specific phenomena (Yamatogi and Ohtahara, 1981). If treatment does not control infantile spasms, the children develop other seizures and the EEG no longer shows the hypsarrhythmia characteristic of infantile spasms (Yamatogi and Ohtahara, 1981). Ultimately, 25% of children with infantile spasm develop Lennox-Gastaut syndrome (see the review in Frost and Hrachovy, 2003).

**Behavioral Aspects of Infantile Spasms**

In the absence of early seizure control (Kivity et al., 2004), the developmental outcome for these children is poor (Dulac et al., 1986, 1993; Favatta et al., 1987; Fois et al., 1984; Glaze et al., 1988; Guzzetta et al., 1993; Jeavons and Bower, 1964; Hrachovy et al., 1991; Jonas et al., 2004; Kurokawa et al., 1980; Lacy and Penry, 1976; Matsumoto et al., 1981; Riikonen, 1982; Vigevano et al., 1993). Children who respond to medical treatment with seizure control (Koo et al., 1993; Riikonen, 1982; Schlumberger and Dulac, 1994) have a better developmental outcome than those who do not respond. In addition to seizure control, there is evidence that developmental regression at the onset of the illness (Dulac et al., 1993; Guzzetta et al.), delayed development prior to

the onset of infantile spasms (Guzetta et al., 1993; Koo et al.; Ohtahara et al., 1993; Riikonen, 1982; Schlumberger and Dulac, 1994), and impaired visually mediated social interaction following ACTH treatment (Dulac et al., 1993) are associated with a poor cognitive outcome.

About 6% of children with infantile autism had hypsarrhythmia in the first year of life (Olsson et al., 1988). Follow-up of children with infantile spasms also reveals varying degrees of impaired social relationships (Caplan et al., 2002b; Dulac et al., 1993; Jambaque et al., 1993) and autism (Askalan et al., 2003; Riikonen, 2001). Riikonen (1982) reported that about 10% of the infantile subjects they followed met criteria for infantile autism, particularly those with EEG and CT evidence for temporal lobe abnormalities. About two thirds of children with infantile spasms who have autism also meet criteria for hyperkinetic disorder (Riikonen and Amnell, 1981), and about 15% of children with infantile spasms have severe “nonautistic” overactivity (Caplan and Gillberg, 1998).

**Diagnosis**

A 4- to 8-month-old infant with onset of clusters of unilateral or bilateral jerks, after normal or abnormal development, with and without developmental arrest, should have an EEG to rule out infantile spasms as soon as possible. Table 22.2 lists the neurological disorders to be included in the differential diagnosis of infantile spasms.

**TABLE 22.2**  
**DIFFERENTIAL DIAGNOSIS OF INFANTILE SPASMS IN INFANCY**

**1. Other Seizure Disorders**

- a. Febrile seizures
- b. Nonfebrile seizures
  - (i) Generalized tonic-clonic seizures
  - (ii) Partial seizures
  - (iii) Benign myoclonus
  - (iv) Myoclonic epilepsy
    - Benign
    - Severe

**2. Neurocutaneous Disorders Causing Seizures in Infancy**

- a. Neurofibromatosis
- b. Sturge-Weber syndrome
- c. Tuberous sclerosis
- d. Incontinentia pigmenti
- e. Linear nevus sebaceous syndrome

**3. Dystonia**

- a. Glutaric aciduria
- b. Transient paroxysmal dystonia of infancy

**4. Breathholding spells**

- a. Cyanotic
- b. Pallid

### Treatment

The classical and most successful short-term treatment of infantile spasms is with ACTH, but vigabatrin is also possibly effective (see the review in Mackay et al., 2004). Prednisone, valproic acid, other AEDs (felbamate, nitrazepam, topiramate), and their combinations have been variably successful (Mackay et al.). The long-term developmental outcome is related to early rather than late control of infantile spasms, the absence of underlying pathology as in symptomatic infantile spasms, and no early developmental regression (Mackay et al.)

### Lennox-Gastaut Syndrome

This epileptic syndrome is characterized by early onset of intractable seizures (tonic, generalized tonic-clonic, atypical absence, atonic and myoclonic), bilateral slow spike and wave complexes (1.5 to 2 Hz) while awake, and paroxysmal fast activity (8–26 Hz) during non-REM sleep on EEG (see the review in Markland, 2003). About 25% of children with infantile spasms go on to develop Lennox-Gastaut syndrome. Follow-up of children with Lennox-Gastaut syndrome reveals continued seizures in about 60% (Goldsmith et al., 2000) and mental retardation in about half, particularly in children with minor motor seizures and multifocal independent spikes (Ohtsuka et al., 1990).

### Behavioral Aspects of Lennox-Gastaut Syndrome

Children with Lennox-Gastaut syndrome usually have marked language delays. As in other cases of mental retardation, the children are sometimes irritable and hyperactive. These behavioral symptoms might decrease with seizure control and exacerbate with increased seizure frequency or when the children are on high doses of AED polytherapy.

### Diagnosis

A diagnosis of Lennox-Gastaut syndrome is based on the EEG finding of interictal slow spike and wave discharges in a child with early onset of poorly controlled mixed seizures and developmental delay.

### Treatment

Until the development of new AEDs and vagal nerve stimulation, the treatment response of children with this syndrome was poor. Benzodiazepines such as nitrazepam and clonazepam were somewhat successful in decreasing the seizure frequency of these children. Although felbamate improved control of drop attacks and tonic seizures (Felbamate Study Group, 1993), its use in children has been limited by the need for frequent blood studies due to possible aplastic anemia. Among the new AEDs, lamotrigine and topiramate improve seizure control in these patients (see the review in French et al., 2004). Vagal nerve stimulation led to a median reduction of seizure frequency in 50 children by 42% (Frost et al., 2001) and to a significant 4.5-month increase in the mental age of children with more than a 50% reduction in their seizures (Majoie et al., 2001).

## Epilepsies and Syndromes Undetermined Whether Focal or Generalized

### Landau-Kleffner Syndrome (Acquired Epileptic Aphasia)

All children with this syndrome have aphasia and epileptiform abnormalities on EEG (Landau and Kleffner, 1957; see the review in Galanopoulou et al., 2000). About two thirds of the children develop clinical seizures (Beaumanoir, 1985; Bishop, 1985) that are focal motor or generalized tonic clonic seizures (Hirsch et al., 1990), easy to control (Gascon et al., 1973; Landau and Kleffner), and resolve by age 15 years (Beaumanoir, 1985). Due to the benign course of the clinical seizures, this syndrome is classified as one of the benign epilepsy syndromes. The course of the aphasia, however, is fluctuating with remissions and exacerbations (Billard et al., 1991; Deonna et al., 1977; Paquier et al., 1992). A few children make some speech and language gains, but most children continue to be aphasic. Children with a later onset of Landau-Kleffner syndrome have a better prognosis (Bishop, 1985).

The syndrome occurs in males more than in females and begins between ages 5 to 7 years (Nevšimalová et al., 1992). In most cases the aphasia appears after normal language development and presents with word deafness or auditory agnosia (Aicardi, 1986; Bishop, 1985; Deonna et al., 1977; Dlouhá and Nevšimalová, 1990; Gascon et al., 1973; Landau and Kleffner, 1957). These children appear not to hear what is being said to them by their parents, who then increase the volume of their speech. The child's responsivity to verbal language decreases gradually and he or she becomes unresponsive. In addition to expressive difficulties, 90% of these children have receptive difficulties (Deonna et al., 1989). Older children who acquired reading and writing skills before the onset of their aphasia lose these skills (Rapin et al., 1977). Most children with Landau-Kleffner syndrome do not learn to write or to sign (Deonna et al., 1989). Some children use gestures and other forms of nonverbal communication to get their needs met.

The EEG abnormalities typically involve bilateral independent temporal or temporoparietal spike and wave discharges, bilateral 1 to 3 Hz spike wave activity maximal over the temporal areas, generalized sharp waves or spike wave discharges, and multifocal or unilateral spikes (Bishop, 1985; Deonna et al., 1977; Nakano et al., 1989; Paquier et al., 1992). These EEG abnormalities are continuous or nearly continuous during sleep, and in some cases they meet the criteria for electrical status epilepticus.

It is unclear if there is a causal relationship between the three components of this syndrome: aphasia, epileptiform abnormalities involving the temporal lobe, and seizures. Among the theories on the etiology of this syndrome, some suggest that continuous convulsive discharge (Deonna, 1991; Dulac et al., 1983; Gordon, 1990; Landau and Kleffner, 1957; Pateau et al., 1999), focal subacute encephalitis (Gascon et al., 1973; Perniola et al., 1993; Ravnik,

tis (Gascon et al., 1973; Perniola et al., 1993; Ravnik, 1985), cerebral arteritis (Pascual-Castroviejo, 1990), deficits in high level auditory processing (Bishop, 1985), or an encephalopathic process (Holmes et al., 1981; Perniola et al., 1993) cause the aphasia.

#### Behavioral Aspects of Landau-Kleffner Syndrome

Children with this syndrome develop mild to pronounced behavioral disturbances (Humphrey et al., 1975) including hyperactivity, aggression, depression (Sawhney et al., 1988; White and Sreenivasan, 1987), and psychosis (Dugas et al., 1982; Gordon, 1990; Humphrey et al., 1975; Zivi et al., 1990).

#### Diagnosis

This diagnosis should be considered when faced with a child who presents with gradual loss of expressive language skills after a period of normal development, in the context of seizures and epileptiform EEG abnormalities. Among the behavioral disorders, children with developmental dysphasia have a history of impaired language development and an increased rate of EEG abnormalities while awake (Nasr et al., 2001) and during sleep (Echenne et al., 1992). Unlike autistic children, children with Landau-Kleffner syndrome are socially relating and responsive and use nonverbal communication to make their needs known. Like children with Landau-Kleffner syndrome, some autistic children develop seizures and epileptiform abnormalities (Tuchman and Rapin, 1997; Caplan and Gillberg, 1998).

Among the neurological disorders, children with onset of Rasmussen encephalitis during the toddler period lose language, like children with Landau-Kleffner syndrome. However, they present with difficult-to-control sensorimotor seizures, which may be almost continuous. Language loss occurs after the onset of seizures in these young cases of Rasmussen encephalitis. In contrast, the seizures of Landau-Kleffner syndrome can begin before, during, or after the onset of aphasia (Deonna et al., 1977; Gascon et al., 1973; Landau and Kleffner, 1957).

A tumor that involves the speech areas might cause loss of language skills and seizures (Nass et al., 1993). Imaging findings of a space-occupying lesion would help make the definitive diagnosis. There are no typical magnetic resonance imaging (MRI) (Sankar et al., 1990), single-photon emission computed tomography (Guerreiro et al., 1996; Tauma et al., 1995), or positron emission tomography findings (Rintahaka et al., 1995; Sankar et al., 1990) in children with Landau-Kleffner syndrome.

Children with the syndrome of continuous spike and wave sleep, to be discussed next, have marked behavioral changes other than language loss, and their EEG abnormalities occupy 85% of slow wave sleep and disappear during REM sleep. In contrast, the epileptiform discharges of children with Landau-Kleffner syndrome are activated at sleep onset and during REM (Genton and Guerrini, 1993).

#### Treatment

Valproate, ethosuximide, and some benzodiazepines alleviate the seizures not the aphasia of children this syndrome. Treatment with steroids (Lerman et al., 1991; Marescaux et al., 1990), ACTH (Perniola et al., 1993), nifedipine (Pascual-Castroviejo, 1990), sulthiame (Wakai et al., 1997), and subpial resection (Sawhney et al., 1995) has been associated with improved language skills in these children.

#### Continuous Spike and Wave During Slow-Wave Sleep

Continuous spike and wave during slow sleep syndrome occurs in 0.5% of children (Morikawa et al., 1985) and involves behavioral changes, intellectual deterioration, seizures, and continuous spike and wave during at least 85% of slow-wave sleep (Bureau et al., 1990; Perez et al., 1993; Tassinari et al., 1982). Due to the long duration of the epileptic discharges during slow-wave sleep, this syndrome has also been called electrical status epilepticus during slow-wave sleep (Tassinari et al., 1982).

This syndrome begins in children, ages 4 to 6 years, after normal or abnormal development and presents with subtle behavioral or intellectual changes followed by marked deterioration of behavior and intellect (Perez et al., 1993; Tassinari et al., 1982). Children with continuous spike and wave sleep have motor seizures, nocturnal partial motor seizures or generalized convulsive seizures, and subsequent development of absences or atypical absences, which are well controlled with AEDs and remit by age 15 years (Boel and Caesar, 1989; see the review in Galanopoulou et al., 2000; Perez et al., 1993).

Sleep EEGs reveal continuous generalized spike and wave during 85% of slow-wave sleep. Awake EEGs, however, may be normal (Perez et al., 1993; Tassinari et al., 1982), or reveal sporadic generalized spike and wave (Boel and Caesar, 1989), or focal paroxysmal discharges (see the review in Galanopoulou et al., 2000).

#### Behavioral Aspects of Continuous Spike and Wave Sleep

In 25% of the children, the behavioral changes are the first sign and include inattention, hyperactivity, impulsiveness, loss of sense of danger, aggressiveness, mood changes, disinhibition, mouthing of objects, reduced play, and perseveration (Perez et al., 1993). In others, subtle cognitive changes first occur (Boel and Caesar, 1989; Perez et al., 1993; Roulet et al., 1991) with subsequent downhill cognitive deterioration (see the review in Galanopoulou et al., 2000). Several studies have described language disturbances in 40 to 60% of the cases with an expressive aphasia (see the review in Galanopoulou et al., 2000).

#### Diagnosis

This syndrome should be considered in children who present with gradual onset of inattention, hyperactivity, impulsiveness, behavioral regression, intellectual deterioration, and seizures after prior normal or abnormal develop-

ment. A sleep EEG will provide a definitive diagnosis. The differential diagnosis should include neurological disorders that cause dementia in children (Table 22.3), benign seizure syndromes, such as Landau-Kleffner syndrome, and psychiatric disorders, such as disintegrative psychosis, pervasive developmental disorder, and schizophrenia.

Among the neurological disorders, the onset of Landau-Kleffner involves gradual appearance of auditory agnosia and later onset of aggressive and hyperactive behavior (Landau and Kleffner, 1957). In contrast, children with continuous spike and wave sleep present with behavioral disturbances or cognitive deficits, as well as expressive aphasia (see the review in Galanopoulou et al., 2000). Their communicative deficits involve the form and content of their speech, as well as their expressive skills (Boel and Caesar, 1989; Genton and Guerrini, 1993; Paquier et al., 1992; Perez et al., 1993; Tassinari et al., 1982). The characteristic EEG findings of continuous spike and wave sleep are generalized and occur only in slow-wave sleep compared to the focal temporo-parietal epileptic discharges in Landau-Kleffner syndrome that are found in the sleep and awake states (Genton and Guerrini, 1993).

Among the psychiatric disorders, children with disintegrative psychosis, also known as Heller's syndrome or de-

mentia infantilis, have marked regression in multiple areas of their functioning following at least 2 years of normal development (American Psychiatric Association, 1994, p. 74). The children have associated mental retardation, EEG abnormalities, and seizure disorder. In some cases, one of the disorders listed in Table 22.3 might cause this syndrome. In most cases, however, extensive investigation does not reveal an underlying cause.

Most of the cases of pervasive developmental disorder begin in infancy or during the toddler period and involve impaired development of communication and social reciprocal interaction skills, as well as stereotyped, behavior, interests, and activities (American Psychiatric Association, 1994, pp. 70–71). In contrast, they clearly demonstrate a gradual and progressive regression in behavioral and cognitive functioning from the previous normal or abnormal baseline. Finally, they might present with disorganized behavior and what might appear to be formal thought disorder (Perez et al., 1993). However, they do not have hallucinations or delusions, and their cognitive deficits are apparent.

#### Treatment

Although clinical seizures respond well to AEDs, control of the electrical status is more difficult and has been achieved with high doses of ACTH and prednisone, ethosuximide, benzodiazepines, and combinations of AEDs (see the review in Galanopoulou et al., 2000). Reports differ on the efficacy of treatment of the electrical status on the children's behavior and cognition. Some researchers describe reversibility of the behavioral and cognitive changes with control of the electrical status (Bureau et al., 1990; Tassinari et al., 1982). Others (Perez et al., 1993; Boel and Caesar, 1989) have found behavioral and cognitive improvements but noticeable residual deficits in these areas of functioning.

## PSEUDOSEIZURES

### Definition and Incidence

Pseudoseizures, epileptic-like phenomena due to psychological causes, have also been called hysterical seizures, psychogenic seizures, and more recently nonepileptic events. The term "pseudoseizure," unlike the terms "hysterical" and "psychogenic," refers to the clinical phenomenology rather than to the psychological cause of these episodes. Pediatric pseudoseizures can be due to an underlying conversion disorder, a factitious disorder, misinterpretation of seizures by the adults who care for the child, or a Munchausen syndrome by proxy. In children under age 5 years, the majority of cases of nonepileptic seizures involve daydreaming, physiological events, such as inattention/daydreaming, stereotyped movements, hypnic jerks, and parasomnias that are misinterpreted by parents as epileptic seizures (Kotagal et al., 2003).

Despite the morbidity and marked cost to health care services, only few studies and case reports describe

pseudoseizures in children and adolescents (see the review in Papavasiliou et al., 2004). About 12.5% of children referred to a pediatric neurology inpatient service (Schneider and Rice, 1979) and 15.2% referred to a pediatric epilepsy monitoring service (Kotagal et al., 2002) are given a diagnosis of pseudoseizures.

The disorder is more common in children with confirmed epileptic seizures (19–46%) (Kotagal et al., 2002) and in nonepileptic children who are exposed to this disorder through a family member, a neighbor, or a friend (Goodyer, 1985). There are both age- and sex-related differences in the incidence of pseudoseizures. Pseudoseizures occur more frequently in adolescents than in younger children (Finalyson and Lucas, 1979; Gross and Huerta, 1980; Mohr and Bond, 1982). In adolescence, but not in middle childhood, pseudoseizures occur more commonly in girls (Finalyson and Lucas, 1979; Gross and Huerta, 1980; Kotagal et al., 2002; Mohr and Bond, 1982) who also tend to have a more chronic course than boys (Schneider and Rice, 1979). In middle childhood, a high rate of prior head trauma was noted in boys with pseudoseizures (Pakalnis and Paolicchi, 2003b).

### Clinical Manifestations

Although pseudoseizures mimic all seizure types, earlier studies suggested that in middle childhood they most commonly present with atypical movements and behaviors (Sas-

sower and Duchowny, 1992), whereas in early adolescence pseudoseizures begin to mimic generalized tonic–clonic convulsions and complex partial seizures (Sassower and Duchowny). One study found no significant difference across ages in the presentation of motor pseudoseizures compared to unresponsive events (Kotagal et al., 2002).

Table 22.4 compares the clinical manifestations of epileptic and pseudoseizures. Despite differences in the clinical manifestations of epileptic and pseudoseizures, these are not always clear-cut and one cannot base the diagnosis of pseudoseizures solely on the clinical picture (see Diagnosis).

In terms of onset, epileptic seizures start suddenly or after a brief aura that is stereotyped and consistent across epileptic events. In contrast, pseudoseizures begin gradually with a buildup of anxiety or some other emotion, a “weird” poorly defined feeling, or hyperventilation. Typically, pseudoseizures do not occur when the child is alone. Epileptic seizures, however, occur when the child is alone or with others.

Generalized tonic–clonic seizures often begin with a cry followed by a sudden fall to the ground, which injures the patient. Pseudoseizure patients might cry out after slumping to the ground without sustaining any bodily injuries. During a motor seizure, the clonic-like movements of the child with pseudoseizures look more like thrusting, jerking, or side-to-side rolling movements that are unsynchronized

**TABLE 22.4**  
**CLINICAL MANIFESTATIONS IN EPILEPTIC AND PSEUDOSEIZURES**

Clinical Manifestations	Epileptic Seizures	Pseudoseizures
<b>Onset</b>		
Premonition	Brief stereotyped aura	Ill-defined “weird” feeling
Evolution	Sudden	Gradual
Environment	Anywhere, with or without people present	Only in presence of others
<b>Description of Seizure</b>		
Generalized tonic–clonic Motor component	Cry, sudden fall, injury Synchronized clonic movements	Slumps, cry, no injury Unsynchronized, thrusting, jerking, side-to-side rolling
Complex partial	Automatic, quasipurposive Motionless stare	Varied Wavering stare
<b>Level of consciousness</b>		
Ictal	Marked change, unresponsive	Inconsistent response
Postictal	Tiredness, confusion, irritability	Resumption of activities
Repeated seizures	Clouding of consciousness	Clearheaded
<b>Continence</b>		
Urinary	Frequent	Rare
Fecal	Infrequent	Infrequent
End of seizure	Abrupt	Waxes and wanes
Duration	Brief	Brief to hours

compared to the synchronized and brisk movements of the clonic phase. The distribution of these movements does not follow known anatomical patterns. Other motor behaviors described in pseudoseizures include episodic staring, blinking, grimacing, laughing, crying, hand and head movements, and unresponsiveness (Wyllie et al., 1990).

The automatic and quasipurposive behaviors of complex partial seizures are sometimes difficult to differentiate from the complex behaviors that occur in children with pseudoseizures. Pseudoseizures that resemble complex partial seizures involve a wavering rather than a motionless stare with a preoccupied look. There are marked changes in the level of consciousness in children with generalized or complex partial seizures, and they do not respond to environmental stimuli. Children with pseudoseizures appear unresponsive, but might respond inconsistently to their environment.

In addition to differences in onset and clinical manifestations, urinary or fecal incontinence occur during epileptic seizures, not pseudoseizures. Epileptic seizures are brief events that last seconds to minutes and end abruptly. The duration of pseudoseizures varies and can last as long as hours with waxing and waning of symptoms.

The postictal period also differentiates between these two conditions. The child with pseudoseizures resumes previous activities without confusion or tiredness. In contrast, epileptic seizures are often accompanied by postictal sleeping, confusion, or irritability. If the child with pseudoseizures has repeated events, he or she is clearheaded between events, whereas the child with repeated epileptic seizures becomes more obtunded and confused.

### **Associated Psychopathology**

A wide range of psychopathology is associated with pseudoseizures including conversion, affective, and anxiety disorders (Kotagal et al., 2002; Wyllie et al., 1999). Learning disorders or poor school achievement, as well as environmental stressors in the family or social milieu, are consistent findings in children with pseudoseizures. Sexual or physical abuse is also described (Gudmundsson et al., 2001; Pakalnis and Paolicchi, 2003a, 2003b; Wyllie et al., 1999).

### **Pseudoseizures Due to Conversion Disorder**

In a conversion disorder (American Psychiatric Association, 1994, p. 457), the child's seizures or convulsions suggest that he or she has epilepsy and suffers significant distress or impairment from these attacks. Appropriate investigations do not confirm the epileptic basis for these episodes. Psychological factors in the form of conflicts or stressors, however, initiate or exacerbate these attacks. The child with a conversion disorder does not intentionally produce or feign the seizures.

The underlying primary conflict in pseudoseizures usually involves the child's difficulty expressing negative feelings, such as anger. Social difficulties, strife with parents, learning difficulties (Silver, 1982), or sexual abuse (Alper et

al., 1993) can give rise to the negative feelings associated with the primary conflict. Expression of the primary conflict through seizures usually leads to significant attention from caregivers, friends, teachers, and others. This secondary gain reinforces the conversive symptoms and prevents the child from dealing with his or her problems in an adaptive manner.

The children's affective response can often be described as "la belle indifference." They usually minimize or deny any concern about the problems and difficulties in their lives even when these are significant. These children, however, respond with concern only about their attacks.

In terms of outcome, given the maladaptive nature of the symptoms of this disorder, a definitive diagnosis is needed as soon as possible. Wyllie et al. (1990) reported a good outcome in 14 of 18 children and adolescents diagnosed with nonepileptic seizures who had their symptoms for a mean duration of 7 months. Rather than duration of illness, Gudmundsson et al. (2001) found that among psychiatrically hospitalized children with pseudoseizures, more types of seizures, younger age at presentation, and female gender were associated with a better outcome.

### **Misinterpretation of Children's Behavior**

Misinterpretation of the child's behaviors as epileptic seizures can reflect parental anxiety (Meadow, 1989). Several investigators have shown that the primary reason for nonepileptic events in children, particularly those with impaired intellectual function, was misinterpretation of behavior by parents and caretakers (Duchowny et al., 1988; Holmes et al., 1983; Neil and Alvarez, 1986). These behaviors included staring episodes, abnormal reactions to environmental stimuli, and repetitive movements, such as rocking, shaking, or arm waving. Unusual movements based on abnormal muscle tone were also often misinterpreted as seizures (Holmes et al., 1983; Neil and Alvarez, 1986). Unlike Munchausen syndrome by proxy (discussed later), these cases usually present with only one episode of factitious complaints. In addition, the parent's main concern is that their child recover rather than that the child be put through repeated medical examinations and procedures to determine that he or she is ill, as in the Munchausen syndrome by proxy.

### **Factitious Disorders**

Factitious disorders (American Psychiatric Association, 1994, p. 474) involve intentional production or feigning of seizure symptoms specifically to assume the sick role. Unlike malingering, there are no external incentives for these behaviors, such as avoiding a legal responsibility like going to school. More commonly, the parent rather than the child has the factitious disorder and imposes a diagnosis of epilepsy on the child, as in Munchausen syndrome by proxy. To date, many of the cases of Munchausen syndrome by proxy present with seizures (see the review in Barber and Davis, 2002). In Meadow's original series

(1984) of 76 cases, 32 children had a primary diagnosis of epilepsy. In 21 cases the mothers fabricated the symptoms of the illness. In 11 cases the mothers caused seizures by suffocation, carotid sinus pressure, or use of drugs. Sixteen of the children in Meadow's sample had medical symptoms other than seizures. In Rosenberg's (1987) series, 42% of the 117 cases presented with seizures. It is important to note that Munchausen syndrome by proxy can also occur in a child with genuine epilepsy.

Unlike other disorders, clinicians do not usually observe the seizures of children with epilepsy and need to rely on parental report for a description of the clinical manifestations of the child's seizure (Meadow, 1984). Since it is difficult to confirm parental reports, it is relatively easy for a parent to fabricate a history of seizures and a lack of response to AEDs in the child (Meadow, 1984).

These cases present with a history of uncontrolled seizures, an inconsistent description of the child's seizures, repeated normal EEG recordings, repeated consultation with different physicians, particularly if the physician determines that there is no evidence that the child has epilepsy. Only the parent, not medical or school personnel have observed the child's seizures. The mothers of these children (McGuire and Feldman, 1989), sometimes employed in the health care field, are often very knowledgeable about epilepsy, EEG findings, and the use of AEDs. They are concerned and devoted to the child and appear at ease in the hospital and even form close relationships with hospital staff. The fathers usually are absent or play no role in the process so that they appear to be in "passive collusion" (Meadow, 1991) with the mother. In some cases of Munchausen syndrome by proxy, the father has been described as the perpetrator (Makar and Squier, 1990).

### Diagnosis

The possibility of pseudoseizures should be entertained in cases of unexpectedly poor seizure control despite adequate AED levels, inconsistent seizure pattern, marked change in clinical presentation of seizures, and normal EEG recordings. A definitive diagnosis of the disorders underlying pseudoseizures is based on the lack of correlation between "seizure" behaviors and epileptic activity on video/EEG. Some researchers claim that provocative testing with suggestion can be a good and inexpensive tool to diagnose pseudoseizures in adults (Bazil et al., 1994) and in children (Sassower and Duchowny, 1992). Studies in adults attest to the reduced sensitivity of prolactin in differentiating epileptic from nonepileptic seizures (Shukla et al., 2004; Willert et al., 2004). However, although an increase in prolactin occurring 10 minutes after a seizure is a somewhat sensitive (64%) indicator of epileptic seizures (generalized tonic-clonic, complex partial), a negative serum prolactin within the first 100 minutes is highly predictive (98%) that a child did not have an epileptic seizure or had a pseudoseizure (Banjee et al., 2004).

From the psychiatric perspective, to make a diagnosis of conversion, one must demonstrate both a primary conflict and secondary gain. The absence of a correlation between clinical seizures and epileptic activity on video-EEG alone is not indicative of pseudoseizures due to conversion if there is no evidence for both primary and secondary conflicts.

A diagnosis of misinterpretation of a child's behaviors as seizures is also best diagnosed by video-EEG. Psychiatric evaluation of the parent(s) and child can help rule out conversion and factitious disorder. It will also help determine underlying parental anxiety or difficulty coping with the child's epilepsy or behavior.

The diagnosis of Munchausen syndrome by proxy involves careful demonstration that the parent, usually the mother, has fabricated or is causing the child's symptoms. To do this, one has to methodically document all information obtained from the mother and check it for consistency in terms of dates, times, and descriptions of seizures. In addition, one needs to obtain information on previous and current AED blood levels to determine if the mother is overmedicating or undermedicating the child (Meadow, 1991). Furthermore, one should contact physicians who have previously cared for the child and find out if the mother left these physicians after they concluded that there was no evidence of a seizure disorder. Video-EEG recordings of the child's "seizures" and parent-child interactions can provide important information on the factitious nature of the disorder and the mother's inability to parent (Epstein et al., 1987). A detailed psychiatric evaluation of the mother and child are also needed to make a definitive diagnosis of Munchausen syndrome by proxy.

### Differential Diagnosis

When presented with a child who might have pseudoseizures, it is important to rule out neurological, sleep, and systemic disorders that might mimic seizures. For more detailed reviews of these disorders, see Sassower and Duchowny (1992), Mahowald and Rosen (1990), and Oppenheimer and Rosman (1983). Table 22.5 lists the diagnoses that should be considered in the differential diagnosis of pseudoseizures.

### Neurological Disorders

Among the neurological disorders, movement disorders could mimic seizures, particularly if they are associated with sudden movements or tonic posturing. Unlike epileptic and pseudoseizures, none of these disorders are associated with change in state of consciousness even when they present with bilateral symptoms. Moreover, the symptoms of movement disorders occur when the child is alone or with others and change over time. Like pseudoseizures, however, the symptoms might last from seconds to hours. A family history of a movement disorder might support this diagnosis.

Migraine in middle childhood is not always associated with a headache and can present with confusion or disorientation (Gascon and Barlow, 1970), a transient hemi-

- (v) Hypnagogic hallucinations and sleep paralysis
- (vi) Nocturnal myoclonus

paralysis that might mimic a Todd's paralysis, and visual aura (Bodensteiner, 1990), symptoms that occur in children with pseudoseizures. It is important to note that migraine and epilepsy frequently coexist in the same child (Septien et al., 1991). Although migraine and epilepsy can cause a headache, a migrainous headache occurs at the beginning and an epileptic headache at the end of the episode. Migraine headache in the child is usually associated with a family history of migraine.

Children with vertigo appear pale and complain of nausea, vomiting, dizziness, and ataxia (Basse, 1964). Unlike children with pseudoseizures, these children look sick, are frightened, and cling to their parents (Dunn and Snyder, 1976).

### Sleep Disorders

Night terrors present as crying or screaming, a state of panic, semipurposeful, and automatic behaviors that occur while the child is in deep sleep and unable to be roused. They might mimic a pseudoseizure, but the child with night terrors returns to sleep with no recollection for the night's events. Children with pseudoseizures remember their episodes and they occur in front of other people. The child with sleep walking gets out of bed with a glassy look in the eyes, walks around the house, and can be easily led back to bed. Sleep studies provide a definitive diagnosis by demonstrating that night terrors occur in stage 3 or 4 of nonREM sleep and sleep walking in REM sleep.

Children with narcolepsy fall asleep suddenly and might also have drop attacks due to sudden loss of muscle tone

(cataplexy), hypnagogic hallucinations, and sleep paralysis. Unlike pseudoseizures, rapid eye movements herald the onset of the narcolepsy, and sudden fright or excitement usually induce the cataplectic attacks.

### Systemic Disorders

There are cardiopulmonary, autonomic, gastrointestinal, and metabolic disorders that can mimic seizures. Of these, syncope or fainting occurs most commonly in school-aged children. Syncope is often precipitated by an intense emotional stimulus, a systemic illness, or a mechanical cause, such as prolonged standing. Like pseudoseizures, the loss of consciousness of syncope occurs gradually, and the child becomes limp and usually falls backward without rigidity, clonus, incontinence, or physical injury. Children who present with these symptoms should have a cardiac evaluation to determine if they have cardiogenic or simple syncope. Some children might need Holter monitoring to rule out arrhythmias.

Breath-holding spells or infantile syncope should be considered in the differential diagnosis of pseudoseizures in young children. They begin between the ages of 6 and 18 months and subside by age 6 years in most cases (Lombroso and Lerman, 1967). In the cyanotic type, the child usually starts to cry vigorously because of some frustration or a sudden fright, then becomes apneic and cyanotic, loses consciousness, and the limbs become rigidly extended. The child regains consciousness in less than 1 minute. About 20% of children with breath-holding spells develop syncope later in life (Lombroso and Lerman, 1967). The child with pallid infantile syncope responds to a fright without crying but with pallor, loss of consciousness, and associated clonic jerks.

### Treatment

Wyllie et al. (1990) suggest that psychiatric intervention should not begin until a definitive diagnosis of pseudoseizures is made. A psychiatric evaluation can begin as soon as the epileptologist thinks that the child might have pseudoseizures. Typically, this occurs after the first few days of telemetry. Once the psychiatric and neurological diagnostic procedures confirm a diagnosis of pseudoseizures, the child and family should be given diagnostic feedback. In giving the feedback, the pediatric neurologist should first inform the child and family of the nonictal nature of the child's seizures. The psychiatrist then explains the possible psychogenic basis for the child's attacks. The pseudoseizures are no longer called seizures, but "attacks," "episodes," or "the problem" (Aylward, 1984). It is important to ensure that the child and parents do not perceive the feedback as suggesting that the child has been faking the attacks (Aylward). In addition, the feedback should provide the child with an easy out without losing face (Aylward). Many parents have difficulty accepting a psychiatric diagnosis of pseudoseizures and need to be helped to accept this diagnosis.

The aims of psychiatric treatment are to stop the child's episodes and to teach the child adaptive coping strategies for dealing with his or her difficulties expressing negative affect or anger. Decreasing in the amount of attention and secondary gain the child receives during his or her episodes will usually reduce the frequency of attacks. To achieve this goal, one has to work with both the parents and siblings. If the child is having episodes at school, the psychiatrist also needs to work with the teachers and school nurse. A behavioral approach is often helpful in decreasing the secondary gain. In parallel with the psychiatric intervention, the child's AEDs should be gradually decreased or maintained at a lower dose if the child also has epilepsy.

In cases where the frequency of pseudoseizures is so high that it impairs the functioning of the child and family, psychiatric hospitalization needs to be considered. Once the frequency of episodes has decreased sufficiently so the child can function, one needs to work psychotherapeutically with the child and family. The length of treatment is dependent on the severity of the child's underlying emotional difficulties and those of his immediate family.

In Munchausen syndrome by proxy cases, once the diagnosis has been confirmed, the responsible physician needs to report the case to the local child protection authorities and then confront the mother with this diagnosis in the presence of the child protective services. Child protective services need to remove the child from the parents' care to ensure the child's safety and the child's AEDs are gradually withdrawn. The length and indications for treatment of the child and parent(s) vary in different cases.

## **PEDIATRIC EPILEPSY: SCHOOL ACHIEVEMENT, COGNITION, LANGUAGE, AND BEHAVIOR**

The previous sections of this chapter characterized the phenomenology, clinical, and behavioral manifestations of different epilepsy syndromes in childhood and adolescence. This section reviews the impact of epilepsy on children's academic, cognitive, linguistic, and psychosocial functioning. Using a developmental and integrative perspective, it also examines how children's developmental level and neurocognitive functioning interact with their academic and psychosocial functioning.

### **Academic Achievement and School Factors**

School, with its focus on academic achievement, acquisition of knowledge, and socialization, represents one of the primary developmental contexts and tasks for children and adolescents, including those with epilepsy. The sequelae associated with management of a chronic illness like epilepsy can substantially affect children's school experience in the areas of academic underachievement, increased remedial

placement, grade retention, and negative student attitudes toward school and learning (Olson et al., 2004).

Academic underachievement is prevalent in pediatric epilepsy (Fastenau et al., 2004). Epilepsy patients have a higher risk of learning disorders (Motamedi and Meador, 2003) and score significantly below both their healthy peers and those with other chronic illness across academic content areas. For example, Austin et al. (1999) found, in a 4-year longitudinal study, that children with epilepsy performed significantly worse than children with asthma on measures of reading, mathematics, language, and vocabulary. Subjects with the highest seizure severity performed most poorly on the measures of academic achievement. Antonello (1999) found that, after adjusting for IQ, 9- to 13-year-old children with epilepsy read more slowly than healthy children, and those with left-side complex partial seizures, as compared to either right-side complex partial seizures or primary generalized epilepsy, showed the most impairment in math and reading skills. Williams et al. (1996a) demonstrated that children with poorly-controlled complex partial seizures performed more poorly on measures of reading and attention than did children with better controlled seizures. In contrast to the preceding findings, Mitchell et al. (1991) found no relation between either seizure severity or duration of illness on academic achievement.

The academic underachievement of children with epilepsy places them at increased risk for grade retention and special education services. Bailet and Turk (2000) found that children with idiopathic epilepsy had higher rates of grade retention and placement in special education classes than did their healthy siblings. Likewise, Oostrom et al. (2002) found, both before diagnosis and over a period of 1 year after diagnosis, significantly more children with epilepsy, 51 versus 27% of their healthy classmates, required special education services. School difficulties, such as poor grades, remediation, or retention, can decrease a child's self-esteem and affect his or her learning style (Aldenkamp, 1983). Sturniolo and Galletti (1994) showed that emotional maladjustment in children with idiopathic epilepsy was associated with poor school performance. Similarly, Oostrom et al. (2003) found that children with epilepsy had poor motivation and attitude toward school and felt less socially accepted at school than did their healthy classmates.

The academic and school-related difficulties experienced by children with epilepsy reflect the interrelations among psychosocial and neuropsychological factors. For example, Fastenau et al. (2004) found both a direct association of neuropsychological functioning with achievement (e.g., verbal, memory, and executive function factors strong relation to reading, math, and writing) as well as a moderating role of family functioning on academic achievement in pediatric epilepsy patients ages 8 to 15 years. Specifically, a supportive and organized home environment moderated the impact of neuropsychological deficits on children's academic achievement (Fastenau

al.), conceivably by requiring consistent homework completion, regular sleep, and medication schedules. Williams et al. (2001) noted that the academic underachievement of children with epilepsy may be related to lower self-esteem, inattention, or memory inefficiency. Controlling for intelligence in a sample of 65 children with well-controlled epilepsy, Williams et al. (2001) found that attention was the only variable associated with achievement scores. The lower academic achievement and school problems may be related to both cognitive and psychosocial factors.

### Cognition

Because epilepsy disrupts brain maturation, it has been thought to produce nonspecific cognitive consequences (Lassonde et al., 2000). Past and current research has documented a link between epilepsy and cognitive impairment in children (e.g., see the review in Nolan et al., 2003). To understand how pediatric epilepsy disrupts cognitive functioning and subsequently children's academic performance and behavioral adjustment, we briefly review the complex relation between epilepsy and cognition, focusing first on general cognitive function. However, because cognitive impairment may affect a variety of neurocognitive skills (e.g., attention, perception, concept formation, reading, thought process, learning, memory, and problem solving) (Motamedi and Meador, 2003), the specific neurocognitive skills of attention, memory, and executive functions, as well as how seizure variables modify children's cognitive abilities, are also reviewed.

While generally within the normal range, the IQ scores of children with epilepsy are distributed more toward the lower end of functioning (Black and Hynd, 1995; Motamedi and Meador, 2003). Caplan et al. (2004) found that 5- to 16-year-old children with complex partial seizures earned significantly lower standardized IQ and language scores than healthy subjects while controlling for demographic and perinatal factors. Using a test-retest design, Bjornaes et al. (2001) assessed the long-term consequences of refractory seizures on intellectual functioning and found that mean IQ scores decreased in children with epilepsy. One possible explanation for the cognitive impairment noted in children with epilepsy is not that they are experiencing cognitive decline, but rather acquiring skill at a slower rate or have a decreased capacity to learn compared to healthy peers (Cornaggia and Gobbi, 2002).

Assessment of seizure variables (e.g., seizure type, frequency, severity, localization of seizure activity, age at onset, duration, and number of AEDs) is somewhat challenging as seizure variables are themselves interrelated (e.g., number of AEDs may reflect seizure severity). In addition, seizure variables, such as the severity of the child's seizure disorder, might differentially affect child adjustment, and, in turn, cognitive functioning. Nonetheless, this research has yielded additional understanding of the link

between pediatric epilepsy and cognition. For example, generally, there appears to be a positive association between severity of epilepsy and cognitive impairment. Several clinical studies have indicated that high seizure frequency (e.g., Caplan et al., 2004; Hermann, 1982; Rodin et al., 1986; Seidenberg, 1989), early onset (Schoenfeld et al., 1999; Smith et al., 2002), or a history of status epilepticus (Singhi et al., 1992) are associated with poor academic performance and lower IQ in children with epilepsy. Cornaggia and Gobbi (2002) and Schoenfeld et al. (1999) noted that cognitive impairment was more pronounced in children with a higher lifetime total number of seizures, particularly if they had multiple seizure types (Cornaggia and Gobbi).

Finally, use of multiple AEDs in children with epilepsy is a marker for intractable seizures, severity of epileptic disorder, multiple seizure types, and often early onset of epilepsy. While treatment with AEDs may improve learning by reducing the number of seizures, negative side effects of AEDs such as sleepiness, slowed reaction time, and attentional difficulties may also impair learning and cognitive performance (Cornaggia and Gobbi, 2002). Although beyond the scope of this chapter, it is important to note that, because some AEDs produce global changes in excitatory neurotransmitters, such as glutamate (Ortinski and Meador, 2004), and others in inhibitory neurotransmitters, such as gamma amino butyric acid (Keller et al., 2002), they might cause or exacerbate both cognitive and behavioral difficulties in children with epilepsy.

### Executive Function

As with seizure severity, seizure variables, such as type of seizure disorder and localization of epileptic focus may differentially affect the nature of the cognitive impairment experienced by children with epilepsy. Executive functions are one neurocognitive skill in which this has been examined. Research has documented executive function like deficits (e.g., impairment of planning, working memory, impulse control, attention, and set shifting) in children with epilepsy, similar to the deficits seen in children diagnosed with ADHD and adults with frontal lobe lesions (Hernandez et al., 2002; Lassonde et al., 2000). Not surprisingly, this has most often been noted in children with frontal lobe epilepsy, a rare form of pediatric epilepsy. For example, Culhane-Shelburne et al. (2002) found that children with this seizure disorder showed deficits in planning and executive functions but not in verbal and nonverbal memory, while the opposite pattern was true for children with TLE. Similarly, Hernandez and colleagues (2002, 2003) found that children with frontal lobe epilepsy, as compared to temporal lobe or generalized epilepsy, had more deficits in the executive function tasks of planning and impulse control, performance speed, motor coordination rigidity, and more intrusion and interference errors on a task of verbal recall. Finally, Riva et al. (2002) noted that children with frontal lobe epilepsy with a left, in compari-

son to a right-sided EEG foci showed more deficits in categorization, verbal long-term memory, and detailed visuo-spatial analysis. More studies are needed to replicate these findings given that the sample sizes for the previously cited studies have all been relatively small, ranging from 8 in the Riva et al.'s (2002) study to 32 in the Hernandez et al. (2002, 2003) research.

### Attention

Attention, an important aspect of general cognition and component of executive functions, encompasses sustained, selective, or divided attention. Attention problems are frequently seen in children with both new onset and chronic epilepsy (Caplan et al., 2004; Dunn et al., 2003; Oostrom et al., 2003). In his early studies on children with epilepsy, Stores (1973, 1978b) described parent and teacher reports of inattention and hyperactivity, but no evidence for impaired vigilance, impulsivity, or distractibility based on laboratory measures. Semrud-Clikeman and Wical (1999) found that children with comorbid complex partial seizure disorder and ADHD had increased reaction time and made significantly more errors of omission and commission than did healthy children, but were similar in performance on these attentional tasks to children diagnosed with only epilepsy or ADHD. Similarly, medically and surgically treated children with epilepsy evidenced slow reaction time, increased errors of omission, and variability in response, but no increase in errors of commission (Aldenkamp et al., 2000; Billingsley et al., 2000; Mitchell et al., 1993; Oostrom et al., 2003; Semrud-Clikeman and Wical 1999; Lendt et al., 2002).

The attentional problems of children with epilepsy and ADHD are related to lower IQ scores (Kinney et al., 1989; Williams et al., 1996b), impaired memory (Billingsley et al., 2000), and poor school performance (Oostrom et al., 2003; Williams et al., 2001). From an integrative perspective, Oostrom et al. (2003) found that children with prior school or behavioral difficulties and those whose parents responded maladaptively to the new epilepsy diagnosis performed more poorly on a reaction time task than did patients without these additional risk factors. According to Motamedi and Meador (2003), the attentional difficulties of children with epilepsy may affect their encoding of new information leading to memory problems. Finally, from a practical perspective, Kadis et al. (2004) suggested that attentional problems may also underlie everyday memory problems found in children with intractable epilepsy.

### Memory

Memory, a specific neurocognitive ability, represents the complex skills of information storage and retrieval. General conceptualizations of memory include its division into short- and long-term memory, with the latter further subdivided into implicit and explicit (semantic and episodic) memory. Decreased memory skills have been reported in children with epilepsy (e.g., Nolan et al., 2004). For example, Pavone et al. (2001) found nonverbal and

delayed memory disturbances in 16 children with absence epilepsy compared to matched control subjects. Williams et al. (2001b) assessed the verbal memory of 8- to 13-year-old children with well controlled seizures: 44 children with complex partial seizures and 21 with generalized seizures. They found that children with both seizure types performed better on short-term memory tasks than long-term delayed recall tasks, although no differences in memory performance were noted based on seizure type. In contrast, Nolan et al. (2004) found that syndrome type differentially affected memory functioning in children with epilepsy. Specifically, of the 70 subjects, ages 6 to 18, with absence, frontal lobe, or temporal lobe epilepsy, those with TLE evidenced significantly worse verbal memory functioning than the other two groups. Moreover, Nolan et al. (2004) found that longer duration of intractable epilepsy was associated with reduced memory ability. Finally, Lespinet et al. (2002) found that children with epilepsy onset at age 5 or before showed substantial verbal and nonverbal memory deficits, whereas subjects with onset at age 10 or older evidenced minor deficits consistent with lateralization (i.e., verbal deficits with left TLE and nonverbal deficits with right TLE).

Other researchers have assessed the link between pediatric epilepsy and memory in subjects undergoing epilepsy surgery using a presurgical and postsurgical test-retest design. Using this paradigm, Mabbott and Smith (2003) assessed the verbal and visual memory of 44 children and adolescents with focal epilepsy who underwent either right, left, or extratemporal excisions and found that all surgical groups improved on the visual memory task of facial recognition after surgery. In contrast, Kuehn et al. (2002), also using a presurgical and postsurgical test-retest design, found no significant improvement in the memory functioning of 20 subjects with temporal and 6 with extratemporal resections. Unlike what has been found in adults, they did not find that children with surgically treated left TLE had more verbal and those with right TLE had more visual memory deficits.

### Cognition and Psychopathology

As noted earlier, both general and more specific epilepsy-related cognitive impairments are detrimental to children's academic achievement. Likewise, cognitive impairments, ranging from minimal to more severe, also affect the psychosocial and behavioral functioning of children with epilepsy. In children with average IQ scores who had complex partial seizures, Caplan et al. (2004) found that mild verbal IQ deficits, but not seizure variables, predicted psychopathology. Buelow et al. (2003) found pediatric epilepsy patients with an IQ of 85 or lower had more behavior and mental health problems than children with higher IQ scores. In the most severe form, the presence of epilepsy and mental retardation increases the severity of psychopathology in children (see the review in Caplan and Austin, 2000).

## Language

Language, communication, and speech delays are a pervasive type of developmental difficulty, which may result from specific language impairment, cognitive impairment, hearing impairment, or chronic illness (Watkins, 1994) such as epilepsy. Language delays may include difficulties in the areas of expressive, receptive or pragmatic skills, phonological and grammatical rules, word learning, semantics, recognizing and using speech regularities, vocabulary, using clarification responses, repairing conversational breakdowns, and modifying speech to fit the social situation (Rice, 1991). These same types of language difficulties are seen in children with epilepsy.

Farwell et al. (1985) found that 6- to 16-year-old children with epilepsy made more mistakes on language-related tasks than on other cognitive tasks. Regarding children with complex partial seizures, Antonello (1999) found they had both expressive and receptive language delays, while Schoenfeld et al. (1999) found they performed significantly worse than their siblings on linguistic tasks of word knowledge, category fluency, and response to commands of increasing length and complexity, even after controlling for IQ. In addition, Caplan et al. (2001, 2002a, 2004) reported that children with epilepsy had both basic and higher-level linguistic deficits. Despite average IQ scores, they had significantly lower language age scores than normal children (Caplan et al., 2004), as well as more illogical thinking, discourse deficits, and poor monitoring and correction of communication breakdowns (Caplan et al., 2001, 2002a). Evidence for significantly more language deficits in younger compared to older children with epilepsy led Caplan et al. (2001) to conclude that epilepsy syndromes, particularly complex partial seizures and primary generalized epilepsy, impact the ongoing development of children's communicative skills. Moreover, Saltzman et al. (2002) found that a higher proportion of children with seizure onset prior to age 5 showed speech deficits as compared to children with seizure onset after age 5.

From an integrative perspective, linguistic impairments exert comprehensive deficits on the cognitive and psychosocial functioning of children with epilepsy. Wheless et al. (2002) noted that language development may be disrupted in children with epilepsy given the disorder's negative effect on intellectual functioning. Impairment in specific linguistic skills may also, in turn, impact children's memory and learning. Likewise, impaired linguistic functioning has lasting negative consequences on the academic and social adjustment of children with epilepsy (Wheless et al., 2002). For example, Caplan et al. (2004) noted that verbal deficits were predictive of behavioral difficulties in children with complex partial seizures. More specifically, the presence of illogical thinking and discourse deficits, as noted in the Caplan et al. studies (2001, 2002a), might increase the social difficulties of these children because their peers have difficulty following what they are talking about.

## Developmental and Integrative Summary

From an integrative perspective, epilepsy has a profound impact on children's adjustment across the developmental domains of academic achievement, cognition, language, and psychosocial functioning. Moreover, the way in which epilepsy influences these domains of functioning varies depending on the interrelations among these factors and the child's developmental level. For example, throughout childhood, seizures have important implications for brain development in that they may interfere with neural maturation and subsequently with brain structure, which may then have both immediate and lifelong cognitive implications (e.g., Hermann and Seidenberg, 2002). In middle childhood, seizures may negatively impact children's ongoing acquisition of higher level cognitive and linguistic skills, as well as their success in achievement and socialization tasks, which are tantamount to maturational success during this developmental period. Finally, evidence for continued maturation of brain regions involved in higher level integrative functions, such as language and cognition during adolescence (Gogtay et al., 2004; Sowell et al., 2003), points to the potential negative cognitive impact of epilepsy on older youth. In addition, the adolescent maturational challenge of developing a self-identity and autonomy may also be compromised in youth with epilepsy given their increased dependence on parents and necessary adherence to seizure-reducing medication and schedule routines.

Although a review of the social and family factors relevant to pediatric epilepsy is beyond the scope of this chapter, it is important to briefly note that peer and family influences may differentially affect the interaction of epilepsy with neurocognitive and psychosocial factors across children's developmental level. For example, the unpredictability and possible severe consequences of seizures causes anxiety and fear for parents of children with epilepsy (e.g., Austin et al., 1993; Ziegler, 1985). Thus, parents must negotiate the difficult task of providing adequate supervision without being overanxious or overprotective, thereby limiting children's participation in typical socialization experiences and development of age-appropriate autonomy. In contrast, a supportive and stable family environment may serve a protective function and promote positive adjustment for children with epilepsy (Fastenau et al., 2004).

# Prematurity and Cerebral Palsy

23

*Agnes H. Whitaker, MD   Judith F. Feldman, PhD   John M. Lorenz, MD  
Naomi Breslau, PhD   Nigel Paneth, MD*

Prematurity and cerebral palsy are related but distinct topics in pediatric neuropsychiatry. While prematurity is a risk factor for cerebral palsy, at least half of all persons with cerebral palsy are born at term (Nelson & Grether, 1999). Therefore, a separate section is devoted to each condition. Side by side, the two topics offer a clinically relevant framework for reviewing the relation between abnormalities in early brain development and neurobehavioral outcomes.

## PREMATURITY

Prematurity, that is birth at less than 37 weeks of gestation, is an essential topic in pediatric neuropsychiatry for several reasons. First, preterm birth is a common event, affecting about 1 in every 10 families in the United States (Mattison Damus, Fiore, Petrini, & Alter, 2001). Second, preterm birth provides a window into the genetics and epigenetics of human brain development, injury, plasticity, and recovery (Luciana, 2003). Third, preterm birth is the second leading cause of neonatal death, the first leading cause of morbidity in infancy and early childhood, and a risk factor for morbidity at least into young adulthood (Msall & Tremont, 2002b).

### Definitions

Gestational age (GA) has traditionally been defined as the number of gestational weeks (GW) since the first day of the last menstrual period as recalled by the mother. Fetal size, as assessed with early ultrasound, is also now used to esti-

mate GA. Premature refers to birth at <37 GW, and very premature to birth at <32 weeks (Green et al. 2005). The lower limit of viability is now considered to be 22 to 23 GW. Because GA is a major determinant of birthweight (BW) and because the latter is more accurately and easily measured, researchers often use BW rather than GA to define high risk samples.

GA and BW, although related characteristics of an infant, are not synonymous. GA is essentially an index of organ maturity, while BW is an index of overall growth. A baby is born at low birth weight (LBW; < 2,500 g) either because it was delivered preterm or because it grew slowly in utero or some combination of the two. Infants with BW in the lowest 10th percentile of birthweight for GA or BW or two standard deviations or more below the mean for GA are termed small for gestational age (SGA). One disadvantage of using a LBW sample for studying predictors and sequelae of preterm birth is that nearly half of heavier LBW infants (1,500 to 2,500 grams) are full-term but SGA. By contrast, at least 96.8% of infants born at 1,500 g, or below, were born preterm. Therefore studies of prematurity usually use samples that are very low birthweight (VLBW) (<1,500 grams; 3lbs 5oz) or extremely low birthweight (ELBW) (< 1,000 grams or 2lbs 3 oz) or even smaller. In the literature, VLBW and ELBW are often used interchangeably with "preterm."

The age of a preterm neonate is often expressed as postmenstrual age in weeks, GA + postnatal age. When comparing preterms in the first year of life to normative data or to full-term infants, clinicians and researchers commonly use corrected age rather than chronological age. Corrected age is defined as postnatal age minus the number of weeks

by which delivery was premature. Beyond age one, the value of correcting for prematurity is a matter of some debate (den Ouden, Rijken, Brand, Verloove-Vanhorick, & Ruys, 1991).

**Trends in Incidence, Prevalence, Mortality, and Morbidity**

Between 1980 and 2000, the prevalence of preterm births in this country rose 17% (from 10.0 to 11.8%), while infant mortality declined 45% (from 12.6 to 6.9%), most markedly among the extremely preterm (Mathews, Menacker, & MacDorman, 2002). At the same time, the rates of major disabilities such as cerebral palsy, mental retardation, blindness, and deafness among children born preterm remained steady at around 10%. As a result, the actual numbers of children with major disabilities related to prematurity has increased (Hack & Fanaroff, 2000).

The major disabilities associated with preterm birth are usually detected by age 2 years. The risk of major disability increases markedly with decreasing BW/GA (see Table 23.1). Many less severe but still impairing outcomes, including learning, attention, and behavior problems, are not apparent until school age or beyond, and also show a BW/GA gradient (Msall & Tremont, 2002b). These high prevalence/low severity problems are all too common (Allen, 2002).

**Preterm Delivery**

About 25% of preterm deliveries (PTD) are therapeutic, that is due to medical intervention for maternal or fetal problems. The the remaining 75% are due to premature rupture of membranes (25%) or spontaneous preterm delivery (Moutquin, 2003).

**TABLE 23.1**  
**SEVERE DISABILITY IN LOW BIRTH WEIGHT SHOWS A BIRTH WEIGHT GRADIENT**

BW Category	Adjusted Odds Ratio	95% Confidence Interval
450–749	97.50	(70.37, 135.11)
750–999	40.01	(31.59, 50.68)
1,000–1,499	15.84	(13.66, 18.36)
1,500–2,499	3.29	(3.04, 3.56)
2,500–2,999	1.39	(1.30, 1.48)
3,000–4,749	1.00	(Reference Category)
4,750–6,000	1.52	(1.11, 2.08)

**TABLE 23.2**  
**EPIDEMIOLOGICAL RISK FACTORS FOR AND ASSOCIATIONS WITH PRETERM BIRTH**

Risk Factors
h/o previous preterm birth (the earlier the birth, the higher the risk)
multiple gestation
maternal in utero exposure to diethylstilbestrol
Associations
maternal social disadvantage
maternal infection (genital urinary tract, periodontitis)
African-American ethnicity
single marital status
cigarette smoking
second trimester bleeding
low pre-pregnancy BMI (esp., among white women)
maternal age <20 y and >35 y
artificial reproductive technology
mother doing physically demanding work

**Risk factors for Preterm Delivery**

Table 23.2 lists risk factors for preterm delivery (Berkowitz & Papiernik, 1993). The largest single risk factor is previous preterm delivery. Women with a history of prior preterm delivery are at risk for spontaneous delivery of another preterm baby in 15 to 80% of subsequent pregnancies depending on the population studied (Carr-Hill & Hall, 1985; Cunningham, et al., 1997; Ekwo, Gosselink, & Moawad, 1992). Mothers who were themselves preterm are more likely to have a preterm infant, and the risk increases as the mother’s own birth GA decreases. It is likely that in most cases preterm delivery reflects a gene-gene interaction or gene-environment interaction (Ward, 2003).

In the United States, for poorly understood reasons, African American mothers have a rate of preterm birth (17.0%) that is nearly twice that of other ethnic/racial groups. Puerto Rican mothers have the next highest rate (13.5%); Cuban American, Mexican American, Central and South American mothers have rates similar to non-Hispanic whites (10.4%). Among both African American and nonHispanic white women, the risk of preterm delivery is inversely related to education, income, and occupation (Mathews et al., 2002). The mechanisms by which social disadvantage increases risk for preterm delivery are poorly understood.

Large scale prevention programs in the 1980s and 1990s based on detection and remediation of social and medical risk factors in Table 23.2 did not reduce the rates of preterm delivery. Research is now focusing on gene–environment interactions and pathological pathways more proximate to the the event of preterm delivery (Lockwood & Kuczynski, 2001; Rondo, et al., 2003).

### Management of Preterm Delivery

Tocolysis is presently the cornerstone of management for threatened spontaneous PTD. Tocolytic agents either inhibit uterine muscle stimulators or stimulate the inhibitors. At best, they can prolong pregnancy for up to 72 hours. While this may improve survival at the lower extremes of GA, the safety and effectiveness of tocolytics remain controversial (Gyetvai, Hannah, Hodnett, & Ohlsson, 1999).

### Complications of Premature Birth

#### Environmental Stress in the Neonatal Intensive Care Unit

The intensive care required to salvage more immature neonates is associated with stress. Examples include equipment that limit positive interactions with caregivers, high noise levels, constant bright light, and pain (Perlman, 2001). The hospital course often is prolonged; the average hospital stay for VLBW infants less than 28 weeks GA is approximately 100 days (Stevenson, et al., 1998). Evidence from animal studies suggests that even in the absence of medical complications or focal brain injury, sustained environmental stress may have adverse effects on brain development and behavior (Anand & Scalzo, 2000; Grunau, 2002).

#### Medical Complications

Largely as a result of organ immaturity, the preterm neonate is at high risk for developing medical complications that may adversely affect neurobehavioral outcomes either directly or indirectly through brain injury. These include low Apgar score, pulmonary complications, prolonged bradycardia and hypotension, hypothyroxinemia of prematurity,

hyperbilirubinemia, retinopathy of prematurity, necrotizing enterocolitis, and malnutrition (Perlman, 2001).

#### Neonatal Seizures

About 4% of preterm neonates have seizures, a higher rate than in older preterm or full-term neonates (Sheth, 1998). Compared to seizures in term neonates, seizures in preterm neonates are more likely to be accompanied by autonomic signs (changes in blood pressure, pulse, and respiration). While between 20 to 40% of term neonates who suffer seizures develop disability, almost 90% of preterm neonates with clearly defined seizures do so (Scher et al., 1993). Animal studies suggest that recurrent neonatal seizures are associated with longterm changes in cerebral excitability and mossy fiber sprouting in the hippocampus in the absence of evident cell loss (de Rogalski, Minokoshi, Silveira, Cha, & Holmes, 2001).

### Prematurity and Brain Development

Growing evidence suggests that *prenatal* brain injury may precede and even be a contributory trigger for preterm delivery. The evidence for this is strongest for inflammatory insults due to intrauterine infections. Intrauterine infection has been implicated in the white matter damage associated with cerebral palsy (Leviton, et al., 1999).

At this time far more is known about the risks that preterm birth carries for *postnatal* brain development. As shown in Figure 23.1, the brain of a preterm infant born at 25 GW has only just begun the major events of brain organization and myelination, which start at around 20 and 24

**Figure 23.1** Plasticity in relation to stages of neurodevelopment. In the human, brain development proceeds in a sequence, as described in the text. This sequence begins with neurogenesis and ends with synaptic pruning. Following early brain damage, plasticity varies according to when the injury took place in the sequence. Animal studies suggest that plasticity will be low during the period of cell migration, corresponding to the second and third trimesters of pregnancy (second panel) and during adulthood (last panel) when synaptic networks have stabilized. Plasticity will be highest prior to synaptic stabilization during early and middle childhood (third panel). From Luciana, M (2003) Cognitive development in children born preterm: Implications for theories of brain plasticity following early injury. *Development and Psychopathology*, 15:1017-1047; (Reprinted with the permission of Cambridge University Press)

weeks, respectively, and continue postnatally for several years after birth and into adulthood. At 25 weeks, the human brain has only a thin layer of cortex, with barely visible gyri and immature Sylvian fissures; myelination is incomplete. Thrust into a physical environment for which it is not yet prepared, the preterm infant born at 25 weeks must accomplish *ex utero* the entire third trimester of brain development; a daunting challenge for an immature organism.

The preterm brain has certain site-specific vulnerabilities due to the timing of birth in relation to the stages of brain development (Perlman, 2003; Volpe, 2001). These vulnerabilities affect at least seven anatomic structures or regions. The first two, the germinal matrix and the cortical subplate, are transient brain structures that set the stage for both brain organization and myelination; the third, the subcortical white matter, is important both for connectivity and for cortical organization; the remaining four, the basal ganglia, the hippocampus, the cerebellum, and the cerebral cortex, are important gray matter structures.

### Patterns of Neuropathological, Qualitative Brain Imaging, and Clinical Findings

Progress in understanding the relation between brain injury and later disabilities and impairments in preterm infants requires iterative cross-walks between two types of studies: those that examine the relation between brain imaging abnormalities and postmortem findings and those that examine the relation between brain imaging abnormalities and outcomes in survivors. Although quantitative brain imaging methods (discussed later) are emerging as important research tools, qualitative brain imaging methods such as ultrasonography (US) and magnetic resonance imaging (MRI) remain the clinical standards and have been the most extensively studied in relation to postmortem findings and clinical outcomes.

Based on postmortem exam, brain lesions in the preterm infant can be classified into four general categories: (1) hemorrhages in nonparenchymal areas of the brain, (2) white matter damage, (3) ventricular enlargement, and (4) lesions in other brain locations—cerebellum, basal ganglia, hippocampus, brain stem, and cortex.

#### Hemorrhages in Nonparenchymal Areas of the Brain

This category groups together the two most usual sites of origin of hemorrhage in the preterm brain, the germinal matrix and (less often) the choroid plexus with two common loci for their extension, the intraventricular and subarachnoid spaces. Cranial US through the anterior fontanelle typically visualizes germinal matrix hemorrhage (GMH) and intraventricular hemorrhage (IVH), while the other two are commonly encountered at autopsy.

Postmortem study of infants who were scanned before death confirmed that US echodensities in the periventricular region and in the ventricles were related to GMH/IVH

(Figure 23.2). In the early 1980s, GMH/IVH was present in up to 40% of VLBW infants, but its prevalence has fallen to around 25%. The balance of evidence suggests that premature infants with US evidence of GMH/IVH and no other brain lesions, experience relatively small elevations in risk of neurodevelopmental disorder in some studies (Pinto-Martin, et al., 1995; Whitaker, et al., 1996) and no elevation in risk at all in other studies (Kitchen, et al., 1985; Papile, Musick-Bruno, & Schafer A, 1983). This absence of adverse impact may reflect recovery due to reversion of astrocytes to radial glia and reactivation of radial glia in the germinal layers (Ganat, Soni, Chacon, Schwartz, & Vaccarino, 2002; Vaccarino & Ment, 2004).

#### White Matter Damage

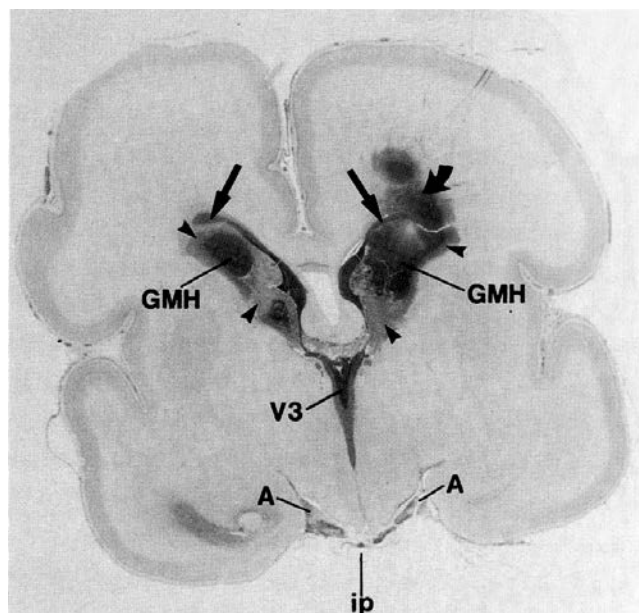

White matter damage (WMD) encompasses a variety of neuropathologic entities, hemorrhagic and nonhemorrhagic, held together by one common feature: they tend to target developing white matter. One important neuropathologic form of white matter damage is periventricular leukomalacia (PVL). PVL is focal coagulation necrosis in the periventricular regions. More recent neuropathologic studies also refer to a more diffuse form of white matter damage whose characteristic histopathology is marked astrocytosis and activated microglial cells (Okoshi, et al., 2001). The mechanisms implicated in diffuse white matter damage (e.g., excitotoxicity, oxidative stress, inflammation) are similar to those for focal white matter damage.

#### Focal White Matter Damage

On neonatal US, PVL appears as echodensities and echolucencies in the periventricular region of the brain parenchyma, (Figure 23.2) frequently accompanied by ventricular enlargement. Recent advances in neonatal intensive care may have resulted in a decrease in the prevalence of focal abnormalities on US and MRI (Heuchan, Evans, Henderson Smart, & Simpson, 2002; Volpe, 2003).

In a regional LBW cohort born 1984 to 1987 and screened with serial cranial US, focal white matter damage occurred in around 8% of the survivors. Focal white matter damage was associated with markedly increased risk of disabling cerebral palsy by age 2 (Pinto-Martin, Riolo, Cnann, Holzman, & Paneth, 1993) and mental retardation by age 6 (Whitaker, et al., 1996). In LBW infants without disabling cerebral palsy or mental retardation, focal white matter damage was associated at age 6 with visual perceptual impairments and with attention deficit hyperactivity disorder (Whitaker, et al., 1996; Whitaker, et al., 1997), and, at ages 6 and 9, with minor motor problems but not general intelligence (Pinto-Martin, Whitaker, Feldman, Van Rossem, & Paneth, 1999).

Stewart et al. (1983) observed similar findings in a hospital-based cohort screened with serial cranial US and prospectively examined at 1, 4, 8, and 14 to 15 years in London. MRI findings at the adolescent follow-up indicate that,

**Figure 23.2** Germinal matrix and intraventricular hemorrhages and parenchymal hemorrhagic infarction: pathologic section (a) and in vivo sonogram (b). There are bilateral germinal matrix hemorrhages (GMH) extrinsically compressing and narrowing the frontal horns of the lateral ventricles, which contain ventricular hemorrhage (a—large arrows). The sonogram suggests bilateral intraventricular hemorrhages within the frontal horns (b—vertical arrows), but the adjacent germinal matrix hemorrhages cannot be delineated because the spared normal germinal matrix (a—arrowheads), which separates them from the intraventricular hemorrhage, cannot be visualized separately on sonography. The left frontal parenchymal hemorrhagic infarction (a—curved arrow) appears as a focus of increased echogenicity on sonography (b—curve arrow) contiguous to the echogenic lateral ventricle. Intraventricular hemorrhage is visible within the third ventricle (V3), and subarachnoid hemorrhage can be seen within the interpeduncular (ip) and ambient (A) cisterns on the pathologic section but not on sonography. (From Nigel Paneth et al. (2004). *Brain Damage in the Preterm Infant. Clinics in Developmental Medicine* (No. 131). Figure 7.7 p. 131. Reprinted with permission from Lippincott Williams & Wilkins.)

while neonatal US accurately identified serious permanent brain lesions, it missed a large proportion of abnormalities. When compared to full-term controls, preterms without major disabilities were far more likely to have abnormalities on MRI; indeed 55% of the preterms had unequivocally abnormal scans and 15 had equivocal scans as read by neuro-radiologists blind to US findings or control status (Stewart et al., 1999). Thinning or atrophy of the corpus callosum, one of the commonest abnormalities, was seen in 42% of the preterms but in only 14% of age and sex matched controls who had been born at term (Stewart et al., 1999). Of great interest, qualitative MRI abnormalities at adolescence were related to behavioral problems and premorbid adjustment, but not to neurological outcomes or to neuropsychological test performance (with the single exception of word production) (Rushe, et al., 2001). Another hospital-based study, found a comparable rate of qualitative abnormalities on MRI (42.5%) in a sample of preterm adolescents, but no relation of these abnormalities to ADHD, low IQ, or dyspraxia (Cooke & Abernethy, 1999).

Many preterm infants imaged with MRI at term age have diffuse excessive high signal intensity (DEHSI) in the white matter (Counsell, Rutherford, Cowan, & Edwards, 2003). Counsell, Allsop, et al. (2003) have argued that DEHSI in preterm infants represents diffuse white matter abnormality. Reviewing a series of studies of diffuse white matter damage in preterm infants, Volpe (2003) has argued that diffuse white matter damage, similar to focal white matter damage, represents injury to preoligodendrocytes by infection or ischemia or an interaction between the two (Counsell, Rutherford, et al., 2003). Death of these cells accounts for the subsequent failure of white matter development as identified by diffusion weighted MRI imaging and of myelination, as identified on conventional MRI.

The diffuse white matter damage may explain some of the milder impairments seen by school age in preterm survivors. A recent study found that school-age children who were born preterm and escaped major disability had diffuse abnormality of cerebral white matter on MRI that was closely correlated with minor motor impairment but not with full scale IQ (Abernethy, et al. 2003).

### Ventricular Enlargement (VE)

VE is the third general category of brain abnormality found on postmortem in preterm infants. Traditionally VE and hydrocephalus have been interpreted as sequelae of IVH. But there is increasing evidence that VE often, perhaps even always, reflects some degree of diffuse white matter damage that leads to a paucity of myelin producing oligodendrocytes and finally late VE (hydrocephalus *ex vacuo*). Evidence that VE is usefully viewed as a form of white matter damage is provided by Leviton and Gilles (1997).

Ment et al. (1999) demonstrated a strong association of US evidence of VE with adverse neurodevelopmental outcome at age 4.5 years. In their study, 56% of infants with VE demonstrated IQ scores below 70 as compared with 13%

of those without VE. Stewart and Kirkbride (1996) found that 14-year-old adolescents born preterm had both a high incidence of VE and poor school performance.

### **Lesions in Other Brain Locations**

The fourth neuropathological category includes the forms of brain abnormalities about which we know the least. Peneth et al. (1994) found that 28% of 74 neonatal deaths in a regional cohort of infants weighing less than 2 kg had cerebellar hemorrhages at autopsy, 17% had basal ganglia necrosis and 16% had lesions of the brain stem.

Linear echogenicity within the basal ganglia and thalamus of preterm infants occurs in approximately 5% of preterm infants. (Chamnanvanakij, Rogers, Luppino, Broyles, Hickman, & Perlman, 2000). At 18 months adjusted age, preterm infants with Linear echogenicity as compared to a control group matched for BW and GA, had significantly lower scores on the mental and motor scores of the Bayley scales and on a rating of motor quality.

In one consecutive series, cerebellar hemorrhage occurred in 28% on LBW infants (Paneth et al., 2004, p. 183). Follow-up to age 4 has found that cerebellar hemorrhage was associated with cognitive rather than motor deficits (Merrill, Piecuch, Fell, Barkovich, & Goldstein, 1998). A retrospective study of MRI abnormalities in a preterm birth cohort, found cerebellar infarction and atrophy as evidenced on MRI in about 8% and 5% of the infants, respectively (Mercuri, et al., 1997), almost always accompanied by MRI abnormalities elsewhere in the brain, the most common being IVH.

Because lesions of the brain stem are not generally imaged in life, their contribution to development cannot as yet be assessed.

The cortex, which is only millimeters wide in infants born at the junction of the second and third trimester, has rarely been described as a site of gross structural lesions on postmortem in premature infants. However, histopathological postmortem work in human infants suggests that focal white matter damage may lead to reorganization of both local and distant neocortical gray matter (Marin-Padilla, 1997). This may explain the relation between US evidence of focal white matter damage and both general and specific cognitive deficits.

## **Magnetic Resonance Imaging: Diffusion Tensor Imaging, Volumetric, and Functional Studies**

### **Neonatal Studies**

Using diffusion tensor imaging, Huppi et al. (1998a) and Huppi, et al. (2001) found rapid changes in the microstructural organization of white matter between 28GW and term as well as both local and distal effects of focal white matter damage on the development of white matter fiber tracts.

Using quantitative volumetric MRI, Huppi et al. (1998) found that the preterm brain undergoes the developmen-

tal changes between 28GW and term that would normally occur during the third trimester. These changes include an increase in the volume, surface area, and sulcation of the cerebral cortex and an increase in the volume of the cerebral white matter. They also found, however, that both the volume of the myelinated white matter and the volume of cerebral cortical gray matter were reduced at term in preterm infants who previously had sustained focal WMD (termed PVL by the investigators); these findings are consistent with neuropathological studies (Marin-Padilla, 1997)

One study suggests that, even in the absence of focal white matter damage, cortical surface area and complexity is impeded in preterm infants (Ajayi-Obe, Saeed, Cowan, Rutherford, & Edwards, 2000). In a sample of 14 extremely preterm infants in which none of the infants had focal WMD and but seven had isolated GMH/IVH, they found that the cerebral cortex of the preterm infants at 38 to 42 weeks postmenstrual age, had less surface area and was less complex in terms of folding than that of term infants. At age 2, 40% of the preterms had global developmental delay, but none had major neuromotor deficits

### **School Age**

In a study that compared 25 preterm 8-year-olds to 39 term controls using volumetric analyses, one investigator (Peterson, et al., 2002) found that several cortical regions, most prominently the sensorimotor regions and also premotor, midtemporal, parietooccipital, and subgenual cortices, were significantly smaller in the preterm group compared with term controls. Other structures also found to have smaller volumes in preterms were the cerebellum, basal ganglia, amygdalae, hippocampus, and corpus callosum. Structures having larger volumes in preterms were the occipital and temporal horns of the ventricles. The findings in the preterm group were associated with lower GA at birth. Sensorimotor and midtemporal cortical volumes correlated significantly with full scale, verbal and performance IQ. The authors suggest that the volume reduction is due to more subtle problems in blood or oxygen delivery than acute hemorrhage or severe asphyxia.

The same investigators (Peterson, et al., 2002), using functional MRI, found that the brain activation patterns of 8-year-old preterms during semantic processing resembled those of term controls during phonemic processing. These findings were interpreted as indicating that preterm children may process meaningful language as though it were meaningless sounds. However, the possibility that the unusual activation patterns in the preterms might reflect a more general cognitive dysfunction or lag was not ruled out, given that the preterms also had somewhat lower IQs than the term children.

### **Adolescents**

A quantitative MRI study of very preterm adolescents found a 6.0% decrease in whole brain volume, an 11.8% decrease

in cortical gray matter volume, and decreases in right (15.6%) and left (12.1%) hippocampal volumes compared to full-term controls (Nosarti, et al., 2002). This study did not examine the relation between brain volumes and cognition. Another study of the same sample found that preterm subjects had significantly reduced cerebellar volume compared to term-born controls (Allin, et al., 2001). While there was no relation between cerebellar volume and motor neurological signs, cerebellar volume was significantly related to several cognitive test scores, including full scale IQ.

### **Adults**

A study using computational morphometry found that lateral ventricular volume was significantly greater (by 41%) in VLBW adults compared to sibling controls (Allin, et al., 2004). The ratio of gray to white matter was significantly greater (by 10%) in those with VLBW, suggesting an abnormality in the organization of the cerebral cortex. Within the VLBW group there was a strong relation of greater lateral ventricular volume with less gray matter in subcortical nuclei and limbic cortical structures and less periventricular white matter. They conclude that the brains of VLBW adults have an abnormal distribution of gray matter and abnormal interregional and intraregional connectivity, and that these abnormalities result from the way normal brain development interacts with early brain lesions (Marin-Padilla, 1997; 1999). The relation between volumetric MRI abnormalities in adulthood and cognitive or motor test performance has not yet been reported.

Noting that thinning or atrophy of the corpus callosum, particularly the posterior portion, is one of the most common brain abnormalities found in very preterm survivors. Santhouse et al. (2002) examined the functional significance of perinatal corpus callosum damage in preterm adults. They compared seven very preterm males with callosal damage as previously identified by qualitative MRI scan at adolescence to nine very preterm males without evidence of callosal damage and to seven full-term controls with respect to activation patterns on auditory and visual tasks requiring callosal transfer. The very preterm males with callosal damage had significantly different activation patterns compared with the two comparison groups. On the visual task, the group with callosal damage manifested additional activity in the right dorso-lateral prefrontal cortex, which the investigators interpret as consistent with the recruitment of working memory to compensate for impaired callosal function. On the auditory task, the group with callosal damage manifested a deficit of activity in the right temporal lobe, which the investigators interpret as consistent with left hemisphere or bilateral representation of timbre discrimination rather than the right hemisphere specialization found in normals. Overall, the investigators suggest that their findings point to neural compensation that is specific to the sensory modality involved and suggest the plasticity of the brain in the face of early brain damage.

### **Plasticity of the Preterm Brain**

One of the more striking impressions that one carries away from the literature on brain imaging and outcomes in preterm survivors is the subtlety of the cognitive and motor impairments relative to the dramatic regional reductions in white and grey matter as measured on MRI. This suggests a remarkable plasticity of the preterm brain. Principles of plasticity following early brain injury in term infants have been reviewed recently by Stiles et al. (2005). For a comprehensive review of evidence for brain plasticity in preterm survivors, the reader is referred to Luciana (2003).

### **Neurobehavioral Sequelae of Preterm Birth**

Survivors from the start of the modern era of neonatal care are now entering young adulthood. Outcome studies discussed next are mainly limited to these and later cohorts; that is, from the 1980s and beyond. Where evidence is available, outcomes are related to early biological and social risk factors. Excellent reviews of the methodological issues in preterm outcome research are available (Aylward, 2002; Kiely & Paneth, 1981; Saigal, 2000).

### **Need for Special Educational Services and Placements**

School-related difficulties are among the most common problems confronting children born prematurely and at VLBW. More than half of VLBW and 60 to 70% of ELBW children require special educational assistance at some point in their school career (Aylward, 2002); by adolescence, ELBW children will have exceeded their peers in use of remedial or special educational services by eightfold to 10-fold. Similar figures for disabilities and special educational needs, and their inverse relation to birthweight, have been reported from numerous regional and population-based studies (Bowen, Gibson, & Hand, 2002; Buck, Msall, Schisterman, Lyon, & Rogers, 2000; Corman & Chaikind, 1998; Horwood, Mogridge, & Darlow, 1998; Klebanov, Brooks-Gunn, & McCormick, 1994; Pinto-Martin, et al., 2004; Saigal, et al., 2003).

### **Performance on Achievement Tests**

By the middle school years ELBW children are about three to five times more likely than their age mates to have a problem with reading, writing, or spelling. Even among those scoring in the normal range of intelligence, children born prematurely are likely to have lower scores on tests of academic achievement (Taylor, Hack, Klein, & Schatschneider, 1995). In regional samples of ELBW children followed to school age in four different countries, below-normal scores on standardized tests ranged from 19 to 54% for reading, from 24 to 69% for arithmetic, and from 35 to 61% for spelling (Saigal, et al., 2003). Achievement deficits present in the early or middle-school years have been found to persist through high school (Breslau, Paneth, & Lucia, 2004; Saigal, et al., 2003).

Achievement is often especially low in arithmetic (Breslau, Johnson, & Lucia, 2001; Elgen & Sommerfelt, 2002; Rickards, Kelly, Doyle, & Callanan, 2001). In a preliminary attempt to locate the neurological substrate of this specific mathematical deficit, one study used MRI morphometry to compare two groups of preterm adolescents, matched on gender, age, and relevant perinatal variables; one with mathematical ability scores below expectation, based on intelligence testing, and another with math scores at expected levels. There was less grey matter in a specific area of the left parietal lobe in the preterms with below-expectation math scores (Isaacs, Edmonds, Lucas, & Gadian, 2001).

### General Cognitive Abilities

In a regional birth cohort of LBW infants (Whitaker, et al., 1997), the prevalence of mental retardation (MR) was 5%; twice the amount expected based on population norms. In that cohort, focal white matter damage was the most powerful predictor of severe to moderate MR, followed by germinal matrix/intraventricular hemorrhage and by mechanical ventilation. Social disadvantage was not a predictor of severe to moderate MR.

When children with major disabilities are excluded from consideration, preterm children as a group, generally have mean scores falling in the average (or low average) range on a variety of tests of general cognitive ability; however, they also show a fairly consistent deficit (varying from 5 to 15 points) relative to their term-born peers (Aylward, 2002). A recent meta-analysis of 15 follow-up studies found the weighted mean difference between groups to be about 10 points (2/3 of a SD) (Bhutta, Cleves, Casey, Craddock, & Anand, 2002). A 10-point downward shift of the mean for the distribution of IQ implies an increment of about 21% in the proportion of preterms scoring below normal (i.e., having an IQ < 85).

### Language

Between infancy and preschool, preterm children are more likely than full-term peers to have phonological and articulation problems (Briscoe, Gathercole, & Marlow, 1998). However, findings from older preterm children generally have been mixed. For example, at early school age, two population-based studies found normal language development in preterm samples (Scottish Low Birthweight Study Group, 1992; Whitaker, et al., 1996). Other studies have found delays in language ability and sentence repetition in early and middle childhood (Allin, et al., 2001; Breslau, Chilcoat, DelDotto, Andreski, & Brown, 1996; Largo, Molinari, Pinto, Weber, & Duc, 1986; Le Normand & Cohen, 1999; Wolke & Meyer, 1999).

Some studies report comparatively poor performance for preterm children in only selected aspects of language. According to a recent review (Aylward, 2002), preterms more consistently show deficits relative to term controls on tests of expressive language and on tests of complex grammar and syntax, than they do on tests of receptive language.

### Motor Problems

In the neonatal period, a choreiform movement disorder has been described in a subgroup of premature infants with chronic lung disease. Although the abnormal movements improve with time, survivors exhibit cognitive problems (Perlman & Volpe, 1989).

By age 2, most cases of disabling cerebral palsy (DCP) are evident. DCP is the most serious of the motor impairments for which those born extremely preterm are at excess risk, occurring in about 10% of this population. Disabling CP is strongly related to focal white matter damage on neonatal cranial US. Nondisabling CP, principally mild spastic diplegia, is only modestly related to focal white matter damage (Pinto-Martin et al., 1996).

By middle and late childhood, milder motor impairments, such as those which contribute to the hidden disability associated with prematurity are evident (Bracewell & Marlow, 2002). Many of these less severe types of disability are often grouped together as Developmental Coordination Disorder (DCD). There is not yet a consensus on how to operationalize DCD; because of differing criteria and tests used in different studies, prevalence figures are uncertain. A recent report from a geographically-defined cohort in the U.K. (Foulder-Hughes & Cooke, 2003) found motor impairment to be diagnosed in up to 42.7% of 7 to 8 year olds born at < 32 GW.

In another regional cohort study of LBW children (Pinto-Martin, et al., 1999), assessments at 6 and 9 years of age with a motor problems inventory showed that the mean problem scores of nondisabled children in all birthweight groups were at or above the cutpoint identifying the top 10% of the standardization sample at both ages, and showed a significant birthweight gradient, with the highest problem scores in the lowest birthweight groups. In this same study, motor problems at both ages were significantly associated with neonatal US findings of focal white matter damage independently of other prenatal, perinatal, and neonatal risk factors (see also Levene, et al., 1992; Marlow, Roberts, & Cooke, 1989; Sullivan & McGrath, 2003).

### Ophthalmological Problems and Visual Impairment

Strabismus and refractive disorders (especially myopia) affect, respectively, nearly 15% and 20% of preterm children. Those with retinopathy of prematurity are at highest risk. More severe impairments include amblyopia, retinal detachment, optic nerve injury, and cortical injury. Together with strabismus and myopia, these impairments affect up to one third of nondisabled VLBW adolescents (Powls, Botting, Cooke, Stephenson, & Marlow, 1997). An additional 30% have impaired visual function on tests of contrast sensitivity and stereopsis. Overall, 64% of VLBW children had abnormalities on at least one measure as compared to 36% of NBW children. Poor contrast sensitivity and strabismus were related to poor motor skills, while poor contrast sensitivity and poor visual acuity were related to lower IQ. Reduced contrast sensitivity was the most sensitive predictor

of impaired motor and cognitive function. White matter damage on US and MRI was related to strabismus, but not to reduced contrast sensitivity,

#### Visual–Perceptual and Visual–Motor Impairment

Preterms perform poorly on a broad range of visual–perceptual and visual–motor tests (Hård, Niklasson, Svensson, & Hellström, 2000; Luoama, Herrgard, & Martikainen, 1992). Poor performance on both a test of visual–motor skill and a motor-free test of visual–perceptual skills was associated with neonatal US evidence of focal white matter damage in nondisabled LBW 6-year-olds (Whitaker, et al., 1996).

#### Hearing

The prevalence of sensorineural hearing loss (SNHL) in very premature infants ranges from 0 to 9% and increases with decreasing GA (Msall and Tremont, 2002). SNHL is associated with severe respiratory illness and prolonged hospitalization; it has been suggested that this association might be a consequence of auditory nerve damage caused by noise levels in the NICU. Neonatal hyponatremia is also associated with SNHL.

#### Attention

In infancy, preterms have consistently been found to have less mature attention, as reflected in their longer looks and fewer shifts of gaze compared to controls matched on socio-economic status and age post-conception (Rose, Feldman, & Jankowski, 2004); these less mature patterns were found to be associated with aspects of medical risk in the preterm group, including days on oxygen and with mechanical ventilation. Preterm infants with respiratory distress syndrome, compared to preterms without RDS and to full-term infants, have also been found to have smaller heart rate responses, indicative of less intense attention, during periods of orienting to and sustained looking at a stimulus (Richards, 1994).

Findings for laboratory measures of attention in childhood, findings have been somewhat inconsistent. One study (Herrgard, Luoma, Tuppurainen, Karjalainen, & Martikainen, 1993) found no difference between preterms (< 32 weeks) and full-term controls on several attention tests. Another (Breslau, Brown, et al., 1996) found no difference between LBW and normal birthweight (NBW) groups on tests of sustained attention. Other studies have found performance on attention measures to be related to neonatal medical morbidity in preterms and to be poorer in LBW or VLBW children compared to NBW controls (Taylor, et al., 1995), though some of these findings, with the exception of accuracy on a vigilance test, disappeared when IQ was controlled (Taylor, Klein, Schatschneider, & Hack, 1998). In another study (Breslau, Chilcoat, et al., 1996) the poorer performance of preterms compared to controls withstood control for IQ on a test of focused attention, but not vigilance.

#### Processing Speed

Speed of information processing has been considered to be a fundamental component of individual differences in cognition generally. It is sometimes thought to be the basis for *g*, the factor representing the shared variance (correlation) among all cognitive tests and is important to the correlation between intelligence and achievement. As assessed with an encoding speed task, perceptual speed tasks, reaction time tasks, and decision time tasks, preterms have been found to be slower than full-terms at school-age (Rose & Feldman, 1996). Interestingly, when assessed with a choice reaction time task at age 11, preterm children were actually faster than full-terms when there was but one response choice, but became increasingly slower as the choices multiplied.

#### Memory

Memory is not a unitary construct; some types of memory have been found to be more affected in those born prematurely than others. Forms of memory that are particularly affected by prematurity are those dependent on structures in the medial temporal lobe (the hippocampus, dentate gyrus, subicular complex, and the adjacent perirhinal, entorhinal, and parahippocampal cortices). Collectively, these forms of memory are known as declarative (or explicit) memory and are characterized by recollection of facts (semantic memory) and events (episodic memory) and, in principle, are capable of entering consciousness. By contrast, forms of memory that do not depend on the medial temporal lobe, collectively known as nondeclarative (or implicit) memory, are nonconscious, and have not been found to be affected by premature birth. Nondeclarative memory is a catch-all category that includes procedural memory (skills and habits), classical conditioning, and nonassociative learning, among other things.

One of the most widely studied types of declarative memory is recognition, the capacity to distinguish things previously encountered from new ones. This type of memory has been shown to be particularly affected by prematurity even in its earliest-appearing form, in infancy (Nelson, 1995; Rose, et al., 2004). Several other forms of declarative memory have also been found deficient in preterm relative to full-term groups, including list learning, recall, memory span, working memory, and so on (Curtis, Lindeke, Georgieff, & Nelson, 2002; Luciana, Lindeke, Georgieff, Mills, Nelson, 1999; Taylor, Klein, Minich, & Hack, 2000). Everyday memory (a form of episodic memory), has been found to be impaired, compared to full-term controls, in preterm adolescents who were also found to have reduced bilateral hippocampal volumes on MRI, despite equivalent head size and an otherwise neurologically normal presentation (Isaacs, et al., 2000).

#### Executive Function

Executive function (or executive control) tasks require inhibition, planning, and/or application of strategies; good

performance is thought to depend on mature functioning of frontal lobe structures. The few studies thus far which have examined executive function in preterm children found their performance poor compared to controls (Frisk & Whyte, 1994; Luciana, et al., 1999). A more precipitous decline in the performance of VLBW children compared to controls has been found with increasingly difficult memory tasks (Rose & Feldman, 1996). This exaggerated decline in response to cognitive challenge may be one of the factors behind the delayed emergence of some academic problems in children with VLBW.

## Behavior and Psychopathology

### Regulatory Problems in the NICU

Neurobehaviorally, there are several respects in which preterm/very low birthweight newborns, as a group, have been found to perform more poorly than full-term/normal birthweight peers, even when both groups are examined at equivalent postmenstrual ages. For example, when assessed at 40 weeks postmenstrual age with MRI and a modification of the Neonatal Behavioral Assessment Scale (NBAS) (Als, Duffy, McAnulty, 1988), healthy preterm infants were found to have not only less grey and white matter differentiation and myelination, but also significantly poorer functioning, in four neurobehavioral areas: autonomic regulation, motor responsiveness, state organization, and attention compared to full-term controls. Yet, these same preterms had actually improved in both respects over earlier assessments done at birth. However, the NBAS and similar tests have little or no test-retest reliability and no predictive validity for later development. Thus it is unclear what they imply, if anything, about any long-term impact of prematurity.

### Behavior Problems

Parents and teachers have often reported elevated levels of behavior problems in preterm children (for reviews see Buka, Lipsitt, & Tsuang, 1992; Chapieski & Evankovich, 1997. Though they can be detected earlier (Rose, Feldman, Rose, Wallace, & McCarton, 1992), behavior problems in preterms become more noticeable and impairing during the school years, when high levels of such problems interfere with normal activities and learning.

One of the most widely used behavior problem scales, the Child Behavior Checklist (Achenbach, 1991), assesses eight problem dimensions which are grouped into broader areas of behavioral difficulty. When preterm children are found to have more problems overall than controls, they most often show elevated scores on the Social and Attention Problem scales. The degree to which these problems may be characteristic of preterms was underscored in a recent paper which compared behavior problems obtained by parent report among school-aged children born at < 1,000g from four different countries: the

U.S., Canada, the Netherlands, and Germany (Hille, et al., 2001). Despite somewhat different approaches to early socialization and education of children in these four countries and the administration of the same instrument in different languages, the behavioral profiles of the ELBW cohorts were strikingly similar, suggesting that social and attention problems, in particular, are common sequelae of prematurity across cultures. Another study, however, suggested that the elevation in preterms on the attention problems scale of the CBCL may be found mostly among children in the lower end of the socioeconomic spectrum (Breslau & Chilcoat, 2000).

### Psychopathology

A number of studies have used structured psychiatric diagnostic interviews to assess a range of psychiatric disorders in preterm/LBW survivors. A consistent finding has been an excess of Attention Deficit Hyperactivity Disorder (ADHD) in preterm/LBW survivors relative to term/normal birthweight controls (Botting, Powls, Cooke, & Marlow, 1997; Breslau, 1995; Szatmari, Saigal, Rosenbaum, & Campbell, 1993; Szatmari, Saigal, Rosenbaum, Campbell, & King, 1990). Breslau, et al. (1996a) found that urban, but not suburban LBW survivors had an excess of ADHD relative to normal birthweight controls at age 6. In a large regional LBW birth cohort, independent predictors of ADHD at age 6 included neonatal cranial US consistent with white matter damage as well as male sex, a proximal measure of social disadvantage and both maternal smoking and mild alcohol consumption during pregnancy (Whitaker, et al., 1997).

The relation of prematurity and LBW to substance use is inconsistent. One community-based study (Chilcoat & Breslau, 2002) found a significantly higher incidence of drug use among 11-year-old boys (but not girls) with LBW compared to NBW controls (OR = 2.0), while a regional cohort followed to adulthood (Cooke, 2004) found less self-reported alcohol and drug use in preterms compared to controls, but equivalent rates of smoking. Another study (Hack, et al., 2002) found that adults born at VLBW were less likely than normal birthweight controls to report alcohol and drug use. It is not clear, however, whether the apparently encouraging findings regarding alcohol and drug use might reflect ongoing dependence of VLBW survivors on their families due to residual cognitive and social problems (Harrison, 2002).

A metaanalysis has suggested that LBW is a modest but definite risk factor for schizophrenia (Kunugi, 2001). However, other studies have found that prematurity, but not LBW, is associated with risk for schizophrenia. One study found that, in patients with schizophrenia, prematurity (but not poor fetal growth), was associated with premorbid social withdrawal and an early age at illness onset, whereas poor fetal growth (but not prematurity) was associated with low educational achievement (Smith, et al., 2001).

## Quality of Life in Adolescence and Adulthood

Despite their objectively greater functional impairment, preterm groups do not necessarily report more negative perceptions of quality of life (QOL) than full-term controls. For example, in a Canadian cohort of ELBW adolescents and NBW controls, although the mean score on a health-related quality of life scale was higher in controls, the vast majority of the ELBW group viewed their QOL as satisfactory (Saigal, et al., 1996), and the ELBW teenagers did not differ from their controls in self-esteem (Saigal, Lambert, Russ, & Hoult, 2002). Similarly, preterms and full-terms followed to adulthood in the U.K. reported no difference in six of eight QOL domains (physical functioning and general health being the two exceptions). One study of preterms even reported the counter-intuitive relation of better self-perceived QOL to more severe neonatal cranial US findings, based on birth record search (Feingold, Sheir-Neiss, Melnychuk, Bachrach, & Paul, 2002). And, even when preterm adolescents did rate their QOL as poorer than full-term peers, they were not unduly worried about their future (Walther, den Ouden, & Verloove-Vanhorick, 2000). Saigal et al. (1996) suggested that disabled preterm children may adjust their expectations downward so that they perceive their quality of life to be better than an outsider might see it.

## Special Topics

### *Small for Gestational Age (SGA)*

As noted earlier, SGA refers to an infant having weight at birth in the lowest portion (generally, the lowest 10%) of a weight-for-gestational-age reference standard. A more stringent standard, namely, the lowest 2% of a weight-for-gestational-age distribution, has been proposed on the grounds that higher percentages may include infants who are merely genetically small. Intrauterine growth restriction (IUGR) refers to an SGA infant for whom there is also evidence of a pathologic restriction of fetal growth due to adverse genetic or environmental influences. (Henrickson & Clausen, 2002).

A disproportionate number of adults who were born with IUGR seem predisposed to hypertension, heart disease, obesity, and type II diabetes (McClellan & Novak, 2001). According to the fetal origins hypothesis (a.k.a., the Barker Hypothesis or fetal programming), these adult disease states are thought to result from fetal adaptations to poor nutritional status that are harmful under conditions of good nutrition later on (Barker, 1995). However, this literature is controversial (Paneth, Ahmed, & Stein, 1996; Paneth & Susser, 1995).

Evidence regarding cognitive compromise in children born with IUGR is inconsistent, and may have to do with quality of postbirth nutrition; for a review, see Grantham-McGregor (1998). Evidence regarding behavioral and emotional problems also is mixed. In a study from Western Australia (Zubrick, et al., 2000), severe IUGR children had

significantly elevated risk for mental disorder (OR 2.9; 95% CI: 1.18, 7.12). Meanwhile, the British Cohort Study, which used the 5th percentile of weight-for-gestational-age as the cutpoint for defining SGA, found no longterm social or emotional consequences (Strauss, 2000). This was also the case for a large multicenter Scandinavian cohort (Sommerfelt, et al., 2001). In this latter cohort, SGA versus AGA status explained only 1% of variance in a summary score of child behavior problems

### *Male Vulnerability*

National birth registry data indicate an excess of males among preterm births (Ingemarsson, 2003). A recent meta-analysis of results from such studies found an overall OR (95%CI) of 1.12 (1.09, 1.15) for the association of maleness with prematurity (Zeitlin, et al., 2002). Males are also more likely to develop complications associated with preterm birth, in particular pulmonary morbidities and intracranial hemorrhage and, in consequence, their rates of neonatal mortality are higher than for females (Vatten & Skjaerven, 2004).

In studies examining longterm outcomes of prematurity, males have been found to have higher rates of neurosensory disability (Whitfield et al., 1977), poorer general cognitive ability (Hindmarsh, O'Callaghan, Mohay, & Rogers, 2000), and academic performance (Johnson & Breslau, 2000; O'Callaghan, et al., 1996) than their female counterparts. Preterm males with sonographically identified perinatal brain injury have been found to have IQ scores at age 4 to 5 years about half a standard deviation lower than girls with the same degree of perinatal injury (Raz, et al., 1995).

### *Catch Up*

With respect to physical growth, recent population-based studies have found that, despite some catch-up, growth parameters continue to be below normal into adolescence for a higher proportion of ELBW survivors than their term controls (Ford, Doyle, Davis, & Callanan, 2000).

With respect to cognitive growth, findings are mixed. For the most severely affected preterm children (e.g., those with ELBW and those with PL/VE), cognitive abilities generally either decline or remain stable at their initially low levels relative to peers. Meanwhile, for those without major complications and those born at heavier birth weights, subsequent interventions and socioeconomic circumstances play a major role in determining whether performance relative to peers improves, declines, or remains the same as they grow older. Most studies find that, while rates of severe disabilities tend to remain stable over age, there is an overall trend for increasing rates of more subtle problems through early, middle, and high-school ages (Saigal, 2000). This trend is exemplified in a full-population cohort of children born at < 1,500g or < 32 GW followed to age 14 (Walther, et al., 2000). In that cohort, problems in basic functions (e.g., speech, mobility) decreased from age 5 to 10 years of age while psychological

problems (negative mood, poor concentration) increased (Theunissen, et al., 2000).

### Summary of Prematurity

Preterm birth now affects 1 in 10 families in the United States and is a major risk factor for major disability and impairment, especially at the lower extremes of gestational age. The largest single risk factor for preterm delivery is a previous preterm delivery, pointing to a genetic contribution. Thus far, however, the causes of preterm delivery remain a mystery, frustrating efforts at prevention. In preterm infants, white matter damage, both focal and diffuse, is a risk factor for motor disability and impairment; white matter damage also may affect the organization of important grey matter structures, such as the cortex. Even in the absence of known brain injury, the brains of healthy preterms differ from those of term infants and these differences are apparent in different age groups, including adults. The functional significance of these differences requires further study. It is important to note, that at least half of preterm survivors are doing remarkably well and most are satisfied with their quality of life.

## CEREBRAL PALSY

Cerebral palsy, the most common physical disability of childhood in developed countries, affects one in 500 school-age children (Stanley, Blair, & Alberman, 2000). The disabling forms of cerebral palsy exact an enormous toll from individuals, their families, and society (Honeycutt, Dunlap, Chen, & Homsy, 2004), while milder forms of motor impairment place an individual at risk for social isolation during school-age years (Skinner & Piek, 2001).

### Background

#### Definitions

The term cerebral palsy describes a group of disorders of the development of movement and posture, causing activity limitation, that are attributed to non-progressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, cognition, communication, perception, and/or behavior, and/or by a seizure disorder (Bax M, et al., 2005). Postneonatal events such as meningoencephalitis, trauma, or occlusion of a cerebral artery account for only 12 to 21% of cases of CP in developed countries, but are more common in the developing world (Emond, Golding, & Peckham, 1989).

The manifestation of motor impairment due to brain injury or anomalies may change over time. Abnormalities of motor tone or movement in the first several weeks or months after birth may gradually improve during the first year. Conversely, relatively nonspecific motor signs, such as

hypotonia, that are seen in this early period may evolve over the 2 years into spasticity and extrapyramidal abnormalities.

Based on the predominant type of motor impairment, CP is classified as spastic, dyskinetic, ataxic, or mixed (see Table 23.3). For infants born in the Western world since 1980, spastic CP is the most frequent type and accounts for approximately 85% of cases, with estimates ranging from 76 to 93% (Colver & Sethumadhavan, 2003; Mutch, et al., 1992; Paneth & Kiely, 1984). Spasticity is defined as a velocity-dependent resistance of muscle to stretch, or excessive inappropriate involuntary muscle activity, associated with upper motor neuron paralysis or syndrome. Spasticity develops when injury to the corticospinal tracts decreases cortical excitatory input to reticulospinal and corticospinal tracts. This in turn decreases the number of effective motor units, producing aberrant muscle control and weakness. At the same time, the loss of descending inhibitory output through the reticulospinal tract and other systems increases the excitability of gamma and alpha neurons, producing spasticity (see Sanger, 2003).

Spastic CP is classified further, according to its topography, into quadriplegia (involvement of all four limbs), diplegia (significant leg involvement with less prominent effect on the arms), and hemiplegia (involvement of an ipsilateral arm and leg). The term double hemiplegia implies bilateral involvement characterized by greater involvement of the arms than the legs. Movement disorders (such as dystonia) can coexist with the predominant motor impairment. Because at present there is no reliable objective measure of muscle tone, the topographic classification of spasticity is somewhat unreliable between clinicians.

The inclusion of a measure of functional motor capacity in the diagnostic process improves the rate of diagnostic agreement between clinicians; the rate of agreement is greater for disabling than nondisabling forms of CP. For this reason, it has been argued that only disabling CP should be included in case registers for epidemiological studies of CP (Palisano, et al., 1997b). A simple five-level system for rating activity restriction that correlates highly with the International Classification of Impairments, Disabilities, and Handicap (WHO, 1980). Levels I and II correspond to nondisabling or mildly disabling CP, while Levels III to V correspond to moderately to severely disabling CP (Palisano, et al., 1997b). Children with spastic hemiplegia typically are mildly disabled (activity restricted), children with spastic diplegia, choreoathetoid CP, and mild ataxia are moderately disabled, while children with spastic quadriplegia are severely disabled (Palisano, et al., 1997a).

### Trends in Incidence and Prevalence

The prevalence of CP in the Western world is about 2 to 3 per 1,000 live births (Stanley, et al., 2000). Information about the prevalence and time trends of CP has been most completely described for patients in the United Kingdom,

**TABLE 23.3****CEREBRAL PALSY: CLASSIFICATION, ASSOCIATED FEATURES, AND RISK FACTORS**

Type/Frequency/ Age at Dx	Motor Features/ Functional Level	Epilepsy	Other Features	Risk Factors
<b>Spastic CP</b> —80% of all cases	<ul style="list-style-type: none"> <li>Pyramidal signs, with distal weakness, hypertonicity, and hyperreflexia (<i>damage to cortico-spinal tracts</i>)</li> </ul>

\*School age prevalence per thousand live births.

Sweden, and Australia. For the period from 1967 to the early and mid-1980s, data from these countries showed an increase in the live birth prevalence of CP in children with low birthweight with a leveling off thereafter (Hagberg, Hagberg, Beckung, & Uvebrant, 2001; Stanley & Watson, 1992). The only population-based study of CP in the United States has found a modest increase in the prevalence of CP, but only in normal birthweight one year survivors (Winter, Autry, Boyle, & Yeargin-Allsopp, 2002).

CP occurs more commonly in children who are born very preterm than in mildly premature children. A recent study in Sweden found that of 241 children with CP, 36% were born at less than 28 GW, 25% at 28 to 32 GW, and 2.5% at 32 to 38 GW and 37% at term. Of these 241 children, 33% were hemiplegic, 44% diplegic, and 6% quadriplegic (Hagberg, et al., 2001).

In developed countries, the natural history of CP has improved over the past 50 years. If appropriate health care is

available, affected children without significant comorbidities have life spans approaching that of the general population. However, life span is shorter in persons with quadriplegia, hydrocephalus, lack of basic functional skills, refractory seizures, and profound mental retardation (Hutton & Pharoah, 2002).

### Clinical Patterns, Pathological Findings, and Imaging Studies

#### Full-Term Infants

Spastic hemiplegia is most typical of full-term infants. Cerebral injury in the distribution of the middle cerebral artery is the most common finding on postmortem and in patients evaluated with CT and MRI (Scher, Belfar, Martin, & Painter, 1991; van Bogaert, Baleriaux, Christophe, & Szliwowski, 1992; Wiklund & Uvebrant, 1991). These studies find necrosis and atrophy with or without gliosis, but it is not known when the ischemic or hemorrhagic disturbance began. For reasons not understood, right-sided hemiplegia occurs as twice as frequently as left-sided hemiplegia (Ment, Duncan, & Ehrenkranz, 1984).

Periventricular atrophy suggesting white matter abnormality is present in some children with hemiplegic CP and gross malformations of cerebral development are found in about one sixth. The CT or MRI is normal in another one quarter to one third of children with presumed congenital hemiplegia. The lack of areas of injury or abnormality on brain imaging supports the idea that some CP is related to abnormalities of brain development at the microscopic level. Consistent with this possibility, no abnormalities of any kind were found in the obstetrical history of a majority of infants with hemiplegia in two separate studies (Cohen & Duffner, 1981; Levy, Abrams, Marshall, & Rosquette, 1985).

In patients with quadriplegic CP, MRI findings include multiple cystic lesions in the white matter, diffuse cortical atrophy, cavities that communicate with the lateral ventricles, and hydrocephalus (Truwit, Barkovich, Koch, & Ferriero, 1992). Choreoathetoid forms of CP, which often include spasticity, tend to occur in term infants. Dystonia of the extremities often also co-occurs with spasticity but is often missed. On postmortem the histopathological appearance of the basal ganglia often resembles marble (*status marmoratus*). Persistently hypotonic or atonic CP suggests the involvement of the cerebellar pathways. Long tract signs such as brisk tendon reflexes and extensor plantar responses frequently accompany the hypotonia.

#### Preterm Infants

Until recently, the predominant view was that spastic quadriplegia was typically (although not invariably) associated with term delivery, while spastic diplegia was typically (although not invariably) associated with preterm delivery. This view accorded with what was known, based on neuropathological studies and early brain imaging, about the differing typical distribution of white matter injury in

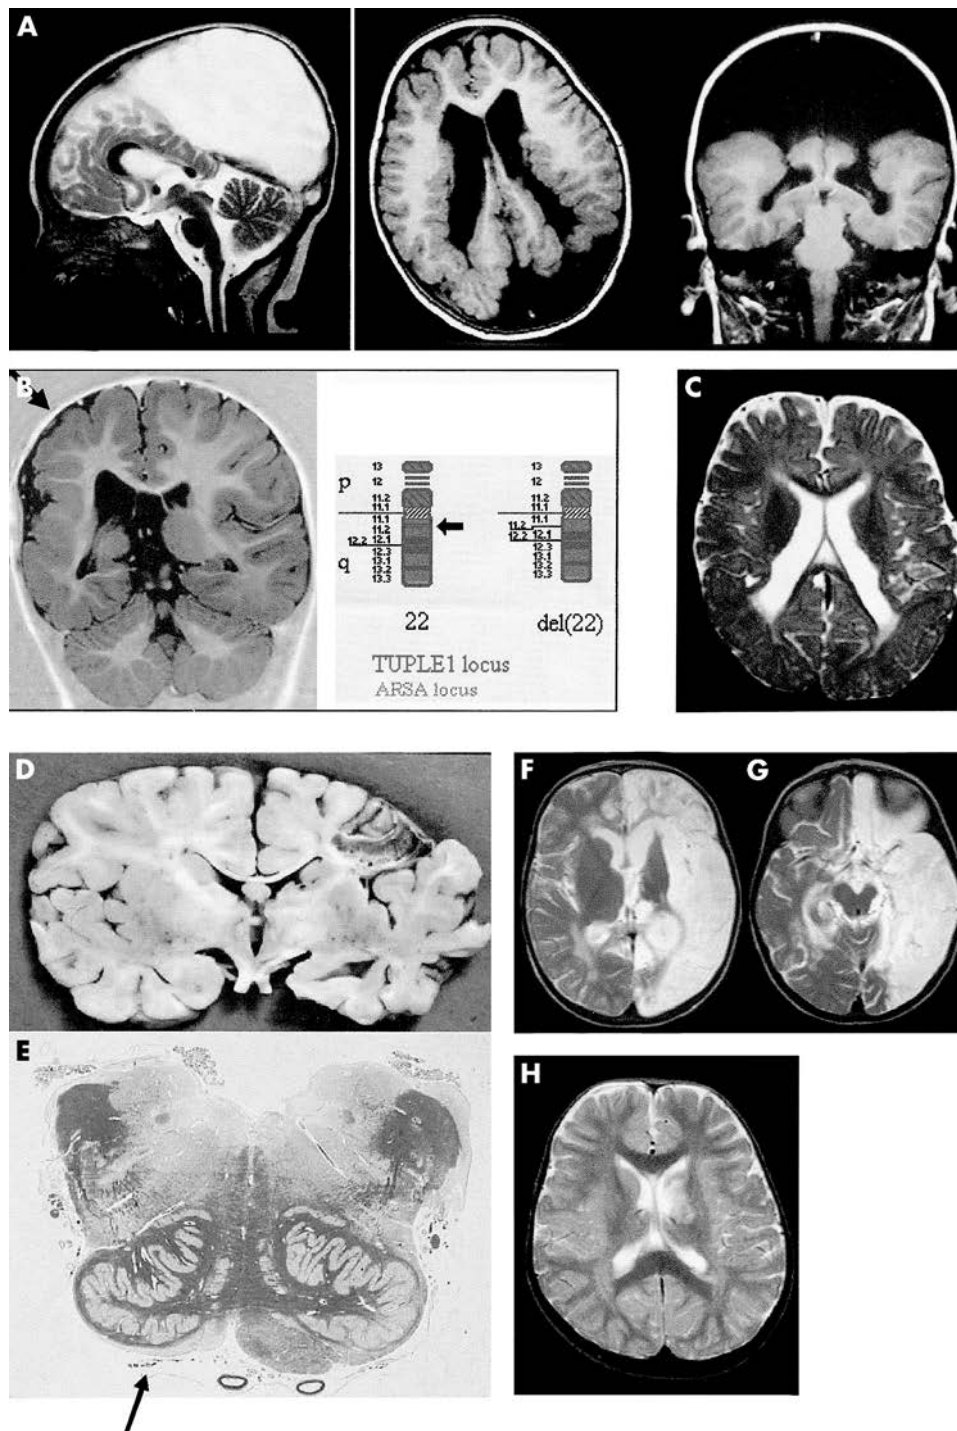

term and preterm infants. Parasagittal white matter injury in term infants and periventricular white matter injury in preterm infants have been attributed to gestational age-related differences in regional vulnerability of white matter to injury. However, recent epidemiological and brain imaging studies cast some doubt on this picture. Epidemiological studies of cohorts born since 1980 and found that spastic cases with predominantly lower limb involvement (about 33%) were equally distributed among preterm and term infants (Colver & Sethumadhavan, 2003). Moreover, in recent MRI studies of children with spastic CP, there has been no clear association between periventricular white matter injury and spastic diplegia or between parasagittal white matter injury and quadriplegia (Krageloh-Mann, 2000). Figure 23.3 shows examples of neuroimaging and neuropathology of the cerebral palsies with brief clinical descriptions.

### Risk Factors and Pathogenesis

The view that intrapartum asphyxia was the predominant cause of CP was entrenched in the lay and professional mind until fairly recently (Gibbs, Rosenberg, Warren, Galen, & Rumack, 2004). This misconception gradually yielded to a series of important neuroepidemiological studies, beginning in the late 1970s with the Collaborative Perinatal Project (Nelson & Ellenberg, 1978) and including, in the United States, the Neonatal Brain Hemorrhage Study (Pinto-Martin, et al., 1993), the California Cerebral Palsy Project (Cummins, Nelson, Grether, & Velie, 2003; Grether, Nelson, Walsh, Willoughby, & Redline, 2003) and the Developmental Epidemiology Network (Leviton et al., 1999). In an attempt to evaluate the relative contribution of different risk factors, epidemiologists have used analytic models that evaluate later events (for example those occurring during delivery) in the light of earlier events (e.g., maternal characteristics before pregnancy, first trimester events) (Nelson & Ellenberg, 1986). As a result of these studies, we now know that the brain insults causing CP can occur prenatally, perinatally, postnatally or in some combination of these. (Kuban & Leviton, 1994) Table 23.4 summarizes epidemiologic risk factors for CP classified according to whether they occur before pregnancy, during pregnancy, or during the perinatal period.

At this time most cases of CP cannot be prevented. In a contemporary case series representing 217 cases of systematically assessed CP over a 10-year period, a plausible risk factor was identified in 82.0% of cases (Shevell, Majnemer, & Morin, 2003). The five most common factors were periventricular leukomalacia (white matter damage) 24.9%, intrapartum asphyxia 21.7%, cerebral dysgenesis 17.1%, intracranial hemorrhage 12.9%, and vascular, 9.7%. A single factor was found for 66.4% of the cases and multiple factors in 15.6% of cases. The risk factor profile varied according to the topography of the CP, gestational age, and source of the patients. Features associated with the

**Figure 23.3** Neuroimaging and neuropathology of the “cerebral palsies.” Note the heterogeneity of brain disorders. (A) Bilateral schizencephaly with grey matter lining the ventricles. This boy had visual function but it is not clear where the “visual cortex” is located. Note the effects on the corpus callosum. He had some head and trunk control but no mobility. His main clinical problem was intractable seizures and feeding difficulties. (B) Right hemisphere polymicrogyria (arrow) secondary to 22q deletion presenting as a classical left hemiplegia in the second six months of life. This girl has no fits, no feeding difficulty and no speech problems. She is not prone to infection. She walked at a typical age for hemiplegia (18–22 months). The left hemisphere is normal. This is yet another example of the importance of scanning children with CP. (C) Periventricular leucomalacia (PVL). Scan taken at 10 months age. Born prematurely at 27 weeks gestation. Note how the posterior horns of the lateral ventricles abut on the cerebral cortex along with an extremely thin corpus callosum. There is high signal change in what remains of the white matter. In contrast with hydrocephalus, the ventricles have sharp outlines indicating they are not under pressure. (D) Coronal section through hemisphere of 8-month-old infant showing old left cortical-subcortical infarct with thin internal capsule. (E) Transverse section through the medulla of the same infant as in panel D. Note the virtual absence of the pyramid on the right (arrow, E) due to a loss of descending corticospinal tracts. (F) Devastating destruction of the left hemisphere from herpes simplex encephalitis at 18 months of age. This girl lost the power of speech, feeding, sitting, and walking in the acute phase but regained all these over the following year. She is prone to seizures which are controlled with anticonvulsants. Despite her tremendous recovery, she has a dense right homonymous hemianopia and hemiplegia (without neglect) with learning difficulties. Note the smaller left cerebral peduncle in panel G. (H) Left postvaricella “capsular infarct” in a male toddler. The lesion involves the internal capsule, lentiform nucleus, and thalamus. All of these pathologies may be said to contribute to the “cerebral palsies”. (From Jean-Pierre Lin. *The cerebral palsies: a physiological approach*. from the *J. Neurol Neurosurg Psychiatry* 2003;74: i23–i29. With permission from the BMJ Publishing Group)

Chorioamnionitis
Premature separation of the placenta
Preterm birth
Multiple birth
Low Apgar Score
Transient Hypothyroxinemia of the Preterm
Hyperbilirubinemia
Newborn encephalopathy
Hypocapnia from mechanical ventilation

---

child's CP such as microcephaly, neonatal complications, and prior or concurrent epilepsy, were observed to be predictive of etiologic yield (Shevell, et al., 2003). At the level of the individual patient, the identification of risk factors provides answers to questions about recurrence risks, may reduce unnecessary investigations and empowers the family and child by providing knowledge.

### Neonatal Markers for CP

On neonatal neurological exam, qualitative abnormalities of spontaneous motor activity in newborns and young infants are thought by some authorities to be early predictive markers for later spastic CP; in particular, infants who later develop spastic CP have an absence of fidgety movements, a spontaneous movement pattern that is normally present from 3 to 5 months (Ferrari, et al., 2002).

With respect to brain imaging in the neonatal period, current practice parameters recommend routine screening with cranial US on all preterm infants of < 30 GW (Ment, et al., 2002). Screening should be done once between 7 and 17 days of age and repeated between 36 and 40 weeks postmenstrual age so as to detect intraventricular hemorrhage, focal white matter damage (sometimes referred to as periventricular leukomalacia), and low pressure ventriculomegaly, which provide prognostic information on long-term developmental outcome. In term infants with clinical signs of encephalopathy, a history of birth trauma, low hematocrit, or coagulopathy, MRI should be done between days 2 and 8 to assess the location and extent of injury. In particular, basal ganglia and thalamic lesions identified by conventional MRI are associated with poor developmental outcomes (Ment, et al., 2002).

### The Initial Diagnosis of CP

Practice parameters for the evaluation of cerebral palsy have recently been published by the American Academy of Neurology (Ashwal, et al., 2004). (See Figure 23.4.)

#### History and Physical Exam

The chief complaint typically is a concern that the child is not attaining motor milestones at the expected time in the first 2 to 3 years of life. At the outset of the diagnostic process, a careful history must ascertain that the child is not losing motor function given that a number of symptoms and signs are common to both CP and neurodegenerative/metabolic disorders (Gupta & Appleton 2001). A review of family history, maternal history, and pregnancy experience is necessary.

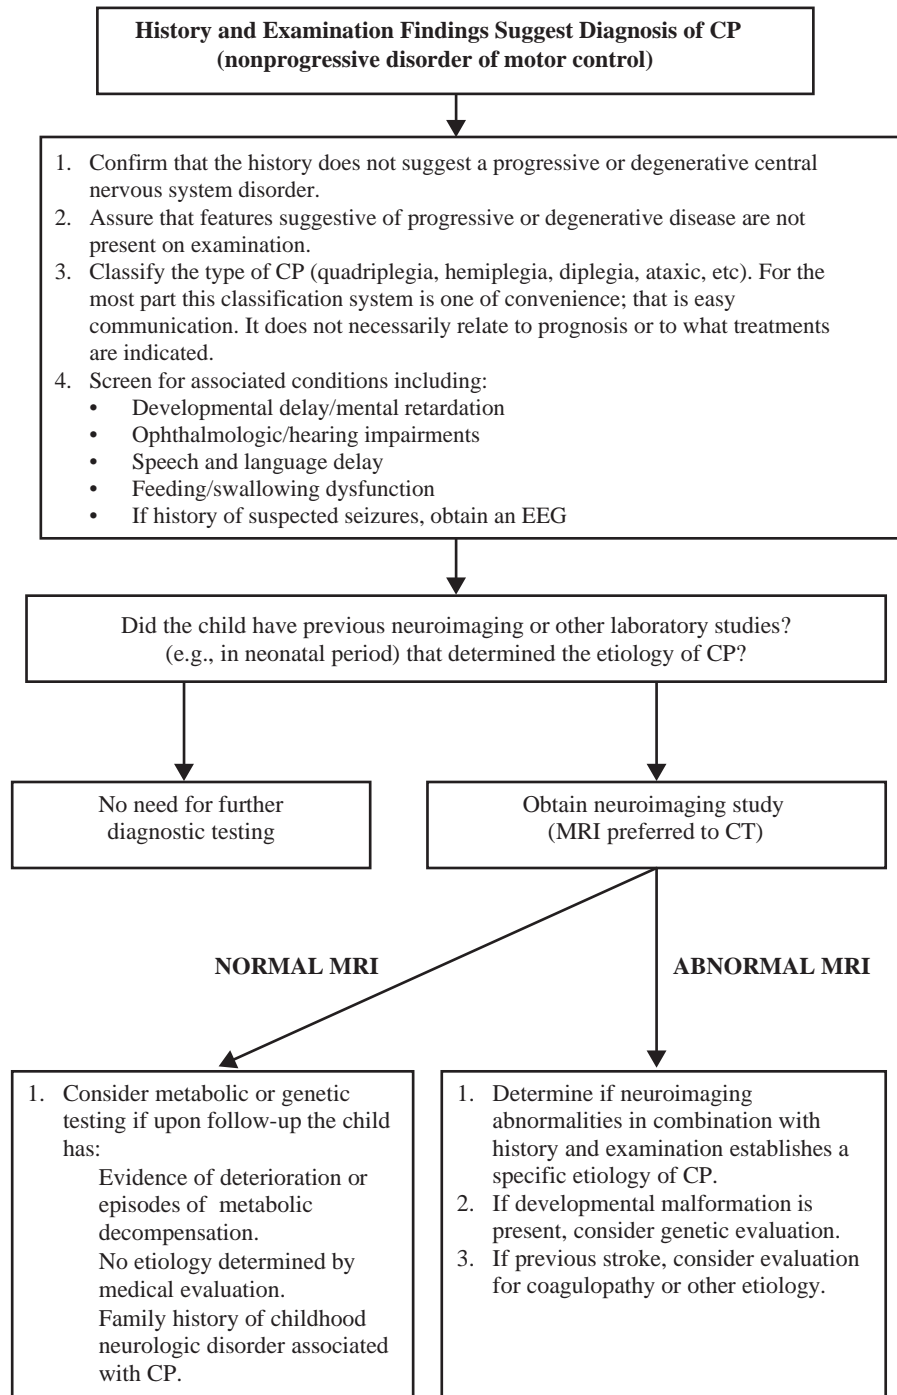

The physical exam localizes the motor abnormalities to the brain as opposed to the motor unit (anterior horn cell, peripheral nerve, nerve-muscle junction, muscle). The observations on which the diagnosis of CP is based include motor function (e.g., ability to sit independently, ability to walk) and muscle tone and reflexes (e.g., deep tendon, primitive and protective reflexes). Dynamic deformities and movement disorders can be accentuated during ambulation or other activities.

CP usually is not difficult to diagnose in the patient who has not attained motor milestones, who is not losing function, and whose muscle tone is generally high. However, one commonly encounters patients who have not met milestones and whose muscle tone is normal or low. In these cases, important findings on exam that would be consistent with CP include persistence of the primitive reflexes past the time that they should have vanished or the failure to develop protective reflexes at the expected time. For example, the Moro reflex and tonic neck reflex should not be obtainable after 6 months of age; side protective reflexes should be elicitable after 5 months of age and the parachute reflex after 10 months. If the primitive reflexes have disappeared at the appropriate time and if the protective reflexes have emerged as expected, then one should think of a motor unit disease, such as spinal muscular atrophy or congenital myopathy rather than CP (Russman, 1992).

The diagnosis of CP in the hypotonic child can be especially difficult, and may require repeated examinations and more than one opinion. An important sign in the physical exam is that of hand preference. A child should not cross the midline when reaching for an object until after 1 year of age and should not show hand preference until 18 to 24 months of age. Evidence of handedness prior to this time suggests a hemiplegia (Russman, 1992).

The physical exam should establish whether signs of CP are present and if so permit classification of the type of CP (quadriplegia, hemiplegia, diplegia, ataxic, etc.). The normal examination in the first 6 months of life does not exclude the possibility of mild or moderately severe

## EVALUATION OF THE CHILD WITH CEREBRAL PALSY

**Figure 23.4** Algorithm for the evaluation of the child with cerebral palsy (CP). Screening for associated conditions (mental retardation, vision/hearing impairments, speech and language delays, oral motor dysfunction, and epilepsy) is recommended. Neuroimaging (MRI preferred to CT) is recommended for further evaluation if the etiology of the child's CP has not been previously determined. In some children, additional metabolic or genetic testing may be indicated. From: Ashwal S, Russman BS, Blasco PA, Miller G, Sandler A, Shevell M, et al. Practice parameter: diagnostic assessment of the child with cerebral palsy: report of the quality standards subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society. *Neurology*, 62:851-863. (Reprinted with the permission of the American Academy of Neurology)

The new emergence of neurological abnormality after the first 6 months of life can be attributed to progressive myelination, which is reflected in changes in the neurological exam. While most severe cases of CP are identified by 24 months of age, some cases, particularly of dystonic CP, do not become manifest until adolescence; in these cases the static lesion or anomaly was present early in de-

velopment but clinically silent until uncovered by brain maturation.

Screening for conditions that commonly co-occur with CP such as mental retardation, ophthalmologic abnormalities, hearing impairments, speech and language disorders, and disorders of oral-motor functioning should be part of the initial assessment.

### Laboratory Tests

Current practice parameters (Ashwal, et al., 2004) recommend brain imaging as a first step in order to determine whether a brain abnormality exists that may, in turn, suggest etiology and prognosis. MRI is preferred to CT because of the higher yield in suggesting an etiology and timing of insult leading to CP (see Brain Imaging, below). MRI has been found to identify major brain malformations in up to 12% of cases. Because these malformations (e.g., lissencephaly, schizencephaly, or pachygyria) are increasingly associated with specific genetic disorders, their presence in children with CP indicates the need for further genetic testing. Cerebral malformations are also found in certain neurometabolic disorders (e.g., peroxisomal disorders); these disorders can present within the first years of life with motor impairment that may appear to be nonprogressive. Metabolic disorders that may be misdiagnosed as CP are reviewed by Gupta and Appleton (2001).

Even in the absence of cerebral malformation, metabolic and genetic testing should be considered in the following situations: (a) absence of a definite preceding prenatal, perinatal, or postnatal insult, (b) presence of a positive family history of CP, (c) occurrence of developmental regression (loss of abilities), (d) presence of oculomotor abnormalities, involuntary movements, ataxia, muscle atrophy, or sensory loss. Because the incidence of cerebral infarction is high in children with hemiplegic CP, testing for coagulation disorders may be considered. Currently EEG is not recommended except when there is clinical suspicion of seizures (Ashwal, et al., 2004).

### Disclosure

Research evidence indicates that, when interviewed, around half of parents of children with physical disability report dissatisfaction with the manner in which the disclosure was handled (Sloper & Turner, 1993). Evidence-based clinical guidelines for the sensitive disclosure of a diagnosis of CP have been advanced by Baird, McConachie, and Scrutton (2000), and the reader is urged to consult them.

### Prognosis for Motor Function

When the diagnosis of CP is disclosed to parents, their first question is often "Will my child walk?" As reviewed by Sala and Grant (1995), three major factors (primitive reflexes and postural reactions, gross motor skills, and topography of CP) contribute to the inability to ambulate independently. Specifically, the persistence of primitive reflexes and absence of postural reactions by age of 2 is associated with poor prognosis for independent ambulation. Sitting without support by the age of 2 years is associated with attainment of ambulation. Children with spastic hemiplegia will walk independently, those with spastic diplegia will walk independently 85% of the time, and those with spastic quadriplegia are the least likely to walk independently. It must be noted, however, that there

is wide variation in estimates of the likelihood of ambulation in children with spastic quadriplegia, ranging from 0 to 72% (Bottos & Gericke, 2003). In addition to these clinical criteria, a reliable and valid prognostic system that uses the GMFM is now available at [www.canchild.org](http://www.canchild.org) (Rosenbaum, et al., 2002).

Once achieved, independent walking is not necessarily maintained through adolescence and adulthood. Those who reach independent walking by the age of 3 years have a higher chance of maintaining the ability to walk than those who did not achieve it by that age. Important factors that influence the maintenance of ambulatory capacity are joint deterioration, physiological, or psychological burnout and surgery (Bottos, Felicciangeli, Scuito, Gericke, & Vianello, 2001).

On the other hand, CP diagnosed in the first 2 years of life may resolve during early childhood, especially if the functional impairment is mild (Ford, Kitchen, Doyle, Rickards, & Kelly, 1990). In the Collaborative Perinatal Project, 118 out of 229 children who had signs of CP at 1 year of age were found to be free from motor handicap when reexamined at age 7. Mild CP resolved in 72% of cases, but only 3% of severe cases resolved. However, mental retardation and nonfebrile seizures were almost 10 times more likely in children with resolved CP than in children with no history of CP (Nelson & Ellenberg, 1982). Thus it appears that even the child who improves is at risk for associated conditions.

### Implications of Early Motor Status for Intervention and Management

By the age of 3 years, children generally fall into one of three groups: (1) those who are not sitting independently, but do exhibit locomotion patterns that require at least some trunk control such as crawling and bottom shuffling, (2) those who are sitting independently, but who have yet to develop independent walking and, (3) those who have already achieved independent walking (Bottos & Gericke, 2003).

For children in the first group, some authorities feel that the clinician and family should not wait to see whether the child will eventually become an independent walker due to maturation and therapy. These children need assistive devices to promote motor independence (typically this means a powered wheelchair). Without such assistance, their development will be hampered by ineffective mobility, fatigue, and reliance upon others. For children in the second group, physiotherapy may be indicated, together with the use appropriate orthoses and orthopedic surgery. After the age of 7 years, physiotherapy aimed at promoting walking should be limited, because independent walking is unlikely to be achieved after that age, particularly when spasticity is present. Even when walking is attained, assistive mobility devices should be used to widen the child's motor autonomy and avoid early physiological burnout. This is particularly true for

those with mild and moderate motor impairment who may be more likely to struggle to keep up with peers. Children in the third group need close monitoring and need to have periodic session of physiotherapy well into adulthood in order to prevent deformities (Bottos & Gericke, 2003).

When gross motor impairment is minimal and orthopedic care is not indicated, it may be preferable to not make a formal diagnosis of CP because the diagnosis may carry the stigma of associated problems that may not be present, such as mental retardation (Russman, 1992). However, parents may need to be advised that other professionals they encounter may use the term CP, so the reasons for not making a formal diagnosis should be openly explained to the parents.

### Cognitive Implications of CP

In most patients a prognosis about intellectual development must be deferred pending the development of language. Testing language is based on testing earling intelligence and early tests depend inordinately on visuomotor skills. Therefore in questionable situations a prognosis cannot and should not be rendered until after age 5 years. In the athetoid patient who might have a severe dysarthria, a prognosis about intelligence should be postponed until school age. An examiner experienced with the severely disabled dyskinetic population should perform the evaluation because the motor disability could lead to misleading scores. While severe cognitive impairment is rare among those with hemiparesis (about half of whom generally score in the normal range), it predominates among those with quadriplegia (Fennell & Dikel, 2001). Cognitive impairment is most severe among those with seizure activity (Vargha-Khadem, Isaacs, van der Werf, Robb, & Wilson, 1992).

In general, children with CP tend to have lower performance than verbal IQ scores (Fedrizzi, et al., 1996; Goodman & Yude, 1996; Ito, et al., 1996; Muter, Taylor, & Vargha-Khadem, 1997); the difference is unrelated to side of lesion (Muter, et al., 1997). However, it is the performance portion of the IQ tests used in these studies that most depends on motor skills. Tests with a yes/no or multiple-choice format, where answers can be indicated with minimal motor input and with no penalty for slow response times, allow clear separation of motor and cognitive abilities. Two recent studies using such techniques demonstrated greater visual-perceptual than language impairment in children with CP (Sabbadini, Bonanni, Carlesimo, & Caltagirone, 2001; Stiers, et al., 2002). In one of these studies patients indicated answers using prosthetic pointing devices (Sabbadini, et al., 2001). In this study, eight individuals with severe neuromotor and verbal disabilities performed comparably to 19 controls matched for mental age on all tests of language except for comprehension of syntactically complex sentences.

### Psychosocial Issues in CP

Children with chronic functional limitations have considerably more difficulties in the social and behavioral aspects of their lives than typical children. Intellectual and behavioral problems in children with hemiplegic CP reported by teachers in mainstream schools indicate that such children are at a high risk for rejection by peers, for lack of friends, and for victimization (Yude & Goodman, 1999).

Brain damage is a risk factor for childhood psychiatric disorder. In the Isle of Wight study, children with CP were three times more likely to have a psychiatric disorder than peers in the general population. This finding was not accounted for by differences in IQ or physical handicap (Rutter, 1989), suggesting that brain injury accounted for the behavioral difficulties. A more recent population-based study found that parent-reported behavior problems were five times more likely in children with CP than in children with no health problems; behavior problems were even more common in children with both CP and mental retardation. The most frequent problems were dependency and headstrong and hyperactive behavior (McDermott, et al., 1996). The pharmacologic treatment of ADHD symptomatology in children with CP has received little attention. A single controlled study found that methylphenidate resulted in an improvement in ADHD symptoms, as assessed by both parent and teacher ratings (Gross-Tsur, Shalev, Badihi, & Manor, 2002).

### Medical Management of CP

Assisting persons with CP requires a team approach in which the family and patient are leaders whenever possible.

#### *Motor Function, Mobility, and Posture*

The elimination of spasticity allows many patients with CP to use what selective motor control they possess more functionally. Spasticity associated with CP can lead to musculoskeletal complications such as contracture, pain, and subluxation.

Management of spasticity in the patient with CP involves multiple approaches, including environmental interventions such as minimizing sleep deprivation, alleviating pain, therapeutic use of heat, and/or deep tissue massage and reducing prolonged periods of immobility. Multiple oral medications are used to treat spasticity but have limited efficacy in most patients due to unacceptable side effects. Injectable neuromuscular blocking agents balance muscle power across joints by effecting selective denervation of muscles and nerves; botulinum toxin A is now the most widely used blocking agent (Bottos, Benedetti, Salucci, Gasparoni, & Giannini, 2003; Edgar, 2001). Neurosurgical interventions include the baclofen pump and selective dorsal rhizotomy. Placement of a pump to allow the delivery of baclofen directly to the spinal cord is more effective at reducing spasticity and dystonia without the cognitive side effects that are frequently seen with oral ad-

ministration of the drugs. Selective dorsal rhizotomy involves the selective ablation of dorsal nerve rootlets and results in reduced tone in the lower extremities. Surgical tendon release is also used widely to help ambulation in CP (Koman, Smith, & Shilt, 2004). However, little careful evaluation has been done of the comparative efficacy of these modalities. Specialty organizations such as United Cerebral Palsy Association and the American Academy for Cerebral Palsy and Developmental medicine have Web sites ([www.ucpa.org](http://www.ucpa.org) and [www.aacpdm.org](http://www.aacpdm.org), respectively) that can be informative and helpful to parents.

## Epilepsy

Children with CP are at excess risk for epilepsy. In the general pediatric population, the prevalence of epilepsy is 3 to 6 per 1,000. By contrast, in a population-based study of children with CP, the prevalence of epilepsy was observed to be 38%. All children with quadriplegic CP and about one third of children with other types of CP developed epilepsy. Children with mental retardation have a higher frequency of epilepsy than those without mental retardation (Carlsson, Hagberg, & Olsson, 2003).

## General Treatment Principles

The WHO model of health and disease focuses on the promotion of function and participation as the broad goals of medicine. It provides an important framework to guide modern thinking about treatment for children with CP (World Health Organization, 2001).

First, communication skills must be promoted. Without this ability, even with a normal intellect, the patient is isolated. Treatment of children with CP in the past has often focused on improving motor function, and communication has been relatively neglected (Russman, 1992).

Second, the achievement of functional abilities that facilitate autonomy must be emphasized. The liberal use of adaptive equipment may support early development of capacities with the important effect of improving overall development. The common concern that making things too easy for children will inhibit normal function is without basis. Robust evidence exists that the provision of powered mobility to children with disability as young as 36 months can have positive impact on social, language and play skills and promote independent movements (Butler, 1991).

Third, modern services for persons with CP need to be offered within a family-centered model in which parents and providers work together as partners. Parents' satisfaction with services is inversely related to their stress in their dealing with their child's treatment; their satisfaction is greater and their stress less with family centered as compared to other treatment models (King, Rosenbaum, & King, 1996). There is also an association between family-centered service and parents' mental health (King, King, Rosenbaum, & Goffin, 1999).

Finally, goal setting should be a collaborative effort between parents (and older children) and health care providers. CP is a chronic condition that requires intensive planning for full participation in the community. "This challenge is one that must be addressed by the whole community, and should involve the imagination and political will of professionals and families from all areas of society. To do less would be marginalize young people with CP and to squander the developmental and functional gains they have made in their developing years" (Rosenbaum, 2003, p. 973).

# Traumatic Brain Injury

24

**Sharon Arffa, PhD, MPPM**

Traumatic brain injury in children and adolescents reflects a complex interplay of neurobiological and psychosocial factors; it is not a unitary entity. The child's age at the time of injury plays a significant role in the etiology and severity of the trauma, as well as in associated medical complications and outcome. Subsequent development, as well as psychosocial factors, also has an impact on recovery. There are also substantial methodological issues related to the measurement of the severity of the injury and the outcome.

In this chapter, the multiple mechanisms of injury and the unique features of the immature brain are reviewed. In addition, outcome studies are critically evaluated. This information provides a framework for a rational approach to the choice of treatments. To provide a broad conceptual framework, this chapter deals with studies of adults with traumatic brain injury as well. The response of the child's nervous system to other forms of brain injury (e.g., strokes) is reviewed. The neurocognitive and neurobehavioral outcomes are considered separately and cover issues such as severity of injury, age at injury, lesion location, and the influence of psychosocial factors. Finally, guidelines for the diagnosis and management of neurobehavioral disorders secondary to traumatic brain injury are discussed.

## TERMINOLOGY

The terms *head injury* and *brain injury* are frequently used synonymously with traumatic brain injury but are less precise. Head injury also includes lacerations or external trauma to the face and head, as well as intracranial events; brain injury, a less specific term, is applicable to nontraumatic insults, such as cerebrovascular events or tumors. *Traumatic brain injury*, a far more precise term, is defined as physical damage or impairment in function of the brain secondary to the exchange of acute mechanical energy. This definition typically excludes brain injury resulting from

birth trauma; poisoning and asphyxia; soft tissue injuries to the face and scalp; or nondepressed skull fracture (Fife et al. 1986). *Concussion* is an elusive term with a history that dates to the middle ages. It has come to mean different things over the years but in 1966, the Congress of Neurologic Surgeons developed a consensual definition recognizing a concussion as an immediate and transient disruption of neural function. This is essentially synonymous with mild traumatic brain injury, and both terms are used in this chapter.

Traumatic brain injury is further classified as either "open" or "closed." These two types of traumatic brain injury differ substantially in both the pattern of brain injury and the associated neurobehavioral outcome. *Open* traumatic head injury occurs when the skull has been penetrated, such as with missile wounds or depressed fractures. In missile wounds, the extent of the neuroanatomic disruption is dependent on the path and velocity of the object or bullet, the scatter of bone chips, and the contusion and cerebral edema resulting from the entry wound (Bigler 1991). In contrast, *closed* traumatic brain injury typically results from rapid acceleration and deceleration injuries of the brain within the cranium as a result of high-speed accidents with sudden impact. In this situation, damage to the brain results from cerebral edema, hemorrhage, and ischemia (Jennett and Teasdale 1981).

## CLASSIFICATION AND MEASUREMENT IN TRAUMATIC BRAIN INJURY

Level of consciousness, overall somatic injury, extent and duration of posttraumatic amnesia, other cognitive and neurobehavioral disturbances, and degree of neurocognitive dysfunction in the early posttraumatic period, and severity of injury are extremely important factors in determining outcome. A number of scales for measuring such factors have been developed.

### Level of Consciousness

There is a spectrum of altered levels of consciousness, ranging from the fully conscious state to a confusional state, to stupor and coma (Plum and Posner 1980). Coma is a state in which patients lie with eyes closed and show a lack of awareness and responsiveness to external and internal stimuli. Comatose patients do not react to noxious stimuli with defensive, localized movements and do not speak (Salzman 1990).

Level of consciousness is extremely difficult to assess in very young infants. For example, stupor can be difficult to distinguish from normal sleepiness. Moreover, the motor examination is easily misinterpreted. Even in the presence of massive brain damage or increased intracranial pressure, babies may appear normal; they open their eyes and move spontaneously. Bicycling movements; rhythmic movements of the lower extremities; may be misinterpreted as normal activity but may actually be a manifestation of seizure activity in young infants. Limb withdrawal to pain; a primitive reflex; may be misinterpreted as well. The neurological examination in the infant should assess visual fixation and sucking responses, and cry (unconscious infants do not cry). A vigorous cry and facial grimace to trapezium pinch appears to be the most reliable measure of level of consciousness in young infants (Bruce and Zimmerman 1989; Ewing-Cobbs et al. 1995).

The Glasgow Coma Scale (Teasdale and Jennett 1974) continues to be the standard index to assess initial level of consciousness. Severity of injury in traumatic brain injury frequently has been defined by initial Glasgow Coma Scale score, either alone or in conjunction with other indices. This scale is also used to track recovery from coma in patients with traumatic brain injury. The Glasgow Coma Scale assesses function in three domains: eye opening, verbal response, and motor response. It yields a range of scores, from 3 to 15. Coma is defined as a score of 8 or less (Eisenberg and Werner 1987).

For the very young and preverbal child, the Glasgow Coma Scale is inappropriate. It is a less reliable and less successful predictor of outcome in children than in adults, in part because the same score in adults and children may not represent the same degree of primary irreversible brain damage (Bruce 1983). For example, an infant would not score more than a 4 on the motor examination (flexor withdrawal) and more than a 2 on the verbal examination (incomprehensible sounds). However, modifications of the Glasgow Coma Scale have been developed for infants and toddlers (Raimondi and Hirschauer 1984; Yager et al. 1990). These include recording ocular responses and reinterpreting "verbal response" to encompass vocalizations, crying, fixation, and following in response to speech and to exclude meaningful communications.

The Children's Coma Scale (Table 24.1) contains these modifications and eliminates from the motor examination segment the requirement of following commands. Al-

though matching of anatomic level to coma severity level is inexact, there are significant differences between the Glasgow and Children's Coma Scales. Higher integrative cortical functions are not assessed by the Children's Coma Scale, and brain-stem functions are emphasized. The Glasgow Coma Scale (and the Children's Coma Scale) becomes more reliable when patients are measured at the same time postinjury, preferably on arrival at the emergency room (Kraus and Sorenson 1994).

### Overall Somatic Injury

Because traumatic brain injury is often associated with injuries to other areas of the body, measures have been devised to obtain an index of overall injury severity, which facilitates triage and helps in the assessment of long-term outcome potential. The Abbreviated Injury Severity Scale (Joint Committee on Injury Scaling 1980) measures cumulative damage across six body regions, including the head. Severity ratings on this scale include loss of consciousness, length of coma, and neuroradiological findings (Tables 24.2 and 24.3). A revision, the Injury Severity Score (Table 24.4), is the most commonly used multiple injury assessment technique. The Injury Severity Score is calculated by summing the squares from the three most severely injured body regions. A high Injury Severity Score is correlated with both disability and mortality (Baker et al. 1974a).

### Posttraumatic Amnesia

*Posttraumatic amnesia* refers to the period following recovery from coma in which continuous memories are not stored (Russell and Smith 1961). In this sense, posttraumatic amnesia is synonymous with anterograde amnesia, although Russell and colleagues included both length of coma and anterograde amnesia in their measurement of posttraumatic amnesia.

The duration of posttraumatic amnesia has become an important benchmark for prediction of outcome (Williams 1992). The period of posttraumatic amnesia is, on average, four times longer than the coma stage (Guthkelch 1979). In the dense stage of posttraumatic amnesia, patients who are able to speak repeatedly ask the same questions and do not remember having had meals or visits from close family members. In the second stage, information may be retained for short periods but is not permanently stored. Later, a few important events, such as the visit of a close friend or a medical procedure, may be recalled.

The recovery of islands of memory can be mistakenly identified as the end of posttraumatic amnesia. For example, a patient may remember arriving in the ambulance or being prepared for surgery, but nothing else until the next day (Gronwall 1989). Since it is difficult to verify subjective memories without the presence of an eyewitness, it is also difficult to distinguish confabulation from true recall. Weinstein and Lyerly (1968) reported that confabulation

**TABLE 24.1**  
**COMPARISON OF GLASGOW COMA SCALE (GCS) AND CHILDREN'S COMA SCALE (CCS)**

A. GCS	CCS	B. GCS	CCS
Eye opening	Ocular pursuit	15	
4 Spontaneous	4 Pursuit	14	
3 Speech	3 Extraocular muscles intact, pupils reactive	13	
		12	11
		11	
2 Pain	2 Fixed pupils or extraocular muscles impaired	10	
		9	
1 None	1 Fixed pupils and extraocular muscles paralyzed	8	10
		7	9
Verbal response	Verbal response	6	8
5 Oriented	3 Cries		5
4 Confused	2 Spontaneous respirations	4	7
3 Inappropriate	1 Apneic		6
2 Incomprehensible			5
1 None			4
Motor response	Motor response	3	3
6 Obeys commands	4 Flexes and extends		
5 Localizes pain	3 Withdraws from pain		
4 Flexor withdrawal	2 Hypertonic		
3 Extension	1 Flaccid		

### C. Testable functions

	Higher integrative	Cortical	Subcortical	Brain stem
GCS	12–15	9–11	5–8	3–4
CCS	None	11	8–10	3–7

Note: A. Number allocations to neurological observations. Ocular pursuit, rather than eye opening, is measured in the CCS. Verbal responses measured in the CCS include crying and respiration; speech is not required. Following commands or localizing pain is not measured in the CCS Motor Response section.

B. The GCS ranges from 3 to 15; the CCS ranges from 3 to 11.

C. Comparison of integrative, cortical, subcortical, and brainstem functions as expressed by coma scores on the respective scales. Higher integrative cortical functions are indicated by GCS of 12 to 15, whereas those functions are not assessed by the CCS. Increased emphasis on brain-stem function is also noted in the Children's Coma Scale.

Source: Reprinted from Raimondi AJ, Hirschauer J. Head injury in the infant and toddler: Coma Outcome Scale. *Child's Brain* 11:12–35, 1984. Used with permission.

occurred in 60% of a sample of patients with severe head injury. Therefore, the conservative approach is to consider the possibility of confabulation in all patients with significant head injuries.

To avoid some of the problems of assessing subjective memories, posttraumatic amnesia can be defined as disorientation to person, place, and time. However, disorientation is not the same as posttraumatic amnesia, and the two can be dissociated. For example, a patient may correctly answer questions about person, place, and time but have no recollection of having been asked. For adults, the point at which they can accurately report what has happened to them and the circumstances of their hospitalization and accurately state the month, year, day of month, and day of week has been taken as the resolution of posttraumatic amnesia (Gronwall 1989).

The Children's Orientation and Amnesia Test (Ewing-Cobbs et al. 1989) (Fig. 24.1) is designed to evaluate posttraumatic amnesia in children ages 3 through 15 years. It is

a short, 16-item measure that assesses general orientation, temporal orientation, and immediate and remote memories. It has been normed for ages 3 through 15 years and can be repeated daily to assess recovery. The end of posttraumatic amnesia is defined by a criterion score. Before the development of the Children's Orientation and Amnesia Test, posttraumatic amnesia measurement in children was estimated through parent and child interviews. The duration of posttraumatic amnesia, as measured by the Children's Orientation and Amnesia Test, was found to be related to neurological indicators of severity as well as to memory functioning 1 year after injury (Ewing-Cobbs et al. 1989).

### Other Cognitive and Neurobehavioral Factors

The term *posttraumatic amnesia* has been criticized because it addresses only memory disturbance; while arousal, attention, mood, and behavior may be altered during this stage as well (Trzepacz 1994). A patient who is emerging

**TABLE 24.2**  
**ABBREVIATED INJURY SEVERITY SCALE (AISS)**

Abbreviated injury score:	1 Minor	2 Moderate	3 Severe, not life-threatening	4 Severe, life-threatening	5 Critical, survival uncertain

**Laceration or rupture** of complete patellar tendon

---

Note: This table is a simplified chart incorporating Abbreviated Injury Scale criteria for grading the severity of an injury in seven body regions.

<sup>a</sup>Injuries scored as facial injuries in the Injury Severity Score are noted with an (F).

Source: Greenspan L, McLellan BA, Greig H. Abbreviated injury scale and injury severity score: a scoring chart. J Trauma 25:60–64, 1985. Used with permission.

**TABLE 24.3**  
**ABBREVIATED INJURY SEVERITY SCALE—MAXIMUM INJURY**

External	Secondary or tertiary burns including incineration >91% of total body
Head	Crush or ring fracture, crush/laceration brain stem (hypothalamus, medulla, midbrain, pons)
Neck	Decapitation
Thorax	Total severance aorta, chest massively crushed
Abdomen/Pelvis	Spinal cord crush/laceration or total transection
Spine	Spinal cord crush/laceration or total transection with or without fracture C3 or above

Note: This chart depicts maximum injury (i.e., injury severity score of 75 automatically assigned) for the six body regions of the injury Severity Scale: (1) external injuries refer to burns, contusion, lacerations, and abrasions; (2) head and neck injuries include injuries to the cervical spine, spinal cord, skull, brain, and ears; (3) face injuries include injuries to the mouth, eye, nose, and facial bones; (4) chest injuries include injuries to internal chest cavity organs, diaphragm, thoracic spine, or rib cage; (5) abdominal or pelvic content injuries include injuries to the internal abdominal cavity organs and lumbar spine; (6) injuries to extremities and pelvic girdle include sprains, fractures, amputations, and dislocations except those to skull, spinal cord, or rib cage. Note that the regions for the Abbreviated Injury Scale do not always coincide with the Injury Severity Scale regions.

from coma displays inability to focus attention, disorientation, memory disturbance, higher-order cognitive deficits (such as concreteness), agitation or lethargy, and emotional lability (Goethe and Levin 1984; Trzepacz 1994). A disturbance in sleep/wake cycle and a fluctuating course of cognitive and neurobehavioral problems may be found as well. Hallucinations; defined as sensory perceptions without external stimulation of visual, auditory, olfactory, gustatory, or tactile organs that are perceived as real by the patient; are not commonly experienced by patients with traumatic brain injury but have been documented (Goethe and Levin 1984). Delirium, as defined in DSM-IV (American Psychiatric Association 1994), refers to an abnormal state of consciousness preceding stupor and coma, marked by restlessness, affective instability, cognitive deficits, disorientation, and disturbances of the sleep/wake cycle. Although delirium occurs in the course of recovery from trau-

matic brain injury, this term is used only infrequently in this context.

Several different instruments have been developed to evaluate these neurobehavioral factors during recovery from traumatic brain injury. The Neurobehavioral Rating Scale (Levin et al. 1987b) (Fig. 24.2), which is used to monitor broader psychiatric symptoms during recovery, contains 27 clinician-rated items addressing cognitive disturbance, mood alteration, and perceptual disturbance. The Ranchos Los Amigos Scale of Cognitive Functioning (Hagen et al. 1972) (Table 24.5) is commonly used in cases of traumatic brain injury, particularly at rehabilitation centers. It provides a tool for assessing behaviors typical of the eight stages of recovery, from deep coma to purposeful, appropriate behavior. Although clinically useful, it is not sufficiently quantifiable to be appropriate for research (Lehr 1990).

### Degree of Neurocognitive Dysfunction in the Early Posttraumatic Period

The resolution of posttraumatic amnesia is followed by the early posttraumatic period (Gronwall 1989). Although generally oriented in time and able to remember events from the previous day, the patient may show slowing in reaction time and mental processes, susceptibility to distraction, and poor concentration. Because rapid improvement can occur during this early stage and attention span is still limited, lengthy neurocognitive evaluations are impractical. However, a brief battery of neuropsychological tests can be useful in documenting the degree of neurocognitive dysfunction and in determining disposition. One such battery (reviewed in Arffa 1995) includes brief attentional tasks such as the Wechsler Intelligence Scale for Children—III or IV (WISC-III; Wechsler 1991; WISC-IV, Wech-

## Children's Orientation and Amnesia Test

### INSTRUCTIONS:

Begin by introducing yourself by name (e.g., Dr. \_\_\_\_\_) and ask the child to be sure to remember your name. Points for correct responses (shown in parentheses after each question) are scored and entered in the columns on the extreme right side of the test form. Enter the total points accrued for the items in the lower right corner of the test form. Children ages 3–7 years are administered only the General Orientation and Memory sections of the test. The entire test is administered to children ages 8–15 years.

### GENERAL ORIENTATION:

**POINT**

- |   |       |
|---|-------|
| 1. What is your name? First (2)_____ Last (3)_____  | _____ |
| 2. How old are you? (3)_____ When is your birthday? Month (1)____ Day (1)____   | _____ |
| 3. Where do you live? City (3)_____ State (2)_____  | _____ |
| 4. What is your father's name? (5)_____ What is your mother's name? (5)_____  | _____ |
| 5. What school do you go to? (3)_____ What grade are you in? (2)_____   | _____ |
| 6. Where are you now? (5)_____ (may rephrase question: Are you at home now? Are you in the hospital? If rephrased, the child must correctly answer both questions.) | _____ |
| 7. Is it daytime or nighttime? (5)_____   | _____ |

### TEMPORAL ORIENTATION:

- |   |       |
|---|-------|
| 8. What time is it now? (5)_____ (correct = 5; <hour off = 4; 1 hour off = 3; >1 hour off = 2; 2 hours off = 1) | _____ |
| 9. What day of the week is it? (5)_____ (correct = 5; 1 off = 4; 2 off = 3; 3 off = 2; 4 off = 1)               | _____ |
| 10. What day of the month is it? (5)_____ (correct = 5; 1 off = 4; 2 off = 3; 3 off = 2; 4 off = 1)             | _____ |
| 11. What is the month? (10)_____ (correct = 10; 1 off = 7; 2 off = 4; 3 off = 1)                                | _____ |
| 12. What is the year? (15)_____ (correct = 15; 1 off = 10; 2 off = 5; 3 off = 1)                                | _____ |

### MEMORY:

- |  |       |
|--|-------|
| 13. Say these numbers after me in the same order. (Discontinue when the child fails both series of digits at any length. Score 2 points if both digit series are correctly repeated; score 1 point if only one is correct.) 3 5____; 58 42____; 643 926____; 7,216 3,279____; 35,296 81,493____; 539,418 724,856____; 8,129,365 4,739,128 (14) | _____ |
| 14. How many fingers am I holding up? Two fingers (2)____ Three fingers (3)____ 10 fingers (5)____   | _____ |
| 15. Who is on <i>Sesame Street</i> ? (10)_____ (can substitute other major television show)  | _____ |
| 16. What is my name? (10)_____   | _____ |

**Figure 24.1** Children's orientation and amnesia test. Reprinted from Ewing-Cobbs L, Levin HS, Fletcher JM, et al. The Children's Orientation and Amnesia Test: relationship to severity of acute head injury and to recovery of memory. *Neurosurgery* 27:683–691, 1990. Used with permission.

## Neurobehavioral Rating Scale

**DIRECTIONS:** Place an X in the appropriate column to represent level of severity of each symptom.

	Not present	Very mild	Mild	Moderate	Moderately severe	Extremely Severe severe
<p><b>1. Inattention/reduced alertness:</b> Fails to sustain attention, easily distracted, fails to notice aspects of environment, difficulty directing attention, and decreased alertness</p>						
<p><b>2. Somatic concern:</b> Volunteers, complains, or elaborates about somatic symptoms (headache, dizziness, blurred vision) and about physical health in general</p>						
<p><b>3. Disorientation:</b> Confusion or lack of proper association for person, place, or time</p>						
<p><b>4. Anxiety:</b> Worry, fear, and overconcern for present or future</p>						
<p><b>5. Expressive deficit:</b> Word-finding disturbance, anomia, pauses in speech, effortful and agrammatic speech, and circumlocution</p>						
<p><b>6. Emotional withdrawal:</b> Lack of spontaneous interaction, isolation, and deficiency in relating to others</p>						
<p><b>7. Conceptual disorganization:</b> Thought processes confused, disconnected, disrupted, tangential social communication, and perseverative</p>						
<p><b>8. Disinhibition:</b> Socially inappropriate comments and/or actions, including aggressive/sexual content, or inappropriate to the situation, and outbursts of temper</p>						
<p><b>9. Guilt feelings:</b> Self-blame, shame, and remorse for past behavior</p>						
<p><b>10. Memory deficit:</b> Difficulty learning new information, rapidly forgets recent events, although immediate recall (forward digit span) may be intact</p>						
<p><b>11. Agitation:</b> Motor manifestations of overactivation (kicking, arm flailing, picking, roaming, restlessness, and talkativeness)</p>						

**Figure 24.2** Neurobehavioral rating scale. Reprinted from Levin HS, High WM, Goethe KE, et al. The neurobehavioral rating scale: assessment of the behavioral sequelae of closed head injury by the clinician. *J Neurol Neurosurg Psychiatry* 50:183–193, 1987. Used with permission.

	Not present	Very mild	Mild	Moderate	Moderately severe	Extremely severe
<b>12. Inaccurate insight and self-appraisal:</b> Poor insight, exaggerated self-opinion, and overrates level of ability and underrates personality change in comparison with evaluation by clinicians and family						
<b>13. Depressive mood:</b> Sorrow, sadness, despondency, and pessimism						
<b>14. Hostility/uncooperativeness:</b> Animosity, irritability, belligerence, disdain for others, and defiance of authority						
<b>15. Decreased initiative/motivation:</b> Lacks normal initiative in work or leisure; fails to persist in tasks, and is reluctant to accept new challenges						
<b>16. Suspiciousness:</b> Mistrust, belief that others harbor malicious or discriminatory intent						
<b>17. Fatigability:</b> Rapidly fatigues on challenging cognitive tasks or complex activities; lethargic						
<b>18. Hallucinatory behavior:</b> Perceptions without normal external stimulus correspondence						
<b>19. Motor retardation:</b> Slowed movements or speech (excluding primary weakness)						
<b>20. Unusual thought content:</b> Unusual, odd, strange, and bizarre thought content						
<b>21. Blunted affect:</b> Reduced emotional tone, reduction in normal intensity of feelings, and flatness						
<b>22. Excitement:</b> Heightened emotional tone, increased reactivity						
<b>23. Poor planning:</b> Unrealistic goals, poorly formulated plans for the future, disregards prerequisites (e.g., training), and fails to take disability into account						
<b>24. Lability of mood:</b> Sudden change in mood that is disproportionate to the situation						
<b>25. Tension:</b> Postural and facial expression of heightened tension, without the necessity of excessive activity involving the limbs or trunk						
<b>26. Comprehension deficit:</b> Difficulty in understanding oral instructions on single or multistage commands						
<b>27. Speech articulation deficit:</b> Misarticulation, slurring, or substitution

sler 2003), Digit Span and Arithmetic subtests, the Verbal and Visual Memory subtests from the Wide Range Assessment of Memory and Learning (Sheslow and Adams 1990), and executive function tests such as the Wisconsin Card Sorting Test (Heaton et al. 1993) and the Controlled Oral Word Fluency Test (see Lezak 1994).

### Level of Severity

Assessment of severity is probably the most important measurement in traumatic brain injury. Incidence and outcome researchers typically rely on categories of “mild,” “moderate,” and “severe” when studying differences in rates of traumatic brain injury, sequelae, and recovery. The severity of the injury is defined in terms of its consequences and not the characteristics of the injury itself (e.g., velocity or angle of the blow).

There is no uniformly accepted classification of severity, and this is one of the major sources of variability in outcome research (Levin et al. 1995). Traditionally, severity has been assessed on the basis of initial level of consciousness, duration of coma, and extent of posttraumatic amnesia (Goethe and Levin 1984). However, other definitions have taken into account necessity for brain surgery, length of hospitalization, abnormalities on neuroradiological examination, and even quantitative analysis of computed tomography (CT) (see, e.g., Marshall et al. 1991).

“Mild” traumatic brain injury is frequently defined as a transient loss or altered state of consciousness and amnesia, but specific criteria have varied widely. Kraus and Sorenson (1994) found that in 35% of research studies from 1984 to 1994, mild traumatic brain injury was defined as no loss of consciousness, whereas in 36% of studies a loss of consciousness of 15 to 60 minutes was required. The Glasgow Coma Scale score used as the criterion for mild traumatic brain injury has also varied. In 59% of the research reports reviewed by Kraus and Sorenson (1994), a Glasgow Coma Scale score of 13, 14, or 15 was used as the criterion for mild traumatic brain injury, whereas in 24% a Glasgow Coma Scale score of 8 or 9 to 15 was used. The duration of posttraumatic amnesia is also quite variable in definitions of mild traumatic brain injury. Chadwick and colleagues (1980), for example, specified a posttraumatic amnesia duration of more than 1 hour to less than 1 week as indication of mild injury, whereas Asarnow and colleagues (1991) used a criterion of less than 4 hours.

“Moderate” traumatic brain injury is generally defined as a loss of consciousness lasting more than 30 minutes and less than 24 hours (Annegars et al. 1980). Kraus and colleagues (1984) also required a hospital stay of 4 to 8 hours and neurosurgery or abnormal CT. Most commonly, a Glasgow Coma Scale score of 9 to 12 is used to define moderate traumatic brain injury.

**TABLE 24.5**  
**RANCHOS LOS AMIGOS SCALE OF COGNITIVE FUNCTIONING**

#### EARLY STAGES OF RECOVERY

##### Level I—no response

The patient appears to be in deep sleep, with no eye opening or response to external stimulation.

##### Level II—generalized response

The patient reacts nonpurposefully and inconsistently to stimulation.

##### Level III—localized response

The patient reacts purposefully to stimulation but is inconsistent. He or she may turn his or her head toward sound.

#### MIDDLE STAGES OF RECOVERY

##### Level IV—confused/agitated

The patient shows heightened activity level. Aggression or excessive irritation disproportionate to stimulation may occur. Patient is confused and is severely limited in ability to process information. No self-care functions.

##### Level V—confused/inappropriate/not agitated

The patient is alert and able to respond to simple commands in a fairly consistent manner. He or she is highly distractible and cannot sustain and focus attention. Memory is severely compromised, and new information is not learned. When aphasia is not present, the patient makes inappropriate verbalizations. The patient may be able to assist with self-care functions.

##### Level VI—confused/appropriate

Goal-directed behaviors may be observed, but these involve overlearned or automatized skills such as feeding or brushing teeth. Attention and memory are improving but are still impaired. The patient may be inconsistently oriented and recognizes caretakers.

#### LATE STAGES OF RECOVERY

##### Level VII—automatic/appropriate

The patient may be able to follow a routine when prompted and may be independent or semi-independent, with self-care. The patient, however, lacks insight into his or her condition and shows poor judgment and problem-solving skills.

##### Level VIII—purposeful/appropriate

The patient is completely oriented, is independent, and is capable of self-care. Memory has improved; the patient can recall past events and shows capacity for new learning. Some continued compromise in reasoning and judgment may be present.

**TABLE 24.6****SUGGESTED CRITERIA FOR SEVERITY RATINGS IN TRAUMATIC BRAIN INJURY**

Severity of TBI	Length of Coma	Initial GCS Score	Duration of PTA	CT Criteria
Minimal	No LOC		1–5 min; confusion with or without amnesia	
Very mild	No LOC		5–60 mins	
Mild	30 mins	13–15	1–24 hrs	Negative
Moderate	30 mins–24 hrs	9–12	>24 hrs, but <7 days	Negative/positive
Severe	>24 hrs	3–8	8–28 days	Positive
Very severe	>24 hrs	3–8	>28 days	Positive

Note: Three gradations of mild injury are suggested; in minimal and very mild severity levels, medical attention may or may not be sought. TBI = traumatic brain injury; GCS = Glasgow Coma Scale (see Table 24.1); PTA = posttraumatic amnesia; CT = computed tomography; LOC = loss of consciousness.

“Severe” traumatic brain injury has been defined as loss of consciousness lasting longer than 24 hours (Annegars et al. 1980, Whitman et al. 1984) and depressed level of consciousness initially (i.e., Glasgow Coma Scale score  $\leq$  8) (Kraus et al. 1984, Rimel et al. 1981). Very severe traumatic brain injury has been defined as loss of consciousness or posttraumatic amnesia lasting longer than 7 days (Qennett 1983).

More recently, the utility of more gradations in the measurement of traumatic brain injury severity has been noted, particularly in the area of sports related concussion (Cantu 1998, Kelly 1995, Johnston et al. 2001). Suggested criteria of severity levels are presented in Table 24.6.

Advances in neurodiagnostic imaging may help in refining severity ratings. For example, with the expanding use of magnetic resonance imaging (MRI), which can identify surface contusions, many mild injuries may be reclassified as moderate.

## EPIDEMIOLOGY

Our understanding of traumatic brain injury in children has been advanced through descriptive epidemiology. Knowledge of the incidence, developmental trends, and risk factors of pediatric brain injury is useful in a number of ways. Awareness of medical sequelae common to certain types of injury in population subsets can facilitate medical decision making. Furthermore, the premorbid characteristics of the child and family can help the neuropsychiatrist identify risk factors for neuropsychological or psychiatric sequelae and aid in planning for the care and treatment of the child. Perhaps most important, public awareness of the magnitude of the problem can be advanced, and effective prevention programs can be developed.

Despite the methodological problems associated with the definition of traumatic brain injury and case ascertainment, estimates of incidence rates have been more similar than dissimilar. In six reports on the epidemiology of head trauma in the general population, the incidence ranged

from 180 to 295 per 100,000. In each study, males outnumbered females, the peak age was most frequently cited as 15 to 19 years, and motor vehicle accident was the most frequent cause of injury (Frankowski et al. 1985). The incidence of traumatic brain injury in pediatric populations is similar to that reported for adults. A mortality rate of 10 per 100,000 children (Annegars 1983) places head trauma as the major cause of death in children. However, children and adolescents are consistently reported to have a lower mortality rate than adults (Goldstein and Levin 1987) and a much lower rate than the elderly (Annegars et al. 1980; Jennett et al. 1980). The death rate in males was estimated to be four times that in females (Frankowski 1985).

Mortality statistics show only one part of the picture. Approximately 100,000 to 170,000 children are hospitalized each year with traumatic brain injury, and six times that number visit the emergency room (Eiben et al. 1984; Kraus et al. 1986). These figures indicate that traumatic brain injury is a major public health problem and represents a significant health-related financial burden (Gottschall 1993). Kraus and associates (1990) reported that the costs of hospital care alone for pediatric traumatic brain injury exceed 1 billion per year. All the direct costs (other medical costs, nursing costs, and pharmaceuticals) add an additional 1,810 million in the 0- to 4-year-old range, 4,026 million in the 5- to 14-year range, and 8,934 million in the 15- to 24-year ranges (Rice and MacKenzie 1989).<sup>1</sup>

The rate, severity, and mechanisms of traumatic brain injury vary with the child's age. A steadily increasing rate of injury was recognized up through age 14 years, with a dramatic peak occurring beginning at age 15 (Kraus et al. 1986; Rivera and Mueller 1986) (Fig. 24.3). Ninety-three percent of all head trauma in children (Kraus et al. 1986), compared with 80% in adults (Kraus and Sorenson 1994),

<sup>1</sup> Indirect costs fill such categories as loss of output and productivity in the workforce, caretaker opportunity costs, costs incurred from mental/social sequelae such as homelessness, incarceration, increases in other health expenditures, and costs from transfer payments such as welfare and disability.

**Figure 24.3** Incidence rates of traumatic brain injury (TBI) by age and sex. Adapted from Kraus JF, Black MA, Hessol N, et al. The incidence of acute brain injury and serious impairment in a defined population. *Am J Epidemiol* 119:186–201, 1984. Used with permission.

has been classified as mild. Mild injury is most common in 10- to 14-year-old children, but nearly the same proportion of mild injuries occurs in children ages 5 to 9 years. The peak incidence of severe and moderate injury occurs at age 15 years, but a relatively high proportion of such injuries also occurs in infants younger than 1 year of age (Fig. 24.4). Males are known to have a much higher rate of traumatic brain injury than females, but ratios vary, from as high as 4:1 to 1:1, as a function of age and mechanism of injury. In infancy, males are injured as frequently as females, but beginning at age 5 years, there are significantly more head injuries in boys than in girls (Fife et al. 1986).

Falls and transport-related accidents account for up to 83% of all traumatic brain injuries in children, although the proportion attributed to falls and transport injuries

**Figure 24.4** Traumatic brain injuries (TBI) by age and severity. Reprinted from Kraus JF, Fife D, Cox P, et al. Incidence, severity, and external causes of pediatric brain injury. *Am J Dis Child* 140:687–693, 1986. Copyright 1986, American Medical Association. Used with permission.

varies widely from study to study (Kraus 1995). Injuries sustained during sports and recreation, assault, child abuse, and some types of birth injury account for the remainder of traumatic brain injuries in children.

The risk of traumatic brain injury associated with a specific mechanism varies as a function of age. In infancy, traumatic brain injury from child abuse accounts for most cases; in the preschool age group, falls are the predominant mechanism; and in the early elementary school age group, pedestrian accidents are the most common source of traumatic brain injury. In 10- to 14-year-old children, there is a dramatic increase in injuries from sports and bicycle accidents. Beginning at age 15 years, motor vehicle accidents in which the victim is an occupant become the most frequent cause of traumatic brain injury (Kraus et al. 1986; Rivera and Mueller 1986). The mechanisms of all forms of traumatic brain injury, and for severe traumatic brain injury only, in 1,544 children admitted to Allegheny General Hospital, a large western Pennsylvania trauma center, from 1987 to 1994 are outlined in Figures 24.5 and 24.6 (Arffa 1995).

Demographic risk factors for all childhood injury include poverty, single-parent households, and congested living conditions. A parental history of psychiatric disorder, drug and alcohol abuse, or physical illness is another risk factor. Unsupervised play is also reported frequently among children with traumatic brain injury and can be a direct cause of the injury (Chadwick et al. 1981; Klonoff and Paris 1974). Children with cognitive problems are at greater risk for a history of traumatic brain injury than are peers with normal cognition. Children with traumatic brain injury are more likely to have a history of behavior disorder (Bijur and Haslum 1995; Brown et al. 1981; Chadwick et al. 1981; Klonoff 1971; Klonoff and Paris 1974; Arffa & Goldstrum 2003a,b), although Pelco and colleagues (1992) and Donders (1992) did not find this relationship. Arffa (1995) found that in a series of 100

**Figure 24.5** Mechanism of traumatic brain injuries (TBI) by age, for 1,544 patients hospitalized at a northeastern trauma center from 1987 to 1994. MVA = motor vehicle accidents. Cases of child abuse were not recorded; bicycle-related injuries include accidents involving bicycles and motor vehicles.

**Figure 24.6** Mechanism of severe traumatic brain injuries (TBI) (GCS = 3–8) by age, for 248 patients hospitalized at a northeastern trauma center from 1987 to 1994. MVA = motor vehicle accidents. Cases of child abuse were not recorded; bicycle-related injuries include accidents involving bicycles and motor vehicles.

pediatric patients with traumatic brain injury from 1993 to 1995, 55 had a history of either school learning difficulties or behavior or emotional disturbance. Arffa and Goldstrum (2003a) found injured preschoolers had higher rates of developmental and behavioral problems than controls, but head injured preschoolers actually had significantly greater history of developmental delay before their injuries.

Child behavioral characteristics associated with high traumatic brain injury rates include impulsivity, aggression, and attention-seeking behavior. In contrast, in the toddler age group, behavioral factors are related to the home environment (Matheny 1987). A history of previous traumatic brain injury is also associated with an increased risk of further traumatic brain injury (Annegars 1983). The occurrence of multiple episodes of traumatic brain injury is strongly related to socioeconomic factors and the behavioral characteristics of the child, such as hyperactivity and aggression (Bijur and Haslum 1995).

## Falls

Falls account for 4% of deaths in children (Table 24.7). Psychosocial factors are prominent in falls (Sieban et al. 1971; Spiegel and Lindaman 1977). The rate of death is higher in urban areas, where falls may occur from greater heights (Kottmeier 1995; Reynolds et al. 1971). Children survive falls from comparable heights more often than do adults (Barlow et al. 1983), although some of the highest fatality rates occur among very young children (Reynolds et al. 1971). Overall mortality rates from falls in 1.6% (Wang et al. 2001), and intracranial injury is most always the cause of death. Falls account for a significant proportion of nonfatal cases of pediatric traumatic brain injury as well (Annegars et al. 1980; Rivera and Mueller 1986). Children under the age of 4 years, particularly males, are

susceptible (Kottmeier 1995). Most falls occur during the summer, and they occur more often during the afternoon (Barlow et al. 1983). The incidence of walker injuries is especially high during infancy (Rieder et al. 1986). Falls from windows are more common in toddlers, and falls from fire escapes or roofs are more common in older children (Barlow et al.).

The physical characteristics of the young child in a free fall are thought to contribute to the higher number of central nervous system (CNS) injuries and skull fractures in this age group. The proportionately larger and heavier head of the child leads to a head-first orientation in the fall and head-first impact. Injury from head-first impact is likely to be more severe than that from a transverse fall, in which the force is distributed over a larger body surface (Kottmeier 1995).

## Motor Vehicle Accidents

Motor vehicle accidents are a major source of fatal injuries (Annegars 1983). Thirty percent of deaths in children under the age of 18 years are due to motor vehicle accidents (Pautle et al. 1995). The percentage of injuries related to motor vehicle accidents increases progressively with age (Frankowski 1985). From ages 15 to 19 years, males outnumber females in motor vehicle accidents by 2.1:1 (Fife et al. 1986), and the rate of fatalities is higher among males.

To understand the biomechanics of motor vehicle accidents, it is useful to separate the accident into three or four separate “collisions” (Pautle et al. 1995). The first impact to the vehicle is followed closely by the occupant’s impacting a portion of the vehicle. A third collision occurs internally as the brain strikes the interior of the cranium.

Frontal impact of the vehicle carries the greatest risk to occupants. Further insult can occur as unrestrained objects in the vehicle are propelled forward into the occupant. An unrestrained occupant is thrown forward until, in frontal collisions, the head meets the windshield. The rear seat is commonly thought to be safer because there are no steering wheels, dashboards, or windshields, but fatality rates for backseat occupants are approximately equal to those for front-seat occupants (Still et al. 1992). Injuries also occur from noncrash events. Excluding frontal collisions, the risk of fatality is actually greater in noncrash events than in collisions (Peterson and Royer 1991). Children are frequently fatally injured by ejection, or falls from the vehicle (Howard et al., 2003). Sudden stops or swerves can also lead to impact within the vehicle (Pautle et al. 1995).

The younger child’s relatively large head, higher center of gravity, and weak neck and shoulder muscles can make him or her more susceptible to acceleration and deceleration injuries (Ward 1995a). When unrestrained, the child can become a projectile, moving head first until stopped by a stationary object (Pautle et al. 1995).

**TABLE 24.7**  
**CHARACTERISTICS OF THE COMMON MECHANISMS OF TRAUMATIC BRAIN INJURY IN CHILDREN AND ADOLESCENTS**

Mechanism	Mortality	Morbidity	Biomechanics	Pathophysiology/Complications
Falls	Account for 4% of deaths in children; higher (13–20%) mortality in urban areas because of tall buildings; mortality highest among young children, but older children survive better than adults <sup>1–3</sup>	13–69% of all traumatic brain injuries in children <sup>4</sup> ; 1.7:1 male:female ratio; major cause of head injury in children 4 years and younger; common in summer months <sup>5,6</sup> ; Psychosocial factors prominent (i.e., low-socioeconomic, urban housing, single-family household) <sup>7,8</sup>	Larger and heavier head of preschooler leads to head-first orientation, resulting in greater central nervous system injury and skull fracture <sup>2</sup>	Fracture most common, followed by central nervous system injury <sup>2</sup> Deceleration injuries with falls from heights <sup>2</sup> Intracranial mass lesions common in older children <sup>9</sup>
Motor vehicle accidents	Account for 30% of all deaths in children; highest mortality in children 15–19 years of age and in males <sup>10,11</sup>	Account for 25%–77% of all traumatic brain injuries in children, depending on the study <sup>4</sup> Morbidity increases with age: highest (70%) in males 15–19 years of age <sup>12,13</sup>	“3 or 4 impacts”: 1) to vehicle, 2) to occupant, 3) to brain hitting interior of cranium, and 4) from flying objects <sup>11</sup> Injuries greatest in frontal impact and unrestrained occupants; rear seat $\leq$ front seat fatalities, and morbidity is increased in ejection from vehicle <sup>11,14,15</sup> Child becomes projectile when unrestrained <sup>11</sup>	Deceleration injuries potentiated in young children because of large, heavy head and weak shoulder muscles <sup>16</sup>
Pedestrian accidents	Dominant mechanism of traumatic brain injury death in children ages 1–9 years <sup>12,18</sup>	Children ages 5–9 years (pedestrian mechanism accounts for 39% of all head injury in this age range) and males most at risk <sup>12,17</sup> Driver negligence and careless crossing by child implicated <sup>19–21</sup>	Older children are thrown onto hood, often sustaining multiple impact injuries; small children roll under vehicle <sup>22</sup>	Multifocal injuries may be present in cases of multiple impact
Bicycle/sports accidents	Greater mortality in bicycle–motor vehicle accident <sup>10,23,24</sup> Equestrian sports have 2.5% mortality rate <sup>41</sup>	11% of all and 3% of severe traumatic brain injuries are recreationally related, <sup>10,23–26</sup> more severe in adolescents 70% of bicycle injuries are in children younger than 10 years of age; sports injuries occur more frequently and are more severe in adolescence <sup>10,23–26, 38</sup> ; common in males, in summer months, and between 3:00 and 9:00 PM <sup>25</sup> ; All-terrain vehicles: more severe injury in younger child <sup>27</sup> Football most hazardous, up to 200,000 concussions <sup>39</sup> ; high schoolers fare worse than collegiates 40 injuries reduced with better coaching standards <sup>28,29</sup>	Most bicycle–motor vehicle accident victims make contact with front end of vehicle; children younger than 12 years of age often hit from left side <sup>25</sup> Second impact syndrome controversial <sup>42</sup>	More severe injuries occur in unhelmeted cyclist <sup>25,27</sup>

(continued)

**TABLE 24.7**

(continued)

Mechanism	Mortality	Morbidity	Biomechanics	Pathophysiology/ Complications
Child abuse	1,000 to 2,500 cases per year <sup>30</sup> Most common in young children <sup>31-34</sup>	64% of all and 95% of severe traumatic brain injuries in children 2 years of age and younger <sup>31-34</sup> Males and females at equal risk <sup>35</sup>	Shaken baby syndrome includes violent shaking and impact <sup>36-38</sup>

### Pedestrian Accidents

Injuries resulting from pedestrian accidents are most common in older preschoolers and young school-age children (Frankowski 1985). In this age range, fatalities occur more frequently from pedestrian accident injuries than from passenger motor vehicle accident injuries (Rivera and Barber 1985; Tanz and Christoffel 1985). Among those sustaining injury in pedestrian accidents, boys outnumber girls by 1.7:1 (Rivera and Barber). Most often, the child is struck by the front of the automobile and is thrown forward onto the hood. The child may continue rolling and sliding, potentially incurring additional impact injuries. Small children may roll under the vehicle (MacKay 1992). Injuries occur most frequently when children dart out into the street rather than cross at intersections (Rivera and Barber; Stevenson et al. 1992). Driver negligence and alcohol use by drivers contribute to these accidents and the resultant injuries (Baker et al. 1974b; Wolfe and O'Day 1982).

### Sports-Related Injuries

As many as 11% of pediatric head injuries and 3% of severe head injuries are recreationally related (Annegars 1983; Waller 1985). Compared with motor vehicle accidents and falls, sports injuries account for a much lower percentage of traumatic brain injury in children under age 12 years (Bruce et al. 1982), but the percentage increases greatly in adolescence (Conn et al, 2003; Poirier and Wadsworth, 2000). Adolescents also suffer more severe sports-related injuries, and among those sustaining such injuries, males significantly outnumber females. Although contact sports

have the highest risk of concussion, there are reports of substantial concussion in winter sports, sports with risk of falls such as gymnastics, and nonorganized sports like rollerblading (Kushner 2001). Of all injuries incurred in the sport, mild traumatic brain injury accounts for 7.3% of injuries in football, 4.4% in wrestling, 3.9% in boys soccer, 4.3% in girls soccer, 3.6% in girls basketball, and 2.5% in field hockey (Powell and Barber-Foss 1999).

Football is the most hazardous organized sporting activity, with two thirds of football-related deaths resulting from traumatic brain injury (Mueller and Blythe 1987). High school football players alone have 200,000 concussions per year. High school football players were more cognitively impaired after concussion than their college cohorts, suggesting a more protracted recovery pattern in this age group, yet few are required to stop playing, and many have multiple concussions (Collins et al 2002; Field et al 2003; Langburt et al 2001; Genuardi and King 1995; Gerberich et al. 1983; Thurman et al. 1998). Better standards for football helmets and rules regarding blocking and tackling have helped to reduce the head and spinal cord injuries associated with football (e.g., Albright et al. 1985).

Hockey contributes about five concussions per 1,000 player/game hours (Goodman et al 2001). Heading is a factor in soccer related injuries, and although subjective complaints are high (Tysvaer and Storli 1981), cognitive function does not appear significantly disrupted (Janda et al. 2002). Golf injuries are caused by impact with the ball or club and 37 traumatic brain injuries in children 3 to 13 were reported in a single emergency room in a 7-month period in the United Kingdom (MacGregor 2002). New

sporting fads are novel sources of traumatic brain injury. The “scooter phenomenon” led to 19 concussions in children and adolescents in a single year in one Swiss town (Mankovsky et al. 2002). More snowboarding injuries are concussive injuries, while skiers injure other body parts more often (Skokan et al. 2003). Sledding may be one of the largest contributors of concussion in children (Hackam et al. 1999). Of inline skating injuries, head and neck injury occurred only in 16% of cases in a Canadian town (Nguyen and Letts 2001). An average of 31 pediatric equestrian injuries per year in a Boston hospital, and head injuries are second to orthopedic injuries in frequency, and carry a 2.5% mortality rate (Ghosh et al. 2000). Use of motorbikes and all-terrain vehicles is more likely to result in traumatic brain injury when the vehicles are driven on roadways and when the driver is unhelmeted, inexperienced, and young (Wesson et al. 1995).

Incidence rates of bicycle injury are considerably higher when injuries due to collision with a motor vehicle are included. Nearly 70% of all bicycle-related head injuries occur in children under age 15 years (Friede et al. 1985, Kraus et al. 1987; Spaite et al. 1991). Preschoolers make up only 5% of bicycle-related injuries and are less likely to be injured in the street, although they sustain traumatic brain injury at the same frequency and the same level of severity as older children (Powell et al. 1997). Among those sustaining bicycle-related injuries, boys outnumber girls by 3:1 (Kraus et al. 1987; Spaite et al. 1991). Most victims make contact with the front end of the vehicle, but they also are often hit from the left side when darting out into the street; this is true particularly among children younger than 12 years of age. Injury most often occurs in spring and summer months and between 3:00 and 9:00 PM. (Annegars 1983; Fife et al. 1983). Unhelmeted children are more likely to sustain more severe injuries (Sosin et al. 1996; Spaite et al. 1991).

Gunshot injuries are often listed under sports-related injuries even though a majority occur not in the context of recreation, but with accidental discharge or as an act of violence. Thirty-two head and neck gunshot wounds in children 3 to 17 were identified over 3 years in Houston, Texas, and carried a very high mortality rate even with low velocity missiles (Kountakis et al. 1996).

### Child Abuse

Twelve- to 14-year-old children are more likely than children of other ages to be the target of physical abuse, but severe and fatal injuries occur most often in infants and young children. As many as 64% of all, and 95% of serious, traumatic brain injuries in the first and second years of life are thought to result from nonaccidental injury (Billmire and Myers 1985; Duhaime et al. 1992; Hahn et al. 1983; Keenan et al. 2003; Kraus et al. 1990). Nonaccidental injury causes 2,000 to 5,000 deaths per year (Cohn 1983). Males and females are equally affected, although females may suffer more abusive incidents. Abuse is more common in

families with psychosocial adversity, such as poverty and poor living conditions (U.S. Department of Health and Human Services 1989).

Behavioral indicators of abused preschoolers include social withdrawal, dependence, overcompliance, lack of curiosity, and flattened affect. Alternatively, modeling of aggressive behavior, hyperactivity, and agitation have been reported. Abusive parents often know little about normal child development. The more the child is perceived as different, the more likely he or she is to be abused. Therefore, children who were born prematurely and/or have congenital defects, mental retardation, developmental delay, or frequent physical illnesses are at greater risk for abuse (Cohn 1983; Helfer and Kempe 1987).

## PATHOPHYSIOLOGY

It has become the convention to separate primary causes of traumatic brain injury from their sequelae, even though secondary complications may occur within minutes of the initial insult, and the brain tissue damage from the primary impact develops over hours and even days after the injury (Honig and Albers 1994; Jennett and Teasdale 1981; Pang 1985; Teasdale and Mendelow 1984).

### Primary Brain Damage

Primary injuries result from events that take place within the first few milliseconds of an injury. Skull fractures and brain contusions or lacerations can occur on impact. The term *contusion* is used to describe a wide range of blunt injuries, from a small bruise on the crests of the gyri to a large coalescing clot, better termed an *intracerebral hemorrhage* (Jennett and Teasdale 1981; Teasdale and Mendelow 1984). The condition of the cranium does not correlate well with the severity of brain damage. Although localized contusions and lacerations often occur beneath depressed or compound skull fractures, the extent of injury can be limited, and clouding of the sensorium or loss of consciousness can be absent (Harwood-Nash et al. 1971; Jennett and Teasdale 1981; Miller and Jennett 1968).

Also, extensive contusions, lacerations, and hemorrhage can occur without skull fracture. Lacerations of the brain and rupture of the blood vessels can result from pulling and stretching during movement after an injury, and contusions often result from impact of the brain against the inner surface of the skull. Contusions commonly affect the undersurface of the frontal lobes and the tips of the temporal lobes, most likely because the brain impacts against the bony protuberances of the anterior cranial fossa and sphenoid region (Miller and Becker 1982). Even with a blow to the back of the head, frontal and temporal contusions will occur much more frequently than occipital lesions.

Contrecoup injuries are thought to occur from the brain and skull recoiling from impact (Pang 1985). In infants

younger than age 5 months, surface contusions and contrecoup are uncommon (Ward 1995a).

Diffuse axonal injury is currently thought to be one of the primary mechanisms of damage in closed traumatic brain injury. This has been studied primarily through animal models and histological exam after death as non-invasive procedures are not available (Smith et al. 2003). Acceleration and sudden deceleration of the brain, and, even more important, rotation of the brain around its axis, cause stretching and tearing of the long white matter tracts (Adams et al. 1989; Povlishock 1992, 1993; Teasdale and Mendelow 1984). Damaged axons, even those not mechanically ruptured at the time of impact, undergo a cascade of well-known cellular changes leading to cell death (Jennett and Teasdale 1981; Povlishock 1992). Ommaya (1982) thought that the surface of the brain was affected in milder injuries and that more central areas were affected in more severe concussions. The role of axonal damage is supported by studies which found that the duration of unconsciousness is related to degree of axonal injury, with widespread severe damage leading to deep or persistent coma (Teasdale and Mendelow 1984). Although definitive research on the elastic properties of the neuron has yet to be conducted, young children may be more vulnerable to diffuse axonal injuries because unmyelinated fibers may be more vulnerable to shearing (Ward 1995b).

### Mild Traumatic Brain Injury

Mild traumatic brain injury has been associated with well-known neurocognitive and neuropsychiatric symptom patterns, yet its pathophysiology remained an enigma until recently. Both animal and human research studies have revealed cellular and subcellular changes, vascular changes, and neurochemical reactions that can account for the morbidity in concussion. The exact mechanism remains elusive, and there may indeed be several varieties of mild traumatic brain injury. Mechanical impact stretches the axon, affects the axonal cytoskeleton, causing sudden neuronal depolarization, which disrupts axonal transport (Shetter and Demakis 1979). A cascade of neurochemical, ionic, and metabolic changes ensue (Hovda et al. 1995). Neuroexcitatory amino acids, such as glutamate and aspartate, are released, increasing glycolysis, resulting in metabolic depression (Christman et al. 1994; Povlishock 1992, 1993; Povlishock and Coburn 1989). Reuptake is inhibited causing increased receptor cell firing, and oxygen free radicals; nitric oxide can be particularly damaging when released in excess. Vascular changes have also been reported. Blood-brain barrier breakdown results in ischemic degeneration in the hippocampus in animal models of severe brain injury (Ward 1964), which may account for memory disruption. Hippocampal micro-hemorrhaging was found on autopsy of an adult male with symptomatic, prolonged mild traumatic brain injury, who died from an unrelated condition (Bigler 2003). Cerebral blood flow abnormalities appear

responsible for some ongoing postconcussive symptoms, as evidenced by reduced cerebral circulation time (Taylor 1966) and vasoconstriction (Gilbert 1968). Intracranial pressure alterations are not prominent in mild traumatic brain injury (Denny-Brown and Russell 1941), nor is it associated with diffuse axonal injury (Adams et al. 1982).

In mild traumatic brain injury, damaged axons are scattered throughout the white matter and are surrounded by healthy brain tissue. This unique situation, in which damaged neurons are contained in an intact environment, may precipitate a regenerative process observed as reactive sprouting and growth cone formation. The progress of this regenerative response appears to correlate with functional recovery. However, the neurophysiological factors responsible for neuronal recovery are complex and numerous, and beyond the scope of this chapter (see Bach Y Rita for an excellent review, 2003).

### Secondary Brain Damage

Secondary brain damage occurs as a result of later-developing lesions or physiological processes stemming from the primary injury. Intracranial factors include hematomas, brain swelling, infection, subarachnoid hemorrhage, hydrocephalus, and seizures. Extracranial factors include respiratory failure and cardiovascular compromise with hypoxia. With a given Glasgow Coma Scale score, outcome will be poorer and will involve injuries to other organ systems when secondary brain damage is sustained, but the complex relationship between multiple organ or bodily system compromise and brain injury is not well defined (Bruce 1995).

Epidural hematomas often result from a tear of the meningeal artery. These hemorrhages can expand very rapidly and require prompt surgical evacuation. Epidural hematomas are somewhat more common in children and adolescents and are associated with an 18% mortality rate (Ward 1995a). Subdural hematomas are rare in childhood and are associated with greater overall severity of traumatic brain injury than in adults. The exception is subdural hemorrhages in infants, which are frequent sequelae of child abuse (Caffey 1972, Ward 1995a).

Brain swelling results from two mechanisms. Increased cerebral blood volume leads to failure of vascular autoregulation in the brain. There is also true cerebral edema, which can be vasogenic or cytotoxic. Both brain swelling and mass lesions increase brain volume and can lead to increased intracranial pressure. The brain attempts to accommodate the added volume and increasing intracranial pressure by making adjustments to blood flow and cerebrospinal fluid. When brain volume exceeds the capacity of this autoregulation, intracranial pressure rises rapidly (Fig. 24.7). Subsequent compromise in cerebral perfusion pressure and cerebral blood flow can lead to ischemic damage. Such ischemia is associated with poorer outcome and is characterized on CT scan by a low-density

**Figure 24.7** Intracranial pressure-volume of mass curve indicating change to uncompensated state. When mass increases, some compartments decrease to compensate. Intracranial pressure (ICP) increases rapidly when brain mass exceeds the capacity of the systems to compensate. CSF = cerebrospinal fluid. Reprinted from Ward JD. Craniocerebral injuries, in *Management of Pediatric Trauma*. Edited by Buntain WL. Philadelphia: WB Saunders, 1995, pp. 178–188. Used with permission.

brain ratio and an indistinct separation of white and gray matter (Bruce 1995).

Ischemic injury can also result from increased intracranial pressure; brain shift that compresses or damages arteries; arterial spasm; and complications from extracranial events, such as respiratory compromise or frank apnea. Ventricular enlargement is commonly seen months to years after severe brain injury and results from atrophy of the white matter. Progressive hydrocephalus is rare but can be caused by scarring. Abscess formation within the brain is a complication of penetrating traumatic brain injury and is usually prevented by debridement of the brain and closure of the dura and skin (Reitan and Wolfson 1986; Teasdale and Mendelow 1984).

After traumatic brain injury, early seizures occur in 6% of mild and 35% of severe traumatic brain injuries in children (Bruce 1993). Seizures associated with mild traumatic brain injury are unique to childhood (Jennett and Teasdale 1981). Early seizures are more common in children under age 5 years; they generally occur within the first 24 hours and do not predict outcome (Hauser 1983). One third of patients have only a single seizure.

Early seizures should be distinguished from later-onset epilepsy, which develops in 5% of patients with traumatic brain injury. Partial seizures are more common than generalized seizures. Localized scar tissue within the brain is one source proposed for this complication. However, vascular lesions, gliosis, disruption of glial–neuronal relationships, and disruption of inhibiting systems are also thought to be causes of posttraumatic epilepsy. Epilepsy occurs more commonly following penetrating head injury and is more likely to occur as the level of severity increases. Individuals with intracerebral hematoma and prolonged loss of consciousness also are more likely to develop epilepsy. Injuries to the posterior frontal and parietal regions are more likely to result in later-onset epilepsy (Hauser 1983; Jennett and Teasdale 1981). It is common for adults with a history of early seizures to develop later-onset epilepsy, but this is not the case for pediatric patients.

### Child Abuse

*Shaken baby syndrome* is characterized by acute subdural hematoma and retinal hemorrhages. Shaking a young

infant causes deceleration and rotational force injuries and is believed to involve an impact injury as well (Caffey 1972; Duhaime et al. 1992; Sato et al. 1989). Apnea and hypoxia are common consequences of inflicted brain damage. Immediate medical attention is often not sought following abuse, and this can set the stage for a cascade of secondary damage to ensue. The unconscious child is put to bed and breathing is further compromised, leading to further increased intracranial pressure and ischemia. Medical attention may not be sought until the situation has progressed to deep coma. At presentation, the infant may be in coma or cardiac arrest, with bulging fontanelles and retinal hemorrhage, but often no external evidence of head injury (Bruce 1995). CT scan may show subdural hemorrhage and low-density brain swelling, and MRI often shows multifocal hemorrhage (Bruce and Zimmerman 1989). Infants who present with reduced consciousness have a poor outcome (Reece and Sege 2000): one third will die, one third will have severe disability, and one third will have a moderate to good recovery (Bruce 1995).

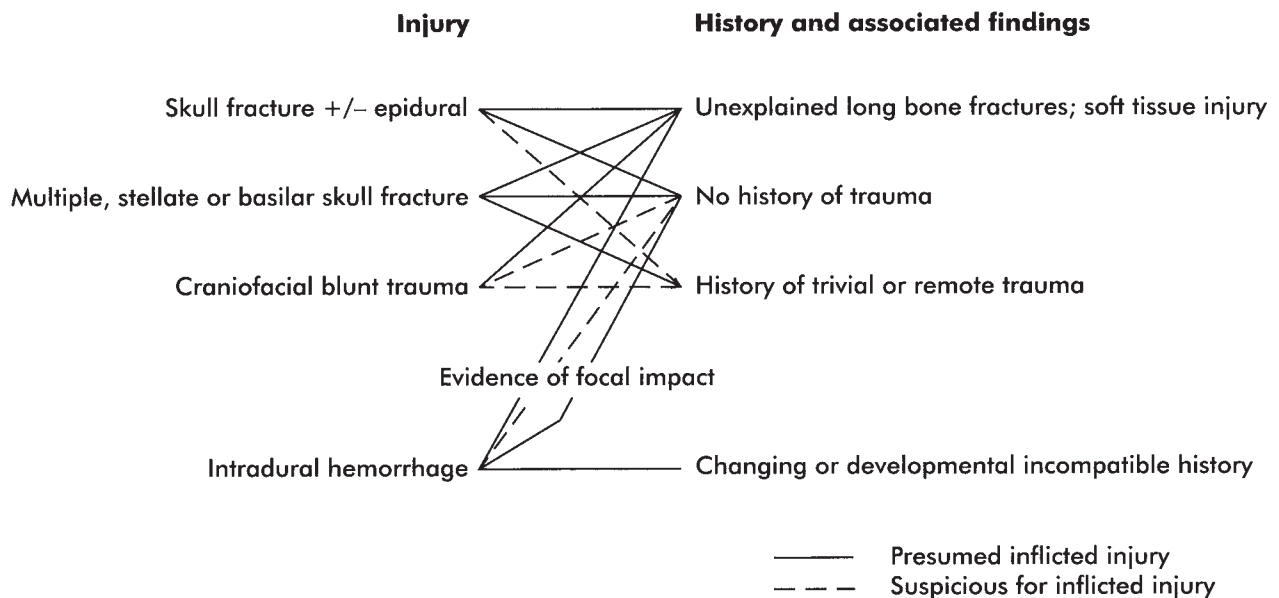

Several physical signs are considered pathognomonic for abuse. Subdural hematoma is a case in point. In infancy, subdural hematoma is an infrequent result of falls, even from heights. Metaphyseal fractures and failure to thrive are signs that raise the possibility of abuse in a given child (Figs. 24.8 and 24.9). Fractures and wounds at different stages of healing, and external marks that conform to the shape of a hand, teeth, or object, are also suggestive of abuse. In addition, parents often give vague or contradictory accounts of the "accident" (Billmire and Myers 1985; Hettler & Greenes, 2003).

**Figure 24.9** Cranial computed tomography (CT) image from 2-month-old infant who was born at 36 weeks' gestation with inflicted traumatic brain injury. Patient was brought to the emergency department in status epilepticus, and CT showed bilateral subdural hematomas. Skeletal survey showed healing fractures in the tibia and femur. Courtesy of I. Jarjour, M.D., Allegheny General Hospital, Pittsburgh, Pennsylvania.

### Sports-Related Injuries

When the athlete's head is at rest and struck by another object (as in a "left hook"), maximal damage is usually sustained beneath the site of cranial impact. When the athlete is in motion and strikes his or her head with a moving object, maximal injury is sustained opposite the site of impact or *countra-coup*. Shearing from rotational forces can be significant in high velocity impacts. The

**Figure 24.8** An algorithm for determining presence of inflicted injury in very young children. *Solid lines* indicate a "presumed" inflicted injury, and *dashed lines* indicate less conclusive or "suspicious" findings. Reprinted from Duhaime AC, Alario AJ, Lewander WJ, et al. Head injury in very young children: mechanisms, injury types, and ophthalmologic findings in 100 hospitalized patients younger than 2 years of age. *Pediatrics* 90:179-185, 1992, p. 180. Reproduced by permission of *Pediatrics*.

athlete who sees the blow coming will tense his neck muscles, and thereby suffer less of these rotational-related injuries (Cantu 1986).

The previous section on the pathophysiology of mild traumatic brain injury explains much of what occurs in sports-related injury. However, the concepts of second-impact syndrome is unique to the sports literature. "Vascular congestion syndrome" was initially reported by Kelly (1991) after a high school football player died from uncontrollable increases in intracranial pressure after sustaining two concussions in a game. There are 25 to 30 putative cases of second impact syndrome (Cantu and Voy 1995; Mueller et al. 1996), but McCrory (2001) recently critically reviewed these data. McCrory studied the case reports of athletes who had severe, unexplained cerebral swelling after concussion, and found many did not have conclusive evidence of a concussion in temporal proximity to the offending insult. He also recognizes that the syndrome is, curiously, seen only in the United States, while other countries may report significantly higher rates of concussive injuries during sporting. All the published cases of second impact syndrome occurred in adolescents, and this age group may have a higher rate of cerebral swelling and disturbed autoregulation after mild traumatic brain injury regardless of whether there was a second impact.

Another concept unique to sports-related traumatic brain injury is *dementia pugilistica*, identified initially from the sport of boxing, and due to repeated blows to the head, is characterized by chronic headache, imbalance, fatigue, dysarthria, and neurocognitive and functional deficits. Distinct neuroanatomical abnormalities have been found throughout the brain (Stiller and Weinberger 1985) in adults. The sport is uncommon in pediatric circles.

On a final note, many studies suggest that regular helmet use and design specific to the sport can ameliorate the occurrence and severity of sports-related concussion.

## OUTCOME

Recovery is related to the severity of initial brain damage, primarily diffuse axonal injury. A secondary mass lesion that initially depresses consciousness may cause only reversible brain injury if treated promptly. Whereas children may be less vulnerable to mass lesions, they may be more susceptible to bilateral diffuse brain swelling and to subsequent ischemic injuries (Bruce et al. 1978, 1979). Ischemia is probably the most pernicious of the secondary complications. Recent human trauma research efforts in neuropharmacology have been aimed at introducing agents, such as free radical inhibitors, early in medical treatment to attempt to attenuate some of the secondary damage that ensues in the immediate surround of ischemic lesions (Honig and Albers 1994). There have been some limited, favorable outcome data, but studies with children are extremely rare (Ward 1995b).

The Glasgow Coma Scale is a useful method of grading severity and predicting outcome in adults (Levin et al. 1990; Taylor 1992), although in the 13 to 15 range, GCS is unrelated to later neuropsychiatric sequelae (McCullagh et al. 2001). However, this scale is less reliable in pediatric cases, especially those involving infants and preschoolers (Bruce 1983), and it is not entirely clear that the scale predicts cognitive outcome in this population. Length of posttraumatic amnesia may serve as a better predictor of neurocognitive outcome than length of coma in adults (Shores 1989), and it predicts later memory function in children (Ewing-Cobbs et al. 1990). Neurological indices of pupillary and brainstem reflexes are good predictors of independence, whereas hemiparesis and early seizures are not (Eisenberg 1985; Hauser 1983; Levin et al. 1990). Elevated intracranial pressure portends a poor outcome.

## Overall Outcome

The Glasgow Outcome Scale (Jennett and Bond 1975) has become the standard instrument to measure outcome after traumatic brain injury in adults. Outcome is divided into five categories: (1) death, (2) persistent vegetative state, (3) severe disability, (4) moderate disability, and (5) good recovery. A lower rate of severe injuries during childhood (Kraus et al. 1986) and multiple medical problems in the elderly may contribute to this trend in overall mortality rates (Goldstein and Levin 1987). Although considerable discrepancy exists among research reports, most evidence suggests that mortality rates may be lower in children compared with in adults, when rates are equated for severity of injury (Alberico et al. 1987; Bruce et al. 1979; Kraus et al. 1986; Luerssen et al. 1988). Nevertheless, infancy does appear to be a vulnerable period, with a high rate of mortality from severe injury (see, e.g., Luerssen et al. 1988).

Infants and children are generally recognized to have a greater potential for neurological recovery than adults, especially with anoxic and ischemic insults (Ashwal et al. 1992). The persistent vegetative state following traumatic brain injury is rare in childhood (occurring in fewer than 1% of children admitted to hospitals for traumatic brain injury), and 90% of pediatric traumatic brain injury survivors will recover to a moderately disabled state or better after 3 years (Bruce et al. 1978, 1979). Because children, compared with adults, are less likely to die and because they recover well physically and are less likely to be left with permanent neurological sequelae such as aphasia, it has been commonly assumed that traumatic brain injury is less pernicious in childhood. This is not the case, however, when one looks at academic, neuropsychological, or psychiatric criteria (Fletcher et al. 1995). Neuropsychological studies suggest that cognitive deficits in childhood may linger, and to a greater degree than in adulthood (Brink et al. 1970; Fletcher et al. 1987). The Glasgow Outcome Scale apparently is not sensitive to unique factors in childhood such as the effect that brain injury has on disrupting later

development of function (Fletcher et al. 1987). Because a child is in a developing state, a return to a previous level of functioning is not the same as recovery if the child has not returned to the same trajectory of developmental progress.

### Neuropsychological Deficits

There is general agreement on the short-term neuropsychological effects of pediatric traumatic brain injury, but less consensus exists regarding long-term effects. Severity of injury interacts with other factors influencing neurobehavioral recovery from traumatic brain injury. These factors include age at which the injury was sustained, extent of injury (focal vs. diffuse lesions), and time since injury.

#### *Specific Age Factors Contributing to Outcome and Recovery*

Both animal and human studies of brain injury suggest that the age at which the injury was sustained is a major contributor to eventual outcome. This set of research data provides a conceptual framework for understanding the effects of traumatic brain injury in children. In contrast to a commonly held belief, recent evidence does not support the notion that the young brain is less vulnerable to insult or recovers better than the mature brain. Emerging evidence suggests that there are cognitive effects that can occur late, which are attributed to patients' "growing into their deficits," especially executive function deficits (Grattan and Eslinger 1991; Kolb 1995; Slomine et al. 2002).

The assumption that the immature CNS affords greater plasticity was based in part on the view that different brain regions could support the function subserved by the damaged region. The basis for this view was the relative sparing of language in young children who experience significant left-hemisphere damage, including hemispherectomy. However, although children resume the capacity to speak, they may also manifest more subtle communication dysfunction. It is likely that the age limit for hemispheric transfer of function may be lower than was commonly believed (Kolb 1995). In addition, sparing of communication skills may occur at a price, such as lowered overall IQ (Boll and Barth 1981).

Language recovery may be unique in childhood simply because the etiology and pathophysiology of the injury differ from that in adults. Much of the research on recovery from aphasia was obtained from studies on adults who suffered vascular lesions, which are rare in childhood. When vascular lesions are present in childhood, deficits appear more similar to those in adults (Dennis 1980). This point signals that one must be cautious when contrasting adult and childhood recovery from traumatic brain injury, because pediatric cases differ from adult cases in common mechanisms of injury, severity of injury, and medical complications.

Studies of recovery from focal damage indicate that some functions, such as language, may recover better than

others. Woods (1980) did not find evidence of compensation of visuospatial function after right-hemisphere damage in early infancy. Relevant to outcome in pediatric traumatic brain injury is the research considering recovery of executive function after early insult. Goldman (1971, Goldman et al. 1970) found that orbitofrontal lesions produced similar deficits in young and mature monkeys but that there was relative sparing of function following dorsolateral lesions.

The extent of injury may influence recovery, with less recovery expected when an entire functional area is affected. With diffuse cerebral injury, residual cognitive deficit may be more severe when the injury occurs in early infancy rather than in later childhood. However, we now know that the relationship between age at injury, lesion site and size, and cognitive outcome is complex (summarized in Kolb 1995). IQ is particularly vulnerable to early brain damage (Boll and Barth 1981).

Fletcher and Levin (1988), in a review of research on age factors in traumatic brain injury, found evidence for greater compromise in children younger than 6 years of age. However, the findings from earlier studies that show worse outcome in the younger sample may have been colored by a high rate of traumatic brain injury from abuse. It is now known that abused children may suffer more severe injuries, may differ from nonabused children prior to the injury, and have a worse general outcome after traumatic brain injury (Goldstein et al. 1993, Michaud et al. 1992; Trickett et al. 1991). When a subsample of physically abused children was removed from analyses, younger and older children with severe injury were equally compromised from traumatic brain injury (Kriel et al. 1989). Nevertheless, age effects noted in other studies that did not include abuse as a confound suggest somewhat worse outcome in younger children when severity of injury is equated with that in older children (Ewing-Cobbs et al. 1987; Gulbrandsen 1984, Levin et al. 1982). This is especially true for the preschool age group (Michaud et al. 1993; Wrightson et al. 1995). Slomine and associates (2002) found evidence that children injured at a young age where more likely to demonstrate executive function deficits than those injured later.

There is increasing evidence that skills in a rapid state of development at the time of injury may be more vulnerable to the effects of traumatic brain injury. Preschoolers are likely to demonstrate compromise in motor and expressive language skills (Ewing-Cobbs et al. 1989), and school-age children may be more compromised in reading (Barnes 1999; Shaffer et al. 1975) as well as written language (Ewing-Cobbs et al. 1987).

#### *Time Since Injury*

Adults and children differ in the time it takes to reach a stable point in recovery. The severity of injury is also a factor. In adults, the Glasgow Outcome Scale reliably predicts the amount of disability in 90% of victims within the first 6

months after the event (Jennett 1983). In children younger than 14 years of age, motor and sensory deficits recovered within 3 months, at which point the recovery was considered stable (Black et al. 1971). However, neurocognitive recovery can be more prolonged, particularly after more severe injuries. After milder injuries, neurocognitive recovery takes place within the first 6 to 12 months after the injury and slows after 12 months (Brooks and Aughtson 1979; Jones 1990). Plateaus may be reached after 1 year in moderate to severe injuries as well (Yeates et al. 2002). The recovery gradient may remain steep through the second year for very severe injuries and may continue into the third year (Chadwick et al. 1981). Simple information-processing deficits present 3 years after injury can be considered permanent, and compromise in more complex intellectual skills can be considered permanent after 5 years (Long et al. 1984). Lingering sequelae can be observed after traumatic brain injury of any degree of severity, even after mild injury.

### Neurocognitive Deficits Related to Severity of Injury

Mild traumatic brain injury commonly results in reduced information-processing capacity. In the early posttraumatic phase, the patient may process information more slowly, be inattentive and distractible, and appear forgetful (Gronwall 1989). Memory, attentional, and information-processing deficits form the core cognitive constellation known as *postconcussion syndrome* (Table 24.8). Postconcussion syndrome also includes a number of physical and emotional complaints. Studies in which groups of adult patients with mild traumatic brain injury were paired with orthopedic control groups indicate that certain somatic complaints and patterns of cognitive dysfunction may be specific to traumatic brain injury, whereas pain and emotional distress may be a nonspecific response to trauma in general. Postconcussion syndrome frequently resolves 1 to 3 months after the injury, but a subgroup of mildly injured patients may suffer more lingering neuropsychological deficits and/or subjective discomfort. Cognitive performance follows a predictable recovery curve, but subjective

complaints do not (Alexander 1992; Cicerone and Kalmar 1995; Gerber and Schraa 1995).

The incidence and source of postconcussion syndrome in adults, particularly persistent subjective complaints, have been the focus of considerable controversy in recent years (see, e.g., Bohnen et al. 1994). Postconcussion syndrome is easily and reliably feigned (Mittenberg et al. 1992) and is subject to considerable secondary gain from litigation compensation (Youngjohn et al. 1995). Personality factors, such as somatization, also play a role (Kazmark et al. 1995). On the other hand, positron-emission tomography (PET) and neuropsychological test data, and even histological examination provide support for neuropathology of postconcussion syndrome even in the absence of abnormalities on MRI or CT (Bigler 2003). These findings are unrelated to history of loss of consciousness. The most pronounced neuropathology is found in frontal and anterotemporal regions (Ruff et al. 1994).

Thus, although malingering or somatization may indeed be factors, there is strong evidence for an organic etiology in certain cases of persistent postconcussion syndrome, particularly when neuropsychological deficits are present. High-speed motor vehicle accident, age over 30 years at time of injury, and early presentation of cognitive dysfunction are relatively more common among patients with persistent postconcussion syndrome (Leininger et al. 1990). Factors that may make adjustment more difficult in the period following the injury include immediate return to school or work, emotional reactions to the accident, and preexisting obsessive-compulsive disorder or other anxiety disorders (Ruff et al. 1986). Symptoms common to post-traumatic stress disorder do not occur in mild traumatic brain injury (Sbordone and Litter 1994).

Information-processing deficits occur in children and adolescents following mild traumatic brain injury, particularly in the acute stages (Bassett and Slater 1990; Levin and Eisenberg 1979a, 1979b). Although initial cognitive deficit is apparently a common sequela of pediatric head injuries of mild severity, there is little evidence of sustained neurocognitive or learning deficit in the majority of children (Asarnow et al. 1995; Bawden et al. 1985; Bijur and Haslum 1995; Chadwick et al. 1980; Gulbrandsen 1984; Levin et al. 1988). Research on traumatic brain injury in preschoolers is quite limited and inconsistent. Short-term prospective studies suggest preschoolers recover much the same as older children after mild traumatic brain injury (Anderson et al. 2000; Arffa and Goldstrum 2003a). Other studies suggest that preschoolers may be especially vulnerable to mild head injury, and it may take years for the deficit to become fully apparent (Gronwall et al. 1997; Wrightson et al. 1995). For example, Roberts and colleagues (1995) described a young child who sustained whiplash injury in a motor vehicle accident without loss of consciousness. Staring spells, brief confusional episodes, and emotional outbursts were noted 2 years after injury, and epileptiform activity was documented on the electroencephalogram (EEG) 4 years

**TABLE 24.8**  
**POSTCONCUSSION COMPLAINTS**

Cognitive Complaints	Emotional Symptoms	Somatic Symptoms
Poor concentration	Depression	Fatigue
Forgetfulness	Anxiety	Dizziness
Slowness in thinking	Irritability	Blurred vision
Indecisiveness	Reduced tolerance for frustration	Oversensitivity to light and noise
	Low self-confidence	Tinnitus
		Sleep problems
		Poor coordination

after injury. PET scan revealed hypometabolism in both temporal lobes, and neuropsychological testing documented verbal and visual memory deficits. The outcome for children sustaining multiple concussion has not been adequately addressed in the pediatric literature (Bijur and Haslum 1995), although there is emerging literature from sports medicine indicating greater neurocognitive compromise with multiple concussions.

There is comparatively little research on reported post-concussion complaints in children and adolescents. Casey and colleagues (1987) reported minimal reporting of physical and emotional symptoms in children with “minor” traumatic brain injury (i.e., no loss of consciousness or altered level of consciousness); headache was more frequently reported following mild traumatic brain injury in children (Farmer et al. 1987; Klonoff et al. 1977; Lanser et al. 1988) and preschoolers (Arffa and Goldstrum, 2003c). Children with moderate traumatic brain injury showed significantly more postconcussion complaints than did children with other injuries both acutely and after 6 months (Barry et al. 1994). Persistent postconcussion syndrome has received little attention, and the frequency with which it occurs (or even whether it occurs) in pediatric samples is not known.

More severe injuries in childhood result in persisting neurocognitive compromise (Table 24.9). Excellent reviews are available on this subject (Dalby and Obrzut 1991; Fletcher and Levin 1988; Fletcher et al. 1987; Levin et al. 1995; Yeates et al. 2002). There is a moderate correlation between length of coma and both psychometrically assessed IQ (Brink et al. 1970; Chadwick et al. 1981; Johnston and Mellitz 1980; Klonoff and Paris 1974; Levin and Eisenberg 1979b; Levin et al. 1982; Winogren et al. 1984) and school achievement (Shaffer et al. 1980). Persistent problems in school achievement are common (Berger-Gross and Shackelford 1985; Brink et al. 1970; Ewing-

Cobbs et al. 1998; Fuld and Fisher 1977; Heiskanen and Kaste 1974; Klonoff et al. 1977).

Language deficits do not conform to any particular dysphasic pattern, and receptive language function is relatively spared (Ewing-Cobbs et al. 1985, 1987; Levin and Eisenberg 1979a). Language problems at the discourse level may be particularly persistent (Chapman 1995; Dennis and Barnes 1990), and the role of the frontal lobes in this type of communication disorder has been highlighted in both adults (Alexander et al. 1989) and children (Chapman 1995).

Attention and memory deficits are common after severe pediatric traumatic brain injury. They tend to persist for at least 1 year and may lead to academic failure marked by problems in assimilating new information (Gaidolfi and Vignolo 1980; Kaufman et al. 1993; Levin and Eisenberg 1979a, 1979b; Levin et al. 1982, 1988). Immediate or short-term memory deficits may be common in developmental disorders such as attention-deficit/hyperactivity disorder (ADHD) and dyslexia, but longterm memory deficits in these disorders are uncommon. The anatomic regions responsible for the transfer of verbal and visual information into longterm storage are discrete and localized and thus vulnerable to damage from traumatic brain injury. Memory deficits, therefore, appear to be unique to acquired brain injury in children, although it is possible that mental retardation with or without autism may be another manifestation of a developmental amnesia (Pennington 1991).

Visuomotor and visuospatial deficits are present in some patients (Bawden et al. 1985; Chadwick et al. 1981; Hannay and Levin 1984; Klonoff et al. 1977; Levin and Eisenberg 1979a, 1979b; Levin et al. 1982).

The impact of traumatic brain injury on executive function in children is an evolving and promising area of research. Executive deficits are cognitive processes that include voluntary initiation and inhibition of behavior; selective attention; planning; organization; and ability to switch sets. These deficits result from damage to the prefrontal regions or their connections, as well as diffuse injury. Although the advanced organizing functions of the frontal lobes may not be functional until adolescence (12 to 15 years) or adulthood (see, e.g., Golden 1981), there is evidence for an evolving functional state of the frontal lobes. Animal and human studies provide support for the development of core frontal lobe skills as early as 6–9 months in humans and at parallel ages in monkeys (Diamond and Goldman-Rakic 1989). Developmental researchers (Chelune and Baer 1986; Dennis 1991; Levin et al. 1991; Mateer and Williams 1991; Passler et al. 1985; Welsh and Pennington 1988) have documented the expected ages for mastery in a wide range of executive functions, with continued development noted at least through age 15 years. In adults and children, neuropsychological evidence of executive function deficits secondary to traumatic brain injury has been identified that correlates with the CT and MRI findings (Goldstein and Levin 1991; Levin et al. 1995; Slomine et al. 2002).

**TABLE 24.9**  
**NEUROCOGNITIVE DEFICITS SECONDARY TO SEVERE TRAUMATIC BRAIN INJURY IN CHILDREN**

Intelligence	Intellectual level depressed with longer periods of unconsciousness
Achievement	Persistent academic problems noted in reading, math, and other areas of school achievement
Language	Dysnomia, dysgraphia, reduced verbal fluency, problems in writing to dictation, problems in discourse (i.e., misinterpretation of ambiguous messages)
Attention/memory	Persistent deficits common
Visuomotor	Problems on tasks of speeded performance and reaction time; visuospatial deficits noted
Executive function	Problems in planning, strategy development

Finally, there has been some support for “cognitive reserve” theory (Ropacki & Elias, 2003) suggesting that a previous brain insult (or other conditions that diminish cognitive reserve such as substance abuse), potentiate the cognitive sequelae that adults experience after mild to moderate traumatic brain injury.

### Behavioral and Psychiatric Disorder Secondary to Traumatic Brain Injury

Early uncontrolled research identified high rates of psychiatric disturbance in groups of patients with brain damage of multiple etiology (Gudmunsson 1966; Holdsworth and Whitmore 1974; Pond and Bidwell 1960). More recent controlled studies confirmed that brain injury increases the likelihood of psychiatric disturbance (Brown et al. 1981; Rutter et al. 1970; Seidel et al. 1975; Shaffer et al. 1975; Weiland et al. 1992). Psychiatric disorder is twice as likely to be found in children with cerebral damage from multiple causes than in children with physical disabilities or chronic illnesses or healthy control children. Increased rates of psychiatric disorder have been correlated with more severe brain injury, greater cognitive impairment, and complicating psychosocial difficulties (Breslau 1985, Kirkwood et al 2000; Rutter et al. 1970; Seidel et al. 1975; Schwartz et al. 2003; Taylor et al. 2002).

Behavioral morbidity may be more common with early bilateral damage than with unilateral damage (Chelune and Edwards 1981). Behavioral disturbance is also greater if seizure or EEG disturbance occurs at younger ages. Disturbance of functioning like that present in epilepsy may be more harmful than actual removal or decay of tissue, since beneficial neuroplasticity may not occur. However, these findings may simply reflect a greater degree of brain pathology or effects of longterm anticonvulsant treatment (O’Leary et al. 1983).

Although brain damage increases the likelihood of psychiatric disturbance, it does not predispose one to a specific disorder or symptom cluster (Rutter et al. 1970). The pattern of psychiatric disorder in individuals with brain damage is similar to that seen in the general population (Bijur and Haslum 1995; Shaffer 1985). The effect of early brain injury may be to increase the variability of behavioral response (O’Leary and Boll 1984), a hypothesis that is consistent with the fact that psychiatric disturbance results from an interplay of direct and indirect effects of brain damage, secondary emotional responses, and family and environmental contingencies.

#### Injury Severity

In traumatic brain injury, a specific interaction between behavioral disturbance of recent onset and head injury severity/neurocognitive sequelae has been found. Findings from studies of this phenomenon vary considerably depending on what criteria were used to describe behavior problems or change (e.g., Brink et al. 1980; Fletcher et al. 1990; Rivara et

al. 1994). In studies by Rutter and colleagues (Brown et al. 1981; Rutter et al. 1983), the rate of new-onset psychiatric disorder in children with severe head injury was three times that in orthopedically injured control patients. In a recent study (Schwartz et al. 2003), behavioral dysfunction was recognized in 36% of severely injured, in 22% of moderately injured children with traumatic brain injury, compared to a 10% occurrence in the orthopedic control group. Behavioral disposition may actually worsen over time in persons with severe injury (Fletcher et al. 1995; Schwartz et al. 2003). A severity threshold was proposed; the risk of psychiatric disorder is much higher in very severe injury (defined as posttraumatic amnesia lasting 22 days or longer) than in severe (posttraumatic amnesia lasting 7 to 21 days) or mild injuries. Threshold effects noted in other studies (e.g., Levin and Eisenberg 1979b) were lower than those found by Brown and colleagues. No significant difference in rate of new psychiatric disorder was observed in children with mild injuries and orthopedic control groups (Brown et al. 1981; Fletcher et al. 1990; Rutter et al. 1983). Preinjury behavior was related to behavioral outcome in Rutter and colleagues’ studies; more than half of the children with a doubtful disorder developed a definable disorder, and all had symptoms.

Psychiatric disorder was found to be related to length of posttraumatic amnesia, presence of neurological abnormalities, and degree of intellectual impairment, but persisting neurocognitive dysfunctions were less predictive of behavioral disturbance after 1 year. These findings suggest that other factors, such as noncompliance with treatment recommendations, presence of litigation, deviant patterns of relating in the family, and psychosocial adversity, were instrumental in causing later behavioral dysfunction (Brown et al. 1981; Fletcher and Levin 1988; Fletcher et al. 1990; Rutter et al. 1970; 1983; Shaffer et al. 1975, 1980; Schwartz et al. 2003; Taylor et al. 2002).

#### Age at Injury

In comparison to neurocognitive morbidity, there is less support for increased risk of behavioral problems in younger age groups (Fletcher et al. 1990; Klonoff and Paris 1974; Shaffer et al. 1975). Johnston and Mellitz (1980) suggested that age was not a good predictor of behavioral outcome once length of coma was controlled. Preschoolers have not been extensively studied. In one retrospective study (Michaud et al. 1993), children injured as preschoolers showed increased behavioral morbidity at school age. The authors suggested that injury during the preschool years may cause more behavioral disturbance than does injury later. However, Arffa and Goldstrum (2003b) found a very high initial base rate but no evidence of new behavioral disorder in mildly to moderately injured preschoolers at a 6 month follow-up.

However, age at injury may affect the manifestation of the behavioral disturbance. Klonoff (1971) reported that the most common complaints in the postacute period of

traumatic brain injury in preschoolers were irritability and personality change and in school-age children headache and dizziness. Brink and colleagues (1970) found that children age 10 years and younger had symptoms of hyperactivity, destructiveness, decreased attention, impulsivity, and aggression, whereas children older than 10 years of age showed affective disturbance and poor judgment.

### Symptoms/Disorders

After severe traumatic brain injury, a large variety of psychiatric symptoms can be found (Black et al. 1971; Brink et al. 1980; Shaffer 1995), and disinhibited, socially inappropriate behavior is more common than other behaviors (Brown et al. 1981). Insensitivity to emotional cues, even the misreading of positive emotions as negative, may be a factor leading to social compromise (L. Peterson 1991). Even with cognitive recovery, children with severe head injuries had more behavioral problems, were more socially inept, and had poorer adaptive living skills than their sibling control (Perrott et al. 1991). Two of five children manifesting disinhibition in the study by Brown and colleagues (1981) later received a diagnosis of ADHD. Depression has recently been identified after moderate-to-severe pediatric traumatic brain injury, on clinicians and family reports. The child or adolescent did not self-report depressive symptoms, but this may be a failure of self-awareness. Depressive symptoms correlate with family pathology but not cognitive dysfunction (Kirkwood et al. 2000; Viguier et al. 2001). Depressive symptoms resolve faster than externalizing symptoms (Bloom et al. 2001).

Overall, the risk of later-developing schizophrenia is increased in a head-injured population (2 to 3% risk) compared with the neuropsychiatrically normal population (0.8% risk) (Davidson and Bagley 1969; Wilcox and Nasrallah 1987). It is uncertain, however, whether brain injury raises the threshold for schizophrenia or whether the familial characteristics of children at risk for schizophrenia are the same as those for children at risk for head injury (i.e., impaired caretakers who also suffer schizophrenic disturbance).

### Lesion Location

Lesion location has been tied to certain psychiatric disorders in adults with traumatic brain injury. For instance, depression and mania have been tied to right frontal lobe damage. Mania is a rare complication of traumatic brain injury and may require focal right-hemisphere lesions and a genetic predisposition for affective disorder. Acute-onset depression is thought to be lesion-related, whereas depression of later onset may be mediated by psychosocial factors. Paranoid delusional syndromes have been reported in both right and left frontal lesions, sometimes coupled with lesions elsewhere (Guze and Gitlin 1994; Jorge et al. 1993; Malloy and Duffy 1994; Starkstein et al. 1990).

There is comparatively less research involving pediatric traumatic brain injury samples. Shaffer and colleagues (see

Shaffer 1995) found increases in affective symptomatology in children with lesions localized to the right frontal and left temporoparietal regions. Sollee and Kindlon (1987) found a lateralized effect in a pediatric group with brain injury of mixed etiology. Externalizing symptoms were correlated with dominant hemisphere lesion, and internalizing symptoms, excluding neurovegetative symptoms, were related to right-hemisphere damage. In an epileptic sample followed throughout childhood, a schizophrenia-like psychosis was recognized in 13 children with lesions bilateral or localized to the left hemisphere (Lindsay et al. 1979).

The frontal lobes have recently been implicated in numerous psychiatric symptoms, but, again, more is known about the adult than the child in this regard (Barkley et al. 1992). Although subdivisions of the frontal lobes are highly interconnected, there do appear to be symptom patterns tied to the different regions. Orbitofrontal damage leads to distractibility, stimulus-bound behavior, disinhibition, and dyscontrol behaviors. Dorsolateral lesions cause syndromes of executive dysfunction such as the inability to shift sets, to plan, and to organize. Mesial damage has been related to apathy and lack of spontaneity (Duffy and Campbell 1994; Malloy and Duffy 1994; Malloy and Richardson 1994). Sophisticated neuroimaging has helped to document the vulnerability of the frontal regions, most commonly the orbitofrontal region, in adults with traumatic brain injury (Ichise et al. 1994).

Our understanding of the effects of frontal damage in childhood has been limited by the paucity of knowledge about the normal development of executive functions, the relatively low incidence of focal frontal lesions in children, the relatively recent development of neurodiagnostic imaging to the point that it is possible to identify frontal pathology, and the limited amount of extended follow-up. However, several case studies of perinatal and childhood frontal lobe damage suggest syndromes similar to those seen in adulthood. Cognitive inflexibility, social disability, reduced empathic ability, self-regulatory deficits, and problems in deploying attention are observed. As in adults, frontal lobe damage in children does not lead to significant reduction in overall IQ, although pervasive dementia may follow severe early frontal lobe damage with subcortical involvement. Functional subdivisions develop during childhood, and variants of the frontal lobe syndrome, including lateralized effects, are reported in children. For example, one child who sustained right frontal damage was able to use verbal mediation to guide behavior, whereas another with left frontal damage was not. In another child, a mesial frontal lobe syndrome marked by asplontaneity was diagnosed at age 9 years (Benton 1991; Grattan and Eslinger 1991).

A delay in the onset of symptoms has been reported with all types of brain injury, but particularly with frontal injury in childhood. One case discussed by Grattan and Eslinger (1991) involved a youth who sustained frontal damage at age 7 years and who appeared spared from behavioral effects until adolescence, when progressive social

and emotional deterioration was evidenced. There is some support for delayed onset of symptoms in animal models as well (Goldman and Alexander 1977).

Although frontal lobe syndromes bear some similarity to ADHD, and there is evidence linking frontal lobe function to this disorder (Chelune et al. 1986; Lou et al. 1984); children with ADHD do not grow up to show cardinal features of these syndromes. In addition, although hyperactivity does occur with frontal lobe pathology, it is certainly not a prominent feature (Benton 1991; Grattan and Eslinger 1991).

### Psychosocial Factors

The ultimate expression of psychiatric symptoms depends on personality and psychosocial factors predating the injury, as well as the family's ability to cope afterward (Fig. 24.10). In one study, more than half of the children with adjustment problems following traumatic brain injury had a history of adjustment problems premorbidly (Brown et al. 1981). Longer-lasting behavioral problems are associated with family distress, including marital discord, parental psychiatric disturbance, and single-parent households (Brown et al. 1981, Fletcher et al. 1990; Perrott et al. 1991; Yeates et al. 1997).

**Figure 24.10** Psychosocial adversity and the development of “new” psychiatric disorders after traumatic brain injury. Numbers along vertical axis correspond to likelihood of development of psychiatric disorders (1 = as likely, 2 = two times more likely, etc.). Under conditions of high adversity, even control subjects developed psychiatric disturbance. Psychiatric disturbance was two to three times more likely in individuals with severe injury under conditions of high psychosocial adversity. Mild injury was defined as posttraumatic amnesia of at least 1 hour but no more than 7 days, limits that exceed those currently used. Reprinted from Rutter M, Chadwick O, Shaffer D. Head injury, in *Developmental Neuropsychiatry*. Edited by Rutter M. New York: Guilford, 1983, pp. 83–111. Used with permission of Guilford Press.

Severe head injury in children places significant stress on the parent–child relationship. Children with severe head injury are significantly more demanding than their siblings (Perrott et al. 1991). One study of abused children with neurocognitive dysfunction found that in 50% of the children the neurological impairment was a consequence of the abuse, whereas in the other 50% it was a contributory factor. Failure of the family members to move through a grieving process can lead to poor adaptation and unrealistic expectations, as well as conflict with doctors and caregivers (Birmaher and Williams 1994).

### DIAGNOSIS

Unlike the situation that the clinician faces in dealing with the adult patient with traumatic brain injury, with children, a parent or caretaker is usually available to provide history unencumbered by the neurocognitive limitations that result from the injury. Parental report of the injury and subsequent behavioral change is likely to be most valid when obtained in proximity to the event. It is not uncommon, however, for neuropsychiatric evaluation and treatment to be pursued years after a traumatic brain injury, when specific details of the injury and immediate aftermath have faded from memory. It is also apparent that some parents, at a loss to explain their child's behavioral problems, may retrospectively attribute them to an identifiable past event. Other parents, uncomfortable with the prospect of an organic etiology, may highlight situational or other environmental factors.

Because neurobehavioral symptoms have multiple causes, a comprehensive history should be obtained, including developmental, academic, medical, social, and psychiatric histories. Hospital records of acute treatment provide critical data on injury severity and medical complications and should be reviewed (Taylor and Price 1994). As many as 32% of children with head injuries may have a preexisting learning disorder or history of school failure (Rutter et al. 1970). An important source of collateral information in these cases can be school records and yearly standardized achievement test scores. When available, previous psychological or psychiatric evaluations can be indispensable in defining baseline level of disturbance. Even with memories clouded by time and personal attributions, the parent is, in all likelihood, the best source for a history of behavioral change following traumatic brain injury in children. Specific details, including the exact behaviors or symptoms exhibited and the age at onset and the duration or frequency of symptoms, should be elicited.

Thus, comprehensive medical, neurological, and neuropsychiatric assessments are essential in evaluating the behavior problems of a child or adolescent with a history of traumatic brain injury. Behavioral rating scales are an efficient and inexpensive way to gather large amounts of information on behavioral adjustment, although none

has been developed specifically for the pediatric head-injured population. A broad focus instrument, such as the Child Behavior Checklist (Achenbach and Edelbrock 1983), can be used along with scales that highlight certain cluster symptoms. Structured interviews for children may be selectively tapered after initial screening with a behavior checklist. Taylor and colleagues (1995) recently developed a structured interview to identify behavioral changes and maladaptive family reactions secondary to traumatic injury.

Finally, diagnosis is limited by the classification systems we use. A child may display multiple symptoms, but these symptoms may not meet the DSM-IV criteria for a specific disorder. Cataloguing and rating the severity of behavioral symptoms, independent of psychiatric diagnosis, can be useful in designing treatments. Prigatano (1992) discusses the need to distinguish between primary and secondary behavioral symptoms. For example, aggression may be considered a “side effect” of frontal damage since such damage limits the repertoire of behavioral response and the ability to process complex social interchanges.

### Neurodiagnostic Studies

Defining the relationship between neurobehavioral assessments and structural and functional neurodiagnostics is an area of rapidly evolving research. As sophistication in both technologies grow, our ability to diagnose traumatic brain injury in children and provide treatment will greatly improve. Currently, neuroimaging plays a major role in both acute and postacute assessments of traumatic brain injury.

CT scanning is the procedure of choice in the acute setting in cases of traumatic brain injury, as it is quicker and less expensive than MRI, relatively less affected by motion artifact, and contributes information necessary for surgical management (Taylor and Price 1994). Because it visualizes bone better, CT is superior to MRI in the diagnosis of skull fracture. However, MRI is superior to CT in visualizing areas of contusion next to the skull, because bone artifact does not interfere, and is better for identifying diffuse axonal injury involving the deep white matter, corpus callosum, or brain stem. MRI (Levin et al. 1987a; Akhtar 2003) identified abnormalities up to four times more often in patients with mild and moderate traumatic brain injuries than CT. Gennarelli and colleagues (1982) found MRI to be ten times more sensitive than CT in visualizing deep white matter shearing, which is the injury correlated with depth and duration of coma in primates. MRI is also superior to CT in identifying certain intracranial hemorrhages, especially isodense subdural hematomas, in determining the ages of intracranial hemorrhages, and in estimating the overall extent of brain damage in the early postacute period (Alavi 1989; Shores et al. 1990). MRI can be used at later times to identify deep white matter lesions and ventricular enlargement, both of which correlate with clinical outcome and some parameters of neuropsychological study (Verger

et al. 2001; Wilson and Wyper 1992). For these reasons, MRI is the instrument of choice starting 3 days after injury (Taylor and Price 1994).

Functional neuroimaging techniques, such as single-photon emission computed tomography (SPECT), PET, and fMRI, have a demonstrated role in identifying brain abnormalities that correlate with neuropsychological deficit and neurobehavioral symptoms (Ichise et al. 1994; Shores et al. 1990). This kind of imaging is not frequently utilized in the routine care of patients with traumatic brain injuries, although Johnston and colleagues (2001) suggest that fMRI may be useful in return to play decisions in athletes. PET and SPECT can be used to measure cerebral blood flow, cerebral blood volume, oxygen utilization, glucose or protein metabolism, and specific neurotransmitter function and has good spatial resolution. However, it is not available in most hospital settings because it requires expensive equipment and highly trained personnel. Although SPECT has poorer spatial resolution, it is more readily available than PET and, coupled with structural imaging and neuropsychological data, can help in understanding the functional correlates of structural lesions (Wilson and Wyper 1992). The fMRI can be used to detect changes in cerebral blood flow or blood volume, although oxygenation is most common (Johnston et al. 2001).

Neuropsychological testing is the most sensitive method of detecting subtle brain disturbances affecting cognition and behavior, especially after milder injuries (Taylor and Price 1994). Neurocognitive function can be impaired even when the MRI scan is normal (Levin et al. 1993). Recent developments in understanding the normal development of various neurocognitive functions (e.g., Welsh and Pennington 1988), and sophistication in test development and norms (e.g., Heaton et al. 1993), promise to enhance the utility of neuropsychological testing in pediatric traumatic brain injury.

## MANAGEMENT

### Management in the Acute Setting

In the acute setting, the neuropsychiatrist may be called on to rule out alternative and treatable causes of delirium in patients with traumatic brain injury (e.g., medication toxicity) and to establish the role of prior psychiatric disturbance in current presentation, as well as to assess functional capacity and the ability to benefit from rehabilitation. Environmental manipulation, such as minimizing environmental noise, establishing predictability in routine, and utilizing sitters or Naugahyde padded room enclosures, has been useful in controlling agitation that occurs during recovery from coma (Trzepacz 1994). Educating the patient and family about the aftereffects of mild traumatic brain injury may reduce the incidence of emotional and functional sequelae (Mittenberg et al. 1993).

Neuroleptics use is controversial. The sedative effects can increase confusion and lengthen posttraumatic amnesia, lower seizure threshold, and result in anticholinergic toxicity or extrapyramidal reactions (Birmaher and Williams 1994; Smeltzer et al. 1994). There is some experimental evidence that dopaminergic antagonists may impede neuronal recovery (Gualtieri 1991); this is supported by animal study (Feeney et al. 1982, 1990; Goldstein 1993; Hovda and Feeney 1985). However, Elovic and colleagues (2003) note that much of the caution is centered upon typical antipsychotics such as haloperidol, and that the atypical antipsychotics such as clozapine, olanzapine, quetiapine, risperidone, and ziprasidone, target serotonergic neurons and hold considerable promise in the treatment of patients with traumatic brain injury. Neuroleptics are frequently prescribed for agitation. When prescribed for psychosis, it is important to ascertain whether the behavior is psychosis, delirium, or a confabulatory process. The author recalls the case of a 54-year-old nurse hospitalized on a psychiatric unit after rupture of an anterior communicating artery. This woman was initially called delusional as she tried to lead the group therapy sessions on the unit. However, she suffered a dense amnesia after her lesion, and in the absence of ongoing memory, assumed her work role in what appeared to be her work environment. Symptoms were responsive to reality therapy and ultimately transfer from the hospital setting.

Research on psychopharmacology in the acute setting is limited, and most is conducted with adult patients. Two case of methylphenidate to minimally conscious patients, led to one positive response, indicating a role for single subject drug trials (Laborde and Whyte, 1997). Cholinomimetic agents in the promotion of cognitive recovery in the acute period is promising. Citicoline led to decreased length of coma and hospitalization and fostered better rehabilitation potential (Lorenzo 1991). Amantadine may promote faster cognitive recovery when used in the first 3 months (Meythaler et al. 2002), and clinical trials in the pediatric population are currently under way. The neuropsychiatrist practicing primarily in the acute setting may want to explore the research on neuroprotective agents, prominent in the animal literature. Cop-1, a synthetic polymer used in multiple sclerosis, was shown to counteract the loss of neurons from glycolysis in mice (Kipnis et al. 2003).

### Psychopharmacological Management

The current role of psychopharmacology in the postacute setting is to control certain emotional and cognitive target symptoms. To date, there have been few double-blind, placebo-controlled clinical trials specifically aimed at children with traumatic brain injury, and guidelines must be borrowed from the literature on developmental disorder and adults with traumatic brain injury (see, e.g., reviews by Gadow 1992; Ross 1992; Wroblewski and Glenn 1994).

Several caveats are indicated:

1. Monotherapy is better than polypharmacy.
2. Start the medication at low doses and increase gradually.
3. Reassess often.
4. Carefully monitor side effects.
5. Monitor drug-drug interactions.

Psychopharmacological treatment for arousal and attention deficits has gained popularity (Wroblewski and Glenn 1994; Whyte et al. 2002). Stimulants have been effective in reducing distractibility, inattention, and hyperactivity in children and adults with ADHD (Gualtieri 1988); in improving hypersomnia, hypoarousal, and apathy in patients with narcolepsy or Kleine-Levin syndrome (Lemire 1993); and in improving all these symptoms in children with autism or mental retardation (Birmaher and Williams 1994; Birmaher et al. 1988). Because stimulants appear to effect change by modulating dopaminergic and noradrenergic neurotransmitters, especially in the frontal neocortex, they are a rational choice for the treatment of the cognitive sequelae of traumatic brain injury. There is also support from animal research that stimulants may foster cortical recovery (Feeney et al. 1982; Levin and Kraus 1994). Methylphenidate can be used safely in populations of brain-injured individuals who are at high risk for seizures (Wroblewski et al. 1992). The clinical research in traumatic brain injury samples has been inconsistent, especially in children. In 10 controlled studies, psychostimulants led to improved speed of mental processing and observational ratings of mood and behavior (Whyte et al. 2002). However, in the two pediatric samples, one was positive (Mahalick et al. 1998) and the other disappointing (Williams et al. 1998). In a carefully controlled study with adults, there does appear to be some advantage in increasing initial, but not sustained attention (Whyte et al. 2002).

Cholinomimetic agents, many originally developed to treat cognitive disorders in adults suffering from Alzheimer's disease, may be useful in enhancing cognitive recovery after traumatic brain injury in adults (Blount et al. 2002). Small scale clinical studies demonstrated benefits of citicholine (Levin et al. 1991). Physostigmine effectiveness has been inconsistent (Cardenas et al. 1994; Levin et al. 1986). Donepezil led to benefits in two patients (Taverni et al. 1998), three of seven patients (Whitlock 1999), and four patients (Masanic et al. 2001). A retrospective study of 53 patients showed benefits on subjective ratings but not cognitive testing (Whelan et al. 2000). However, only IQ tests were used, and these are not the most sensitive to posttraumatic brain injury cognitive dysfunction.

The neuropsychiatrist must consider medication-induced depression and emotional lability in the differential diagnosis of traumatic brain injury patients with affective symptoms (Silver and Yudofsky 1994). Antidepressants and mood stabilizers have been utilized in the treatment of posttraumatic affective symptoms. Antiepileptic drugs such

as carbamazepine have been helpful in stabilizing mood in adults with traumatic brain injury and have recently been utilized for treatment of behavior disorders in children both with and without epileptic seizures (Evans et al. 1987; Gilberg 1995). Although carbamazepine may be particularly helpful in managing episodic/explosive behaviors associated with EEG abnormalities (Kuhn-Gebhart 1976), worsening of symptoms can occur in some children (Birmaher and Williams 1994). Recently, there has been an explosion of novel anticonvulsants, all of which appear equally effective in seizure control (Hoch and Daly, 2003), although some have more favorable cognitive effects. For example, Galopentin and Lamotrigine were superior to carbamazepine and topiramate (Meador et al. 1999, 2001; Showalter et al. 2000). Tricyclic antidepressants may potentiate seizure potential after severe traumatic brain injury (Wroblewski et al. 1990).

The treatment of aggressive behaviors calls for careful analysis of the behavior and environmental contingencies, diurnal characteristics, and baseline history. Lithium, carbamazepine, propranolol, stimulants, and neuroleptics (especially atypical) have been used in the treatment of aggressive behaviors (Campbell et al. 1984; Elovic et al 2003; Evans et al. 1987; Gadow 1992).

### Behavioral Management Strategies

A multidisciplinary and multimodal approach to behavioral management is best for pediatric traumatic brain injury patients. Specific treatments are selected according to the age, cognitive level, and psychiatric presentation of the child or adolescent and the resources in the home and school. Environmental treatment strategies, recently advocated for adults with traumatic brain injury (Campbell et al. 1994; Mateer and Williams 1991; Sohlberg et al. 1993), are probably easier to apply in pediatric samples, since special educators and mental health providers are often skilled in behavioral treatment.

Traditional behavioral management strategies, such as contingency-reward, response cost, or time-out, may be effectively applied in the environment of the pediatric patient with traumatic brain injury. Children with brain injury respond optimally to a consistent, predictable routine in an environment where sensory stimulation is kept to a minimum. These patients often cannot tolerate multiple options or complex contingency contracts. Providing clear, uncomplicated instructions and breaking multistage problems into steps is advised. Modeling may not be effective without instruction identifying the behavior to change and the target behavior. Some patients may respond to cueing techniques such as “memory books” and cue cards that prompt the desired behavior.

Self-control and other metacognitive techniques are popular in the treatment of children and adolescents with behavior problems (Kendall and Braswell 1993) and can be adopted for use in some traumatic brain injury patients

(Feeney and Ylvisaker 2003; Sohlberg et al. 1993). Teaching systematic problem solving, social skills or conversation training, and verbal rehearsal is suggested for individuals with higher-level executive dysfunctions (see Stuss 1987). Cognitive rehabilitation of related neurocognitive deficit, such as attentional training and memory cueing systems, might augment response to metacognitive techniques (Sohlberg and Mateer 1987).

Emotional reactions to the loss of function may occur in pediatric traumatic brain injury patients who are aware of their deficits (Cicerone 1991). The “sense of self” can be disrupted, particularly in adolescents, for whom identity issues are prominent. The utility of more traditional psychotherapies for brain-injured individuals has been realized only relatively recently (Prigatano 1992). Group therapy is advocated, particularly for adolescents (Barin et al. 1985).

Family involvement is critical to the success of other treatments. Interventions with the family may involve psychoeducational and supportive therapy and grief therapy, as well as cognitive behavior therapy, to increase coping abilities (Barin et al. 1985). Parents of brain-injured children have more stress and psychological distress than parents of orthopedically-injured children (Wade et al. 1998). Family members benefit from education about brain injury sequelae (i.e., attributing amotivational syndromes to frontal pathology and not to recalcitrance). Family patterns that were previously adaptive (i.e., flexibility in rules or routine, tolerance of a high level of emotion) may become devastating to a brain-injured child or adolescent. Dysfunctional patterns present before the injury may be compounded in its aftermath (Wade et al. 2003). Thus, parent effectiveness training may prove to be of merit. Caring for a brain-injured child or adolescent places considerable stress on the parents and siblings in the family. Support and stress management training for, and in some cases psychiatric treatment of, family members may be indicated.

### Rehabilitation and Education

Comprehensive rehabilitation is frequently recommended after significant traumatic brain injury and is designed to correct the physical, speech, and cognitive dysfunction that can follow such injury. Other goals include increasing the child’s capacity for self-care and returning to school or vocational training. Neuropsychiatric consultation in the rehabilitation environment is often integral to maximizing benefit from this setting. Control of aggressive and impulsive behaviors and dysphoria, for example, sets the stage for progress in therapies. Judiciously eliciting the family’s involvement in the rehabilitation process may foster both the child’s recovery and the family’s adaptation to the child’s limitations (Novack et al. 1992).

Children with traumatic brain injury must ultimately return to school and the care of educators. Unlike adults, who may be able to return to a job that offers predictability and routine, children are returned to an environment that

constantly calls for new learning and adaptation to novel settings. At the same time, educational settings may be ill equipped to manage the head-injured child.

Children with head injuries are entitled to special education services under the category of "other health impaired" in the Education for All Handicapped Children Act (PL 94-142) (1976). School districts differ in policy and orientation; some consider augmentation of academic subjects as their sole purpose, whereas others see physical therapy, occupational therapy, speech, and even cognitive therapy as prerequisite treatments to learning. School districts typically only recognize as special-needs students children who sustained severe injury. The child with mild or even moderate injury may return to school without special attention, and sometimes teachers may be unaware of the head injury. Designing the correct educational placement is essential for optimal postacute recovery, even for children with mild injuries. For example, a child with attention and memory problems may adjust best with short homebound instruction followed by a modified program (less demanding course load, alternative test approaches, and/or in-school tutoring). With children who sustained severe injury, school reentry should be approached gradually, with frequent consultation and collaboration with rehabilitation providers and family. Children with severe injury should not be returned to school until a readiness to learn has been established (Cohen et al. 1985).

Children with traumatic brain injury have unique educational needs. Because they are quite different from children with learning disabilities (e.g., memory deficits are unique to acquired brain injury), their needs are often misunderstood by educators. Neuropsychiatric consultation may be helpful both for behavioral difficulties directly caused by cranial trauma and for those that evolve from a mismatch of the child's needs and educational approach.

# Spina Bifida and Hydrocephalus

25

**Gregory S. Liptak, MD, MPH**

## **SPINA BIFIDA AND MENINGOMYELOCELE**

The term *spina bifida*, which means split spine, refers to a group of disorders that are in the family of neural tube defects. Figure 25.1 shows the most common types of spina bifida. Meningomyelocele (or myelomeningocele) refers to the most serious form of spina bifida in which the covering of the spinal cord (meninges) and the spinal cord itself (myelon) are abnormal. The “cele” refers to the fluid-filled sac that herniates through the opening in the back. The overlying skin, vertebrae, and soft tissue are abnormal as well. The major focus of this chapter will relate to meningocele.

In meningocele, the spinal cord is normal but the meninges and overlying structures are not. In occult spinal dysraphism, the overlying skin is intact, although usually a hyperpigmented spot, hairy patch, mass (lipoma) or sinus tract overlying the defect is present. Abnormalities of the spinal cord, such as tethering, a split cord, diastematomyelia (cartilaginous or bony spicule dividing the cord) and/or fibrous bands or tumors (such as lipomas) are common in occult spinal dysraphism and are often asymptomatic in early life but become symptomatic as the child grows. In spina bifida occulta, which occurs in up to 20% of otherwise healthy individuals (Fidas et al. 1987), the posterior arch of the vertebral body is abnormal, but no other abnormalities occur. This condition is benign (Boone et al. 1985), produces no symptoms, and appears to be genetically unrelated to the other forms of spina bifida.

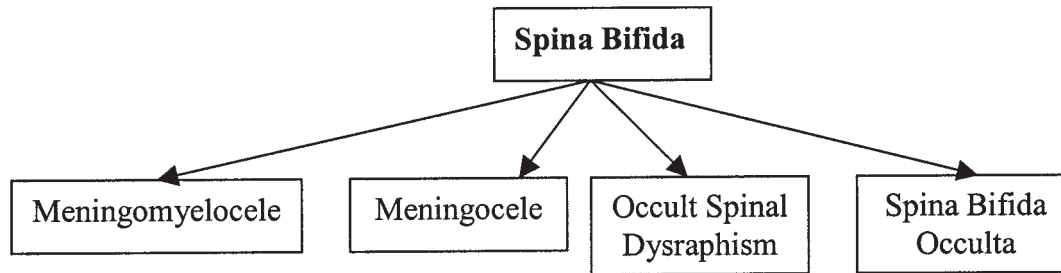

### **Epidemiology, Etiology, and Prevention**

In the United States, the prevalence of meningocele is approximately 60 per 100,000 births (Olney and

Mulinare 1998). It has been described as “the most common severely disabling birth defect in North America” (Fletcher et al. 2002).

The embryonic events resulting in meningocele occur very early in gestation, during the period of neurulation (26 days after fertilization) (Copp, Fleming, and Greene 1998). During neurulation, the neural plate is transformed into a hollow tube. The neural groove folds over to become the neural tube, which develops into the spinal cord and vertebral arches, as well as the ventricular system in the brain. This finely regulated sequence of cell specification and proliferation involves multiple signaling systems. If a portion of the neural groove does not close completely, a neural tube defect results, and the spinal cord is malformed. Although the mechanism of neural tube closure is not fully understood, it does not simply close like a zipper but rather has multiple sites of closure, each of which is under separate genetic and environmental influences (Golden and Chernoff 1995; Urui and Oi 1995; Van Allen et al. 1993).

The causes of neural tube defects remain uncertain. Although both environmental and genetic factors play a role, their interaction is complex (Hall and Solehdin 1998; Volcik et al. 2003). For example, in mice, mutations of over 50 different genes (Juriloff and Harris, 2000) as well as multiple environmental factors can result in neural tube defects (Juriloff and Harris 1998). Men and women with meningocele who can reproduce have a 4% chance of having an infant with a neural tube defect. Specific factors associated with increased risk for the development of neural tube defects include chromosomal disorders (trisomy 13 and 18), advanced maternal age, as well as exposure to a variety of drugs during pregnancy, such as valproic acid (Depakene, Depakote) (Davis, Peters, and McTavish 1994), carbamazepine (Tegretol) (Yerby 2003), and isotretinoin (retinoic acid, Accutane). Other factors include maternal hyperther-

**Figure 25.1** The most common types of spina bifida.

mia (e.g., saunas or high fever) (Sandford, Kissling, and Joubert 1992). Maternal diabetes (Sadler, Robinson, and Msall 1995), malnutrition (Gross et al. 2001), and obesity during pregnancy have also been identified as risk factors (Shaw et al. 2003).

Gender and socioeconomic factors have also been implicated as risk factors. Girls are three to seven times more likely to have meningomyelocele than boys, except for sacral level neural tube defects where the occurrence is equal (Hall et al. 1988). The birth prevalence is greater with lower socioeconomic status and is more common in certain racial and ethnic groups. Thus, obese Latina women who have daughters are eight times more likely to have a child with meningomyelocele than nonobese white women who have sons (Shaw et al. 2000).

The prevalence of meningomyelocele is decreasing as a result of a several factors. Developed countries are now using maternal alpha-fetoprotein serum testing for prenatal screening for neural tube defects (Roberts et al. 1995). Approximately 50% of couples, upon learning that they are carrying an affected fetus, choose to terminate the pregnancy (Forrester and Merz, 2000). Since 1998, the folic acid fortification program has been in effect in the United States and certain foods such as bread, cereals, flour, and rice have been supplemented with synthetic folic acid. However, the amount of folic acid in a typical diet, even with fortification, is not sufficient to prevent neural tube defects. Most obstetricians place women on supplemental folic acid (0.4 mg per day) as soon as pregnancy is diagnosed.

Studies have shown that daily supplemental doses of folic acid can reduce the incidence of new cases of neural tube defects in the general population by more than 50% (Bower and Stanley 1992; Werler, Shapiro, and Mitchell 1993). In a prospective study conducted in China, women who received daily folic acid, 0.4 mg (400  $\mu$ g) given periconceptionally (from just before conception through the first trimester), had a rate of neural tube defects of 1 per 1,000 births compared with a rate of 4.8 per 1,000 in the control group (Berry et al. 1999). As a result, it is now recommended that all women who are contemplating a pregnancy take 0.4 mg of supplemental folic acid per day while they are trying to conceive and during the first 12 weeks of pregnancy (American Academy of Pediatrics 1999; Manning, Jennings, and Mad-

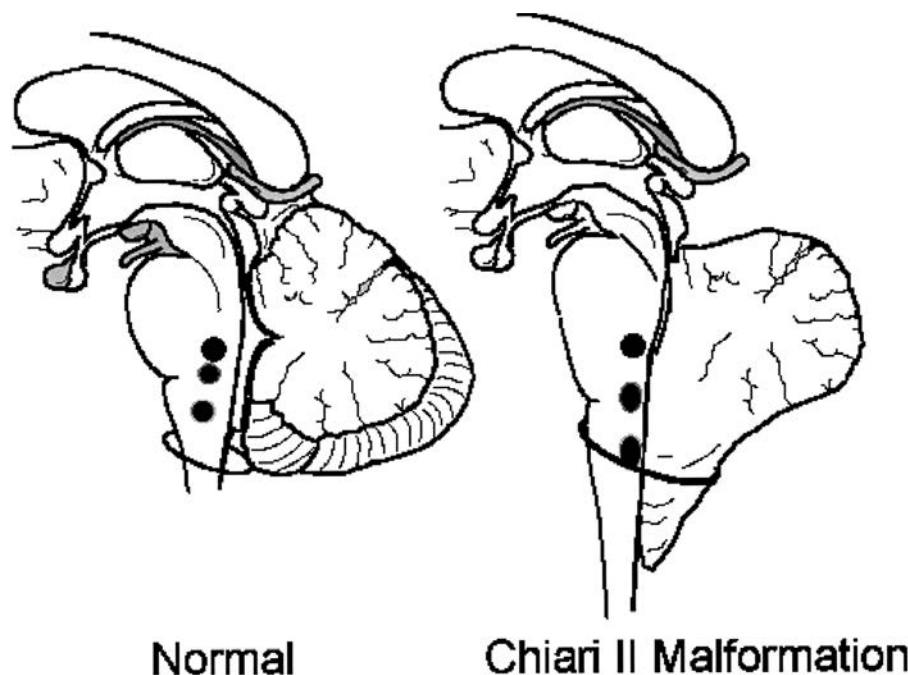

sen 2000). Yet, only about one third of women who are planning a pregnancy take folic acid around the time of conception (Schader and Corwin, 1999) and half of all pregnancies in the United States are unplanned.

### Hydrocephalus

The prevalence of hydrocephalus is about 1 in 2,000 children. Hydrocephalus occurs as a result of an imbalance between the production and absorption of cerebrospinal fluid in the ventricular system so that cerebrospinal fluid accumulates within the cerebral ventricles. The ventricular system is made up of four ventricles connected by narrow pathways. Normally, cerebrospinal fluid is secreted by the choroid plexus in the lateral ventricles, flows through the ventricles, exits into cisterns (closed spaces that serve as reservoirs) at the base of the brain, then over the surfaces of the brain and spinal cord, where it is absorbed into the bloodstream. As cerebrospinal fluid is accumulated in the ventricles, the ventricles enlarge. In the fetus and newborn infant with patent sutures, the head expands. After the sutures are closed, increased intracranial pressure is more severe and can be potentially life-threatening.

The majority of children with meningomyelocele (75%) also have hydrocephalus. However, hydrocephalus often occurs in the absence of meningomyelocele. Hydrocephalus can either be present at birth (congenital hydrocephalus) or can be acquired. In general, most congenital cases of hydrocephalus are multifactorial with a recurrence risk of 4%. Congenital hydrocephalus has a prevalence of 10:1,000 in preterm infants and 1:1,000 in term infants. It is higher in preterm infants because of the higher incidence of intraventricular hemorrhage in small premature infants. A rare (1/30,000 males) X-linked recessive form of congenital hydrocephalus is associated with congenital stenosis of aqueduct of Sylvius (Rosenthal, Joulet, and Kenwick 1992.) This form of X-linked hydrocephalus is the result of mutations in the L1CAM gene, which encodes the L1 protein, a protein involved in neuronal cell adhesion. Patients with this mutation have hydrocephalus, agenesis or hypoplasia of corpus callosum and corticospinal tracts, mental retardation, spastic paraplegia, and adducted thumbs. (Weller and Gartner 2001).

**Figure 25.2** Illustration of Chiari II malformation

Hydrocephalus can be classified as communicating or obstructive. Causes of communicating hydrocephalus include obstruction of the subarachnoid space (following intracranial hemorrhage or infections), developmental failure of arachnoid villi, and excessive CSF production (from a choroid plexus tumor). Obstructive hydrocephalus results from aqueductal stenosis, mass lesions that block the flow of cerebrospinal fluid (neoplasms, cysts, hematomas, aneurysms), or obstruction of the fourth ventricle (Dandy Walker malformation, arachnoiditis).

The Chiari II (previously known as Arnold-Chiari) malformation is frequently associated with meningocele above the sacral level (Griebel, Oakes, and Worley 1991; Rauzzino and Oakes 1995) (Fig. 25.2). This malformation involves the downward displacement of the medulla and cerebellar tonsils through the foramen magnum. Three different types varying in severity have been identified. Type II is typically associated with meningocele and involves the herniation of the medulla, cerebellar tonsils, and vermis through the foramen magnum. The fourth ventricle is at the level of the foramen magnum. In the Type II Chiari malformation, aqueductal stenosis is also present and results in hydrocephalus. In the most severe type of Chiari malformation (type III), the fourth ventricle is displaced below the foramen magnum. Type II and III Chiari malformations result in dysfunction of the medullary outflow cranial nerves.

Using folic acid to prevent meningocele and its associated hydrocephalus and preventing germinal matrix-intraventricular hemorrhage in the premature newborn [which leads to communicating hydrocephalus (Volpe 1989)] (See Chapter 23 on Prematurity) are two strategies to prevent the occurrence of hydrocephalus in newborns. Strategies to prevent germinal matrix-intraventricular

hemorrhage include prevention of premature delivery, antenatal corticosteroids, avoidance of prolonged labor, avoidance of hemodynamic disturbances, prevention of respiratory distress syndrome and its complications (Roland and Hill 2003), and drainage, irrigation, and fibrinolytic therapy after intraventricular hemorrhage occurs (Whitelaw et al. 2003)

Neurosurgical repair of the meningocele in utero has been shown to decrease the severity of the Chiari malformation and the need for shunting for hydrocephalus (Tulipan et al. 2003). However, no effect on lower extremity functioning or bowel and bladder impairments has been found (Tubbs et al. 2003). The National Institutes of Health currently is conducting a randomized study of prenatal surgery in three sites to evaluate the effects of this intervention (NICHD 2004). Earlier attempts at prenatal treatment of hydrocephalus by shunting the fetus were disappointing. Newer technologies such as prenatal magnetic resonance imaging may improve this intervention, however (von Koch et al. 2003).

### Neurological Impairments Associated With Meningocele

The primary neurological abnormalities of meningocele are paralysis, loss of sensation, variable bladder and bowel dysfunction, and Chiari II malformation with associated hydrocephalus. Although most people think only of the spine when they hear the term “spina bifida,” the malformation leading to meningocele affects the entire CNS (Dahl et al. 1995; Gilbert et al. 1986).

A variety of malformations of the brain are associated with meningocele. These include defective myelin-

ization of the brainstem, and neuromigrational anomalies of the cortex and cerebellum (Gilbert et al. 1986). Subcortical abnormalities, including beaking of the colliculi and complete or near-complete fusion of the thalami, are also commonly observed (Gilbert et al.). Agenesis of the corpus callosum commonly occurs in meningomyelocele and can be complete or partial (Barkovich, 2000). This is believed to be a manifestation of the underlying defect in neuronal migration that is associated with spina bifida. In one neuropathological study (Gilbert et al.), 92% of children with meningomyelocele had abnormal migration of cortical neurons, 72% had cerebellar dysplasia, 20% had hypoplasia or aplasia of cranial nerve nuclei, 16% had fusion of the thalami, and 12% had agenesis of the corpus callosum. In a series of MRI studies, Kawamura and colleagues (2001, 2002) found partial agenesis of the corpus callosum, hypoplasia of the cerebral hemispheres, polymicrogyria, heterotopic gray matter, as well as cervicomedullary anomalies, such as herniation of the cerebellar tonsils through the foramen magnum. Other areas of the spinal cord may be involved above the site of the meningomyelocele (for example, syringomyelia), resulting in additional motor and sensory impairment (Dias and Pang 1995).

Not surprisingly, these cerebral anomalies are likely to result in an array of cognitive impairments. Abnormalities of the corpus callosum are negatively related to intelligence (Barf et al. 2003). The corpus callosum provides an important pathway for communication across different parts of the brain. It also contributes to the development of cerebral specialization of language, nonverbal skills (e.g., spatial cognition), and other cognitive skills (Hannay et al. 1999). Children with meningomyelocele who have abnormalities of the corpus callosum have been found to have impaired nonverbal skills (Hannay et al.).

Involvement of the cranial nerve nuclei controlling ocular movements results in strabismus, which is observed in 20% of children with meningomyelocele (Griebel 1991; Lennerstrand, Gallo, and Samuelsson, 1990). Related to the Chiari malformation is an array of symptoms reflecting compromise of the medulla and cranial nerves at that level—difficulty swallowing, choking, hoarseness, breath-holding spells, apnea, stridor and disordered breathing during sleep, upper extremity spasticity, and opisthotonos. Rare sudden deaths from cardiorespiratory arrest related to the Chiari malformation have been reported (Charney et al. 1987; Kirk, Morielli, and Brouillette 1999).

It is important to screen children with meningomyelocele for sleep problems. Disordered breathing during sleep, including apnea, occurs in individuals with meningomyelocele, and has been called “the missed diagnosis” by some (Kirk et al. 1999). It can be the result of obstructive sleep apnea, central apnea, or central hypoventilation (Kirk et al. 2000). Disordered sleep can cause children to be tired during the day, and interfere with their ability to function in school. A formal sleep study can help differentiate between the many problems a child may be having that can cause

disordered breathing during sleep (e.g., upper airway obstruction from enlarged tonsils and adenoids).

Children with meningomyelocele exhibit impairments of many of the functions associated with abnormalities of the cerebellum. Cerebellar dysfunction results in impairments of balance, coordination, motor performance, and sequential motor learning (Van Mier and Petersen 2002). However, it is now recognized that the cerebellum plays an important role in a broad range of cognitive functions (Leiner et al. 1991). The neocerebellum projects to and receives projections from dorsolateral prefrontal cortex (Middleton and Strick 1994). These structures are activated simultaneously during performance of different types of cognitive tasks (Berman 1995; Nagahama 1996). Cerebellar dysfunction appears to result in dysregulation (dysmetria) of response in both the cognitive and emotional realm (Schmahmann 1998). Gao and colleagues (1996) demonstrated that the cerebellum is engaged during the acquisition and discrimination of sensory information. The right posterolateral cerebellar hemisphere assists the left cerebral hemisphere in generating specific types of spoken word associations (Gebhart et al. 2002). Individuals who have had resection of part of the cerebellum secondary to brain tumors have been identified as having a unique syndrome called *cerebellar cognitive affective syndrome*, characterized by impairments in executive function (including planning and sequencing), visual–spatial function, expressive language, verbal memory, and modulation of affect (Levisohn et al. 2000; Riva et al. 2000).

Hydrocephalus affects a number of brain functions. As cerebrospinal fluid accumulation increases, the ventricles increase in size, leading to thinning of the cerebral mantle. This mainly affects white matter and disrupts myelination in the young child, particularly in the posterior regions (Del Bigio 1993). The pathway containing the motor fibers to the legs arises from the medial area of the frontal lobes and descends along the lateral margins of the lateral ventricles. As the ventricles become increasingly dilated, these fibers are stretched and result in spastic paraparesis. In severe, untreated hydrocephalus, the child may be quadriplegic.

Paralysis of upward gaze may also occur with increased intracranial pressure. If the child is shunted promptly (often in the newborn period), there is often dramatic improvement in the spastic paraparesis and ocular abnormalities. In the older child with closed sutures, shunt failure may result in the typical symptoms of increased intracranial pressure—headache, visual dysfunction, spastic paraparesis, and disturbance of consciousness. Tables 25.1 and 25.2 list some abnormalities of the brain and associated findings in children with meningomyelocele.

Epilepsy develops in approximately 15% of individuals with meningomyelocele (Noetzel 1989; Talwar, Baldwin, and Horbatt 1995). The seizures usually are generalized tonic–clonic and respond well to antiepileptic medication. Rarely, a blocked shunt or shunt infection may precipitate seizures.

<i>Brain</i>	
Chiari II malformation	Abnormal swallowing Vocal cord paralysis Apnea, hypoventilation Spasticity of upper extremities Hydrocephalus Sudden death
Hydrocephalus	Stretching of periventricular corticospinal fibers Thinning of corpus callosum Complications of shunting (e.g., ventriculitis) Disruption of myelination Disruption of optic tracts Impaired visuomotor dexterity and visuospatial skills Precocious puberty
Dysgenesis of corpus callosum	Impaired nonverbal skills Disordered pragmatic language skills
Dysgenesis of cerebellum	Impaired balance, coordination, motor performance and sequential motor learning Decreased discrimination of sensory information Cerebellar cognitive affective syndrome (see text)
Abnormal cranial nerve nuclei	Strabismus
Unknown	Epilepsy
<i>Spinal Cord</i>	
Primary Lesion	Motor paralysis Sensory loss Bowel and bladder dysfunction Tethered spinal cord
Split cord lesions (including diastematomyelia)	Neurological deterioration
Spinal cord atrophy	Neurological deterioration
Syrinx (syringomyelia, syringobulbia, hydromyelia)	Neurological deterioration

### Associated Medical Conditions

#### Motor Paralysis and Sensory Loss

Some of the associated impairments that occur with meningocele are shown in Figure 25.3. Motor paralysis and sensory loss occur below the level of the defect in the spinal cord. For example, children with lesions at the thoracic or high lumbar (L1 or L2) level have paralysis of the legs and weakness and sensory loss below the waist, while children with sacral lesions usually have only

mild weakness of their ankles or toes and loss of sensation in the perineum and on their feet. The motor paralysis leads to problems with mobility, contractures, and osteoporosis with pathological fractures. More serious impairment of mobility occurs in children who have meningocele above the sacral level. The higher the level of the meningocele, the greater the muscle weakness, the more ambulation will be impaired (McDonald 1995). For example, children with L3 level often require crutches and bracing up to the hip. Children with thoracic or high-lumbar paralysis may eventually stand upright and walk, but only with support of the hips, knees, and ankles. This support may be provided by extensive bracing and/or mobility devices such as a parapodium (Liptak et al. 1992), reciprocal gait orthosis (Guidera et al. 1993), or hip-knee-ankle-foot orthosis used in combination with crutches or a walker (Mazur et al. 1989). As children approach adolescence and their center of gravity and relative strength change, even those with mid-lumbar level lesions will increasingly rely on wheelchairs for mobility. Paralysis and muscle imbalance around a joint can lead to contractures. For instance, club-foot and other deformations, such as calcaneus deformity, are commonly noted at birth and are related to the lack of normal innervation and resultant fetal immobility. Hip flexion contractures and acquired deformities around the knee, ankle, and foot are common in older children.

Almost 90% of children with meningocele above the sacral level have scoliosis and/or kyphosis. Scoliosis and kyphosis may be congenital or acquired, and may be related to abnormalities of the vertebral bodies, such as hemivertebrae or butterfly vertebrae, to abnormal muscle balance (the muscles act like guy wires on a telephone pole), or to tethering of the spinal cord (see subsequent discussion). The higher the lesion, the more likely the deformity. If untreated, spinal deformities may eventually interfere with sitting and walking and decrease vital capacity. Kyphosis is usually located in the lumbar spine and may be severe at birth. Like scoliosis, it is more common with higher lesions and may progress over time.

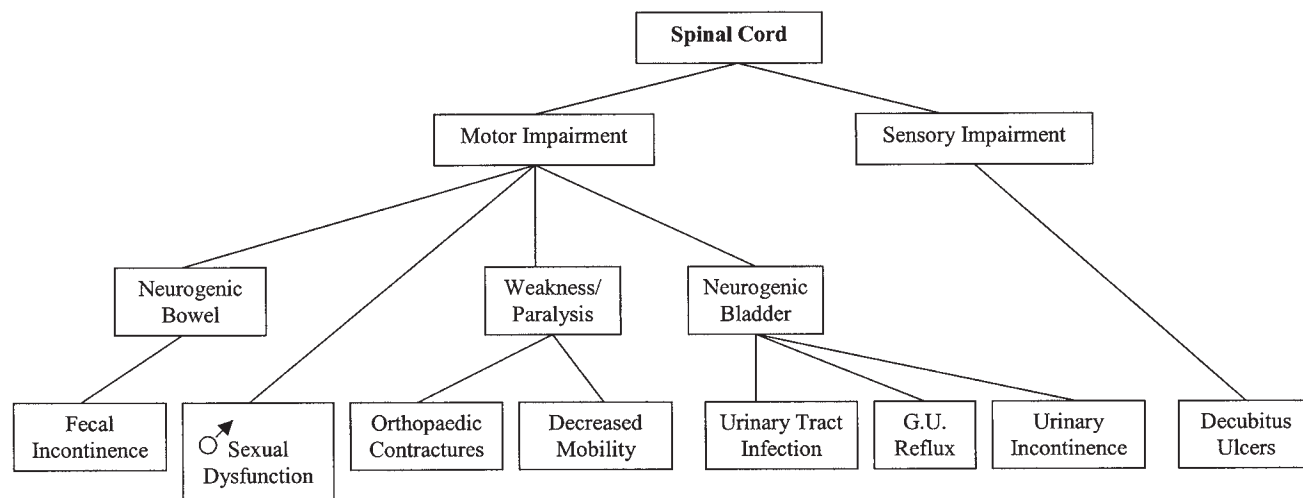

Lacking normal sensory input and the ability to shift position when pressure over a bony prominence becomes uncomfortable, decubitus ulcers are likely to develop in individuals with meningocele. Insensate skin often leads to injuries that would not happen if pain perception was normal (e.g., cutting the bottom of the foot while swimming) and can also lead to lesions that are hard to heal. Individuals who use wheelchairs for extended periods may develop pressure sores on the buttocks or coccyx. Problems with skin breakdown become more frequent during adolescence. The ulcers often resist healing and require extensive treatment because of impaired circulation, continued pressure, contamination by stool and urine, and secondary bacterial infections. Deep decubiti may lead to osteomyelitis of underlying bones.

**TABLE 25.2****SELECT CONDITIONS ASSOCIATED WITH MENINGOMYELOCELE, THEIR EVALUATION AND TREATMENT**

<b>Urogenital System</b>			
<b>Age</b>	<b>Conditions</b>	<b>Possible Tests</b>	<b>Possible Treatments</b>
Newborn/Infant	Hydronephrosis	Renal ultrasound	Intermittent catheterization Vesicostomy
	Urinary reflux	Voiding cystourethrogram	Prophylactic antibiotics Intermittent catheterization Vesicostomy
	Elevated intravesical pressure	Urodynamics	Intermittent catheterization Vesicostomy
	Urinary tract infection	Urine culture DMSA renal scan	Antibiotics
	Renal dysfunction Renal dysgenesis (e.g., horseshoe kidney)	Serum BUN, creatinine, urinalysis Renal ultrasound	Any of the above
Preschool School Age	Infancy issues + continence	Above + urodynamics	Same as above
	Preschool issues + hypertension	Same as above + blood pressure monitoring	Urinary diversion (e.g., appendicovesicostomy)
Adolescence	Female precocious puberty	Serum FSH, LH testing Bone age determination	Leuprolide
	School age + Male sexual function	Same as above	Same as above + sildenafil and others
	Female sexual function		Birth control
<b>Musculoskeletal System</b>			
<b>Age</b>	<b>Conditions</b>	<b>Possible Tests</b>	<b>Possible Treatments</b>
Newborn/Infant	Foot/ankle deformities (e.g., club foot)	Radiograms	Serial casting Surgery
	Hip dislocation	Hip ultrasound or radiogram	Abduction orthosis surgery
	Kyphosis	Radiograms	TLSO
Preschool	Above + hip and knee contractures or rotational deformities	Radiograms	Surgery Above + lower extremity bracing (e.g., HKAFO or RGO, or parapodium)
School age	Impaired mobility		Mobility device
	Diminished range of motion		Therapy, orthotics
Adolescence	Above + scoliosis	Above + MRI scan	TLSO
Adolescence	Same as above	Same as above	Surgery Same as above
<b>Neurological System</b>			
<b>Age</b>	<b>Conditions</b>	<b>Possible Tests</b>	<b>Possible Treatments</b>
Newborn/Infant	Open lesion on back		Antibiotics Closure of lesion
	Hydrocephalus	MRI or CT scan Cranial ultrasound	Ventricular-peritoneal or subgaleal shunt
	Chiari malformation	Cranial MRI or ultrasound Sleep study Pharyngogram (swallow study) Visualization of vocal cords	Posterior fossa decompression
	Spinal cord malformations	Spinal MRI	Surgery
Preschool	Epilepsy	EEG	Anticonvulsants
	Above + spinal cord tethering (minus open lesion)	Cystometrogram Spinal MRI	Surgical untethering
	Ventricular shunt malfunction	Manual muscle strength testing Cranial CT, ultrasound or MRI Shunt tap	Shunt revision
School age	Same as above	Neuropsychological testing	
Adolescence	Same as above	Same as above	Same as above

BUN, blood urea nitrogen; CT, computed tomography; DMSA, dimercaptosuccinic acid; EEG, electroencephalogram; FSH, follicle-stimulating hormone; HKAFO, hip-knee-ankle-foot orthosis; LH, luteinizing hormone; MRI, magnetic resonance imaging; RGO, reciprocating gait orthosis; TLSO, thoraco-lumbar-sacral orthosis.

**Figure 25.3** Impairments found in meningomyelocele

### Genitourinary and Bowel Dysfunction

Because the bladder, urethra, external rectal sphincter, and perineal sensation are all controlled by sacral nerves, bladder and bowel dysfunction are present in virtually all children with meningomyelocele. Even children with sacral lesions and normal leg movement typically have bladder and bowel problems. Neurogenic bowel causes fecal incontinence and is associated with constipation. Neurogenic bladder is associated with numerous urological and medical problems. Not infrequently, these children also have malformations of the kidneys, including horseshoe and absent kidney (Hulton et al. 1990). There are different patterns of bladder dysfunction; some children with meningomyelocele have patulous sphincters and are chronically incontinent. Others have tight sphincters and develop large, distended bladders with increased intravesicular pressure, leading to ureteral reflux, hydronephrosis, and kidney stones, and recurrent bouts of infection. If untreated, irreversible renal damage can result. The management of urinary incontinence depends on the specific type of bladder dysfunction, which cannot be predicted by the level of lesion. Urinary tract infections are extremely common in this population. Bladder augmentation surgery, which is one of the surgical treatments, is associated with a small risk for bladder cancer (Game et al. 1999; Shaw and Lewis 1999). Although most children with meningomyelocele are born with normal kidneys, careful urological evaluation and continuous monitoring is required to prevent damage to the kidneys. Renal failure is not uncommon in adults with meningomyelocele who have not received adequate urological management (Muller, Arbeiter, and Aufricht 2002).

Although 75% of postpubertal males with meningomyelocele are able to have erections (Diamond, Rickwood, and Thomas 1986), most are achieved reflexively by stimulation rather than in response to psychogenic stimuli (Dik et al.

1999; Sandler et al. 1996). Erections are related to level of sensory deficit, with males who have affected sacral level having more erections than those with affected thoracic or lumbar levels. Therefore, their ability to have unaided sexual intercourse from sexual stimulation is limited. In addition, males frequently have retrograde ejaculation, which further limits their reproductive capacity. Cryptorchidism occurs in 15 to 25% of boys with spina bifida (Greene et al. 1985; Meyer and Landau 1984). Many postpubertal women with meningomyelocele are able to experience orgasm during sexual intercourse. However, they typically have decreased genital sensation and less sexually stimulated lubrication. As a result, intercourse without adequate lubrication can lead to vaginal sores.

Precocious puberty (defined as Tanner stage 2 breast or pubic hair development before age 9.2 years) is common in females who have meningomyelocele with hydrocephalus, and less common in females with isolated hydrocephalus (Elias and Sadeghi-Nejad 1994). This is likely due to hypothalamic dysfunction (Perrone et al. 1994). In one study, the incidence of precocious puberty in girls with meningomyelocele was at least 52%. Girls with precocious puberty appeared to have a history of increased intracranial pressure in the perinatal period, greater motor and urological dysfunction, and more shunt revisions than girls in whom precocious puberty did not develop (Proos et al. 1996).

### Tethered Cord

Tethering of the spinal cord may be present at birth in children with little external evidence of spinal dysraphism or can occur after closure of the primary meningomyelocele defect. As the child grows, the spinal cord, which is bound down by adhesions or congenital fibrous bands, becomes increasingly stretched which results in progressive ischemic damage to the cord. Lower extremity

weakness, new contractures, sensory deficits, pain, and bowel and bladder function can occur quite insidiously and ambulation and daily living skills may deteriorate. There may be a rapid progression of scoliosis. Tethered cord syndrome occurs in 3 to 15% of patients with a history of repaired meningocele (Phuong, Schoeberl, and Raffel 2002). Even after surgical repair of the tethering, a significant percent of children will have recurrent or new symptoms consistent with tethering.

### Other Medical Issues

Individuals with meningocele with thoracic to L2 lesions are at increased risk for obesity in part as a result of their decreased activity and energy expenditure (Polito, et al. 1995; Littlewood et al. 2003). However, Fiore and colleagues conducted a study of anthropometric measurements and dietary adequacy in a group of 100 children. Forty of the 100 children and adolescents were classified as markedly overweight (body mass index above the 95th percentile). Five were classified as malnourished or at risk for malnutrition. Most of the obese subjects took in less than the expected recommended daily energy intake; only 25% had an energy intake appropriate for age and gender. The expected correlation between obesity and motor impairment was not found, whereas energy intake was correlated with body mass index. They concluded that obesity in this population resulted from a complex set of factors (Fiore et al. 1998). Obesity is unquestionably one of the several factors that adversely affect mobility and social opportunities, which may in turn contribute to increased inactivity and further weight gain. The medical complications of chronic obesity are an additional problem.

About one third of children with meningocele are short as a result of growth hormone deficiency (Fiore et al. 1998). Untreated children with meningocele and short stature achieve an adult recumbent height falling one standard deviation or more below the mean. Treatment with growth hormone results in an increase of recumbent height into the average range as well as reducing body mass index significantly, thus diminishing the problems associated with obesity (Rotenstein and Breen 1996; Rotenstein and Bass 2004).

An allergy to latex, including anaphylaxis, develops in between 40 and 60% of children with meningocele (Pearson, Cole, and Jarvis 1994; Dormans et al. 1995). The risk of latex allergy increases with age (Mazon et al., 2000) and frequency of surgical procedures (Ellsworth et al., 1993).

### Cognition

Early studies of children with meningocele born before routine ventricular shunting for hydrocephalus showed a high rate of mental retardation among survivors (Foltz and Shurtleff 1963; Laurence and Coates 1962; Shurtleff, Foltz, and Loeser 1973). As ventricular shunting

became more widespread, the occurrence of mental retardation decreased (Brookshire et al. 1995; Fletcher et al. 1992b, Wills et al. 1990). However, even today, children with meningocele who have had an episode of shunt infection (ventriculitis) have significantly lower scores on intelligence tests, often in the mentally retarded range, have more seizures, higher future risks of shunt infection and malfunction, and perform more poorly in school (McLone 1992; Kanev and Sheehan 2003). Some studies have found that frequent shunt revisions have a negative effect on IQ (Mazur et al. 1988; Holler et al. 1995; Hunt et al. 1999; Dennis and Barnes 2002), although others have not replicated this finding (Ralph et al. 2000).

On standard tests of intelligence, children with meningocele and shunted hydrocephalus typically perform worse on performance than on verbal scales, with a verbal performance gap of 0.5 to 1.5 standard deviations (Hurley et al. 1983; Wills et al. 1990; Brookshire et al. 1995; Casari and Fantino 1998). Most studies of cognition in children with meningocele have involved school-aged children. The cognitive profile of preschool children and adults with meningocele are not well understood. Some studies of young adults have shown the same pattern of higher verbal than performance scores on intelligence tests (Dennis and Barnes 2002; Hommet et al. 1999). There is significant variability in intellectual status of children with meningocele, which may be related to genetic as well as medical factors, including the severity of the hydrocephalus, the number of shunt revisions, and the extent of cerebellar dysfunction. As is true of children without meningocele, socioeconomic status is a factor affecting performance on cognitive tests (Bier et al. 1997).

Yeates and colleagues (2003) found that about half of children with meningocele have a cognitive and behavioral profile typical of nonverbal learning disability, described by Myklebust (1975) and Rourke (1989). Children with this syndrome have deficits in tactile and visual perception, complex psychomotor skills, and in dealing with novel circumstances (Rourke et al. 2002). They demonstrate strengths in verbal and auditory abilities (although they have difficulty grasping the pragmatic aspects of language), but have weaknesses in nonverbal areas. Impairment in motor coordination, visual attention, visual-spatial perception, flexibility, abstract thinking, executive function, organizational skills, and generalizing what they have learned (Fletcher et al. 2002).

Children with meningocele have impairments in executive functioning that are similar to those with nonverbal learning disabilities. (Dise and Lohr 1998; Brewer et al. 2001; Fletcher et al. 1996; Mahone et al. 2002). Executive function skills include planning future activities, organizing, inhibiting competing (inappropriate) responses, self-regulation, remembering rules, initiating tasks, and remembering to remember an activity. These children do better thinking in a linear fashion rather than in gestalt terms, and have difficulty with context. Children with nonverbal

learning disabilities have difficulty learning new concepts, especially in novel situations; they rely extensively on previously learned rote information; and adapt poorly to new situations, which affects their ability to learn. Their information processing tends to be unimodal rather than intermodal (Rourke et al. 2002). Metacognitive skills (e.g., mental flexibility, mental efficiency, learning from experience, and conceptual sophistication) are more affected than behavioral inhibition (Mahone et al.). Executive function impairment may make it very difficult for the individual with meningocele to reliably perform necessary daily self-care activities. They may not consistently remember what daily self-care tasks must be performed in what sequence (e.g., understanding the importance of catheterizing on time and the importance of checking for and preventing pressure sores as well as understanding the consequences of failure to do so) (Russel 2004).

Associations between nonverbal skills and MRI findings have been found. For instance, Fletcher and colleagues (1996) found that children with hydrocephalus who had proportionately greater posterior than anterior cerebrospinal fluid percentages had significantly poorer visuomotor dexterity and visuospatial skills than those who had normal percentages of cerebrospinal fluid. Some children with meningocele may have only a few of the features of nonverbal learning disabilities while others may have many severe deficits in the nonverbal learning disability spectrum.

### Attention Deficit–Hyperactivity Disorder

Davidovitch and colleagues (1999) reported that 39% of children with meningocele have some form of attention deficit disorder (most commonly the inattentive type) and about 30% of these children showed a clinical response to methylphenidate; although a small sample, double-blind placebo-controlled study was not informative. Other children may be inattentive and have poor organizational skills, but not have true attention deficit–hyperactivity disorder (ADHD) (Shaffer et al. 1985). In one study (Loss et al. 1996), children with myelomeningocele showed deficits across all four elements of attention (encode, focus/execute, sustain, and shift) compared to their siblings. It can be difficult to differentiate primary ADHD from attention deficits that are secondary to other neurological impairments in children with meningocele, which result in problems with alertness and arousal (Brewer et al. 2001). Their inability to integrate, organize, and interpret information, especially when they try to accomplish unfamiliar tasks, may reflect impaired executive function.

### Language

Children who survived severe, unshunted hydrocephalus were often described as having “cocktail party syndrome” (Tew 1979; Tew and Laurence 1979; Hurley et al. 1990). This refers to the tendency of these children to chatter on

about topics in a superficial, nonmeaningful or inappropriate way. They may use and repeat memorized common phrases, such as, “Hello, how are you today?” or, “What’s up?” They may be able to repeat parts of a story that they have heard without really understanding what the story means. Typically, the content of these verbal expressions is absent or trivial at best. Thus, these children, as well as those who are less affected by hydrocephalus, have difficulty deriving meaning from context (Barnes and Dennis 1998).

Children with meningocele often demonstrate adequate linguistic skills, with appropriate form and structure; yet they too frequently display deficits in semantic-pragmatic skills. As a result, their expressive language often lacks substance and is poorly matched to the communicative context as in the cocktail party syndrome. Studies of school-age children with meningocele have shown that although they use and understand single words, they have difficulty using language in a flexible and adaptive manner (Dennis and Barnes 1993; Dennis et al. 1994; Fletcher et al. 2002). Thus, many children with meningocele have problems with the construction of meaning and in pragmatic communication. They may have deficits in several different aspects of oral discourse, including establishing alternative meanings to ambiguous sentences, understanding figurative expressions, making inferences, and producing speech acts (Dennis and Barnes 1993). In a study of narrative discourse in 100 children with hydrocephalus, Dennis and colleagues (1994) noted that their narratives tend to be less coherent and cohesive than a control group. They conveyed less content, included more ambiguous or implausible material, and were more verbose and less economical in quality.

### Academic Achievement

Children with meningocele often meet discrepancy criteria for learning disability (defined as low academic achievement that is unexpected based on the child’s overall cognitive abilities). Of course, in some cases, the lower level of academic achievement is in line with the IQ.

Several studies have shown that children and adolescents with meningocele perform more poorly than their typically developing peers on measures of intelligence and/or achievement, and are more likely to receive special services, or repeat a grade (Appleton et al. 1994; Fowler et al. 1985; Friedrich et al. 1991; Jacobs et al. 2001; Tew and Laurence 1984). Their learning difficulties often are not particularly apparent in the earlier grades (Rowley-Kelly and Reigel 1993). However, fine motor skill deficits often impair the child’s performance in the early years of elementary school because of their difficulty using scissors, holding a pencil, tying shoelaces, and buttoning buttons. In the later school years, writing is a challenge (Barnes et al. 2002; Dennis and Barnes 2002; Pearson et al. 1988).

A fairly consistent finding in school-age children is deficient performance in arithmetic, which is again reminiscent

of a nonverbal learning disorder. They typically perform more poorly on standardized math tests than do children without spina bifida, and perform more poorly in arithmetic than in language-based tasks, such as reading and spelling. Weak number skills, delays in the ability to count or seriate, can be observed as early as 36 months of age and persist into adulthood (Wills et al. 1990; Dennis and Barnes 2002). The presence of a shunt has been associated with lower IQ scores and lower mathematics scores in some studies (Kalucy, Bower, and Stanley 1996).

Visual-spatial difficulties can make learning certain aspects of mathematics such as geometry a major challenge. Similarly, problems with estimation and the ability to solve word problems are associated with problems in visual-spatial integration (Barnes et al. 2002). These students also have short-term memory impairment, manifested in difficulty with list learning (Cull and Wyke 1984; Yeates et al. 1995; Scott et al. 2003). Children with meningomyelocele also evidence impaired procedural skills that persist to adulthood (Dennis and Barnes 2002). They also have diminished speed of retrieval (efficiency).

The difficulty that children with meningomyelocele experience in academic environments increases as they progress through school. Although they have relatively good mechanical reading skills and, therefore, do not appear to have as much difficulty in this area as they do in arithmetic, when the academic tasks begin to require the ability to comprehend text and make inferences, their difficulty in reading comprehension interferes with their ability to perform (Barnes and Dennis 1992). Moreover, the language difficulties described previously make it hard for them to adequately formulate abstract and coherent verbal responses and written material. They are less likely to advance to postsecondary education than children without meningomyelocele. In one study, 34% of affected children involved in postsecondary education compared to 47% of the general population and were 1 to 2 years delayed in educational attainment compared to age-matched peers (Bomalaski et al. 1995). In another study of 48 adults with meningomyelocele, only seven were attending college. Achievement and IQ scores as well as measures of language and visual-spatial ability differentiated those who attended college from those who did not (Hurley and Bell 1994).

Meningomyelocele may affect academic performance in several ways. First, it has an obvious direct effect on cognition. Second, it is associated with increased absences from school for reasons that may include acute illnesses, visits to health professionals, inappropriate health beliefs and perceptions of vulnerability, and worsening of chronic symptoms. Medical and neurological problems may contribute directly to poor performance in school. Shunt malfunction may present with subtle symptoms including worsening academic performance. Anticonvulsants and anticholinergic medications (used to help manage bladder function) can lead to lethargy and adversely affect school per-

formance. The young child may be absent because of frequent hospitalizations and elective and emergency surgeries. Children with meningomyelocele are pulled out of regular classroom academic sessions for physical therapy and occupational therapy, and for catheterization and other medical procedures. Even today, some children experience restricted or delayed school attendance because of inaccessible school facilities (lack of handicapped access); they often cannot negotiate a flight of stairs or walk with braces and crutches rapidly enough to get to their next class on time (Wasson et al. 1992). They may have to go to another building for therapy, losing significant time from classroom activities. School facilities often do not provide adequate privacy for toileting and self-catheterization and in some settings, trained personnel to assist younger children with catheterization are lacking.

### Social Abilities

Children with meningomyelocele have been found to be socially immature and passive, more isolated, more dependent on adults, and less likely to make independent decisions than children without meningomyelocele (Blum et al. 1991; Holmbeck et al. 2003). Successful social interactions require abilities in verbal pragmatics, social-problem-solving skill, social memory, as well as the ability to predict consequences. For an individual with a nonverbal learning disability, the interpretation of social cues such as facial expressions and body language can become a major problem and lead to confusion and social rejection. Difficulty with visual attention and failure to understand nonverbal cues lead to difficulty interpreting behavior. Although children with meningomyelocele may be talkative, they often interrupt and have difficulty entering conversations correctly.

### Neuropsychiatric Aspects of Meningomyelocele

Studies of self-concept in children with meningomyelocele are equivocal. Some (MacBriar 1983; Murch and Cohen 1989) failed to show a difference between children with meningomyelocele and controls. Others, however, have found significant differences (King et al. 1993; Kazak and Clark 1986; Appleton et al. 1994; Zurmohle et al. 1998). In a recent study, children with spina bifida were found to have lower self-concept than controls. This was particularly true for girls. Furthermore, urinary continence was associated with a more normal self-concept (Moore, Kogan, and Parekh 2004). In a related study, children who had a Malone antegrade colonic enema implanted surgically reported increased self-reliance, independence and a feeling of security, which led to significant improvement in self-esteem (Aksnes et al. 2002.) These results suggest that better continence is associated with better self-concept.

Many children with myelomeningocele face a daunting challenge in terms of having any control over their

environment. In the preschool years, they are often required to undergo repeated surgery (orthopedic, urological, and neurosurgical, when a shunt revision is required). They may spend months in a cast, which effectively immobilizes them. They must deal with pain and the preoccupation with symptoms that often accompany spina bifida. In elementary school, they are notably “different” from the other children, and often must deal with their inability to participate in games with peers and understand academics at the level of their peers. This in turn leads to diminished expectations and lower self-esteem. When a child is able to ambulate with crutches and braces, their energy expenditure is substantial and they must struggle with fatigue. Moreover, their impaired executive function often makes the world appear even more complex. All of this results in a decreased sense of self-efficacy (Mobley, Harless, and Miller 1996) and these children often develop “learned helplessness,” believing that their efforts to change the environment are ineffective. This limits their willingness trying to perform academically or to reach out socially (Peterson, Maier, and Seligman 1993). In adolescence, the awareness of their potentially impaired sexual functioning becomes an issue. Not surprisingly, children with meningocele, particularly girls, are at increased risk for depressive mood, low self-esteem, self-blame, and suicidal ideation. Effective parental support tends to be a moderating variable, especially in girls (Appleton et al. 1997).

## MANAGEMENT OF THE INFANT AND CHILD WITH MENINGOMYELOCELE

The birth of an infant with meningocele requires a very rapid assessment by a team of physicians. Within 2 days after birth, assuming that the infant is medically stable, the neurosurgeon repairs the back lesion, and in many cases if there is any evidence of hydrocephalus, a shunting procedure is performed at the same time or shortly thereafter. If a shunting procedure is not required at that point, the baby will be closely monitored because of the high probability that hydrocephalus will develop. The baby is also evaluated by the urologist and the orthopedic surgeon. When the infant is being managed in a center with a meningocele team a team member meets with the parents and reviews the implications of a meningocele, explains the surgical procedures and the need for close monitoring. Parents need a great deal of support during this period and it is helpful to them to have a trusting relationship with the physicians and nurses who care for the infant.

### Developmental Interventions

Because children with meningocele have multiple impairments that affect development, and are at increased risk for developmental disabilities, they are likely to benefit from

an Early Intervention program (typically from birth to age 3 years). Interventions include physical and occupational therapies, speech therapy, and special educational services. No scientific evaluations of the effectiveness of these early interventions in this population have been conducted to determine the optimal combination of therapies. When the child turns 3 years of age, other programs, typically through the local school district become available. They also should have a formal psychoeducational evaluation before school entry to identify their capabilities, strengths, and weaknesses. This will allow modifications of the school environment and the development of an individualized education program (IEP) (Rowley-Kelly and Reigel 1993).

The Individuals with Disabilities Education Act (IDEA), Public Law 102-119, provides children with meningocele with improved access to educational services in the least restrictive environment. IDEA entitles children with disabilities ages 3 to 21 to a free, appropriate education. Related services must be paid for by the school. A related service is any additional service that is needed to allow the child to benefit from instruction, and includes transportation, audiology, recreation, school health services, psychological services, physical therapy, occupational therapy, speech and language therapy, catheterization, assistive technology, and social work services. Parents have the right to question placement decisions and the right to due process to settle differences. Two criteria have to be met for a child to qualify under IDEA: (1) that the child has a disability, and (2) that special education services are necessary to address the disability. Children who have meningocele can be classified as having a disability under IDEA in several different ways, including the categories “learning disabled,” “orthopaedically impaired,” or “other health impaired.” The second criterion can be met if any aspect of the disability has a negative impact on any aspect of participation in the general curriculum, including academic, behavior, communication, vocational skills, basic life skills, social skills, and physical needs.

If a child with meningocele does not qualify under IDEA, then Section 504 of the Rehabilitation Act of 1973 can provide access to services. This regulation states that no qualified person with a handicap shall be excluded from participation in any program or activity that receives benefits from federal financial assistance. Under this legislation, a child does not have to be enrolled in special education or eligible under IDEA to receive related services from a school. However, parents have fewer rights and children receive fewer services under Section 504.

Strategies to address disorders of cognition in school include remediation (additional instructional time or different instructional approaches to “fix” a certain area of weakness and build strength in a particular area to facilitate potential learning) and compensation (alternative approaches [e.g., assistive technology] to offset, or counterbalance, a learning disability and produce the desired level of performance). For example, in a child who has problems

with executive function, remediation methods could include the following: develop the child's self-awareness of his or her impairments, model the desired behavior (e.g., talking quietly to oneself to solve a problem), review tasks to be completed, use organizers, and outline materials to be learned. Compensatory strategies include providing routine, using checklists, timetables, and teaching coping strategies, such as asking the teacher to slow down or explain a topic again (Tanguay, 2002).

Strategies have been developed to improve social skills, which are as important for well-being as academic and other skills. A number of strategies that have been used include: interventions for parents (Duke et al. 1996), social skills curriculum (McAfee 2002), in vivo coaching, social stories (comic strip conversations), didactic teaching about social skills and emotions, group-based interventions, and peer mentorship (e.g., circle of friends).

In the "circle of friends," children are put in a structured peer network with scheduled time and shared activities. There they can practice various activities together; for example, observing a movie or television show with the sound muted while they try to determine what emotions the actors are portraying. They then practice showing those emotions. They can also play games like liar's bluff, act out specific characters and practice telling jokes. These complex social interactions are broken down by their coach into more discrete activities like eye contact, tone of voice, body language, choice of words, turn-taking, transitions from subject to subject, and so on.

Many references are available to help with social skills training, including the Skill-Streaming series (McGinnis and Goldstein 2000). These books emphasize classroom survival skills, friendship-making skills, dealing with feelings, alternatives to aggression, and dealing with stress. A few case series have examined the effectiveness of these interventions (Minskoff 1980a, 1980b; Loomis et al. 1994; King 1997; Barnhill 2002). However, few, if any, studies have scientifically evaluated these techniques for children who have meningocele.

# Pediatric Brain Tumors

26

*David L. Kaye, MD Patricia K. Duffner, MD*

Brain tumors are the most common solid malignancy of childhood, second only to the leukemias in overall incidence. Most cases are diagnosed before patients are the age of 10 years, although over one third of cases are diagnosed in adolescence. The incidence of childhood and primary brain tumors both benign and malignant is 3.9 cases per 100,000 person-years. The rate is somewhat higher in males (4.2 per 100,000 person-years) than females (3.8 per 100,000 person-years). The Central Brain Tumor Registry of the United States estimated that 3,260 new cases of pediatric brain tumors would be diagnosed in 2004, more than two thirds of which are malignant (Central Brain Tumor Registry of the United States 2002). More than 26,3000 children were living with the diagnosis of a primary brain tumor in the United States in the year 2000; over 80% of these children have malignant brain tumors. The chance of survival of children with brain tumors has increased dramatically over the past 30 years. In the 1960s, a child diagnosed with a brain tumor had approximately a 15% 5-year survival rate. By 1975, 5-year survival rates approached 50%. The most recent 5-year survival rate for children diagnosed before 19 with a primary malignant brain tumor was 64% (Central Brain Tumor Registry of the United States 2002–3).

Most of the changes in survival from 1960 to 1975 were primarily due to advances in surgery, intensive care treatment, and radiation techniques. Further improvements in these areas, as well as the advent of chemotherapy for certain tumors, have led to continued increases in longevity. In addition, there has been a philosophical change in the approach to many children with brain tumors. When the anticipated survival rate was only 15%, concerns over the potential adverse longterm effects of therapy were meaningless. Now that many children will be longterm survivors, attention has been increasingly directed toward quality-of-life issues. As such, today, pediatric neurologists, oncologists, radiation therapists, neurosurgeons, neuropathologists, pediatricians, psychologists, psychiatrists,

and endocrinologists are all an integral part of the team approach to the child with a central nervous system (CNS) malignancy.

## **CLASSIFICATION OF BRAIN TUMORS**

The classification of brain tumors has evolved throughout this century. Currently, the most widely accepted classification is that of the World Health Organization (WHO) (Kleihues et al. 2002). It is a complicated schema that is based primarily on cell type (e.g., astrocytes, embryonal cells, oligodendroglia, ependymal, mixed), with multiple variants based on histological features. The most common types of brain tumors in children are astrocytoma, medulloblastoma, ependymoma, brainstem glioma, and craniopharyngioma (Table 26.1). Glioma is a general term referring to any neoplasm deriving from interstitial tissue cells of the nervous system (e.g. astrocytes, ependymal cells, oligodendrocytes). As such, ependymomas would be a type of glioma. Glioblastoma multiforme, a particularly devastating tumor, is synonymous with grade IV astrocytoma. While most adult brain tumors are metastatic and supratentorial, pediatric brain tumors are typically primary and more varied in location. Often, the literature will refer to the grading of the tumor based on the degree of anaplasia (i.e., “low grade” vs. “high grade,” or grades 1 to 4, with 4 being most anaplastic). Location may also be specified. For example, astrocytomas can originate in the cerebral hemispheres, brainstem, or cerebellum. Although medulloblastomas almost always are located in the cerebellum, histologically similar tumors are occasionally seen in other locations. To describe these latter tumors, it has been proposed by some that medulloblastomas and other histologically similar tumors be referred to as primitive neuroectodermal tumors (Dehner 1986; Fung and Trojanowski 1995; Yachnis 1997). However, the most recent WHO classification distinguishes medulloblastoma from supratentorial primitive neuroectodermal tumors.

**TABLE 26.1**  
**INCIDENCE AND 5-YEAR, 10-YEAR SURVIVAL RATES FOR SELECTED PEDIATRIC (0-19) BRAIN TUMORS**

Tumor Type	Incidence (as % of all PBT's)	5-yr Survival	10-yr Survival
Pilocytic astrocytoma	26	95	92
Embryonal/medulloblastoma	20	55	48
Astrocytoma, NOS	8	77	73
Ependymoma	8	55	47
Glioblastoma	4	19	16
Craniopharyngioma*	4	90+	85
Anaplastic astrocytoma	3	52	47
TOTAL	100	64	60

## PRESENTING SIGNS AND SYMPTOMS

Neuropsychiatric symptoms rarely bring the child with an unsuspected brain tumor to a psychiatrist as the first medical contact. The child with symptoms of brain tumor much more commonly will present with either nonlocalizing signs and symptoms reflecting increased intracranial pressure, or localizing signs reflecting either compression or infiltration of surrounding brain. Typically, the parents report coincident personality and/or cognitive deterioration. Diagnosis is commonly delayed for a number of months after parents note presenting symptoms. Three studies have documented that the mean time to diagnosis of a pediatric brain tumor is 20 to 28 weeks (Flores et al. 1986; Edgeworth et al. 1996; Mehta et al. 2002) with infratentorial tumors being recognized earlier than supratentorial ones.

### Nonlocalizing Neurological Symptoms

Symptoms associated with increased intracranial pressure are headache, nausea and vomiting, and personality change (Child Brain Tumor Consortium, Keene 1999, Mehta 2002). Nearly 80% of children with a brain tumor will present with headache or nausea/vomiting; typically all three symptoms appear together. Unlike children with migraine, in whom there is a crescendo/decrecendo pattern to the headaches with symptom-free intervals, the child with a brain tumor will frequently complain of a steady increase in both the frequency and the intensity of the headaches over time. The exception to this is the very young child with a brain tumor. The typical history is of a 2- or 3-year-old child who repeatedly wakes in the morning with severe headache and vomiting. The pediatrician may suggest that this is due to a flulike syndrome and that the child should be observed. Indeed, the symptoms are evanescent and resolve after 1 or 2 weeks. Unfortunately, several weeks later the symptoms recur with increased intensity, and the diagnosis of an intracranial mass lesion is made. This biphasic pattern reflects the ability of the

young child's skull to expand to accommodate the increasing intracranial pressure. The ability of the sutures of the skull to separate occurs in young children but is not often seen after the age of 5 years.

Warning headache symptoms, according to Medina et al. (1997, 2003), that should raise the index of suspicion of a mass lesion are those that:

1. wake the child from sleep or occur first thing in the morning;
2. are associated with confusion, disorientation, or abnormal neurological findings;
3. are consistently focal in location;
4. increase with Valsalva maneuvers;
5. less than 6 months' duration that do not respond to medical treatment;
6. are associated with nausea and vomiting, especially if family history is negative for migraine.

Nausea and vomiting are also important symptoms of the child with a brain tumor. The vomiting either tends to occur secondary to increased intracranial pressure or may reflect direct involvement of the floor of the fourth ventricle. Projectile vomiting is relatively uncommon.

Personality change and worsened school performance are sensitive indicators of structural CNS disease and occur with tumors in all locations. Lethargy, apathy, irritability, or depression are commonly reported. At times, these symptoms may be the first sign of a mass lesion (see subsequent discussion).

### Nonlocalizing Neurological Signs

Nonlocalizing signs of increased intracranial pressure include papilledema, sixth nerve palsy, and an expanding head circumference. Although it is often difficult to evaluate the young child's optic fundus, such evaluation is an essential part of the examination of the child who presents with headache. Papilledema is associated with normal

visual acuity, but longstanding papilledema will lead to optic atrophy and a consequent decline in vision. At times, papilledema must be differentiated from papillitis. The child with papillitis will have visual loss and a central scotoma, whereas the child with papilledema will have normal central vision but an enlarged blind spot.

Diplopia in children with brain tumors is usually secondary to an abducens nerve palsy. Cranial nerve VI has a very long free intracranial course. Therefore, when a mass lesion increases the intracranial contents of the brain, cranial nerve VI may be compressed against various bony prominences, with the pressure causing a paralysis of abduction. This is a nonlocalizing sign and does not necessarily suggest the true location of the tumor. Diplopia may also occur in children with palsies of cranial nerve III and cranial nerve IV, but these occur less frequently.

The young child will rarely complain of double vision. If the child enters the office closing one eye or turning the head, the physician must be suspicious that diplopia is present. As the image moves into the involved field, the images will separate. The child will close one eye to eliminate the double image or will turn the head such that the nose will obscure the image of the other eye.

### Localizing Neurological Signs and Symptoms

Other than the nonspecific signs of increased intracranial pressure, children with brain tumors will present with signs and symptoms referable to the location of the mass lesion (i.e., cerebral hemispheres, midline, and posterior fossa).

#### Cerebral Hemispheric Location

The most common supratentorial hemispheric tumors are astrocytomas, anaplastic astrocytomas, and glioblastoma multiforme. Other tumors occurring in this region include oligodendrogliomas, meningiomas, and cerebral primitive neuroectodermal tumors. Children with hemispheric tumors typically present late with increased intracranial pressure, because pressure symptoms tend to occur secondary to tumor bulk rather than to obstruction of cerebrospinal fluid (CSF) pathways. Localizing signs and symptoms of tumors in this location include headache, seizures, hemiparesis, hemisensory loss, and hemianopsia. When present, a focal headache is highly correlated with tumor localization, although generalized headaches are more common.

Supratentorial tumors are often epileptogenic in nature. Seizures tend to occur more frequently with slower-growing tumors such as oligodendrogliomas and low-grade astrocytomas than with higher-grade tumors such as glioblastoma multiforme. In those cases of children with seizures in whom an initial evaluation has been negative for a mass lesion, if after several years there is a change in the frequency or the quality of the seizures, a change on electroencephalogram (EEG) pattern from spike to slow wave, or a change in neurological examination and/or change in behavior or school performance, the child must

be reevaluated. A previously unrecognized hamartoma may have dedifferentiated into a malignant lesion. It should be emphasized, however, that most children with seizures do not have an underlying malignancy.

Other signs of hemispheric mass lesions further reflect the site of involvement (e.g., hemiparesis, hemisensory loss, and/or hemianopsias). Hemipareses in this context are usually more subtle than those occurring following a stroke; a drift of the arm, a pronator sign, or a slight dragging of the leg may be all that is identified on careful neurological examination. Indeed, one of the most striking characteristics of some children with large supratentorial mass lesions is the relative lack of symptoms.

#### Midline Location

Midline tumors include optic pathway and hypothalamic tumors (typically pilocytic astrocytomas), as well as craniopharyngiomas and pineal region tumors. This latter group ranges from the highly malignant pineoblastoma to the radiosensitive and chemosensitive germinoma. Children whose tumors involve the optic pathway present with visual loss, visual field abnormalities, or, in the case of tumor involving the optic chiasm, nystagmus. The last-mentioned symptom may at times be confused with congenital nystagmus or spasmus nutans. Hypothalamic and pituitary involvement may produce a variety of endocrinopathies, including precocious or delayed puberty, diabetes insipidus, hypothyroidism, weight loss or gain, and growth failure. Children with tumors in the pineal region typically present with increased intracranial pressure, as well as Parinaud's sign (i.e., failure of upward gaze and disorders of accommodation and convergence secondary to compression of the quadrigeminal plate). Precocious puberty may occur in boys who have tumors in this location.

#### Posterior Fossa Location

Posterior fossa tumors include medulloblastomas, cerebellar astrocytomas, ependymomas, and brainstem gliomas. Most children with posterior fossa tumors present early with signs and symptoms of increased intracranial pressure due to obstruction of the aqueduct of Sylvius or the fourth ventricle. In addition, children with cerebellar tumors present with disorders of coordination that vary in character depending on location of the tumor. Children whose tumors are located in the midline of the cerebellum (vermis) present with truncal ataxia, whereas those children whose tumors are located more laterally in the cerebellar hemispheres present with dysmetria and dysdiadochokinesia. Nystagmus reflects brain-stem involvement. Other cerebellar signs include scanning speech, hypotonia, pendular reflexes, and skew deviation of the eyes.

Children with brain-stem tumors have ataxia, corticospinal tract signs, and cranial neuropathies, but increased intracranial pressure occurs either late or not at all. For example, depending on the location of the mass in the brain stem, the child may have an ipsilateral palsy of cranial nerve VI or cranial nerve VII with ataxia and contralateral

hemiparesis. Lesions of the lower brain stem tend to be associated with hypernasal speech, difficulty with swallowing, and dysarthria. Increased tone in the lower extremities with hyperactive reflexes and extensor plantar responses is commonly seen in children with pontine and medullary lesions. Personality changes are also typical.

### Neuropsychiatric Symptoms as Presenting Signs of Brain Tumors in Children

Despite the critical clinical importance of the pattern of presenting symptoms, research data on this question are limited. Psychiatrists especially would like to know how often children with brain tumors present with neuropsychiatric signs and symptoms only and a normal neurological history and examination. Furthermore, what patterns of symptoms are most likely suggestive of a brain tumor?

In one of the few studies, Keschnor and coworkers (1938) reviewed 530 cases of brain tumors in adults and noted that an early clinical indication of a tumor was a neuropsychiatric symptom in 18% of their patients with supratentorial tumors and in 5% with infratentorial tumors. A more recent study (Zaki et al. 1993) reviewed the presenting symptoms in 1,111 cases (mostly adults) with primary brain tumors. A "mental defect" was the sole presenting sign in 8% of the patients, and, overall, 19% of the patients had a normal neurological examination on presentation.

In the pediatric literature, Flores and coworkers (1986) reviewed the records of 79 children with primary brain tumors. In their series, 9% of the patients presented with a single symptom (including headache, vomiting, weight loss, or mood or behavioral changes) and normal neurological findings. No further description of the neuropsychiatric status was offered. The remainder of the patients had signs and symptoms of increased intracranial pressure or focal neurological deficits. Edgeworth and colleagues (1996) reviewed in more detail the presentations of 74 children with primary tumors. Although vomiting (65%) and headache (64%) were the most common presenting symptoms, neuropsychiatric symptoms were also common (52%), as was deterioration in school function (20%). It was not clear how frequently neuropsychiatric or neurocognitive symptoms were the sole presenting complaint, although on initial consultation the symptoms of 17% of the children were thought to have a psychological etiology. Keene (1999) reported that more than 50% of their series of 74 pediatric brain tumor patients exhibited behavioral changes. Mehta (2002) found that, in their Canadian series of 104 pediatric patients, 66% had nausea/vomiting, 63% headaches, and 50% had behavioral changes at presentation. Nearly 80% of their series presented with either headaches, nausea, or vomiting. Only one had behavioral changes as their sole presenting finding without other symptoms or neurological signs. This was a case presenting as anorexia nervosa but without the body image distortion

and fear of gaining weight so characteristically seen, much like the case series reported by Chipkevitch (1994).

Taken together, this literature would suggest that a significant but very small minority of patients present with broad neuropsychiatric symptoms and no other neurological findings.

The types of symptoms and psychopathology reported in association with brain tumors in children range widely. Although there are no large studies of the incidence of specific neuropsychiatric disorders in this population, there are case reports that describe psychosis (Caplan et al. 1991; Carson et al. 1997; Mordecai et al. 2000), depressive disorders, anorexia nervosa (Chipkevitch 1994; Weller 1982; Heron 1976), aggression (Nakaji 2003; Weissenberger 2001), obsessive-compulsive behaviors and obsessive-compulsive disorder (Caplan et al. 1992; Peterson et al. 1996; Shuren et al. 1995), school refusal (Overmeyer et al. 1992; Stein et al. 1996), learning disabilities, and deteriorations in school performance. In addition, in the adult literature, there are descriptions of mania (Binder 1983; Bourgeois et al. 1992; Starkstein et al. 1988), panic disorder (Filley and Kleinschmidt-DeMasters 1995), other anxiety disorders (Bristow 1991), and schizophrenia (Kan et al. 1989). Taken together, these cases demonstrate a wide variety of psychopathology associated with brain tumors in children and adults.

### Relationship of Tumor Type and Location to Symptoms

There are no data to suggest that the type of brain tumor has any relationship to specific symptoms, although many authors suggest that there is a relationship between the location of the tumor and the type of symptoms. The sparse literature that does exist on this issue relates primarily to adults and was reviewed by Price and coworkers (1992).

Affective syndromes and psychotic symptoms are not uncommon in frontal lobe tumors.

Temporal lobe tumors are often associated with psychosis or schizophrenia-like illnesses, nonspecific personality changes, anxiety symptoms, or mood disorders. Parietal and occipital lobe tumors are generally less likely to cause behavioral changes. Parietal lobe tumors appear to be more likely to result in neuropsychological difficulties (e.g., astereognosis, agraphesthesia, apraxias, dysgraphia, acalculia, finger agnosia, and right/left confusion). Occipital tumors are associated with visual hallucinations in a minority of patients. These hallucinations tend to be unformed images and only rarely are more complex and sustained. Diencephalic tumors typically involve regions that are part of or close to the limbic system. Consequently, neuropsychiatric symptoms are common. Schizophrenia-like illnesses, depression, nonspecific personality changes, and hyperphagia and/or anorexia nervosa (typically associated with hypothalamic tumors) have all been reported. Pituitary tumors generally present with endocrine abnormalities, but

neuropsychiatric symptoms are common as well. Posterior fossa tumors reportedly present less frequently with neuropsychiatric symptoms, although some series report otherwise. The symptoms are highly variable and do not differ from those of supratentorial tumors.

All in all, although tumor location plays a role in presenting symptoms, it is not a major factor. This is probably due to the widespread and complex connections between different areas of the brain disrupted by tumors. Other factors thought to be of greater significance in symptom generation include the extent of the mass, rapidity of growth, presence of increased intracranial pressure, premorbid neuropsychiatric symptoms, and psychological defenses.

## GUIDELINES FOR NEUROIMAGING

Although it is unusual for children to present with clear-cut neuropsychiatric syndromes and no neurological signs and symptoms, this does occur rarely. Typically these cases present in complex ways making it difficult to separate out effects of the tumor per se from life stress, family effects, genetic loading for neuropsychiatric disorders, other medical problems associated with the tumor (e.g., seizures, endocrine abnormalities), and treatment effects.

So where does this leave the clinician? What kind of neurological workup should be carried out on children with neuropsychiatric disorders? Very little has been written about this subject, and major textbooks generally do not address the issue. There is some discussion of this subject in the adult literature (Fillely et al 1995; Weinberger 1984), but findings in adults have limited utility for children and adolescents. We are in agreement with Ron (1989), who states that “to perform costly investigations for every psychiatric patient because of the rare chance of finding a brain tumour is unnecessary and wasteful. In this age of advanced technology, a detailed clinical history and a careful physical examination are still the best predictors of brain pathology” (p. 738).

This perspective is supported by the findings from two studies. Ghaziuddin and colleagues (1993) reviewed the CT scans of 122 child and adolescent psychiatric inpatients. Whereas 22% of these patients’ scans were abnormal, the vast majority were categorized as nonspecific or mildly abnormal. In only two patients were the findings grossly abnormal, and both of these patients had previously diagnosed brain tumors. In no patient was a change in the diagnosis or management made as a result of the CT findings. Adams and colleagues (1996) assessed the value of neuroimaging tests in 111 consecutively admitted adolescent inpatients with first-onset psychosis. None of the patients had abnormal EEGs, and 12% had abnormal CT scans. None of these positive test results identified an unsuspected medical disorder or made a difference in any patient’s clinical management. The authors concluded that

neuroimaging screening tests in first-onset adolescent psychosis have neither demonstrated diagnostic utility nor positive predictive value.

Ryan (1996), in a discussion of Adams and colleagues’ findings, concurs with and modestly expands their recommendations, as does Zametkin in his ten year review of the role of the laboratory (1998). The neurological literature also supports judicious use of neuroimaging (Lewis et al. 2002; Medina et al. 2003; Sudlow 2002). Combining all of these conclusions with our clinical experience, we suggest that neuroimaging screening to rule out brain tumors in the pediatric population be considered in the following situations:

1. New-onset neuropsychiatric disorder with focal neurological signs.
2. New-onset neuropsychiatric disorder with concomitant history of seizures, nausea and vomiting, visual disturbances, motor abnormalities, altered consciousness, or high-risk headaches (see subsection on nonlocalizing neurological symptoms earlier in this chapter).
3. New-onset neuropsychiatric disorder with positive family history of heritable medical condition or stigmata of known medical illness (e.g., neurofibromatosis).
4. First-onset psychosis with uncertain or unreliable medical history.
5. New-onset neuropsychiatric disorder associated with confusion or clear signs of neuropsychological deterioration.

## MEDICAL–SURGICAL TREATMENT OF BRAIN TUMORS

Surgery is the primary treatment approach to the child with a brain tumor. The goals of surgery are to remove the tumor, obtain a tissue diagnosis, reopen CSF pathways, and reduce mass effect. Advances in surgery, including development of the operating microscope, laser, and microsurgical techniques, have allowed the surgeon access to previously inaccessible parts of the nervous system. Even tumors located in the pineal region, brain stem, and midline can be surgically approached in most cases. Some tumors can be cured with surgical excision alone. These include cystic cerebellar astrocytomas, meningiomas, choroid plexus papillomas, and, in cases with severe visual loss, optic nerve tumors. Even if surgery alone is not curative, there is strong evidence to suggest that a gross total resection will measurably improve survivals in certain tumor types, most notably medulloblastoma and ependymoma.

Radiation is administered postoperatively in cases where surgical excision will not provide a cure. The volume of radiation (i.e., whole brain, local, or craniospinal) in these cases is determined by the tendency of the tumor to spread both locally and throughout the CSF pathways. As such, the child with a low-grade supratentorial astrocytoma

will receive local radiation, the child with a medulloblastoma (a tumor that tends to seed the CSF pathways) will receive craniospinal radiation, and the child with a glioblastoma will receive either whole-brain radiation or local radiation with wide ports. Newer techniques to reduce the volume of radiation include three-dimensional conformal radiotherapy. The dose of radiation varies. Children with medulloblastomas typically receive 3,600 centi-Gray units to the neuraxis and 5,500 centi-Gray units to the posterior fossa, whereas children with brainstem gliomas receive 5,500 centi-Gray units to the posterior fossa alone. In recent years, longterm effects of radiation on intelligence, learning abilities, and endocrine function have been described. These studies have led to modifications of both the dose and the volume of radiation for children with brain tumors, especially the very young. Even in older children, current national treatment protocols for medulloblastoma are reducing the amount of radiation to the brain and spinal cord while maintaining high-dose radiation to the primary tumor site. To do this safely, adjuvant chemotherapy is added. It is hoped that a reduction in radiation dose will be associated with comparable survival rates but fewer and less severe adverse effects on intelligence and learning. Whether this is true remains controversial (see section on Neuropsychological Functioning).

Over the past decade, chemotherapy has played an increasingly important role in the treatment of children with brain tumors. Chemotherapeutic agents have primarily been given postoperatively along with radiation, or alone at the time of tumor recurrence. The drugs are typically administered either intravenously or orally. Intrathecal therapy, such as methotrexate, may be associated with severe untoward side effects, and hence this route has been less popular in recent years. The most promising drugs to date include cyclophosphamide, *cis*-platinum and its analogues, etoposide, the nitrosoureas, and vincristine.

Chemotherapy has been the primary postoperative treatment modality for infants and very young children with malignant brain tumors, in whom issues of radiation toxicity have been of the greatest concern. Although results with chemotherapy are generally no better than those achieved with radiation, survival rates in certain tumor types appear to be comparable. It is hoped that the long-term effects of chemotherapy will be fewer and less severe than those associated with radiation to the infant brain.

## NEUROPSYCHIATRIC AND PSYCHOSOCIAL COMPLICATIONS OF BRAIN TUMORS AND THEIR TREATMENT

### Psychiatric Perspectives

As noted, there are numerous case reports and small case series documenting neuropsychiatric disorders in children presenting with brain tumors. We could find no study that

systematically documented neuropsychiatric disorders subsequent to presentation in the pediatric brain tumor (PBT) population. Although some studies do address the general issue of the psychosocial adjustment of children, specific definitions of disorder, dysfunction, or disability are generally lacking. Virtually all of the data from these studies are of a dimensional, as opposed to categorical, nature, and do not use Diagnostic and Statistical Manual of Mental Disorders (DSM) (or comparable) criteria for evaluation of the children. These studies used parent questionnaires and/or nonstandardized interview schedules to assess psychosocial adjustment. Standardized clinical or semistructured interview protocols have not been used.

As a backdrop to further discussion of this topic, it is worthwhile to remind readers of Rutter's Isle of Wight study (Rutter et al. 1970). Although Rutter did not look specifically at the impact of brain tumors on neuropsychiatric disorder, he did look at correlates of neurological disorders in general. In his large population sample of older latency-age children, he found the prevalence of neuropsychiatric disorder to be 7%. This contrasted with a prevalence of 12% in children who had nonneurological, chronic illness and 44% in children with a chronic illness involving the CNS. When these findings were further broken down on the basis of presence or absence of epilepsy, the results were even more striking. Nearly 60% of children with CNS involvement plus epilepsy had a neuropsychiatric disorder. Rates in those without epilepsy approached 40%. Overrepresented were cases of hyperactivity and pervasive developmental disorder in the children with neurological involvement. Thus, we know that CNS disease in general is associated with excess rates of neuropsychiatric disorder, and we might expect that this would also, or even especially, be so for children with brain tumors.

While there is no study that has addressed a population of children with brain tumors in this manner, there recently have been a few reports that take more of a psychiatric perspective. Meyer and Kieran (2002) retrospectively studied 34 "surgery-only" survivors of pediatric malignancies. These children had completed treatment from 2 weeks to 5 years prior to the study. The authors reviewed the data from clinical interviews done as part of their overall medical care and DSM criteria were used to establish whether or not a disorder existed. They found that 46% of their shortterm follow-up (less than 1 year) patients, and 29% of the longterm follow-up (more than 1 year), met criteria for dysthymia or major depression; similar numbers met criteria for a "disruptive disorder"; for anxiety disorders, less than 10% of both groups had a disorder (no different from population expectations). No patients reported suicidal ideation or acts. They concluded that large percentages of pediatric brain tumor patients show psychiatric morbidity in the short and long term. While there have been no other studies in children using DSM criteria, Wellisch (2002) also reported high rates (28%) of major depression in an adult sample of 88 consecutive brain tumor patients. With

respect to suicidal ideation and acts only a few studies have mentioned this, almost always reporting its striking absence. However, these studies typically report this as an incidental finding, and no studies have systematically investigated this issue. It would appear that suicidal ideation and acts are rare in this population but this remains to be confirmed. In another relevant study Ross and colleagues (2003) reviewed the records of all 3,710 Danes who had been diagnosed before the age of 20 and survived any type of cancer for more than 3 years. Using the files of the Danish Cancer Registry and the Danish National Psychiatric Central Register, they observed all cases for a mean of 15 years or until death. Of the entire cohort, 978 were survivors of brain malignancies. They found that while there was no increase in rates of psychiatric hospitalization for cancer survivors as a whole, the brain tumor survivors had over a twofold increase in expected rates of hospitalization (nearly 9% of them had been hospitalized). Exposure to radiation treatment did not increase the risk for hospitalization, although the psychiatric discharge diagnoses suggested elevated rates of schizophrenia and psychotic disorders. This echoes the findings of Loganovsky and Lganovskaja (2000) who, in a population sample study, suggested increasing rates of schizophrenia in those exposed to the Chernobyl accident. The possibility that brain tumors or its treatments might further compromise a genetically vulnerable individual has been suggested by these studies. Aside from these few studies there is no literature that has documented rates of psychiatric disorders or morbidity in the pediatric brain tumor population. While it can be speculated that survivors of pediatric brain tumors would have elevated rates of attention deficit-hyperactivity disorder, mood disorders, and schizophrenia among others, these studies have not been done.

### Psychological and Health-Related Quality of Life Perspectives

Although there are few studies of pediatric brain tumors from a neuropsychiatric perspective, there is a substantial literature addressing “psychosocial” or “health-related quality of life” issues for this population (Fuemmeler et al. 2002). Psychosocial studies generally use standardized parent or teacher questionnaires such as the Child Behavior Checklist (CBCL) or PIC to measure levels of emotional distress, “at risk” or clinical status. These measures have typically been included in broader evaluations of the overall status of survivors, and few studies have queried or observed the children directly. Health related quality of life studies use brief (e.g. 15 question) interview schedules that tap into overall impairment in multiple domains or attributes (e.g. sensory, mobility, emotion/mental health, cognition, self-care, pain). These are complementary perspectives and will be discussed together in this section. These studies are summarized in Table 26.2.

In a study addressing the acute reactions of children with cancer, Mulhern and colleagues (1993) compared the psychosocial status of 81 children with brain tumors and, as a control, 31 children with other types of cancer (mostly acute lymphocytic leukemia). The children in the two groups were 9 and 12 years of age, respectively, and were evaluated within 3 months of their diagnosis. Psychosocial adjustment was measured with the CBCL list. They found that approximately 75% of each group had clinical elevations on at least one subscale of the CBCL and that approximately 20% of both groups scored above the clinical cut-off for total behavior scores on this instrument. There were no differences between the two groups. In this acute phase, the authors noted that 70% of the children with brain tumors had significant cosmetic disfigurement, compared with 23% of those with other types of cancer. They also noted that nearly half of the children with brain tumors had substantial neurological deficit (vs. 4% of those in the control group). Stuber and colleagues (1998) suggested that the acute response to pediatric cancer can be understood from a perspective of post traumatic stress disorder (PTSD) symptoms. These authors suggest that while a full PTSD syndrome is not normative, many children respond to cancer as a repeated trauma and report PTSD symptoms. The model may also apply to parents’ responses. In the only study in patients with pediatric brain tumors to date, Fuemmeler and colleagues (2001) evaluated the families of 19 pediatric brain tumor survivors for PTSD symptoms. They found that 43% of the parents, 7 years after diagnosis of the disease in their child, met criteria for PTSD. Their symptoms were deemed to be in the moderate to severe range, somewhat lower than for other acute stressors (e.g. rape, combat, accident/fire). In summary, this work suggests that in the immediate aftermath of diagnosis, the majority of children with brain tumors show considerable psychological distress. It also suggests that the rate of psychological disorder is elevated, but no more so than in children with other types of cancer. Posttraumatic stress models may help to explain the child’s and parents’ emotional experiences in the short and perhaps long term.

Other studies have addressed longer-term psychosocial adjustment and quality of life of children with brain tumors. A number of studies have examined these issues in the intermediate term (less than 5 years follow-up), generally using the CBCL or PIC. Earlier studies of mixed tumor types found rates of psychological/behavioral morbidity of 42 to 64% (Kun and Mulhern 1983; Mulhern and Kun 1985; LeBaron and colleagues 1988). More recent studies (Mulhern et al. 1994; Slavc et al. 1994; Fossen et al. 1998) found rates of clinical emotional problems in 25 to 62% of school-age survivors. Three other studies used mean CBCL scores to measure psychological adjustment but did not report numbers of patients meeting clinical cutoff scores. Radcliffe and colleagues (1996) evaluated 38 children 2 to 5 years after diagnosis using CBCL (parent and teacher reports) and selected additional self- and parent-report questionnaires. They

<sup>j</sup>Hc = hydrocephalus.

found that mean scores did not differ significantly from test norms. In distinction, Mabbott (2005) obtained CBCL and TRF scores for 53 pediatric brain tumor subjects 3 years after diagnosis. All subjects had posterior fossa tumors and had received radiotherapy. They found that scores for internalizing, social, and attentional problems were elevated 0.5–1 standard deviation above the norm. Carlson-Green (1995) used a similar strategy reporting mean CBCL results for 63 pediatric brain tumor cases 4 years after diagnosis (age 11). Even though the mean scores represented almost one standard deviation above population norms, the results did not reach statistical significance. They noted that family dysfunction, but not illness or treatment factors, predicted clinical emotional/behavioral problems. In summary most, but not all, studies of younger children a few years postdiagnosis report high percentages of survivors with emotional problems.

From a different vantagepoint, a number of researchers have taken a health related quality of life perspective. Barr (1999), using the Health Utilities Index, evaluated 44 patients with pediatric brain tumors at 9.5 years of age (diagnosed at 6). They found that 27% had an emotional disability. In a parallel study using the HUI, Glaser and colleagues (1999) found that 60% of the 30 survivors (age 6 at diagnosis; 10.5 when evaluated) had an emotional disability. In a slightly longer follow-up, Foreman (1999) used the HUI to evaluate 52 patients with pediatric brain tumors at 16 years of age, 8 years after diagnosis. Thirty-five percent had an emotional disability. These health related quality of life studies, as well as that of Jenkin (1999), have reported that relatively few children (4 to 20%) have no deficits in any areas evaluated and that the majority have problems in two or more attribute areas, most notably in the areas of cognition and emotional health. Surprisingly, these studies noted that many (20 to 35%) of the children also experienced significant pain; many (roughly 20%) had sensory deficits, ambulation difficulties, and cosmetic problems. Up to one third had significant neurological sequelae. Taken together, these studies suggest that in the intermediate run, the majority of children face multiple difficulties, especially in cognitive and emotional realms.

Numerous studies have examined longer-term follow-up of patients with pediatric tumors into adolescence (Danoff et al. 1982; Hoppe-Hirsch et al. 1990; Packer et al. 1987; Seaver et al. 1994; Spunberg et al. 1981). Rates of emotional/behavior disorder ranged from 35 to 47%. Hoppe-Hirsch and colleagues (1990) reported that 78% of their patients were disturbed at 10-year follow-up, but there was large attrition, and only 13 patients were included in that analysis. In a study using more detailed psychosocial evaluation, Seaver and colleagues (1994) evaluated 18 patients with posterior fossa tumors. Mean age at diagnosis was 6 years; mean age at follow-up was 15 years. The study used a variety of self-report and parent-report measures (i.e., CBCL, Youth Self Report [of the CBCL], Symptom Checklist-90, and Adolescent Psychosocial Inventory) and a structured clinical interview

(Washington Structured Psychosocial Review). On each individual measure, scores for 25 to 40% of the survivors were in a clinical range, and only 56% of the cohort had normal psychosocial adjustment. Foley and colleagues (2000) compared CBCL results in 29 patients with hypothalamic or optic chiasm tumor with 29 other pediatric brain tumor patients. Results were obtained at 12.5 years old, 6 years after diagnosis. While the two groups did not differ in their scores, 38% of the entire cohort scored in a clinical range for an internalizing disorder and 24% for an externalizing disorder. Unlike Carlson-Green (1995), they found no relationship between family functioning and behavior problems. Syndikus and colleagues (1994) reviewed 156 cases of children diagnosed with a variety of different types of brain tumors diagnosed at a mean age of just under 3 years. Mean age at follow-up was 16 years. Of the 57 survivors, nonspecific emotional or behavioral problems were reported by the parents in 33% of the cases. Generally, these difficulties appeared to be of a depressive nature, but no standardized measures or diagnostic approaches were utilized. In distinction to these reports, Carpentieri (2003) studied 32 pediatric brain tumor patients 5 years after treatment. At a patient mean age of 14.5 years, the Behavioral Assessment System for Children (BASC) was administered to the children, parents, and teachers. While 5 to 15% of the children reported themselves to be in an “at risk” range, this was not significantly different from the standardization sample. Parents and teachers rated problem areas much higher (10 to 20% scoring in an at risk range), and this was especially true for attentional problems and somatization. This discrepancy between informants may reflect neurologically based cognitive deficits, emotionally based denial, situational differences, or other factors. Regardless, when evaluating the literature it is critical to note the informant used.

A few studies have observed survivors of pediatric brain tumor into adulthood, but few have looked at psychological functioning. Mostow and colleagues (1991) followed up 342 pediatric brain tumor survivors at a mean age of 32 years and found that 23% of survivors with supratentorial tumors and 10% of those with infratentorial tumors had an emotional problem. This represented an odds ratio of 19.8 and 2.5, respectively, as compared with matched sibling controls. Lannering and colleagues (1990) described the follow-up status, at a mean age of 19 years, of a group of mixed tumor patients who had survived for a mean of 10 years. The patients in the group had received relatively little radiotherapy. Using a nonstandardized interview, the authors found that 14% had an emotional disorder. In by far the largest study, Zebrack and colleagues (2003), as part of the Childhood Cancer Survivor Study, administered the Brief Symptom Inventory to over 1,100 pediatric brain tumor survivors and 2,817 sibling controls. Unfortunately, this instrument asks about symptoms in the past 7 days only. Study participants were 26 years old at the time. Mean scores were found to be within normal limits, although 11% scored “at risk” versus 5% of sibling controls.

## Social Functioning

Some investigators have addressed the social functioning and difficulties of children with brain tumors. In the immediate aftermath of diagnosis, children's lives are highly disrupted with frequent absence from school and other social activities. Over the next years many have observed changes in social relationship patterns. Earlier studies utilized parent-report CBCL as the measure of social competence and did find a decrease in social competence (Carpentieri et al. 1993; Fossen et al. 1998; Radcliffe et al. 1996). In two of these studies (Carpentieri, Fossen), pediatric brain tumor patients were compared to children with other, nonCNS cancers and found to be functioning significantly worse. Two other studies using parent report measures have confirmed social difficulties. Carpentieri (2003) studied 32 adolescents and young adults diagnosed between 2 and 15 years of age. At a mean age of 14.5, they administered the BASC to parents, teachers, and the youth. While the survivors reported no social problems, the parents endorsed significant problems in leadership. Foreman (1999) evaluated 52 pediatric brain tumor patients with a modified Health Utilities Index completed by mothers. In their study 67% showed evidence of a social impairment. All of these studies are consistent with the review of social competency of neurologically impaired children by Nassau and Drotar (1997). In this review of relevant studies of children with epilepsy, cerebral palsy, and spina bifida, they concluded that there was evidence that these children had lowered social competence compared with healthy children and with chronically (nonCNS affected) ill children. Like the above studies, however, the nature of the social difficulty was unclear. The findings could reflect cognitive deficits (i.e., non-verbal learning disability), sensory deficits, emotional impairments, cosmetic or physical infirmities, or fewer social opportunities.

In an effort to address the mediators of this social deficit, Noll and colleagues (1992) compared results of the Revised Class Play in 15 pediatric brain tumor survivors with 26 children with nonCNS cancer patients, and 16 with sickle cell disease. In the Revised Class Play, children and teachers "cast" classmates in an imaginary play to tap social reputation. While the sickle cell and nonCNS tumor patients were rated similarly to their healthy classmates, the brain tumor sample was described as significantly more sensitive-isolated. In more recent work, this same group (Vannatta et al. 1998) tried to further delineate the nature of the social difficulties. They studied 28 pediatric brain tumor survivors and compared them with 28 matched nonchronically ill classmate-controls. They evaluated these children 3 years after diagnosis (at mean age 14) using multiple teacher, peer, and self-rated sociometric measures. The measures included the Revised Class Play, Three Best Friends, in which children are asked to nominate their three best friends; and the Liking Rating Scale, which generates an average "liking" scale for each child in the class. Results

revealed that the brain tumor survivors were significantly more socially isolated and sensitive, missed more school, and were less frequently nominated as a "best friend." These studies suggest that the social deficit is not merely due to fewer opportunities. One group (Barakat et al. 2003) has attempted to provide a social skills training intervention for pediatric brain tumor survivors and found that a small to medium effect size was attained. More approaches like this can be expected in the future.

## School Functioning and Educational Attainment

Because of concerns about cognitive decline (see subsequent section), it has been assumed that pediatric brain tumor survivors would have widespread school and academic problems. Four studies have looked at school behavior and three (Radcliffe et al. 1996; Glaser et al. 1997; Carpentieri et al. 2003) found that pediatric brain tumor survivors do not show excess behavioral problems in the school setting when compared to age mates. In a smaller study Fossen (1998) used the same Teacher Report Form to compare 16 children with brain tumors and 15 nonirradiated children with acute lymphocytic leukemia. They found that the children with brain tumors had higher total problem scores, although less than 20% were rated in a clinical range.

Many children with brain tumors require special educational services. Early studies (Kun and Mulhern 1983; Mulhern and Kun and Mulhan 1985; LeBaron et al. 1988; Mulhern et al. 1994; Radcliffe et al. 1996; Slavic et al. 1994) used small numbers and documented figures from 22 to 60% requiring these services. Recently, as part of the Childhood Cancer Survivor Study, Mitby and colleagues (2003) surveyed 12,430 survivors (at least 5 years) of childhood cancer and 3,410 sibling controls for utilization of special education services. Among this group were 1,637 brain tumor survivors. While the study showed elevated rates of special education for all cancer survivors (23%), the rates for brain tumor survivors was over 50%, nearly a sevenfold increase versus siblings (8%). Seventy percent of those diagnosed before the age of 5 years required services. Radiotherapy, and the combination of radiotherapy with intrathecal methotrexate, elevated risk substantially. Females were more vulnerable than males.

With respect to educational attainment, a number of longterm studies have documented lesser achievement for survivors of pediatric brain tumors. Earlier and smaller studies showed that most survivors graduate high school, although at lower rates than expected (Hays et al. 1992; Lanering et al. 1990; Mostow et al. 1991; Syndikus et al. 1994). Kelaghan (1988) retrospectively interviewed 2,283 long-term survivors (mean age of 33) of childhood cancer, 338 of whom were survivors of brain tumors. While the cohort as a whole graduated high school at the same rate as sibling controls (86%), the brain tumor patients did so at a significantly

lower rate (77%). They were also much less likely to enter college. Survivors with supratentorial tumors and those receiving radiotherapy fared worse, although nonCNS tumor patients who received radiotherapy did not differ from siblings suggesting a dose effect. In the large study previously cited, Mitby (2003) reported that 18% of 1,637 brain tumor survivors did not graduate high school as compared with 9% of sibling controls. Radiotherapy survivors had lower rates of high school graduation, although this was not statistically significant.

### Employment and Marital Status

Based on longterm follow-up studies into adulthood, it appears that many pediatric brain tumor survivors have deficits in these areas. Mostow and colleagues (1991) reviewed the quality of life in 342 cases of children who survived brain tumors a minimum of 5 years as compared with 479 sibling control subjects. The children were 11 years of age at the time of diagnosis, and the mean age at follow-up was 32 years. Fifteen percent of the brain tumor group had never been employed (vs. 1% of the control group). A majority of the men (56%) and 25% of the women had never married (compared with 9% of the male and 15% of the female sibling control subjects). Cranial radiotherapy increased the risk of never having been employed (21%). Syndikus and colleagues (1994) reviewed 156 cases of children diagnosed with a variety of different types of brain tumors at a mean age of just under 3 years. Of the 26 individuals who reached adulthood, 16 (61.5%) were able to work. Most were unable to live independently, and only one was married. Lannering and colleagues (1990) found that, compared with the control group subjects, survivors had a lower rate of employment (66 vs. 80%) and of marriage (17 vs. 45%). Hays and colleagues (1992) studied a large number of childhood cancer patients (mean age at follow-up was 33 years), of which 22 had had CNS tumors. Rates of employment and marriage were lower in the survivors who had had brain tumors than in those who had not had tumors affecting the CNS. As part of the Childhood Cancer Survivor Study, more recently Rauck and colleagues (1999) tracked over 10,000 childhood cancer survivors to a mean age of 26. Pediatric brain tumor survivors accounted for 1,403 of these survivors. Compared to the general population, rates of marriage were slightly lower for all cancer survivors but were much lower for the brain tumor survivors across the age span. In their early 20s the rate is 50% that of the general population. As survivors grow older, their rates slowly approach the norm, but even over age 40 the rates are lower (77 vs. 88%). Interestingly divorce rates are lower until over age 40 when survivors' rates surpass those of the general population (27 vs. 18%). Like earlier studies, this study found that the marriage deficit was larger for males than females. Langeveld and colleagues (2003) tracked 500 Dutch longterm survivors of childhood cancer. Results were com-

pared with a reference group of 1,092 persons with no cancer history. Substantially lower rates of employment and marriage were found in the group as a whole, but particularly for those with a history of CNS tumors. They were also more likely to live with their parents.

### Summary of Psychiatric and Psychosocial Literature

As described, many of the studies cited have had significant limitations (e.g., small numbers, large attrition, nonstandardized instruments, lack of a clinical or psychiatric perspective, cross sectional and retrospective in nature, and so forth) and are constructed so differently that it is difficult to compare studies and pool data. Despite these limitations, we can tentatively conclude the following regarding the psychiatric and psychosocial sequelae of pediatric brain tumors:

1. In the immediate aftermath, a large percentage of children with brain tumors show elevated levels of distress, but these levels appear to be no more than those for children in the midst of other catastrophic illness. Post-traumatic stress disorder may be a viable model for understanding patient and family experiences.
2. In the intermediate run (3 to 5 years), although a substantial minority of children with brain tumors have emotional or behavioral problems, the vast majority appear to be functioning adequately. In the longer term, difficulties continue, although still the majority appears to be without disorder. The majority of survivors have diminished quality of life and often have cognitive and emotional deficits; sensory, ambulation, self-care, neurological, and motor impairments are also common.
3. In adulthood, 12 to 33% develop significant psychological or emotional problems. Symptoms frequently mentioned are passivity, immaturity, withdrawal, shyness, depression, and anxiety.
4. Although there is sporadic mention of psychiatric disorders (rare cases of suicidal ideation Lannering et al. 1990; Seaver et al. 1994; "psychotic symptomatology", Kun et al. 1983, ADHD, Mulhern et al. 1994), little is known about rates or types of psychiatric disorder in the short or longterm. These issues have not been systematically investigated, although it appears that longterm survivors are at increased risk for psychiatric hospitalization.
5. While pediatric brain tumor survivors are not behavior problems at school they frequently require special education services. Need for these services is common, at roughly 50% of pediatric brain tumor survivors.
6. Whereas the majority of childhood brain tumor survivors, as adults, are able to work, a significant minority are unable to do so, and a larger number experience substantial interference at work as a result of associated neurological, cognitive, emotional, sensory, and motor deficits. There is a suggestion that many, as adults, are unable to live independently, but this is less clear.

7. It would appear that many survivors of childhood brain tumors, especially men, do not marry.
8. Elevated risk for psychosocial difficulties may be associated with the extent of the tumor (Mulhern and Kun 1985), neuroendocrine abnormalities (Syndikus et al. 1994), male gender (Mostow et al. 1991), physical disfigurement (Mostow et al. 1991), and a greater time from diagnosis to evaluation (Seaver et al. 1994). Although exposure to cranial radiotherapy is associated with significant decrements in cognitive functioning, it is less clear that such exposure is associated with psychosocial morbidity. Younger age at diagnosis and treatment is associated with an increased psychosocial morbidity in at least one study (Mostow et al. 1991), but other studies found no correlation.

### **LONGTERM EFFECTS ON NEUROPSYCHOLOGICAL FUNCTIONING**

The neuropsychological functioning of pediatric brain tumor patients has been the focus of more than 100 research and ten review articles (Anderson et al. 2001; Dennis et al. 1996; Duffner et al. 1995, 2004; Gamis and Nesbit 1991; Glauser and Packer 1991; Moore et al. 2005; Mulhern et al. 1983, 1992, 2003; Mulhern and Butler 2004; Mulhern, Merchant et al. (2004); Ris and Noll 1994) in the past 15 years. Clearly, there is a deterioration of cognitive function in longterm survivors of PBTs as suggested by these studies. Numerous risk factors have been considered to explain this decline and are discussed later in this section. The effects of radiotherapy have been the most intensely studied. Because much of the literature on the effects of radiotherapy has focused on patients with leukemia, we include this topic in the following discussion.

#### **Overall Functioning**

The impact of CNS therapy on the IQ of children with leukemia and brain tumors has been extensively studied since the mid-1970s. Most of the early research focused on those children with leukemia who did not have meningeal disease so that the effects of therapy could be assessed in otherwise neurologically intact children. Rowland and colleagues (1984) evaluated 106 children with acute lymphoblastic leukemia. The three treatment arms for CNS prophylaxis were (1) cranial radiotherapy, (2) intravenous plus intrathecal methotrexate, or (3) intrathecal methotrexate. Detailed neuropsychological testing revealed in this study, as well as in others, that children who had received radiation had significantly lower scores on both IQ tests and the Wide Range Achievement Test than did children who had not received radiation. Distractibility and memory deficits have also been identified in children with acute lymphoblastic leukemia who received radiation, particularly those treated in the first decade of life (Goff et al.

1980). Others have found that children who received radiation for leukemia have significantly worse IQ scores compared with their siblings, whereas children who did not receive radiation tend to score approximately the same as do sibling control subjects (Moss et al. 1981). Thus, although, superficially, many children who received radiation for acute lymphoblastic leukemia seem to function well in regular classes, more detailed evaluations reveal significant areas of weakness in intellectual function. The reader is referred to the review by Moleski (2000). Because of the consistency of these findings standard treatment of children with acute lymphoblastic leukemia without CNS disease no longer includes cranial radiotherapy. Instead they are treated with chemotherapy prophylaxis achieving similar survival rates. Although these chemical agents are not benign, it appears that they have less neurocognitive toxicity than cranial radiotherapy. In contrast, radiation remains an integral part of the treatment of children with brain tumors. Evaluating the effects of CNS treatment is much more difficult in children with brain tumors, because surgery, the presence of hydrocephalus, the neurological deficits caused by the tumor, the effects of chemotherapy, and associated seizure disorders and anticonvulsant therapy complicate interpretation of the results. In an attempt to focus on as homogeneous a group as possible, several investigators retrospectively evaluated children with posterior fossa tumors. It was found that 30 to 50% of the children who had received postoperative radiation (with or without chemotherapy) had IQs below 70 and that approximately 10 to 20% had IQs above 90 (Duffner et al. 1983; Hirsch et al. 1979; Raimondi and Tomita 1979). In our study of ten children with posterior fossa tumors, 50% of the patients had IQs below 80, and only 20% had IQs above 100. Of perhaps more concern, in the four children who had had intelligence testing in school prior to the diagnosis and treatment of the tumor, declines in IQ of at least 25 points were found following therapy. Even those children with IQs in the normal range required special educational help because of learning disabilities and attentional problems (Duffner).

Prospective analyses have produced somewhat different results than did the earlier studies. Carpentieri (2003) studied 106 mixed tumor patients at a mean age of 9.5 years, following surgery but before CRT. They found that in this window the group did show cognitive deterioration, especially on performance IQ subtests, reflecting slowed motor output, poor visuo-spatial processing, and decreased verbal memory. Interestingly the FS IQ was 105, VIQ 107, while PIQ 99. Although baseline testing was not available, this study suggests that cognitive changes occur prior to CRT but they appear to be mild. Beebe (2005) prospectively evaluated 103 children with cerebellar astrocytomas who received surgery only. Three months postoperatively the group showed a 4-point loss on FS IQ scores, suggesting that even without radiotherapy there is risk. In an early, longer follow-up study, Hoppe-Hirsch

and colleagues (1990) sequentially evaluated children with medulloblastoma at both 5 and 10 years posttreatment. Five years following treatment 58% of the 120 children had IQs above 80, whereas 10 years after treatment only 15% had IQs above 80. In a smaller, long term followup study, Maddrey evaluated 16 10-year survivors of medulloblastoma. All had received radiotherapy and 60% chemotherapy. At age 22 the mean estimated IQ was 75. Thus, the changes associated with CNS therapy appear to be progressive over a period of at least 10 years after treatment. These findings were confirmed in more recent studies (Ris et al. 2001; Palmer et al. 2001, 2003; Spiegler, 2004) that found that FSIQ decreased 2 to 4 points per year and that the declines continued for a number of years. In the long term, total decreases were typically in the 15- to 20-point range; 10 to 20% tested in a mentally retarded range. Interestingly these studies did not find discrepancies between verbal and performance IQ scores.

In summary, the CNS treatment for both leukemia and brain tumors is associated with progressive decline in general intellectual function as well as learning abilities. On average, patients lose the equivalent of, roughly, 10 to 20 FSIQ points, although many suffer little or no loss (especially older children and adolescents who did not receive radiation), and some suffer catastrophic deterioration. Rates of mental retardation appear to be in the 10 to 20% range, although some older studies showed higher rates especially with longer follow-up.

### Risk Factors for Cognitive Loss

Much of the research in the past several years has focused on risk factors for treatment-induced cognitive decline. Risk factors identified in children with leukemia include having received radiotherapy, early age at diagnosis (particularly age under 4 years), presence of CNS leukemia at diagnosis, and at least one CNS relapse (Meadows et al. 1981; Picard and Rourke 1995). Children with meningeal disease are at particular risk because they tend to have an increased number of radiation courses and a higher incidence of epilepsy, and are most prone to develop leukoencephalopathy, all of which are potent risk factors (Longeway et al. 1990).

Children with brain tumors have also been studied in an effort to identify risk factors, with the ultimate goal of modifying treatment. Studies of risk factors in pediatric brain tumor patients are summarized in Table 26.3.

In the pediatric brain tumor population, the most important risk factor for treatment-induced decline is exposure to radiation, especially at young ages. Although the "safe" age to radiate the brain has not been determined, children younger than 3 to 5 years of age appear to suffer the brunt of intellectual deterioration following CNS therapy. Mulhern and colleagues (1989a) showed that babies with brain tumors may be developmentally delayed even before they receive radiation. They found that at baseline, prior to either radiation or chemotherapy, fewer than 25% had develop-

mental quotients within the normal range! More recent studies (Ris et al. 2001; Reimers et al. 2003) have further confirmed the risk of young age at irradiation. In a large, population-based study, Reimers and colleagues (2003) studied a consecutive sample of 133 irradiated PBT survivors. Performing multivariate statistical analysis, they identified that radiotherapy exposure was by far the biggest risk factor (FS IQ mean for the nonirradiated group was 97; the irradiated group scored 79). Younger age at diagnosis was also a significant risk. They found that the amount of radiation had a significant effect on performance, but not FS or verbal IQ.

In an effort to clarify whether lower dose irradiation lowers the neurocognitive risk, Mulhern and colleagues (1998) studied a small sample of medulloblastoma survivors assigned to either standard or reduced dose CRT. Although they estimated that the reduced dose CRT group scored 10 to 15 points higher on FS IQ the number of subjects was quite small. Ris and colleagues (2001) studied a slightly larger group of similar patients, who all received reduced dose CRT, and found that their FS IQ dropped 4.3 points per year and continued to drop throughout the study period (4 years). Although there was no control group, it was thought that this represented less of a decrement than the 8 points per year loss estimated for standard dose radiotherapy (Silber et al. 1992). Grill and colleagues (1999) followed 31 pediatric brain tumor survivors exposed to varying amounts of irradiation and also found that higher exposure was a significant risk factor. On the other hand Mulhern (2005) prospectively reported on 38 children with medulloblastoma and found that those who received low dose radiotherapy did not appear to score better on a WISC than those who received standard dose. Thus, although some data supports the benefits of reduced dose radiotherapy, other studies have confirmed that lower dose irradiation in the absence of chemotherapy is associated with worse survival rates (Thomas et al. 2000) and therefore is less of an option than had been hoped.

The volume of radiation also appears to be a major risk factor. Thus, the child treated with whole-brain radiation is more at risk than the child who receives either local or no radiation. Of interest, in Ellenberg and colleagues' (1987) study, only those children who had whole-brain radiation had a decline in IQ, whereas those children who had either local or no radiation had no deterioration. Findings from the studies of Kun and Mulhern (1983), Danoff and colleagues (1982), and Grill and colleagues (1999) support the conclusions that wider exposure (i.e., whole brain or craniospinal irradiation) leads to worse outcomes.

Another risk factor is the location of the tumor. Children whose tumors are located in the supratentorial region have intellectual difficulties more often than those whose tumors are located in the posterior fossa (Ellenberg et al. 1987). There is contradictory evidence as to whether children with midline tumors are also at increased risk. In one study, patients whose tumors involved the hypothalamus were 2.5

**TABLE 26.3****RISK FACTORS FOR COGNITIVE DEFICIT IN PATIENTS WITH PEDIATRIC BRAIN TUMORS**

Risk Factor	Association With Adverse Outcome	
	Yes	No
<b>Patient Characteristics</b>		
Younger age at diagnosis	Chapman et al. 1995, Danoff et al. 1982; Duffner et al. 1988; Ellenberg et al. 1987; Garcia-Perez et al. 1993; Ilveskoski et al. 1996; Maddrey 2005; Moore et al. 1992; Mulhern and Kun 1985; Mulhern et al. 1988, 1989a; Mulhern 2005; Packer et al. 1987; Radcliffe et al. 1992; Ris et al. 2001; Seaver et al. 1994; Silverman et al. 1984; Spunberg et al. 1981	Grill et al. 1999; Kun and Mulhern 1983; Mulhern et al. 1994; Syndikus et al. 1994
Gender	Mulhern and Kun 1985; Ris et al. 2001	Kao et al. 1994; Jannoun and Bloom 1990; Reimers et al. 2003; Silber et al. 1992
<b>Pretreatment Characteristics</b>		
Location of tumor	Clopper et al. 1977; Danoff et al. 1982; Dennis et al. 1991a, 1991b, 1992; Ellenberg et al. 1987; Hirsch et al. 1979; Reimers et al. 2003; Slavic et al. 1994	Carpentieri et al. 2003; Jannoun and Bloom 1990; Mulhern and Kun 1985; Radcliffe et al. 1994; Syndikus et al. 1994
Extent/stage Hydrocephalus	Bamford et al. 1976; Bloom et al. 1969; Reimers et al. 2003	Kao et al. 1994; Radcliffe et al. 1992; Danoff et al. 1982; Ellenberg et al. 1987; Jannoun and Bloom 1990; Kao et al. 1994; Kun and Mulhern 1983; Mulhern and Kun 1985; Silber et al. 1992
<b>Treatment Characteristics</b>		
Extent of resection	Packer et al. 1987	Cavazzuti et al. 1983; Ellenberg et al. 1987; Mulhern et al. 1994; Syndikus et al. 1994
Radiotherapy (RT)	Dennis et al. 1992; Duffner et al. 1983, 1988; Ellenberg et al. 1987; Garcia-Perez et al. 1994; Grill et al. 1999; Hirsch et al. 1979; Jannoun and Bloom 1990; Kun and Mulhern 1983; Lannering et al. 1990; Moore et al. 1992; Mulhern et al. 1989a; Packer et al. 1989; Reimers et al. 2003; Riva et al. 1989; Silber et al. 1992; Silverman et al. 1984; Spunberg et al. 1981	Bloom et al. 1969; Bordeaux et al. 1988; Cavazzuti et al. 1983; LeBaron et al. 1988; Mulhern et al. 1994
Whole-brain RT	Ellenberg et al. 1987; Kun and Mulhern 1983	Jannoun and Bloom 1990; Mulhern and Kun 1985; Syndikus et al. 1994
Restricted field RT	—	Danoff et al. 1982; Ellenberg et al. 1987
Dose of RT	Goldwein et al. 1993; Grill et al. 1999; Ilveskoski et al. 1996; Mulhern et al. 1998; Palmer et al. 2001; Ris et al. 2001; Silber et al. 1992	Danoff et al. 1982; Kao et al. 1994; Spunberg et al. 1981; Syndikus et al. 1994
Age at RT	Dennis et al. 1992; Ellenberg et al. 1987; Grill et al. 1999; Jannoun and Bloom 1990; Lannering et al. 1990; Moore et al. 1992; Mulhern et al. 1998; Palmer et al. 2001; Silber et al. 1992	—
Chemotherapy (CMT)	Duffner et al. 1988, Grill et al. 1999, Mulhern et al. 1989a, Riva et al. 1989	Ellenberg et al. 1987; Kao et al. 1994; Packer et al. 1989; Radcliffe et al. 1994; Reimers et al. 2003
RT plus CMT	Duffner et al. 1983, 1988	Syndikus et al. 1994
<b>Post-treatment Characteristics</b>		
Perioperative complications	Chapman et al. 1995; Ilveskoski et al. 1996; Kao et al. 1994; Maddrey 2005; Mulhern et al. 1988, 1994; Packer et al. 1987; Silber et al. 1992	Ellenberg et al. 1987; Radcliffe et al. 1994
Seizures	Mulhern et al. 1988; Syndikus et al. 1994	—
Tumor recurrence	Mulhern et al. 1988	Cavazzuti et al. 1983
Sensory-motor impairment	Mulhern and Kun 1985	Cavazzuti et al. 1983
Long interval after treatment	Duffner et al. 1988; Ellenberg et al. 1987; Hoppe-Hirsch et al. 1990; Maddrey 2005; Moore et al. 1992; Mulhern and Kun 1985; Mulhern et al. 1989a; Packer et al. 1989	Cavazzuti et al. 1983; Kun and Mulhern 1983a; Radcliffe et al. 1992

times more likely to have a lower IQ than were those whose tumors did not involve the hypothalamus (Jannoun and Bloom 1990). In contrast, Ellenberg and colleagues (1987) did not find that children with third-ventricle tumors had significantly lower IQs compared with children whose tumors were either supratentorial or infratentorial in location. Children whose tumors were in the anterior third ventricle seemed to have the most impairment. Reimers and colleagues (2003), on the other hand, found that those with third-ventricle tumors scored higher than survivors with either supratentorial or infratentorial tumors.

Although one of the putative risk factors for intellectual impairment was believed to be hydrocephalus, it has been shown by several investigators that hydrocephalus does not have an adverse impact on intelligence. Hirsch and colleagues (1979) compared the IQs of children treated for cerebellar astrocytomas with those of children treated for medulloblastomas. The children with cerebellar astrocytomas received surgery alone, whereas the children with medulloblastomas received postoperative radiation and chemotherapy. Children with medulloblastomas were found to have more intellectual impairment than did those with cerebellar astrocytomas: 62% of children with cerebellar astrocytomas, but only 11% of the children with medulloblastomas, had IQs above 90. Since both groups of patients had posterior fossa tumors associated with obstructive hydrocephalus, Hirsch and colleagues concluded that it was the postoperative treatment rather than either the posterior fossa location or the hydrocephalus that produced the learning difficulties. A number of other studies failed to confirm a link, although two studies (Parker 1987; Reimers et al. 2003) have supported an association between hydrocephalus with shunt and lower IQ.

Another important risk factor in children with brain tumors is perioperative morbidity. Although the degree of surgical resection does not appear to influence intelligence directly, children with posterior fossa syndrome and other perioperative complications tend to have much more severe neurological and intellectual sequelae (Kao et al. 1994).

Although chemotherapy is not generally considered to adversely influence intelligence, the development of methotrexate-induced leukoencephalopathy is associated with dementia and other neurological complications. The diagnosis of methotrexate (MTX) leukoencephalopathy was first made in children irradiated for leukemia who had also been treated with intrathecal methotrexate. CT scans of 53% of those children revealed calcification in the basal ganglia, hypodense areas, and widened subarachnoid spaces. This finding was termed methotrexate leukoencephalopathy (Peylan-Ramu et al. 1978). The abnormality appeared to develop primarily in those children with leukemia treated with MTX who had received radiation as part of CNS prophylaxis or those who had leptomeningeal disease. In contrast, the child who did not have CNS leukemia and had been treated with MTX but without radiotherapy did not seem to be at

significant risk (Ochs et al. 1980). As higher and more frequent doses of MTX have been utilized, increasing concern has developed about the effects of MTX. A Pediatric Oncology Group (Mahoney 1998) study of children with acute lymphoblastic leukemia who did not receive radiotherapy nor have CNS leukemia demonstrated a high incidence of acute neurotoxicity and abnormal neuroimaging findings.

MTX has also been used in the treatment of children with brain tumors. When this agent was used via the intraventricular route in patients with obstructive hydrocephalus, profound necrotizing leukoencephalopathy occurred. Even in the absence of such a catastrophic complication, MTX leukoencephalopathy may develop in children with brain tumors treated with intrathecal MTX and radiation.

Another important influence on neuropsychological functioning is the presence of seizures and the use of anti-convulsants. Long interval after treatment (i.e., lengthier follow-up) has generally been associated with increased cognitive deficits. This association has usually been attributed to a latency in the full effect of radiotherapy. Other factors, such as gender effects, tumor recurrence, and sensory/motor impairment, have been less well investigated, and their importance is unclear.

In summary, the patients at greatest risk for neuropsychological complications appear to be those who receive radiation (especially higher dose and larger volume), are younger at the time of treatment, receive concomitant intrathecal MTX, and have seizures.

### Mechanisms of damage and specific deficits

A number of studies have documented white matter abnormalities and demyelination as a result of CNS irradiation (Steen et al. 2001; Reddick 2003). It is thought that these findings result from damage to oligodendrocytes, with consequent axonal demyelination, or microvascular damage to endothelial cells, which compromises the blood-brain barrier. This leukoencephalopathy appears to occur subsequent to both cranial radiotherapy and CNS chemotherapy exposure, although more so to the former. These changes have, in turn, been associated with IQ loss.

The specific types of neuropsychological deficits associated with brain tumors have been studied, although a clearly defined composite has not emerged. This should not be surprising given the widely varying locations of tumors. Nevertheless, a number of studies suggest that the greatest difficulties are in attention, memory, sequential processing, processing speed, and visuospatial/perceptual organization. Mathematics skills are frequently mentioned as problematic, as are performance subtests on the WISC (or an equivalent test), although many studies show no difference between verbal and performance subtests (Ris et al. 2001; Palmer et al. 2001). Palmer (2001) has suggested that the IQ deficits result from a difficulty in assimilating new knowledge as opposed to a loss of acquired information.

### Treatment of Neurocognitive Deficits

Few studies have addressed treatment of the neurocognitive deficits associated with pediatric brain tumors, although Butler (2005) recently reviewed this area. Both pharmacologic and educational interventions for the cognitive deficits associated with pediatric brain tumors have been reported. One uncontrolled trial of methylphenidate (DeLong 1992) yielded promising results, while another (Torres 1996) was negative. Recently Thompson (2001) reported a randomized, double-blind, placebo-controlled study of 32 pediatric cancer survivors (acute lymphoblastic leukemia and pediatric brain tumors). During this one-day laboratory study, subjects receiving methylphenidate showed significantly greater improvement on the continuous performance test. Mulhern (2004) extended this investigation to a 3-week placebo-controlled, double-blind trial of low and moderate dose methylphenidate in 83 long term survivors of acute lymphoblastic leukemia and pediatric brain tumors with attentional and academic deficits. Modest but significant improvement was seen in the treated group, although higher dose conferred no advantage. Other investigators have taken a cognitive remediation approach. A seven-member consortium group is currently investigating the efficacy of using a 20 session cognitive rehabilitation program in pediatric brain tumor and acute lymphoblastic leukemia survivors (Butler 2002).

### SUMMARY

Brain tumors are the second most common malignancy, and the most common solid malignancy, in the pediatric population. Because of improved treatments, survival rates have improved substantially in the past 30 years, and as a consequence the population of longterm survivors has grown. The child and adolescent psychiatrist faces two issues in this population. One is diagnosis and its potential for neuropsychiatric presentation. The other is the need for comprehensive treatment frequently required by long-term survivors, who often have psychological, cognitive, and academic difficulties as well as endocrinological and neurological complications.

Although a wide range of psychopathology has been reported as part of the presentation of brain tumors, it is rare to see solely neuropsychiatric signs without neurological signs and/or symptoms. This underscores the importance of the medical history and physical examination in the evaluation of all children and adolescents with significant neuropsychiatric disorders. Neuroimaging should be reserved for selected child and adolescent neuropsychiatric patients.

Although there are few data on neuropsychiatric disorders in survivors, there is a literature on the psychosocial functioning of these patients. As their lives unfold, most appear to be functioning adequately, although not at their premorbid level. Often they are described as immature,

shy, lacking confidence, withdrawn, depressive, and anxious. Although most appear physically normal, many have noticeable neurological impairment, have hearing or visual problems, and are shorter than age mates.

Cognitively, most children with brain tumors function in a normal range, although IQs are low average, which represents a decrement from premorbid functioning. Wechsler Full Scale IQs in these children as a group probably drop 10 to 20 points on average. Attention and memory functions appear to be especially vulnerable and are associated with white matter changes. Older children and those not requiring radiotherapy appear to suffer substantially less in this regard. Younger age and exposure to radiotherapy appear to be the major risk factors for serious loss of cognitive abilities. Of the group of children with brain tumors who become mentally retarded (10 to 20%), most were diagnosed at young ages and had received or were receiving radiotherapy. Most child survivors require special educational services and/or have had to repeat grades because of cognitive loss and extended absences from school.

Little is known about the effects on families and levels of family functioning, although PTSD may be a useful conceptual frame for understanding their experiences and needs. As adults, most survivors of pediatric brain tumors are employed in some capacity and are able to drive. Limitations commonly require that these individuals receive assistance to support work and independent living. They marry, although at much lower rates than in the general population.

In the future, increasing numbers of survivors of pediatric brain tumors can be expected. Child and adolescent psychiatrists can be valuable members of the multidisciplinary teams needed to care for these patients. Although narrowly defined neuropsychiatric needs are not well delineated, currently psychiatrists are uniquely able to integrate neurological, psychosocial, cognitive, and psychiatric approaches and perspectives.

# Pediatric

# Psychopharmacology

27

**Daniel A. Geller, MBBS, FRACP**    **Paul Hammerness, MD**

Since the first edition of this text, there have been important advances in our knowledge of pediatric psychopharmacology. Since the mid-1990s, our understanding and appreciation of both the neurobiological underpinnings of childhood psychiatric disorders as well as neuropsychopharmacology have increased (1), the randomized controlled trials literature has continued to expand, novel agents have come to market, and, in support of pediatric pharmacology research, the president signed the Pediatric Research Equity Act into law on December 3, 2003. This law codifies the protections of the 1998 Pediatric Rule, a Food and Drug Administration (FDA) regulation requiring drug manufacturers to test their products for use in children, which provided incentives to industry to study investigational new drugs (INDs) in children, gave an impetus to the field, and doubled the evidence base for pediatric psychopharmacology. While enactment of this legislation supports the continuation of pediatric clinical psychopharmacology trials, industry as well as federal and other efforts are needed to bridge the large gaps in our knowledge of pediatric psychopharmacology. Indeed, because of the ethical and methodological difficulties in conducting pharmacological research in minors (2), many new medications are used “off-label” after being studied and approved in adults only.

Psychopharmacology may be divided into two broad domains: pharmacokinetics, which refers to the actions of the body upon the drug, and pharmacodynamics, which refers to the actions of the drug on the body at its target site(s). It is now understood that children are not simply small adults and that treatment practices used for adults may not translate well into safe or effective treatments for children. Changes with age in both pharmacokinetic and pharmacodynamic parameters may lead to differences in

clinical response and adverse effect profiles in children versus adults (2). A number of relevant physiological changes occur during growth and development (3). For example, height and weight increase markedly during childhood and adolescence (4). The proportion of total body water and extracellular water decreases from birth, reaching adult values by 12 years of age (5). The percentage of body fat doubles through infancy and then decreases with an increase in lean body mass during early childhood (2), which increases again in later life.

## PHARMACOKINETICS

*Pharmacokinetics* refers to the body's actions on a drug. Unique properties of the drug such as pH, fat solubility, protein binding, and molecular weight will affect its absorption from the gastrointestinal (GI) tract or elsewhere, its distribution (especially in the brain), and its metabolism and eventual excretion (4). Compared with adults, children have more rapid metabolism and excretion of many drugs due to a greater relative liver mass and greater renal clearance. Such factors may produce shorter half-lives of drugs compared with adults, necessitating more frequent dosing schedules to yield steady plasma levels and avoid withdrawal effects. Pharmacokinetic differences between children and adults lessen by late puberty.

### Absorption

Although studies examining differences in drug absorption among children, adolescents, and adults are limited, gastrointestinal absorption rates are generally faster in

children compared with adults (6). Since younger children have decreased gastric acidity (higher pH), weak bases are preferentially absorbed and weak acids more slowly absorbed (5). By adolescence, gastric pH and emptying time are similar to adults. Disturbances in bowel flora, from the frequent use of antibiotics, for example, may lead to changes in intestinal motility and bile acid function in ways not yet studied. The effect of probiotic supplementation on drug absorption, though popular, is also unknown.

### Distribution

Drug distribution is affected by several factors, including extracellular water volume, serum albumin concentration, and percentage of body fat (5). Children have a greater relative, but smaller absolute, extracellular water volume (volume of distribution) compared with adults. Since free drug is distributed into the extracellular volume, the smaller absolute volumes in children will lead to faster equilibration and half-life and higher drug concentration compared to the higher volumes of adults. Because many drugs are highly protein bound, the variable serum albumin concentrations of children may lead to inter- and intraindividual differences in the proportion of drug that is protein bound and consequently the concentration of free and active drug in plasma (5). Any condition that causes a reduction in serum protein concentration, such as nephrotic syndrome, will lead to decreased binding and increased free drug concentration and possible toxicity (4). Because obesity in children has reached epidemic proportions in North America, variability in proportion of body fat is an important factor for drugs that are fat soluble. In addition to having better blood-brain barrier penetration, fat-soluble drugs are stored in fat and redistributed to plasma and brain over time. Morbidly obese subjects may require higher doses of such drugs for these reasons.

For the purposes of psychopharmacology, the brain is the target organ of interest, yet the *in vivo* study of drugs in the brain is severely hampered by the difficulty of assaying the drug at this site. New techniques in noninvasive imaging, especially magnetic resonance spectroscopy may, however, permit repeated *in vivo* sampling of chemicals in the brain at specific sites of interest and offer promise for significant breakthroughs in psychopharmacology. While the permeability of the blood-brain barrier is thought to be compromised in children with neurological insult such as perinatal ischemia, little is known about this important property in children with more subtle developmental disabilities.

### Metabolism and Excretion

As noted earlier, children have greater *relative* liver volume and weight-adjusted mass compared with adults as well as more rapid kidney filtration that may lead to shorter drug

half-lives and the need for higher weight-based dosages (2, 7, 8). Of the four primary hepatic pathways for drug metabolism, oxidation, reduction, hydrolysis, and conjugation (5), oxidative pathways appear to be more rapid in children compared with adults (2). Further, changes in binding capacity of cytochrome P450 enzymes (4) lead to greater oxidation in males compared to females after puberty. Drugs that are primarily excreted via the kidney (for example, lithium) may have a shorter half-life in older children compared with adults, although the clinical significance of this finding is uncertain (7).

## PHARMACODYNAMICS

The mechanism of a drug's action at its target site, in this case the nervous system, and the secondary and tertiary events that lead to a drug's desired activity are termed *pharmacodynamic* actions. While the primary event is frequently at the neuronal membrane such as a receptor or uptake site, it may also be intracellular such as with the highly soluble drug lithium. Secondary and tertiary cascades of effects such as changes in energy metabolism or conformational shape and permeability of ion channels ensue, leading often to intranuclear effects that are translated via transcription and protein synthesis leading to altered neuronal function. We do not know how and whether age-related developmental changes in these pharmacodynamic processes occur and what effects in turn such changes have on the expression of drug actions in humans. Childhood and adolescence are characterized by rapid anatomic and functional changes in the brain that persist into adulthood. While animal data indicate developmental differences in the ontogeny of both serotonergic and noradrenergic systems, which could affect response to psychotropics (9), human studies suggest more stability in serotonergic systems but significant changes in both dopaminergic and noradrenergic systems over the course of development. For example, striatal dopamine receptor density decreases rapidly in the second decade of life. The spontaneous resolution of many chronic tic disorders in adolescence may be a reflection of these changes. This decrease, however, continues throughout life (10) and may result in decreased dopaminergic activity (11) and an increased risk for Parkinson's disease or depression in the elderly. In contrast, noradrenergic activity increases after puberty (12, 13). This finding could explain in part the differential efficacy of the tricyclic antidepressants in adults compared with children.

Lastly, the serotonergic system is a phylogenetically ancient transmitter system that is developed during early fetal life and appears relatively mature in humans at birth. It may be for this reason that serotonergic drugs appear to affect even young children, in contrast to noradrenergic drugs. Serotonin synthesis in preschool children may even reach a 200% increase over adult rates, until near school age when it may drop to adult levels (14).

Attention has focused on serotonin, dopamine, and norepinephrine systems largely because it is these systems that are targeted by our common armamentarium of medications. However, many other neurotransmitter systems that are of interest and may yield important advances in psychopharmacology have yet to be well studied, especially developmentally. Examples include increased acetylcholine concentration in the cortex during adolescence (theoretically leading to improved memory and retention) and the important roles of glutamate and GABA (gamma-aminobutyric acid) over time. Like looking for a lost coin under a street lamp because that is where the light is to be found, our knowledge of developmental changes in pharmacodynamics, outside the halo provided by drugs that serve as pharmacological probes, is extremely limited. It remains unknown whether psychotropics administered to youth can produce changes in the neuroanatomy or neurophysiology of the developing brain that persist after the drug is discontinued; that is, whether permanent changes occur (2). This issue is clearly of great concern as there is at least some animal data suggesting that this is possible (15).

### Compliance

The magnitude of *noncompliance*, that is, of *not* taking medication as prescribed in pediatric medicine, is a clinically significant issue in all populations and at all ages. In youth with psychological and emotional disorders, rates of noncompliance as a limiting factor in treatment efficacy are likely to be even greater. Further, children rarely self-administer, relying on parents to remember and give medications (16). In traditional pediatric settings, noncompliance rates are at least 50% (16). In addition, physicians do a poor job in assessing noncompliance in their patients (17). As in most areas of medicine, the therapeutic relationship is an essential element in drug compliance, but adequate education (*informed consent*), frequent supervision, simplified drug regimens, and peer support can also be helpful (16).

### Special Populations

Psychopharmacological agents may have radically different effects in patients who are neurologically compromised compared to nonneurologically impaired individuals. For example, in patients with perinatal injuries leading to mental retardation, seizures, or cerebral palsy, atypical and unexpected responses may occur so that caution and vigilance are necessary when introducing psychoactive medication into this population. Clearly, a host of illnesses and pathophysiology are represented in these children so that no general rules may be generated for practitioners other than “start low and go slow.”

Because neurologically compromised children are usually excluded from clinical studies and research protocols, the existing literature provides little guidance on their

management. Existing data on drug characteristics and treatment recommendations are therefore derived from neurologically “healthy” subjects.

### Drug Monitoring

Therapeutic drug monitoring in pediatric psychopharmacology has a limited role. First and most important, the correlation between plasma levels and therapeutic effects are often poor and unhelpful, providing no useful information to the clinician. One example is monitoring stimulant plasma levels in the treatment of the child with attention deficit hyperactivity disorder (ADHD) where the correlation between plasma and brain levels is poor and tremendous intraindividual variability occurs. Therapeutic ranges are guidelines only, frequently derived from adult dose titration studies of efficacy and tolerability, and may not apply closely to children. For drugs with a low margin of safety or with potential serious adverse events (such as lithium and the antiepileptic drugs), serum levels are clearly important. By convention, drugs are measured at their trough levels; that is, at the lowest plasma levels obtained just prior to next dosing after steady state is achieved, or about five half-lives.

For off-label dosing in youth, strategies based simply on age, weight, or even body surface area and derived from adult studies may not be correct (5, 8). Body surface area calculations are feasible based on weight and height, but routine measurement of these parameters among child psychiatrists is still not widespread, and their use in clinical settings is not practical because dose guidelines based on body surface area are usually not provided. At a minimum, however, practitioners should endeavor to obtain weight at baseline and regular intervals, since weight-based dosing provides at least some guidance. Ultimately, practitioners must rely on a mix of the evidence-based medical literature that is summarized in this chapter, practice guidelines where available, expert clinical opinion, and individual clinical experience.

## AN EVIDENCE-BASED APPROACH

Treatment decisions are increasingly being made on research-based evidence rather than on expert opinion or clinical experience alone. In 1999, Congress directed the Agency for Healthcare Research and Quality (AHRQ) to undertake a systematic examination of approaches to assess the strength of scientific evidence. Such systems allow evaluation of either individual articles or entire bodies of research on a particular subject for use in making evidence-based health care decisions and to provide some guidance as to “best practices” in the field. Several generic systems were identified that fully addressed key quality domains for systematic reviews, randomized controlled trials (RCTs), observational studies, and diagnostic test studies. For

example, a description of the study population (including inclusion and exclusion criteria), randomization, blinding, interventions, outcomes (including “last observation carried forward” data and description of dropouts), and statistical analysis were key domains for RCTs. Of note, sources of sponsorship or funding were considered key elements for each type of study (e.g., industry sponsored). Systems for grading the strength of a body of evidence, including the quality, quantity, and consistency of studies, are also included in this report (18). These methods have been applied to trials evaluating newer pharmacotherapies for depression as well the treatment of ADHD, where 78 RCTs were included.

A simpler quality rating system was devised by the Texas Consensus Conference Panel on Medication Treatment of Childhood Major Depressive Disorder. This widely imitated system categorizes data into three levels: Level A data consist of both child and adult randomized controlled clinical trials, Level B data consist of open trials and retrospective analyses, and Level C data are based on case reports and expert panel consensus as to recommended clinical practices.

At its best, evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence in making individual patient-care decisions. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external evidence from systematic research (18). Despite the obvious premise of evidence-based medicine, the great variability by region and discipline in current practice in child psychiatry argues against the notion that it is already in widespread use. Following the lead from other disciplines, efforts have been made to present an evidence-based approach in pediatric psychiatry (19, 20). These authors concluded that “although the number of evidence based treatments in child psychiatry is growing, much of clinical practice remains based on the adult literature and traditional models of care” (19, p. 1388). In this chapter, we use an evidence-based approach to clinical pediatric psychopharmacology by attending to the quality of individual studies as well as the strength of the entire body of evidence. Limitations in such an approach abound and include the numerous exclusion criteria used in clinical trials (especially industry sponsored trials) that affect the representativeness of study samples (21), high placebo response rates in child subjects, frequent comorbidity in many if not all child psychiatric disorders and lack of validity of current diagnostic nosology in pediatric subjects.

Finally, in view of the great responsibility involved in prescribing psychoactive agents to minors, diligence is needed in disseminating evidence-based efficacy information as well as accurate safety data to practicing clinicians. A special section of the *Journal of the American Academy of Child and Adolescent Psychiatry* dedicated to a review of safety assessments in pediatric psychopharmacology found inconsistency in safety ascertainment as a major limitation

in identifying drug-induced adverse events (22). In the following section of the edition, Vitiello et al. (2003) (23) described methods for more rigorous, standardized drug safety evaluation. Since we lack a well defined “standard of care” for much of child psychopharmacology practice, the dictum *non nocere* (“do no harm”) is especially relevant.

## OVERVIEW OF PEDIATRIC PSYCHOPHARMACOLOGY

---

In this chapter, we review the clinical pharmacology and the psychotherapeutic use of psychotropics used to manage and treat neuropsychiatric disorders in children and adolescents. The primary agents used in pediatric psychopharmacology, antidepressants, anxiolytics, mood stabilizers, antipsychotics, and stimulants, will be discussed in separate sections, integrating psychopharmacology and clinical application. Pharmacokinetic and pharmacodynamic information relevant to each class is discussed, followed by an evidence-based review of the supporting literature, safety data, and, finally, guidelines regarding initiation and maintenance of clinical treatment and monitoring. For many common applications in pediatric psychopharmacology, there is a dearth of controlled data and limited FDA approval in pediatric populations. As such, clinical use, which covers a broad spectrum of juvenile psychiatric illness, is primarily “off-label” (see Table 27.1), creating a dilemma for clinicians who, in good faith, seek to relieve symptomatic distress in their young patients.

## ANTIDEPRESSANTS

---

This section reviews the neuropsychopharmacology and the psychotherapeutic use of antidepressants used to manage and treat a variety of neuropsychiatric disorders in children and adolescents, not just depression. Selective serotonin reuptake inhibitors (SSRIs) and mixed action agents, including Nefazadone, Bupropion, Venlafaxine, Mirtazapine, and tricyclic antidepressants (TCAs), will be reviewed separately.

## SELECTIVE SEROTONIN REUPTAKE INHIBITORS (SSRIs)

---

### Neuropsychopharmacology

Although usually considered as a single homogeneous class of agents, SSRI medications do differ in their pharmacology and clinical application. The pharmacokinetics and pharmacodynamics of SSRIs is briefly discussed here; more detailed reviews of the neurotransmitter serotonin and the pharmacology of SSRIs can be found elsewhere (24–27). SSRIs available in the United States include citalopram (Celexa), fluoxetine (Prozac), fluvoxamine (Luvox), parox-

**TABLE 27.1****COMMON MEDICATIONS USED IN PEDIATRIC PSYCHOPHARMACOLOGY RANKED BY LEVEL OF SUPPORTING EVIDENCE**

Trade Name	Generic Name	Level of Support	Indication	FDA Approved Age (Years)
<b>SSRIs</b>

<sup>a</sup>Adolescents only.

N/A, Not approved for pediatric use; ADHD: Attention-deficit/hyperactivity disorder; ED: Eating disorder; OCD: Obsessive-compulsive disorder; TS: Tourette's disorder.

Level A data consist of pediatric randomized controlled clinical trials.

Level B data consist of open trials and retrospective analyses.

Level C data are based on case reports or panel consensus as to recommended current clinical practice.

etine (Paxil), and sertraline (Zoloft). At this time only fluoxetine (depression and obsessive-compulsive disorder [OCD]), fluvoxamine (OCD), and sertraline (OCD) are FDA approved for use in children.

### Pharmacokinetics

After ingestion, SSRIs are all well absorbed from the gut but differ in their subsequent bioavailability, metabolism, degree of protein binding, presence of metabolites, and elimination (24, 28) (Table 27.2).

In general, recommended weight-adjusted doses of SSRIs have been similar in children and adolescents compared with adults. Although limited, some information regarding the pharmacokinetic properties of the SSRIs in children have emerged, including studies of sertraline (29–32), fluoxetine (33), and paroxetine (34).

When normalized for body weight, pediatric pharmacokinetic studies have demonstrated many similarities compared to adults, including interindividual pharmacokinetic variation. For example, Strauss et al. (2002) (35) conducted a fluorine magnetic resonance spectroscopy study of

brain fluvoxamine and fluoxetine in pediatric pervasive developmental disorders and demonstrated that SSRI brain concentrations were not different from adult subjects when corrected for body mass. Enhanced metabolic activity may occur, however, in part due to a greater liver-to-body mass ratio in children (36). Findling et al. (1999) (34), for example, demonstrated a T<sub>1/2</sub> of 11 hours for paroxetine, compared to twice that duration observed in adults.

Paroxetine, fluoxetine, and fluvoxamine have demonstrated nonlinear kinetics in adults (24, 28), meaning that clearance or half-life is a function of blood levels. This effect is typically due to the drug's inhibition of its own clearance via inhibition of its enzymatic metabolism, leading to increased half-life with multiple dosing. In a pharmacokinetic study of paroxetine in youth, Findling et al. (1999) (34) reported a 6.9-fold increase in serum drug concentration following a dose increase from 10 to 20 mg. The clinical relevance of this effect may also be seen in "discontinuation syndromes" as blood levels fall and drug clearance speeds up, leading to exponential decline. As such, children taking SSRIs with a short half-life (14-hour) may benefit from twice-a-day administration to avoid withdrawal effects (37). Enteric-coated formulations may in part modify these kinetic characteristics and enhance tolerability (38). Examples include paroxetine-controlled release (Paxil CR), which offers a reduction in absorption rate compared to paroxetine (GlaxoSmithKline, Paxil prescribing information).

Fluoxetine and citalopram possess a chiral center that permits existence of stereoisomeric forms of the molecule, and they were originally marketed as racemic mixtures of enantiomers with different kinetics and dynamics. While (R) and (S) enantiomers of fluoxetine are similar in 5HT activity, (S) fluoxetine is more potent in its p450 inhibition yet has a more potent metabolite (28). Conversely, the newest member of the SSRI class, Lexapro (approved by the FDA in August 2002), the pure (S) isomer of citalopram, displays at least 100-fold 5HT activity compared to the (R) isomer (Forest Pharmaceuticals, Lexapro prescribing information).

Knowledge of SSRI metabolism is clinically useful, as it relates to potential drug interactions and overall drug safety. Although SSRI medications have fewer drug interactions than their predecessors, drug interactions may occur, primarily via the metabolic cytochrome p450 (CYP450) system, such as CYP450 2D6.

Paroxetine and fluoxetine show the most potent CYP450 2D6 inhibition, followed by sertraline, fluvoxamine, and citalopram (39). For paroxetine and fluoxetine, plasma concentrations and dosage have been shown to influence the magnitude of enzyme inhibition (40). Awareness of CYP450 interactions must include clinically significant interactions with herbals or supplements, such as St. John's wort and unwanted pregnancy with concomitant birth control pills (41). Increasingly, controlled studies are including pharmacokinetic sampling to assess the impact of CYP450 genetic polymorphisms on efficacy, safety, and tolerability, particularly

when CYP450-2D6 is the main enzymatic pathway, as 7% of the Caucasian population is naturally deficient in this enzyme. Other mechanisms of drug-drug interaction may also include UDP-glucuronyltransferase inhibition, as described in a case report of a citalopram interaction with clomipramine (42) (Table 27.3).

### Pharmacodynamics

Both the absolute potency of serotonergic uptake inhibition as well as their relative serotonin:norepinephrine uptake inhibition ratio (selectivity) may be important in the action of SSRIs, both of which are far greater than in the predecessor tricyclic antidepressants (TCAs), with the exception of clomipramine. In general, the SSRIs have low affinity for other receptors, such as adrenergic, cholinergic, or histaminic sites. Table 27.4 displays in vitro potency of serotonin uptake inhibition for the SSRIs.

Paroxetine and sertraline show the most potent absolute 5HT reuptake inhibition, while citalopram is most selective (i.e., has the greatest 5HT/NE ratio) (43). With doses commonly used in adult controlled trials, such as 20 mg fluoxetine and 50 mg sertraline, serotonin uptake inhibition has been found to be in the range of 60 to 80% (24). The transmission of synaptic serotonin increases with acute administration of SSRI medications is likely due to reduced sensitivity of 5HT (1A) inhibitory autoreceptors. Desensitization of 5-HT (1A) autoreceptors in the dorsal and median raphe may be due to changes at or distal to receptor-G protein interaction (44). Over time, postsynaptic 5HT<sub>2</sub> receptors are probably also down-regulated (45). While the SSRIs are primarily serotonergic in their actions, ongoing neuropharmacological studies have described paroxetine's marked NE transporter inhibition at doses >40 mg/day (46) and sertraline's potency at the dopamine reuptake site (47).

**TABLE 27.3**  
**CYP450 ISOENZYME INHIBITION BY SSRIs**

Drug	CYP Isoenzymes (in vitro)				
	1A2	2C9	2C19	2D6	3A4
Citalopram	+	0	0	0	0
Fluoxetine	+	++	+ / ++	+++	+ / ++
Norfluoxetine	+	++	+ / ++	+++	++
Fluvoxamine	+++	++	+++	+	++
Paroxetine	+	+	+	+++	+
Sertraline	+	+	+ / ++	+	+

The clinical significance of in vitro data is unknown. In vitro enzyme inhibition data did not reveal an inhibitory effect of citalopram in CYP3A4, and citalopram would be expected to have little inhibitory effect on in vivo metabolism by this enzyme.

0, minimal or no inhibition; +, mild; ++, moderate; +++, strong.

NE/5HT is a measure of serotonin selectivity.

K<sub>i</sub>, inhibitory constant; nM, nanomolar.

## Pharmacotherapy

This discussion of SSRI pharmacotherapy is organized according to primary clinical applications supported by controlled trials, although for many common SSRI applications, there is a dearth of controlled data. Despite widespread use, SSRI medications are certainly not universally effective.

### Randomized Controlled Trials (Level A) Evidence

#### Mood Disorders

Contrary to the adult mood disorder literature, the only controlled evidence demonstrating efficacy in pediatric unipolar depressive disorders is found in studies with SSRI medications. Open-label studies suggest variable response rates to SSRIs in children and adolescents with major depressive disorder (MDD), yet higher than rates observed in controlled studies (40 to 70%). Placebo response rates are also high (30 to 60%) in controlled trials, indicating that overall effect sizes are modest and that underpowered studies are unlikely to demonstrate statistically significant efficacy (type 2 errors). There is no controlled evidence targeted at pharmacological treatment of suicidality in depressed youth (48–50) (Table 27.5).

Several RCTs have demonstrated efficacy of SSRIs for the acute management of major depression. Emslie and colleagues demonstrated significant benefit, in both acute and maintenance fluoxetine treatment, in children and adolescents with depression (51–53). In addition, a multicenter controlled trial of adolescent MDD sponsored by the National Institute of Mental Health (NIMH) demonstrated efficacy of fluoxetine (10 to 40 mg/day) and fluoxetine plus cognitive behavior therapy (CBT) compared to placebo (49). Studies have demonstrated a 40 to 65% response rate to 10 to 40 mg of fluoxetine daily, compared to a 20 to 50% placebo response rate (depending on outcome variable). A

multivariate post-hoc analysis did not identify any variables that might predict a positive response to fluoxetine in this study (54). Fluoxetine has been shown to be beneficial for maintenance treatment in children and adolescents with MDD (48), addressing the uncertainty regarding the impact of SSRIs on recurrence of depressive episodes.

Paroxetine (mean daily dose, 28 mg) demonstrated superiority over placebo (55) and comparability to the serotonergic TCA clomipramine in one randomized multicenter trial of adolescent major depression (56). Although in two prior RCTs, paroxetine did not achieve significant superiority over placebo (57), treatment response stratified by age showed a significant difference in outcome, in that a greater proportion of older youth (>16 years old) were responders ([www.gsk.com/media/paroxetine.htm](http://www.gsk.com/media/paroxetine.htm)). Combined controlled and open trials with sertraline 25 to 200 mg daily have demonstrated significant superiority across multiple measures in adolescents (58) and global improvement measures in children (59) compared to placebo. One 8-week controlled trial of citalopram in pediatric MDD demonstrated significant superiority in change from baseline compared to placebo (60), but a similar study from the UK did not (57).

The 1999 Report of the Texas Consensus Conference Panel on Medication Treatment of Childhood Major Depressive Disorder recommended fluoxetine, sertraline, or paroxetine as first-line agents (61). However, a more recent review of the efficacy and safety of SSRI medications in pediatric depression by the FDA led to the endorsement of fluoxetine only (62). This FDA review followed concerns regarding the safety and efficacy of SSRIs in pediatric populations (see the “Safety” section, presented later).

Expert panels, including a task force convened by the American College of Neuropsychopharmacology in response to these concerns, identified *several* SSRIs (fluoxetine, sertraline, paroxetine, and citalopram) as significantly more effective than placebo in at least one controlled trial.

This panel did acknowledge that paroxetine and citalopram have also registered negative findings (57). While the data regarding SSRI use in youth are growing, clinicians face the difficult task of interpreting the extant literature, particularly when negative trials may not be presented in scientific forums (file drawer effect), when drug trials use weak methodology, when faced with high placebo response rates, and when safety and tolerability are presented in a limited manner (63–65).

### Anxiety Disorders

Extensive evidence from many randomized controlled trials supports the efficacy of SSRIs in adults in virtually all of the anxiety disorders including posttraumatic stress disorder (PTSD). Similarly, but with a less strong evidence base, this class of medications has also been shown to be effective in placebo-controlled studies of pediatric anxiety, primarily in obsessive-compulsive disorder and mixed anxiety cohorts.

### Obsessive-Compulsive Disorder (OCD)

Pediatric OCD pharmacotherapy has been studied more than other anxiety disorders; multiple randomized placebo-controlled studies (mostly industry sponsored) have been conducted in cohorts of children and adolescents with obsessive-compulsive disorder (66, 67). This body of evidence, including more than 19 studies representing more than a thousand children and adolescents, indisputably supports the short- and medium-term efficacy of serotonergic medications (74, 75), including fluoxetine (68, 69), fluvoxamine (70), paroxetine (71–73), and sertraline (29, 74–77) (Table 27.6). Cumulatively, these data constitute the highest level (Level 1) using AHRQ strength of evidence criteria of quality, quantity, and consistency of scientific studies. Five of these studies also report on the longterm efficacy (>12 months) of the SSRIs for OCD in youth showing continuing benefit from treatment without any evidence of loss of efficacy. In fact, in a longterm study reporting on a 12-month extension study of sertraline in youth with OCD, Wagner et al. (2003) (78) found that Children's Yale-Brown Obsessive Compulsive Scales (CY-BOCS) scale scores *continued to improve* throughout the duration of treatment. Overall responder rates, defined by  $\geq 25\%$  reduction in the CY-BOCS, are around 50% and are shown for each SSRI in Table 27.6.

In a meta-analysis of this literature, Geller et al. (2003) (21) (Table 27.7) found that the pooled standardized mean difference (SMD) for results of all studies was 0.46 (95% confidence intervals [CI] = 0.37–0.55), showing a highly significant difference between drug and placebo treatment ( $z = 9.87, p < 0.001$ ). Multivariate regression of the drug effect controlled for other variables showed that clomipramine was significantly superior to each of the SSRIs (chi-square = 16.49,  $df = 4, p = 0.002$ ) but that the other SSRIs were comparably effective.

As noted later, informed consent for the use of SSRIs for OCD must include some discussion of the value of non-

pharmacological treatment, particularly CBT. A federally funded pediatric OCD treatment study (POTS) compared combined CBT and medication to either treatment alone and found that combined treatment had an additive effect on outcome with the greatest overall effect size (79). This approach is likely to become the gold standard for OCD treatment in the future (Table 27.8).

### Mixed Anxiety Disorders

Randomized controlled studies have been conducted on mixed samples of anxiety disorders, reflecting the frequent comorbidity found within childhood anxiety disorders. Following positive earlier open studies (80–82), the first large, multicenter randomized controlled shortterm trial of an SSRI in mixed pediatric anxiety demonstrated significant improvements in the Pediatric Anxiety Rating Scale (PARS) and Clinical Global Impression (CGI) in the actively treated group using fluvoxamine (maximum dose, 300 mg) compared to placebo (83). A further 6-month open treatment extension in this sample demonstrated continued improvement. More recently, Birmaher (2003) (84) demonstrated the benefit of fluoxetine for the treatment of the childhood anxiety disorders social phobia (SP), separation anxiety disorder (SAD), and generalized anxiety disorder (GAD). Only one controlled trial using low-dose sertraline for treatment of pediatric generalized anxiety disorder has been reported to date (85) (Tables 27.9 and 27.10).

### Other Sanctioned Uses (Level B Evidence)

#### Eating Disorders

Despite anecdotal reports of positive outcomes, randomized controlled studies of fluoxetine have *not* demonstrated efficacy in underweight adult anorexia nervosa (AN) inpatients (86). However, it appears that SSRIs *do* have a place in treatment of AN *following* weight restoration (and repletion of neuronal 5HT stores), including treatment of associated depressive symptoms. In one small 12-month controlled study, placebo-treated subjects with anorexia nervosa showed a greater rate of relapse compared to fluoxetine-treated subjects (87). More recently, restrictor-type pediatric-onset anorexia nervosa subjects showed reduction in obsessional thinking and improvement in depression scores with fluoxetine compared to placebo (63 versus 16%) at 1-year follow-up (88). Case reports and open trials document efficacy with other SSRI agents in binge eating and purging disorders using sertraline and fluoxetine combined with psychotherapy. (89).

#### Other Anxiety Disorders

Open studies have shown efficacy of SSRIs in anxiety disorders, including panic disorder (90), social phobia (91), and selective mutism (92). Based on their efficacy for other anxiety disorders, SSRIs are also commonly used in PTSD both for core symptoms as well as comorbid conditions

Source: Adapted from Geller et al. (2003) (21).

(93), and open-label trials have supported this practice (94). SSRIs have been proven effective in the treatment of adult PTSD in multiple controlled trials (95–97).

#### Pervasive Development Disorders/Autism

Only one controlled trial of fluvoxamine in children with autism and pervasive development disorders (PDDs) has been reported. This placebo-controlled 12-week trial of fluvoxamine demonstrated only limited efficacy and poor tolerability (98). Only one child experienced improvement, while 14 of 18 subjects randomized to fluvoxamine experienced adverse effects, including insomnia, hyperactivity, agitation, aggression, *increased* rituals, and anxiety.

#### Novel Uses (Level C Evidence)

##### Disruptive Behavior and Impulse Control Disorders

Open-label reports suggest benefit from treatment with the SSRIs for a variety of disruptive and impulse control symptoms including impulsive aggression (99, 100), self-scratching, self-mutilation, trichotillomania, and sexual behaviors (101–107). SSRIs may have utility in

addressing the comorbid symptoms frequently present in children with oppositional defiant disorder (ODD) and conduct disorder, including dysphoria and anxiety symptoms.

#### Initiating and Maintenance of Medication

Standard informed consent with parents or guardians and assent by the child or adolescent are the first steps in initiating medication. Informed consent includes, at a minimum, a discussion of potential risks and benefits of the proposed treatment, common adverse effects, and alternatives to the proposed treatment (*including no treatment and nonpharmacological treatment*). This discussion should be documented in the medical record. SSRI medication guides for families and clinicians are now available from the FDA ([www.fda.gov/cder/drug/antidepressants/MG\\_template.pdf](http://www.fda.gov/cder/drug/antidepressants/MG_template.pdf)) and jointly from the American Psychiatric Association and the American Academy of Child and Adolescent Psychiatry ([www.aacap.org/Announcements/pdfs/parentsmedguide.pdf](http://www.aacap.org/Announcements/pdfs/parentsmedguide.pdf); [www.aacap.org/Announcements/pdfs/physicians-medguide.pdf](http://www.aacap.org/Announcements/pdfs/physicians-medguide.pdf)).

In the case of a patient with OCD, informed consent should also include a discussion on the value and availability of cognitive behavioral treatments that are recommended as first-line interventions by the American Academy of Child and Adolescent Psychiatry for mild to moderate OCD. The presence of comorbid depression, more severe OCD, lack of intact family, or lack of available skilled CBT therapists all argue for an earlier introduction of medications. When initiating SSRI medications, several variables should be considered, including age, body weight, pubertal status, neurological status, and family history of drug response. The lowest available dose should be used for initiating medication in children or those with neurological insult or developmental delay, while adolescents can begin with dosages intermediate to those used in adult practice. Currently, there is no indica-

**TABLE 27.8**  
**RECOMMENDED DOSE RANGES FOR SSRIs IN PEDIATRIC OCD**

Drug	Starting Dose (mg)		Typical Dose Range (mg) (Mean Dose)*
	Preadolescent	Adolescent	
Clomipramine**	6.25–25	25	50–200
Fluoxetine***	2.5–10	10–20	10–80 (25)
Sertraline***	12.5–25	25–50	50–200 (178)
Fluvoxamine**	12.5–25	25–50	50–300 (165)
Paroxetine****	2.5–10	10	10–60 (32)
Citalopram***	2.5–10	10–20	10–60

\*Mean daily doses used in published controlled trials.

\*\*Doses <25 mg/day may be administered by compounding 25 mg into 5 ml suspension.

\*\*\*Oral concentrate commercially available.

\*\*\*\*Oral suspension available.

**TABLE 27.9**  
**SUMMARY OF OPEN-LABEL SSRI TRIALS IN PEDIATRIC ANXIETY DISORDERS**

Author (year)	Drug	Diagnosis	N	Length of Treatment (Weeks)	Dose Range (mg/day)	Age Range (Years)	Results
Chavira & Stein (2002) (621)	<i>Citalopram</i>	General social anxiety	12	12	10–40 Mean: 35	8–17	83% improved; 42% very much on CGI
Compton et al. (2001) (91)	<i>Sertraline</i>	Social phobia	14	8	Mean: 123 Max: 200	10–17	36% CGI responders
Masi et al. (2001) (622)	<i>Paroxetine</i>	Panic and other anxiety diagnosis	18	2–24	10–40 Mean: 24	7–16	83% CGI responders
Mancini et al. (1999) (623)	<i>Nefazodone</i> <i>Paroxetine</i> <i>Sertraline</i>	GAD, social phobia w/ anxiety or MDD	7	Up to 28	400 50–80 175	7–18	All responded with functional improvements
Renaud et al. (1999) (90)	<i>Fluoxetine</i> <i>Paroxetine</i> <i>Sertraline</i>	Panic w/ comorbid MDD, anxiety	12	6–8 follow-up: 36	20–60 20 125 +/- BZD	8–18	75% showed much or very much improvement on CGI-I
Fairbanks et al. (1997) (81)	<i>Fluoxetine</i>	GAD, SAD, multiple anxiety	16	6–9	Max: 24	9–18	100% CGI responders; SAD and social phobia had best response
Dummit et al. (1996) (92)	<i>Fluoxetine</i>	Selective mutism	21	9	10–60	5–14	76% improved on CGI-I, with more speech in public and at school; social anxiety improved
Birmaher et al. (1994) (80)	<i>Fluoxetine</i>	OAD, SAD, social phobia	21	40	10–60 Mean: 26	Not reported	81% CGI responders
Manassis & Bradley (1994) (82)	<i>Fluoxetine</i>	SAD, avoidant, mutism, OAD	5	6	10–20	Not reported	100% improved on parent and self-reports

tion for baseline laboratory tests (hematological, thyroid, hepatic or renal function tests) before and during the administration of SSRIs (108). Titration schedules should be conservative, with modest increases every 3 weeks or so to allow for improvement to manifest before aggressively increasing doses. An exception may be the treatment of inpatients where more control and supervision is available. Especially for treatment of anxiety disorders, *patience is key to successful outcomes*, since it may take a full 12 weeks for benefits to occur.

Common transient somatic side effects include gastrointestinal upset and headache. Parents should be aware of possible behavioral activation as well as the possibility of manic irritability, euphoria, and explosiveness in unusual and severe reactions, as discussed in the safety section that follows. Severe mood dysregulation on SSRI medications is not necessarily pathognomonic of underlying juvenile bipolar disorder. Clinical experience suggests that children with PDD spectrum disorders may be

particularly sensitive to serotonergic agents. As such, low dosage and slow titration is indicated in this population as well.

#### Maintenance/Monitoring

National psychiatric associations (the American Psychiatric Association [APA] and the American Academy of Child and Adolescent Psychiatry [AACAP]) concur with the need for close monitoring of children and adolescents on antidepressants. The FDA suggests monitoring to include weekly face-to-face contact with patients, family members, or caregivers during the first 4 weeks of treatment, then every other week for the next 4 weeks, then at 12 weeks, and as clinically indicated beyond 12 weeks, but this schedule is more frequent than common current clinical practice and may not be practical in all settings. The APA and AACAP suggest individualized monitoring; clinicians and families should watch for clinical worsening, agitation, irritability, suicidality, insomnia, or any unusual change in behavior,

**TABLE 27.10**  
**SUMMARY OF RANDOMIZED CONTROLLED TRIALS OF SSRIs IN PEDIATRIC ANXIETY DISORDERS**

Author (Year)	Drug	Diagnosis	N	Length of Treatment (Weeks)	Dose Range (mg/day)	Age Range (Years)	Results
Birmaher et al. (2003) (84)	<i>Fluoxetine</i>	GAD, SAD, social phobia	74	12	10–20	7–17	61 versus 35% showed much to very much improvement on CGI, $p = 0.03$ ; pts with SOC and GAD showed better response for med than placebo; severity of anxiety at baseline and positive family history predicted poorer response
Rynn et al. (2001) (85)	<i>Sertraline</i>	GAD	22	9	Up to 50	5–17	90% CGI improvement in active group, 10% in placebo, $p < 0.001$
Walkup et al. (2001) (83)	<i>Fluvoxamine</i>	GAD, SAD, social phobia	128	8	25–300 (mean:110)	6–18	76% responders among active, 29% among placebo on CGI-I, $p < 0.01$
Carlson et al. (1999) (624)	<i>Sertraline</i>	Elective Mutism	5	16	50–100	5–11	All much or very much improved on CGI-I up to 20 weeks
Black & Udhe (1994) (625)	<i>Fluoxetine</i>	Elective Mutism	15	12	12–27	6–12	Fluoxetine was better, although most still impaired; no significant difference between groups on CGI scales

especially during the initial few months of drug therapy or at times of dose changes ([www.fda.gov/cder/drug/antidepressants/MG\\_template.pdf](http://www.fda.gov/cder/drug/antidepressants/MG_template.pdf)).

The limited study of blood plasma levels and clinical response, primarily with fluoxetine, does *not* support routine use of therapeutic drug monitoring (28). Some exceptions may apply, for example, in combined pharmacotherapy or in overdose situations. A study of citalopram presented information on plasma levels in a naturalistic treatment of adolescents with depression (109). Multiple RCTs have not found any clinically significant changes in laboratory parameters such as complete blood count with differential, liver, renal, and thyroid function, or lipid and glucose metabolism nor in electrocardiographic (ECG) parameters (84), precluding the necessity for routine evaluation.

Optimal antidepressant maintenance therapy, discontinuation, and therapy failure are still being studied in adults with mood disorder (110, 111). Limited information can be found for pediatric populations (112). AACAP guidelines suggest continuing antidepressant treatment for

at least 6 to 12 months following clinical response, depending on the patient's clinical status, functioning, support systems, environmental stressors, motivation for treatment and compliance, and the presence of comorbid disorders (108). In those with no response, treatment with adequate and tolerable doses should continue for at least 4 to 6 weeks before considering other treatment options. Overall, allowing sufficient time to achieve clinical response is likely more important than aggressive titration, due to a flatter dose response curve at higher doses (26). These recommendations are generally consistent with the adult literature. Certain factors, such as recurrent, frequent, or severely disabling episodes, suggest the need for longer-term maintenance treatment.

Gradual taper and discontinuation should be timed appropriately, taking into account the impact of psychosocial stressors on clinical condition, such as the beginning and end of the school year. SSRI medications with short half-lives, such as paroxetine, should be tapered more gradually to avoid discontinuation effects (113, 114).

### Safety

In general, SSRIs are well-tolerated medications, and they are safer than their predecessor TCAs, especially in the setting of misuse or overdose. Side effects are usually mild and often dose dependent. Acute effects such as gastrointestinal upset, decreased appetite, headache, restlessness, insomnia, and fatigue may occur, as well as behavioral or mood changes. There are no *known* longterm adverse effects of the use of SSRI medications in pediatric populations.

**Suicidality.** After the UK Department of Health statement in the summer of 2003 alerting the public of a 1.5- to 3-fold increased risk of self-harm or suicidal thinking in youth taking paroxetine, the FDA (Dr. Mosholder, Division of Drug Risk Evaluation) and expert panels conducted an extensive review of SSRI medications in all shortterm pediatric clinical trials.

Although Dr. Mosholder reported a statistically significant association of “suicidality” adverse events (N = 78) with antidepressant drug treatment in shortterm pediatric clinical trials, due to concerns regarding misclassification of cases and prior to a definitive analysis, the FDA contracted Columbia University in the summer of 2004 to perform an independent and blinded review of adverse events. Using original narratives, the panel redefined adverse events from pediatric antidepressant trials as (1) suicidal events (attempts, aborted attempts, interrupted attempts, and suicidal ideation–related events), (2) nonsuicidal events (self-injury or mutilation without suicidal intent, events attributable to other psychiatric symptoms, medical or accidental injuries), (3) and indeterminate events (non-consensus or unable to classify due to limited data) ([www.fda.gov/cder/drug/antidepressants/classification-Project.htm](http://www.fda.gov/cder/drug/antidepressants/classification-Project.htm)).

Following the Columbia classification, Dr. Hammad (FDA, Division of Neuropharmacological Drug Products) performed a new meta-analysis of 95 adverse event cases across 23 pediatric trials. *No individual trial* showed a statistically significant signal for suicidality. However, many trials had a relative risk of 2 or more, and some of the *overall estimates*, across various trial groupings, were statistically significant. Most events were in trials in which the highest proportion of patients had a history of suicide attempt or ideation *at baseline*. Dr. Mosholder concluded that the Columbia reclassification did not materially affect his prior conclusions. Yet the overall risk estimate for “all trials” analysis decreased with the Columbia University reclassification from 1.89 to 1.78, and the risk estimate for SSRI *MDD-only* trials decreased and lost statistical significance. However, for individual drugs, the risk estimates for paroxetine and venlafaxine increased.

Based on these analyses of 24 pediatric antidepressant trials involving more than 4,400 patients, in October 2004, the FDA issued a black box warning on all pediatric antidepressants ([www.fda.gov/cder/drug/antidepressants/](http://www.fda.gov/cder/drug/antidepressants/)

[SSRIlabelChange.htm](http://www.fda.gov/cder/drug/antidepressants/SSRIlabelChange.htm)), as well as a public health advisory ([www.fda.gov/cder/drug/antidepressants/SSRIPHA200410.htm](http://www.fda.gov/cder/drug/antidepressants/SSRIPHA200410.htm)). The FDA concluded there was a greater risk of suicidality during the first few months of treatment in those receiving antidepressants; 4% average risk of such events on drug, and twice the placebo risk of 2%. *No suicides* occurred in these trials. In February 2005, the FDA made an important alteration to its black box labeling language from “antidepressants *increase* the risk of suicidal thinking and behavior (suicidality) in children and adolescents with major depressive disorder (MDD) and other psychiatric disorders” to “antidepressants *increased* the risk of suicidal thinking and behavior (suicidality) *in short-term studies*.”

Although there was a 4% average risk of *spontaneously reported (parent or youth)* suicidal thinking or suicidality on drug versus 2% on placebo, in 17 of these 23 trials, a direct assessment (*standardized youth self-assessment*) of suicidality demonstrated a slight *reduction* in suicidality (<http://www.aacap.org/Announcements/pdfs/physicians-medguide.pdf>). Consistent with this evidence, in the most recent multicenter trial of SSRI in pediatric depression (49), the number of youth reporting suicidal ideation declined from 29% at baseline to 10% at week 12. Suicidal thinking declined in the fluoxetine + CBT group compared to placebo ( $p = 0.02$ ), fluoxetine alone ( $p = 0.002$ ), and CBT alone ( $p = 0.05$ ). There were no completed suicides, and the number of attempts (7 patients; 1.6%) was too small to analyze.

In addition to the evaluation of clinical trial data just described, toxicological and epidemiological data support a favorable risk-benefit ratio of SSRIs in the treatment of depression in youth (115). The Task Force on SSRIs and Suicidal Behavior in Youth (January 2004) posted by the American College of Neuropsychopharmacology (<http://acnp.org>) described toxicological analysis in adults and youth noting that, in those completing suicide, the majority had *not* been taking the antidepressant prior to death. Further, the task force cited international epidemiological data in support of *declining* rates of suicide in youth over the previous decade, coincident with increasing antidepressant prescription rates. The Center for Disease Control (CDC) concurs the overall rate of suicide among youth has declined slowly since 1992 (116).

In an examination of 1996–1998 U.S. suicide rate data from the CDC, with county-level prescription data (ages 5 and older) from a random sample of 20,000 pharmacies, increases in SSRI prescriptions were associated with lower suicide rates (117). These findings were consistent with a similar U.S. analysis in youth from 1990 to 2000; a 1% increase in adolescent use of antidepressants was associated with a decrease of 0.23 suicide per 100,000 adolescents per year ( $P < 0.001$ ) (118). In addition, a retrospective longitudinal cohort study of managed care enrollees aged 12 to 18 years found that antidepressant treatment for at least 6 months reduced the likelihood of suicide attempt

compared with antidepressant treatment for just 8 weeks (hazard ratio = 0.34; CI 0.21, 0.55) (119).

Clearly there is need for ongoing study in this area, to provide a better delineation of risk for a given child or adolescent treated with an SSRI. However, the following risk estimate is offered based on a 4% average risk of spontaneously reported suicide thinking or suicidality on the drug versus 2% on placebo; if a clinician prescribes an SSRI for 200 *new* patients, 8 patients may express increased suicidal thinking or behavior. Of these 8 patients, increased suicidality may be attributed to the underlying depression in 4 patients and attributed to the SSRI in 4 patients (AACAP letter to clinicians, October 31, 2004).

Paroxetine's short half-life, nonlinear pharmacokinetics, and CYP450 2D6 inhibition and metabolism are likely relevant to its side effect profile (63). In a pediatric pharmacokinetic (PK) study of paroxetine, the subject with the poorest 2D6 metabolic activity was the first subject to develop hypomania, at week 3 of treatment (34). Paxil CR, which contains a degradable matrix designed to control release of paroxetine over 4 to 5 hours using an enteric coating to delay release (GlaxoSmithKline, 2004), may provide a useful alternative.

**Activation/Switching.** Activation implies an alteration in mood, anxiety, or behavioral state (such as restlessness) induced by a medication, such as an SSRI. Activation does not signify the presence of hypomania or mania or necessarily herald bipolar disorder. These relatively mild adverse events may be dose related and may resolve with reduction of dose without discontinuation. Contrary to activation, treatment-emergent affective (mood) switching (TEAS) implies a switch from one mood state (depression) to another (hypomania or mania) in the context of an antidepressant, such as an SSRI. While TEAS has been described in the adult bipolar disorder literature, there has been little study in the pediatric literature regarding the phenomenon of switching on antidepressant medications. Martin et al. (120) examined a national database (1997–2000) of 7 million mental health users 5 to 29 years old to assess the risk of mood switching (manic conversion) by age and antidepressant class. The authors found manic conversion in 4,786 patients (5%), with the lowest risk in the SSRI class (hazard ratio 2.1) versus other antidepressant classes (hazard ratio 3.8–3.9). In this review, peripubertal children (10 to 14 years old) were at highest risk of conversion.

In his analysis, Dr. Hammad examined 90 events in all pediatric MDD trials characterized by emergent symptoms of hostility or agitation. No individual trial had a statistically significant result, yet the overall RRs for all drugs, for all SSRIs, and for Paxil were statistically significant, showing an increase in the risk of developing these symptoms compared to placebo.

As depression may be the (unknown or unexpected) index episode of a bipolar disorder, clinicians must monitor

for switching into a hypomanic or manic state. True manic conversion precludes the further use of SSRIs without first achieving adequate mood stabilization. Case reports of treatment-emergent mania or hypomania in children or adolescents treated with SSRI medications have been described across numerous diagnostic categories (121–124). Such SSRI-induced mania or hypomania may require treatment with mood stabilizers beyond discontinuation of the antidepressant.

**Other.** Serious adverse effects, including the serotonin syndrome, have been described in children taking SSRIs (125). Numerous case reports also document the emergence of extrapyramidal symptoms (EPS) as well as tics and myoclonus in children and adolescents treated with SSRI medications (121, 126–131), as well as in adults (132). Hyperreflexic tendon reflexes are common on neurological exam. Animal studies have suggested that SSRIs possess tonic inhibitory properties within the central dopamine system, but it is unknown if this is the cause for motoric adverse effects since their dopaminergic effects are clinically insignificant (45). The amotivational syndrome, previously described in adults taking SSRIs, has been described in several children and adolescents and could also reflect dopamine inhibition (133).

Concerns have been expressed regarding possible decreased growth (101, 134), and increased bleeding rates (135, 136) in SSRI-treated patients. In a population-based cohort study in Denmark and the Netherlands, serotonergic antidepressants increased the risk of gastrointestinal adverse effects in adults, including upper GI bleeding, which was increased in turn by nonsteroidal anti-inflammatory drugs (NSAIDs) and low-dose aspirin (137, 138). Disruption in sleep architecture along with sleep disturbance and subjective accounts of vivid dreaming has also been described with SSRIs, although infrequently in children (139).

### Drug Interactions

Mono-amine oxidase inhibitors (MAOIs) should not be given within 5 weeks after discontinuation of fluoxetine or within 2 weeks after other SSRIs. Conversely, SSRIs should not be administered within 2 weeks after discontinuing MAOI treatment. Inappropriate combination with MAOIs may induce potentially serious adverse effects, including the serotonin syndrome. Interactions with medications that utilize or inhibit various CYP450 pathways may occur, as described in the pharmacokinetic section presented earlier. Clinical effects may reflect 2D6 and 1A2 (TCA, antipsychotics), 2C (TCA), and 3A4 (TCA, erythromycin) enzyme interactions (see Table 27.10). In addition, the SSRIs are protein bound to varying degrees and can displace other protein-bound medications and increase their effects (Table 27.11).

SSRI medications are widely used in part due to their wide therapeutic margin of safety (140, 141). Overdoses do occur, such as a life-threatening overdose of fluvoxamine in

## NOVEL ANTIDEPRESSANTS

### Bupropion/Venlafaxine/Mirtazapine/Trazodone

#### Pharmacokinetics

Pharmacokinetic studies in pediatric populations are extremely limited. For example, Stewart et al. (2001) (146) examined the moderating effects of smoking status and gender on single-dose pharmacokinetic parameters of bupropion in adolescents and found that plasma levels of bupropion and its metabolite hydroxybupropion did not

differ between smokers and nonsmokers. However, the mean area under the curve (AUC) ratio of hydroxybupropion to bupropion was lower than reported in adults. Both bupropion and venlafaxine are available in controlled-release formulations, which may have pharmacokinetic advantages, such as lower peak drug levels and smaller fluctuations between peak and trough plasma levels, resulting in better tolerability (147). Bupropion XL, an even longer-acting formulation, is now available. One 300 mg XL capsule provides comparable equivalence in peak plasma and AUC to 100 mg three times a day immediate-release tablets (GlaxoSmithKline, 2003); this formulation may also have superior tolerability (148). Marked inter- and intra-individual variability was observed in one study of the pharmacokinetics of nefazodone with children showing greater absorption and faster clearance compared with adults (149) (Table 27.12)

**TABLE 27.12**

5HT, Serotonin; CVS, Cardiovascular system; CYP, Cytochrome; P450 DA, dopamine; H1, Histamine; NE, Norepinephrine; T-Max, Time to peak plasma level.

### Pharmacodynamics

This group of antidepressants possesses mixed actions on several neurotransmitter sites, including Norepinephrine (NE), dopamine (DE), and 5HT. Mirtazapine is an antagonist of presynaptic alpha 2-adrenergic autoreceptors as well as presynaptic norepinephrine and serotonin (5-HT) heteroreceptors. It is also a potent antagonist of postsynaptic 5-HT<sub>2</sub> and 5-HT<sub>3</sub> receptors. Net effects of treatment include greater noradrenergic and serotonergic activity, especially at the 5-HT<sub>1A</sub> (auto) receptor (150, 151). Venlafaxine exhibits mixed NE and 5HT activity; 5HT reuptake inhibition predominates at lower doses, while NE reuptake inhibition increases with higher doses, and some dopamine reuptake inhibition occurs at high dose (25, 152). Bupropion exerts its effects via an alternate mechanism with inhibition of both NE and DA reuptake, although its occupancy of the DA transporter (DAT) is low (153). Trazodone possesses 5HT reuptake inhibition and 5HT<sub>2</sub> antagonism, as well as alpha-1 antagonism and antihistamine effects (25). One of the more common uses of trazodone exploits the potential adverse effect of sedation produced by this receptor activity by employing it at night as a hypnotic agent.

### Pharmacotherapy

Mixed neurotransmitter antidepressants may possess special therapeutic utility, such as in conditions refractory to common SSRI agents. Yet even in the extant adult literature, there is little controlled trial evidence available that can guide subsequent treatment for those individuals with no response or partial response to a first-line agent such as an SSRI. Therapeutic strategies may include switching agents within the same class, using another class of agents, or using augmentation with a second drug that has differing pharmacodynamic actions, such as adding noradrenergic or dopaminergic activity to a primary serotonergic drug (154). Bupropion's proposed NE activity, limited CYP-450 interactions, and infrequent sexual side effects has made it a popular augmentation agent in depressed adult partial responders to SSRIs or venlafaxine, and this strategy is supported by efficacy in open trials (155).

In addition, the adult literature suggests that medications affecting multiple neurochemical systems, such as venlafaxine, may achieve higher rates of remission relative to other agents (156, 157). Mirtazapine's increased neuronal cell firing, due to its mixed actions on NE (alpha(2) antagonism) and 5-HT (alpha(1)-stimulation by NE), may result in faster onset of action than more selective antidepressants as suggested by clinical evidence (158).

### Mood Disorders

Despite frequent use in clinical settings of mixed activity antidepressants in youth, very limited data exists regarding their safety and efficacy. Controlled trials in youth have been conducted with bupropion, showing a significant advantage for depression symptoms in a small cohort

(N = 24) (159) and with low-dose venlafaxine (160). In the latter trial, venlafaxine was not superior to placebo for the treatment of depression in children and adolescents, possibly due to the low doses and short duration of this trial. Open-label studies suggest benefit from these agents as monotherapy, as well as in combination treatment, such as venlafaxine combined with lithium in adolescent depression (161).

Trazodone has been used for insomnia in adolescents with depression (162). Such use is well supported by adult practice, in which trazodone is uniquely utilized in the management of insomnia associated with mood disorder or SSRI treatment (163, 164), as well as PTSD, and primary sleep disorders (165, 166). In these adults, trazodone has been shown to have positive effects on sleep without altering normal sleep architecture (167–169). Mirtazapine has demonstrated similar improvement on objective sleep parameters in depressed adults (170) and because of its sedating properties may be useful in agitated depression.

### Anxiety Disorders

There is some rationale for using mixed or dual action agents in pediatric anxiety disorders. For example, individuals with generalized anxiety disorder may benefit from drug activity in both 5HT systems as well as normalization of a presumptive overactive NE system (171). In fact, venlafaxine XR was the *first* antidepressant approved by the FDA for the treatment of GAD (172). Unfortunately, there are no controlled studies of mixed action antidepressants for anxiety disorders in pediatric populations.

The use of trazodone has been recommended by "Expert Consensus Guidelines" for PTSD, when sleep improvement does not improve with first-line agents (173). Open reports also cite improvements in symptoms of mood disturbance and hyperarousal, anger, aggression, restlessness, insomnia, and concentration in youth with PTSD (174).

### Attention Deficit Hyperactivity Disorder

Clinical trials of bupropion for ADHD have included a single site placebo-controlled study (175), a multicenter controlled trial (176), a crossover trial with methylphenidate (MPH) (177), and a study of bupropion sustained release formulation in adolescents with attention deficit hyperactivity disorder and comorbid depression (159). Collectively, these studies show that bupropion is an effective agent for the treatment of ADHD in youth, albeit with a more modest effect size than traditional stimulants. Furthermore, bupropion may have clinical value for youth with ADHD and comorbid substance abuse or dependence, as well as mood disorder (178).

### PDD Disorders/Autism

A small retrospective clinical study with venlafaxine in children with DSM-IV autism spectrum disorder showed some improvement in repetitive behaviors and restricted interests, social deficits, communication and language

function, inattention, and hyperactivity at a very low mean dose of 24 mg daily (179).

### Disruptive Behavior, Impulse Control, and TIC Disorders

Trazodone has been used to treat aggression, including cases with neurological injury, and hydrocephalus in youth (180). Case reports suggest efficacy in reducing refractory aggression, hyperactivity, and self-injurious behavior in children with frontal lobe atrophy (181) or treatment refractory hospitalized aggressive children (182).

### Initiating and Maintenance of Medication

**Initiation.** The principles in initiating this group of medications are similar to those outlined in the SSRI section including obtaining informed consent and consideration of age, body weight, pubertal status, neurological status, and family history of drug response. Medication guides for families and clinicians are now available from the FDA ([www.fda.gov/cder/drug/antidepressants/MG\\_template.pdf](http://www.fda.gov/cder/drug/antidepressants/MG_template.pdf)) and jointly from the American Psychiatric Association and the American Academy of Child and Adolescent Psychiatry ([www.aacap.org/Announcements/pdfs/parentsmedguide.pdf](http://www.aacap.org/Announcements/pdfs/parentsmedguide.pdf); [www.aacap.org/Announcements/pdfs/physiciansmedguide.pdf](http://www.aacap.org/Announcements/pdfs/physiciansmedguide.pdf)).

The lowest available dose should be used for initiating medication treatment in children or those with neurological insult or developmental delay, and titration schedules should be conservative, with modest increases each 3 to 4 weeks to allow improvement to manifest before increasing doses. Prior to initiating bupropion treatment, one should assess for factors that increase risk for seizures (head trauma, prior history of seizure, concomitant medications that lower seizure threshold). Doses greater than 450 mg daily increase the risk of seizures compared to other antidepressants. Baseline cardiovascular parameters (heart rate, blood pressure) should be obtained, particularly when using bupropion and venlafaxine, which can cause diastolic hypertension.

**Monitoring.** As discussed in the SSRI section presented earlier, national psychiatric associations (the American Psychiatric Association and the American Academy of Child and Adolescent Psychiatry) concur with the need for close monitoring of children and adolescents on antidepressants.

Monitoring and maintenance use of this group of medications is according to the principles outlined in the SSRI section; that is, routine serum level assays are not clinically helpful and routine liver, renal, thyroid, glucose, lipid, and hematological monitoring studies are not generally required. However, assessment of cardiovascular parameters (blood pressure, heart rate) is recommended with this group of medications.

### Safety

**Adverse Effects.** In general, these medications are well tolerated clinically in youth. Side effects tend to be mild and dose dependent. In the short term, gastrointestinal upset, constipation, decreased appetite, headache, dry mouth, restlessness, insomnia, fatigue, and sedation may occur. Adverse effects with this group reflect their various pharmacological profiles; histamine blockade with agents such as trazodone and mirtazapine cause more sedation than bupropion and venlafaxine, which possess little such activity.

In adult studies, mirtazapine has been associated with somnolence, increased appetite, and weight gain that are attributed to its antihistaminic (H1) activity at low doses (183). Adult case reports have also described glucose deregulation, weight gain (184), hepatotoxicity (185), hypertriglyceridemia, pancreatitis, and diabetic ketoacidosis with mirtazapine (186). Nicholas et al. (2003) (187) reported significantly increased total cholesterol at week 4 in one controlled study of otherwise healthy adults treated with mirtazapine.

In adults, venlafaxine may be associated with small, but statistically significant, dose-dependent increases in systolic and diastolic blood pressure during acute and continuation therapy. This effect is more frequent at doses at or above 300 mg daily (188). In another study, no differential effect on blood pressure in young (13 to 56 years) versus old (65 to 86 years) depressed patients treated with dosages of 50 to 250 mg daily were found, despite a higher mean weight-adjusted daily dosage in younger patients. No significant changes in systolic blood pressure were noted in either group. In the older group only, there was a 4.7 mm Hg mean increase in diastolic blood pressure ( $p = ns$ ) (189).

Trazodone-associated priapism has been well described in adults and in adolescents (190), although scattered cases also have been reported with use of other medications, including venlafaxine (191). This effect appears related to trazodone's alpha-adrenoreceptor-blocking properties and interference of sympathetic control of penile detumescence (192).

The risk of seizures with bupropion is dose dependent, estimated at 0.1% at 300 mg daily of slow-release formulation compared to 0.4% at doses from 300 to 450 mg of immediate-release drug. Seizure risk may increase 10-fold in dosages greater than 450 mg daily (GlaxoSmithKline). Since its introduction, bupropion has been believed empirically to have fewer cardiovascular adverse effects than other treatments, including in adults with preexisting cardiac disease (193–196). Adverse sexual effects are also uncommon. There are no known longterm adverse effects of using mixed-action antidepressants in pediatric populations; however, controlled longitudinal data are lacking.

**Suicidality.** As described earlier in detail in the SSRI section, the FDA has performed meta-analyses of adverse event cases across antidepressant pediatric trials, including

bupropion, mirtazapine, and venlafaxine. The FDA has instituted the following black box labeling: “antidepressants *increased* the risk of suicidal thinking and behavior (suicidality) *in short-term studies*.”

**Activation/Switching.** As described in detail in the SSRI section, activation implies an alteration in mood, anxiety, or behavioral state (such as restlessness) induced by a medication, such as an antidepressant (197). Activation does not signify the presence of hypomania or mania, nor does it necessarily herald bipolar disorder. These relatively mild adverse events may be dose related and may resolve with reduction of dose without discontinuation. Contrary to activation, treatment-emergent affective (mood) switching (TEAS) implies a switch from one mood state (depression) to another (hypomania or mania) in the context of a treatment, such as with an antidepressant. As depression may be the (unknown or unexpected) index episode of a bipolar disorder, clinicians must monitor for switching into a hypomanic or manic state. True manic conversion precludes the further use of an antidepressant without first achieving adequate mood stabilization.

### Overdose

Retrospective studies of overdose exposure to these agents are available for both adult and pediatric samples. Overdose with bupropion is primarily associated with neurological, rather than cardiac effects. A retrospective review of 7,348 bupropion-only pediatric overdose exposures reported clinical adverse effects in 2,247 exposures overall, but in only 8% of children younger than 6 years old compared to 46% of teenagers (198). Similarly, in a prospective study of bupropion, adverse effects of poisoning in 59 adults and 10 children included tachycardia (83%), hypertension (56%), dose-dependent seizures (37%), gastrointestinal symptoms (37%), and agitation (32%). Only one out of eight children with accidental ingestion had symptoms (vomiting and hallucinations) (199). Bupropion overdose (mean 3.8 g) has been associated with tachycardia, hypertension, and prolongation of QTc of 461  $\pm$  34 msec (200). Rarely death with massive ingestion has been reported; a 26-year-old man ingested 23 g of bupropion, with seizures and cardiac arrest (201).

The relative toxicity of SSRIs and venlafaxine was reviewed and found to be generally similar (140). Seizures occurred in 7 out of 51 venlafaxine overdoses with greater than 900 mg. SSRIs were less likely to prolong the QRS interval and intensive care unit (ICU) admissions were also less likely (140). Venlafaxine’s potential for cardiac and neurotoxicity may be dependent on whether the individual is an extensive or poor metabolizer (deficient CYP2D6 enzyme phenotype) (202). Overdose with 30 and 50 times a normal daily dose of mirtazapine has resulted in full recovery (203); case reports of ingestions including a 3-year-old child did not observe serious sequelae (204). In addition, the clinical trial development program of mirtazapine,

performed in Europe and the United States, evaluated its safety based on data from all patients who took at least one dose of study medication during studies comparing mirtazapine with placebo or other comparators. The only adverse symptom in patients taking an overdose of mirtazapine alone or in combination with other drugs was excessive but transient somnolence (205).

Seizures, hyponatremia, torsades de pointes, prolonged QT, and complete atrio-ventricular (AV) block have all been reported with trazodone overdose (206–209).

### Drug Interactions

Interactions based on pharmacokinetics, specifically the CYP450 system, are shown in Table 27.10. Venlafaxine has modest effect on CYP 2D6 substrates (210). While mirtazapine does not itself substantially inhibit CYP450 enzymes *in vitro* (211), induction or inhibition of CYP450 enzymes by other agents may cause significant increases or decreases in concentration as demonstrated by a 46% reduction in mirtazapine plasma concentration with the addition of phenytoin, a CYP3A4 inducer (212). Mirtazapine and lithium appear to be safe in combination (213).

Few drug interactions are described with bupropion. However, Shad and Preskorn (1997) (214) described an approximately fourfold increase in levels of imipramine and desipramine after the addition of bupropion. Popli et al. (1995) (215) reported that coadministration with carbamazepine may reduce bupropion levels, while valproate levels may increase with concomitant bupropion.

Pharmacodynamic interactions may cause additive degrees of sedation when sedating antidepressants such as trazodone and mirtazapine are taken with other CNS-active depressants. In addition, trazodone may potentiate hypotension when taken with other agents with similar effect.

## TRICYCLIC ANTIDEPRESSANTS

Until the emergence of fluoxetine in 1987, tricyclic antidepressants were mainstay agents in both general and child and adolescent neuropsychopharmacology. Agents include tertiary (imipramine, clomipramine) and secondary amines (desipramine, nortriptyline).

### Pharmacokinetics

Absorption is rapid from the gastrointestinal tract, reaching peak levels in 2 to 4 hours. TCAs are highly protein bound and lipophilic agents. In animals, brain penetration of amitriptyline is enhanced when the blood-brain barrier is deficient, a finding that may have some importance in neurologically compromised children (216). TCAs undergo metabolism via the CYP450 system; the primary metabolic enzyme is 2D6, yet other pathways may be involved, such as CYP2C19 (217). TCAs have a shorter half-life in children

compared to adults (218), and linear pharmacokinetics. Excretion is primarily renal as the inactive metabolite.

Research regarding TCA pharmacokinetics has found an effect of variable CYP2C19 and CYP2D6 genotypes on the metabolism of clomipramine (219). In another study, the duplication of CYP2D6 genes predicted higher clearance of desipramine (220). Novel formulations are under investigation, such as a sustained-release dosage form of clomipramine and osmotic-release (OROS) amitriptyline (221).

### Pharmacodynamics

In addition to inhibition of NE and 5HT reuptake, other putative mechanisms of TCA action include decreasing the density of postsynaptic B-adrenoreceptors and 5HT receptors with chronic administration. However, the final pathway of action is likely to involve modulation of a biochemical chain of events and altered genomic expression (222). Secondary amines such as nortriptyline (NT) and desipramine (DMI) have greater relative effect on NE transmission (and little or no 5HT effect), compared to tertiary amines which usually have both NE and 5HT effects. In addition, secondary amine TCAs have less anticholinergic and antihistaminic activity and consequently fewer such side effects.

Neuroimaging studies include work by Suhara et al. (2003) (223). Using positron emission tomography, the authors showed a high degree of serotonin transporter occupancy with low-dose clomipramine in a comparative occupancy study with fluvoxamine.

### Pharmacotherapy

For children and adolescents, TCAs have proven efficacy in the treatment of enuresis, OCD, and ADHD, with second-line utility in a variety of other neuropsychiatric conditions (224). FDA indications for this class are limited to enuresis (imipramine) and OCD (clomipramine).

#### Mood Disorder

Despite an approximately 80% response rate in adults with major depressive disorder (222), TCAs have not been shown to be significantly effective in juvenile depressive disorders (225, 226). According to a *Cochrane Systematic Review* (227) of 13 trials (506 participants), no overall improvement with TCA treatment compared to placebo was seen for children or adolescents. Subgroup analyses suggested a larger benefit among adolescents (effect size [ES] = -0.47, 95% confidence interval -0.92 to -0.02) and no benefit among children (ES = 0.15, 95% confidence interval -0.34 to 0.64). Interpretation of individual trial results is limited by numerous methodological shortcomings. However, TCAs may be otherwise appropriate in specific pediatric populations, such as treatment-resistant or severe MDD (56, 228).

#### Anxiety Disorders

Despite comparable efficacy to the SSRIs in adult panic disorder (229), with the exception of pediatric OCD, there are limited controlled data in pediatric anxiety disorders. Four double-blind, placebo-controlled studies, evaluating TCAs for the treatment of anxiety-based school refusal produced conflicting results (230–233).

Clomipramine (CMI) may have unique properties among the TCAs as the parent compound has potent serotonergic activity before being metabolized to a secondary amine. Early studies and subsequent multisite industry-sponsored RCTs demonstrated its superiority over placebo and desipramine in both short-term and longer-term RCTs for pediatric OCD (234–236). Meta-analyses in both adults (237–239) and children (21) have suggested that it is significantly more effective than the SSRIs for OCD at all ages. In the latter study, the effect size for CMI was 0.69, which was significantly higher than for each of the SSRIs (21). However, head-to-head studies in adults have failed to show this superiority and also found that SSRIs are better tolerated. Such studies have not been done in youth.

#### Attention Deficit Hyperactivity Disorder (ADHD)

Expert opinion is that tricyclic antidepressants have positive efficacy comparable to that of stimulants (240–242). However, their adverse effect profile limits their utility (240, 241). Agents with efficacy demonstrated in RCTs include imipramine, desipramine, and amitriptyline. In the largest controlled trial of desipramine (DMI) in children, Biederman et al. (1989) observed a robust response in 62 children with ADHD. Four trials comparing TCAs with MPH indicated either no differences in response or slightly better results with stimulants (244).

#### Tic Disorders

Following observation in open reports that the TCA desipramine improved tics as well as ADHD symptoms, Spencer (2003) (243) conducted a 6-week, double-blind, placebo-controlled, parallel trial of desipramine (to 3.5 mg/kg per day) versus placebo. Desipramine significantly reduced tic symptoms by about 30% from baseline relative to placebo using the Yale Global Tic Severity Scale with equal response in both motor and vocal tics.

#### Enuresis

Imipramine has an FDA indication for treatment of enuresis, and until the emergence of the newer pharmacological treatments such as desmopressin acetate (DDAVP) (244), TCAs had a primary role in the management of enuresis. A 2002 Cochrane systematic review of 54 RCTs (N = 3379) of TCAs or related drugs for nocturnal enuresis in children showed that treatment with tricyclic drugs (imipramine, amitriptyline, nortriptyline, clomipramine, and desipramine) was associated with a reduction of approximately one wet night per week. About 20% of the children

became dry while on treatment, but this effect was not sustained after treatment stopped. Overall, these reviewers concluded that although tricyclics and desmopressin are effective in reducing the number of wet nights, most children relapse after stopping active treatment, compared to about 50% relapse after alarm treatment (245).

### **Pervasive Developmental Disorders**

Clomipramine (CMI) showed improvement on standardized ratings of stereotypic and self-injurious behaviors, anger and aggression, impulsivity, and social relatedness in autistic children (246). Efficacy of the serotonergic CMI was superior to the noradrenergic TCA desipramine in another controlled study (247). In a short-term trial, individuals with autistic disorder were randomly assigned to placebo, clomipramine, or haloperidol. Fewer individuals receiving clomipramine were able to complete the trial due to side effects and lack of efficacy or behavioral problems. In the intent-to-treat sample, only haloperidol showed significant improvement from baseline on global measure of autistic severity, as well as specific measures for irritability and hyperactivity (248).

### **Initiating and Maintenance of Medication**

#### **Initiation**

Medication guides for families and clinicians are now available from the FDA ([www.fda.gov/cder/drug/anti-depressants/MG\\_template.pdf](http://www.fda.gov/cder/drug/anti-depressants/MG_template.pdf)) and jointly from the American Psychiatric Association and the American Academy of Child and Adolescent Psychiatry ([www.aacap.org/Announcements/pdfs/parentsmedguide.pdf](http://www.aacap.org/Announcements/pdfs/parentsmedguide.pdf); [www.aacap.org/Announcements/pdfs/physiciansmedguide.pdf](http://www.aacap.org/Announcements/pdfs/physiciansmedguide.pdf)).

In addition to general principles that apply to all medications, the unique side effect profile, particularly suppression of cardiac conductivity, mandates a careful evaluation of baseline physical health, cardiovascular parameters, and ECG prior to initiating TCAs in children. A family history of cardiac illness, such as conduction deficits or early sudden death (as distinct from late-onset coronary atherosclerotic disease), should be elicited. Blood count and liver enzyme assays are often suggested as baseline evaluation. Ideally, initiation of a TCA should be done in cooperation with a child or adolescent's primary care physician. Guidelines have been published regarding the use of TCAs in children and adolescents (249, 250). TCAs are typically begun in the range of 1.0 mg/kg daily, with gradual titration (e.g., q 7 to 14 days). Maximum dosing is 3 mg/kg daily for CMI and NT or 5 mg/kg daily for DMI.

#### **Monitoring**

As discussed in the SSRI section presented earlier, national psychiatric associations (the American Psychiatric Association and the American Academy of Child and Adolescent Psychiatry) concur with the need to closely monitor children and adolescents on antidepressants.

Pulse and blood pressure measurement should be performed at office visits intermittently, as well as an ECG with dosage increases and upon reaching target dose, and then periodically during maintenance therapy at three to six monthly intervals. TCA serum levels are monitored to guide treatment, as well as to assess for potential toxicity. It should also be noted that laboratory reference ranges are broad guides only and that some children may benefit from maintenance at serum levels that are above the upper limit of the reference range. In these cases, close attention to ECG parameters is necessary.

### **Safety and Side Effects**

Adverse effects of TCAs can be attributed to the multiple receptor activity of these agents; antimuscarinic (anticholinergic), antiadrenergic (alpha-1, alpha-2), and antihistaminic. Tertiary amines have greater affinities for these sites and therefore produce more adverse effects. Anticholinergic effects include dry mouth, constipation, blurred vision, and sinus tachycardia. Antiadrenergic effects include orthostatic hypotension, dizziness (alpha-1), and blockade of alpha agonists such as clonidine. Antihistaminic effects include weight gain and sedation.

Clinical trials with TCAs in youth cite frequent adverse effects such as dizziness, headache, tremor, nausea, insomnia, dry mouth, and anxiety (56). According to a *Cochrane Systematic Review* (227) of 13 TCA trials (506 participants), only vertigo, orthostatic hypotension, tremor, and dry mouth occurred more often than with placebo. Dry mouth in children may increase risk for dental caries. Extrapyramidal symptoms have been described in adults using TCAs (251).

TCAs exert a quinidine-like (class 1A antiarrhythmic) effect, which can result in slowed cardiac conduction. Specific electrocardiogram (ECG) changes may occur, such as prolonged PR intervals, increased QRS duration, and increased rate-corrected QT intervals (QTc). In a study evaluating desipramine effects up to 5 mg/kg/day, Schroeder et al. (1989) (252) reported a 21% increase in heart rate and a 2.5% increase in QTc intervals at 4 weeks and 8 weeks, yet no dysrhythmias or clinically significant changes in blood pressure occurred. However, in the following years there were cases of sudden death in children treated with desipramine and imipramine (253–258). Potential contributing factors were noted in each case, including exercise prior to death, history of paroxysmal atrial tachycardia, cardiac vascular anomaly, and family history of early-onset cardiac disease, including sudden death (259). Members of the Work Group on Research and Office of Research of the American Academy of Child and Adolescent Psychiatry (1992) concluded that the rate of deaths during DMI treatment was not clearly statistically increased over the background incidence of sudden deaths in the pediatric population generally. Guidelines regarding unacceptable electrocardiographic indices for the use (or increase) of TCAs have been recommended by the FDA as follows: (1) PR interval >200 ms, (2) QRS interval >30% increased over baseline or >120 ms, (3) blood pressure

>140 systolic or 90 diastolic, and (4) heart rate >130 bpm at rest (260, 261). Finally, a prolonged QTc (corrected QT interval >450 ms) is associated with an increased risk of ventricular tachyarrhythmias and is a contraindication for TCA use (or further increase). TCAs may also lower the threshold for seizures, and brain-injured children may be more prone to this serious adverse effect (262).

### Suicidality

As described earlier in detail in the SSRI section, the FDA has performed meta-analyses of adverse event cases across nonTCA antidepressant pediatric trials. The FDA has instituted the following black box labeling: "antidepressants *increased* the risk of suicidal thinking and behavior (suicidality) *in short-term studies.*"

### Activation/Switching

As described earlier in detail in the SSRI section, activation implies an alteration in mood, anxiety, or behavioral state (such as restlessness) induced by a medication, such as an antidepressant (197). Activation does not signify the presence of hypomania or mania, or necessarily herald bipolar disorder. These relatively mild adverse events may be dose related and may resolve with reduction of dose without discontinuation. Contrary to activation, treatment-emergent affective (mood) switching (TEAS) implies a switch from one mood state (depression) to another (hypomania or mania) in the context of treatment, such as with an antidepressant.

As depression may be the (unknown or unexpected) index episode of a bipolar disorder, clinicians must monitor for switching into a hypomanic or manic state. True manic conversion precludes the further use of an antidepressant without first achieving adequate mood stabilization.

### Overdose

Glauser (2000) (263) has reviewed the associated electrocardiographic abnormalities seen with TCA poisoning; ventricular dysrhythmias, hypotension, heart block, bradyarrhythmias, or asystole can occur. Hypotension, seizures, coma, and death may result. Treatments such as sodium bicarbonate, activated charcoal (which binds TCAs), and hypertonic saline may be helpful. A QRS interval > 100 ms appears to be a predictor of serious complications.

### Drug Interactions

TCA interactions may be based on their pharmacokinetic or pharmacodynamic properties. Concomitant medications that may alter TCA levels include phenothiazines, haloperidol, SSRIs (29), mirtazapine (264), bupropion (214), and venlafaxine (210). Aspirin (ASA) may displace protein bound TCA, increasing the number and severity of adverse events (265). Carbamazepine (CBZ) affects both metabolism and protein binding of TCAs (266). Oesterheld (1996) (267) noted a risk in concomitant medications

that also lengthen QTc, as well as agents that alter the levels of TCAs or their metabolites. Cohen et al. (1999) (268) found no effect of stimulants on the pharmacokinetics of desipramine in children.

TCAs, especially the 5HT-active clomipramine, are not recommended within 2 weeks of discontinuing or starting an MAO-I. The anticholinergic effects of the TCAs provide a relative contraindication for their use in poorly controlled asthmatics on multiple asthma medications (269).

## STIMULANTS

### Neuropsychopharmacology

Since the previous edition of this text, new stimulant formulations have arrived on the market. A summary of methylphenidate (MPH), amphetamine (AMPH; d-AMPH), and magnesium pemoline will be presented.

### Pharmacokinetics

Overall, stimulants are rapidly absorbed and metabolized, and they possess little protein binding. Although individual and comparison drug profiles can be found in the literature, there is tremendous interindividual variability, which precludes direct extrapolation of these concentration-over-time profiles to an individual child or adolescent.

Stimulants are available in several formulations; standard immediate release (IR), first-generation sustained release (SR), and second-generation extended release (ER) compounds, representing novel mechanisms of drug liberation. Products differ in their drug delivery mechanisms and in their proportions of immediate versus extended release drug.

Methylphenidate comprises 4 stereoisomers, d- and l-threo- and d- and l-erythro-MPH; the CNS active threo isomers are found in marketed preparations. Absorption is rapid from the GI tract. Bioavailability of the d-threo isomer is approximately 23%, due to a significant first pass (hepatic extraction) effect. Protein binding is approximately 15%. A primary metabolic site is within the intestinal wall, to inactive ritalinic acid. Time to peak plasma levels is about 1.5 to 2.5 hours, with plasma half-life of about 2 to 3.5 hours (270, 271). The presence of food may delay or reduce peak levels.

Development of SR formulations followed immediate release preparations, yet they were not fully embraced in clinical practice due to an apparent lack of comparative efficacy; in comparison to IR products, plasma concentration over time showed a flatter curve (270). More recently, oral osmotic release system (OROS) technology has led to the marketing of the third generation of MPH drugs such as Concerta, with its unique ascending dose curve (272). Comparisons of mean-concentration-over-time profiles demonstrate pair-wise differences between Concerta and other drug formulations such as Metadate CD (273) and

Ritalin LA (274), and between extended-release agents (271). Swanson et al. (1999) (272) reported pharmacokinetic and pharmacodynamic data in support of the efficacy of OROS technology. An ascending DA release-curve maintained efficacy for ADHD symptoms throughout the day, whereas IR MPH lost 40% of its benefit in the afternoon hours. Another advance is represented by the purified d-threo MPH isomer, Focalin. Phase 2 studies demonstrated pharmacokinetic activity comparable to IR MPH, yet with superior efficacy to placebo up to 6 hours postdose (275).

Adderall and Adderall XR are compositions of mixed salts of l-AMPH and d-AMPH. Absorption of AMPH from the GI tract is rapid. Amphetamine metabolism occurs via several pathways such as hydroxylation and de-amination in the liver (276). However, the majority is excreted renally, unchanged (277). The half-life of its behavioral effects is 3 to 6 hours, although clearance or serum half-life is 12 to 20 hours. Due to the mixed nature of the compounded formulation, variable pharmacokinetic curves are likely. Ingestion of acid, such as ascorbic acid in juices,

will enhance renal clearance and possibly reduce efficacy (276). Absorption of Adderall XR may be slowed in the presence of food, unlike Concerta (278). Only minor differences in Cmax and Tmax have been found in Adderall XR absorption following fasting, sprinkled on food or with a high-fat breakfast (279). Dexedrine is the d-AMPH form of this molecule, and the behavioral half-life is 2 to 6 hours, with a clearance or serum half-life of 12 to 20 hours (Fig. 27.1).

The pharmacokinetics of pemoline produce maximum plasma concentrations 2 to 5 hours after a single, 2 mg/kg oral dose, followed by a slow decline in plasma concentration over time. Marked interindividual variation in elimination half-life and clearance may explain the unpredictable nature of its pharmacodynamic effects (280). In children, the mean elimination half-life of pemoline is considerably shorter than the 11 to 13 hours reported in adults (281). Pemoline undergoes hepatic metabolism, with the remainder excreted renally (280); half is excreted as unchanged drug.

**Figure 27.1** Stimulants: Duration of action. (Adapted from Physician's Desk Reference, 2002.)

## Pharmacodynamics

Stimulants' putative mechanism of action is due to increased synaptic concentration of catecholamines. Increased activity of catecholamines in frontal-striatal pathways is implicated in the mechanism of action in ADHD.

MPH increases striatal DA via blockade of the dopamine transporter (DAT). DAT blockade is followed by increase in DA and DA receptor activation (282). Dose-dependent blockade has been observed; 78% DAT inhibition occurs at a dose of 0.5 mg/kg IV, and 50% DAT inhibition at a dose of 0.25 mg/kg orally (282). Several reports have described reductions in striatal DAT density with MPH treatment (283, 284). In addition, there is significant interindividual variability of DA response to MPH, perhaps reflecting an individual's DA neuron and receptor density (282) as well as pharmacokinetic variability.

Positron emission tomography (PET) scans following administration of the d-threo MPH isomer compared with the l-threo MPH isomer (285), and animal studies demonstrated no therapeutic activity of the l-MPH isomer lending support to efforts to purify the d-threo MPH isomer as found in Focalin. d-MPH was found to have more than three times the potency of l-MPH (286), with both greater DA and NE uptake inhibition (287).

Amphetamine's mechanism of action is slightly different from that of MPH. In addition to DAT blockade, AMPH is taken up into the terminal neuron, causing DA release from storage vesicles within the neuron as well as release into the synapse. Amphetamines also promote NE and 5HT release during in vivo studies (288), as well as having peripheral adrenergic effects (for example, on heart rate and blood pressure), but the clinical significance of any 5HT activity is unknown.

Animal models suggest that the central stimulant effects of pemoline may be due to catecholamine-uptake inhibition, causing indirect DA agonism similar to other stimulants. For example, pemoline inhibited uptake of DA (competitively) and NE (noncompetitively) from striatum and hypothalamus (289). The pharmacodynamic effects of pemoline in youth have been described by Sallee et al. (1992) (290), who correlated plasma pemoline concentration with psychometric measures and analyzed plasma prolactin response to determine the physiological effect of pemoline on dopaminergic transmission.

## Pharmacotherapy

The primary application of stimulants in pediatric psychopharmacology is in the treatment of childhood attention deficit hyperactivity disorder (ADHD). Stimulants may also offer benefit in other neuropsychiatric syndromes, such as mental retardation, chronic fatigue syndrome, chronic depression, multiple sclerosis, and traumatic brain injury.

## Attention Deficit Hyperactivity Disorder (ADHD)

The strength of evidence of this body of literature regarding efficacy of stimulants in ADHD is Level, the highest, using AHRQ criteria of quality, quantity, and consistency of scientific studies. Until the approval of atomoxetine (Strattera), stimulants were the only FDA-approved class of medications indicated for treatment of ADHD.

### Randomized Controlled Trials in ADHD

An extensive body of literature supports the short-term efficacy of stimulant medications in ADHD. The majority of clinical trials involve Caucasian, latency-age boys treated with stimulants (primarily MPH) for a short duration (291, 292). Improvement typically occurs in 65 to 75% of stimulant-treated subjects, compared to a 5 to 30% placebo response (291).

Findings from the NIMH-sponsored Collaborative Multisite Multimodal Treatment Study of Children With Attention-Deficit/Hyperactivity Disorder (MTA) suggest that school-age children with ADHD who received higher and more frequent stimulant doses experienced better outcomes than those children treated with lower and less frequent doses (293, 294). Previously, however, others (295) have noted a *curvilinear* response to stimulants; lower doses produced improvements, with declines in performance at higher doses. Dose-dependent efficacy has been shown in core ADHD symptoms, cognitive function, disruptive behavior, and, more recently, in broader aspects of social-emotional well-being in ADHD youth (296).

Efficacy of the different stimulants shows great individuality in response rates. In one meta-analysis, Greenhill et al. (1996) (297) found equal response to MPH and d-amphetamine in 40%, a greater response to MPH in 26%, and a greater response to d-amphetamine in 35% of subjects tested. An evidence-based review by the Agency for Healthcare Research and Quality (AHRQ) of 78 ADHD studies found 23 studies that compared MPH, DEX, and pemoline, and these studies showed few differences between these drugs (292). However, another meta-analysis of four clinical trials using Adderall and MPH in 188 children with ADHD found a small, but statistically significant advantage of Adderall over MPH (298).

Novel extended-release agents have demonstrated bioequivalence to the IR products (299, 300) as well as superiority over placebo (301, 302). In a multicenter study comparing Metadate CD and Concerta with placebo in children with ADHD, three different patterns of effectiveness across the day were described, consistent with plasma MPH concentrations: (1) Metadate > Concerta > placebo in the morning, (2) Metadate = Concerta > placebo in the afternoon, and (3) Concerta > Metadate = placebo in the evening (301). These differences in clinical effect reflect the differing proportions of immediate- and extended-release drug in each proprietary formulation, indicating that

attention to drug formulation in order to target specific times of the day is worthwhile.

Pemoline has considerably less scientific support compared to MPH and AMPH products. However, a comparison of pemoline to MPH and d-AMPH suggested similar efficacy in childhood ADHD (303), but with a longer duration of action. Behavioral effects last up to 7 hours postingestion (304). Randomized controlled trials have demonstrated efficacy in both adolescent (2.88 mg/kg/day in two divided doses) (305) and adult (2.2 mg/kg/day) populations (306).

### **Tics With Comorbid ADHD**

Despite concerns about the potential for stimulants to exacerbate or even cause tics, longitudinal and naturalistic studies show that stimulants have little impact on the *long-term* course of tic disorders (307–309) and remain effective in those children with ADHD comorbid with tic disorders and Tourette's (310). Tics are therefore no longer considered an absolute contraindication for the use of stimulants, but rather a relative contraindication, especially considering that many children with chronic tic disorders will have comorbid ADHD and could benefit considerably from their use.

### **Mood Disorders**

Stimulants have a role in the management of adult and geriatric unipolar depression, especially in the medically compromised, such as persons suffering from poststroke depression and prominent apathy. However, there is no known controlled evidence for the use of stimulants in depressed youth. Studies to evaluate stimulant effects in bipolar youth with comorbid ADHD are proceeding. One systematic chart review of bipolar youth found greater efficacy in treating ADHD symptoms *following prior mood stabilization* (311) supporting clinical judgment to address the primary mood symptoms before ADHD symptoms.

### **Autism/Pervasive Developmental Disorders With Comorbid ADHD**

Symptoms of ADHD are prevalent in children with autism and pervasive developmental disorders, yet there is little controlled evidence to support the efficacy of stimulants in this population. A small placebo-controlled trial of methylphenidate (0.3 to 0.6 mg/kg/day) conducted in children with autism and symptoms of attention deficit hyperactivity disorder (312) found MPH to be beneficial, but poorly tolerated at the higher dose range.

### **Mental Retardation Syndromes with Comorbid ADHD**

ADHD symptoms are frequently manifest in children with mild to moderate mental retardation (MR) and appear phenomenologically similar to ADHD outside the context of MR. Yet, while expert consensus opinion supports the

use of psychostimulants as the first-line treatment for ADHD in MR (313), low-IQ children with ADHD may respond to psychostimulants with lower or more variable rates, as well as experience increased rates of adverse effects compared to normal-IQ children. Lower-functioning children (314) and children with genetic syndromes, such as fragile X, may be the most vulnerable (315–317).

### **Seizures With Comorbid ADHD**

The prevalence of ADHD symptoms in patients with epilepsy ranges from 40 to 80% (318). Seizures, epileptiform discharges, antiepileptic drugs (AEDs), and underlying brain disease may all contribute to the presence of inattention in these children (319–321). Open and retrospective study has demonstrated relative safety and efficacy of stimulants in small samples of children with ADHD and seizures (320). Like those with MR, children with seizures are generally excluded from controlled drug trials, along with other physically ill youth. However, two controlled trials report on the benefit of stimulants in ADHD children with epilepsy (322, 323).

### **Traumatic Brain Injury**

ADHD-like symptoms and mood disorders have been described as the most common lifetime and new-onset difficulties associated with traumatic brain injury (TBI) in children (324). A controlled trial in pediatric neurosurgical subjects cites efficacy of MPH in a small cohort of children with *acquired* attentional disorders secondary to brain injury (325). Whyte et al. (2002) (326) reviewed the use of stimulants in adults with TBI that describes their role.

### **Uses in Other Neuropsychiatric Conditions**

Psychiatric illness in children and adolescents with neurological or other general medical illness may represent a primary coincident diagnosis, illness secondary to a primary brain or other organ system disease, or some complex interplay of these factors. Effective management of ADHD symptoms in children who are deaf or hard of hearing requires comprehensive and coordinated services (327). Stimulant efficacy in adult narcolepsy has been established, but there are no known applications in pediatric primary sleep disorders.

### **Initiation and Maintenance of Psychostimulants**

#### **Initiation**

Standard informed consent with parents or guardians is the first step in initiating treatment. Common, mild, and dose-related side effects should be anticipated. As always, clinicians should conduct a thorough medical history in the context of a comprehensive psychiatric evaluation. As promulgated by the American Heart Association in large part to screen for those at risk for sudden death, clinical history should include assessment of family history of heart defects, sudden early death, or child history of congenital

or acquired cardiac problems. At intake and with treatment, practitioners should query for syncope, palpitations, or chest pain whether associated with exertion, postexertion, or at rest (328). ECGs are not recommended in routine patients either at baseline or with active stimulant treatment. With any concerning family or patient history, clinicians should consult with primary care physicians and consider cardiology consultation. Due to potential serious liver injury and failure, pemoline is not considered a first-line agent.

Using a stimulant medication involves consideration of practical matters such as time of onset and duration of action. In those children with prominent schoolday symptoms, IR or SR products may be indicated, whereas children with symptomatic impairment throughout the day and into early evening hours may benefit from the newer 8- to 12-hour ER formulations. A combination of IR and SR or ER products is also possible and commonly employed to obtain individually tailored symptom coverage. MPH and AMPH differ in potency by a ratio of about 2:3. As such, appropriate dosing for MPH is 0.5 mg/kg/day to 2 mg/kg/day and AMPH 0.5 mg/kg/day to 1 mg/kg/day. *Optimal dosing is the lowest effective dose.* Children with organic brain disease may be more sensitive to CNS active psychotropic drugs and the general rule of “start low, go slow” applies.

### Maintenance and Monitoring

As suggested by the AACAP and American Academy of Pediatrics, the use of stimulants for ADHD should involve collaboration with families, schools, primary care providers, and other mental health professionals in order to achieve targeted outcomes and to monitor other comorbid conditions and psychosocial stressors. Education and behavioral management combined with pharmacotherapy may offer optimal results for an individual child (294).

In monitoring ADHD symptom response, those with intolerable adverse effects or lack of efficacy with an adequate trial of a first agent should receive a trial of an alternate stimulant. Combination treatment with SR or ER agents may be helpful, such as addition of a small, late afternoon dose of IR drug for management of evening symptoms. Clinical experience suggests that mood lability and rebound phenomena may be less problematic with SR or ER agents, which provide slower fluctuations in blood levels, avoiding the plasma peaks and rapid troughs produced by IR products.

No routine laboratory studies are indicated in maintenance MPH or AMPH stimulant therapy. Vital signs and growth parameters should be routinely monitored (see safety section below). Routine monitoring of pemoline concentration is not useful due to the wide variation in optimum serum concentration and the linear relationship between dose and serum concentration (281). However, monitoring of liver function is advised.

### Safety

Mild and dose-related side effects include insomnia, GI upset and abdominal pain, reduced appetite, headache, and behavioral or mood changes, such as irritability or heightened anxiety. In the Agency for Healthcare Research and Quality evidence-based review of 29 ADHD studies evaluating adverse effects of therapy, side effects were generally mild and dose related (292).

Concern about the longterm effects of psychostimulants on growth followed several decades of the use of stimulants in children. Spencer et al. (1996) reported that the modest height deficits (2 cm) in a large sample of ADHD boys were *unrelated* to stimulant treatment. This finding was similar to prior reports of height deficits of 1 to 3 cm (329). Minimal deficits in height and weight have also been reported with once-daily products, including Concerta (243) and Adderall XR (330). In a thorough review of the evidence, Spencer et al. (2003) (331) suggested that observed height deficits could represent disorder-specific developmental delays. In a 9-month study of OROS MPH, adolescents demonstrated greater than expected growth in height during stimulant treatment, possibly representing catch-up growth (332). A temporary retardation in the rate of growth in weight and height with later catch-up growth has also been observed in children treated with pemoline (333).

In one review, Spencer (2003) (243) found that stimulants transiently exacerbate tics in some children. However, because ADHD typically has its onset several years earlier than tic disorders and many children are already taking stimulants at the time of peak risk for tic onset, a cause-effect relationship is difficult to ascertain. Animal studies have found that stereotypic and self-injurious behaviors may be enhanced in the setting of underlying cortical damage (334) as may be found in certain pediatric neurological syndromes. Nonetheless, as noted earlier in the treatment section, stimulants may be very helpful for some children with tics and ADHD symptoms.

Children with poorly stabilized mania could experience explosive outbursts with methylphenidate (335). One review discusses the risk of stimulants in those at risk, (i.e., those with vulnerability for psychosis) and in situations of stimulant abuse (336).

In one sample, comorbid anxiety did not influence either the tolerability or the efficacy of MPH (up to 0.7 mg/kg/day) upon ADHD symptoms (Diamond et al., 1999) (337).

Modest yet statistically significant elevations in systolic, diastolic blood pressure and heart rate were demonstrated in a review of five RCTs of stimulants and nonstimulants in adults with ADHD (41). Similar minor and clinically insignificant adverse cardiovascular effects have been noted with both methylphenidate and Adderall in samples of children and adolescents (338). Cardiac conduction effects with stimulant use have been infrequently reported, but their clinical importance is uncertain (339).

In February 2005, Health Canada suspended the market authorization of Adderall XR based on safety information concerning the association of sudden deaths, heart-related deaths, and strokes in children and adults taking Adderall and Adderall XR. A public health advisory by FDA followed this report ([www.fda.gov](http://www.fda.gov)). The FDA advisory describes important complicating factors in sudden unexplained deaths (SUDs) in persons taking Adderall. In 5 of 12 cases, underlying structural heart defects were found, such as abnormal arteries, valves, and thickened walls. Several of the remaining cases included other variables, such as a family history of ventricular tachycardia or association of death with dehydration, near-drowning, rigorous exercise, heat exhaustion, or liver or metabolic (diabetes) disease. Duration of treatment varied widely in these cases, from 1 day to as many as 8 years. In considering these reports, it is important to recognize the background population rate for sudden unexplained death (SUD) in children and adolescents varies from 1 to 6/100,000; higher in competitive athletes and in adolescence (340). With 20 cases of SUD per 4 million patient Adderall exposures (adjusted per year), the rate of SD is 0.5/100,000. While the rate of underreporting of SD in children and adolescents is unknown, if one-tenth are reported, the SD rate associated with Adderall administration would remain less than or equal to the population rate of SD. According to the FDA, the number of cases of sudden deaths reported for Adderall is only slightly greater, per million prescriptions, than the number reported for methylphenidate products. It is also important to remember that the stimulants (including Adderall) have relatively benign cardiovascular effects and have no effects on the QTc duration of the ECG.

Reports of pemoline hepatotoxic drug reactions sent to the FDA between 1975 and 1996 were reviewed by Safer et al. (341). In premarketing trials of the early 1970s, hepatic enzyme abnormalities were noted in 1 to 3% of youth receiving maintenance treatment, with some abnormalities confirmed by biopsies. Between 1975 and 1989, 12 cases of jaundice and 6 deaths in youths ascribed to pemoline hepatotoxicity were reported to the FDA. However, the first report in the medical literature of a serious adverse drug reaction ascribed to pemoline did not appear until 1989, and physicians did not generally become aware of potentially serious pemoline hepatotoxicity until the mid-1990s, by which time there had been 13 cases of liver failure, with 11 resulting in death (342, 343). Although the majority of cases of pemoline-associated hepatic injury have been in youth under 12 years of age (344), adult cases of liver failure exist as well (345). An idiosyncratic metabolic process (344) and an autoimmune process (346) have been proposed as pathogenetic mechanisms.

Concerns about abuse of stimulants have been longstanding and drawn considerable attention from some organizations that are philosophically opposed to the use of

psychoactive medications. Without question, isolated cases of stimulant abuse do occur, predominantly in adolescents and often in school settings where stimulants may be readily available. Mood disturbance and nasal septum necrosis (from snorting) are possible results. However, orally administered MPH has a considerably slower rate of uptake centrally, compared with intravenous MPH, and PET studies show that although intravenous MPH has rapid central uptake, this is followed by slow clearance from the brain. These characteristics interfere with the mood elevation produced by frequent administration, unlike cocaine, which is rapidly cleared from the brain (347). Newer and longer-acting agents are much less likely to be abused due to the nature of their formulations. Despite concerns regarding abuse, it should be noted that nonmedicated ADHD patients are at much higher risk for substance abuse than controls *and* medicated ADHD patients due to their impulse-control deficits and novelty-seeking behaviors (348). Therefore, withholding psychostimulant medication from genuine cases of ADHD for fear of stimulant abuse is not supported by the scientific evidence. In cases where abuse is a concern, careful monitoring is nevertheless required.

In those with a seizure disorder, some reports suggest a lowering of the seizure threshold with stimulants (349, 350).

### Drug Interactions

Following an extensive review, Markowitz et al. (351) concluded that the only true contraindication to the use of stimulants is coadministration of MAOIs; their combination may result in serious hypertension. Notably, stimulants do not increase serum levels of TCAs (268), nor do there appear to be serious side effects in combining these treatments (352). However, isolated reports of drug interactions can be found in the literature, such as grand mal seizures with bupropion and methylphenidate combined or pharmacokinetic interactions between cyclosporine and bupropion or methylphenidate (353, 354). From a clinical standpoint, such interactions are rarely a concern.

Despite isolated concerns stemming from reported possible cases of pediatric sudden death with combination MPH and clonidine (355), the FDA could not cite a causal link after investigating this matter. Hypotension was found in all cases, but it was not clearly due to a drug interaction. Subsequent studies found no EKG changes with clonidine treatment (356), though one small sample showed slight increased PR interval with combination MPH and clonidine therapy (357). Current expert consensus opinion supports continued combined use of stimulant and clonidine as an appropriate treatment option (358).

Markowitz (359) reviewed the risks of drug interactions between MPH and antiepileptic drugs (AEDs). In general the risks were considered negligible, but there are case reports of MPH inhibition of phenytoin and primidone

metabolism as well as carbamazepine lowering MPH plasma levels.

### Overdose

Klein-Schwartz (2003) (360) reviewed 7 years of pediatric MPH exposures across U.S. poison centers and found tachycardia, agitation, and hypertension to be the most common events. In only 0.9% of 759 cases were outcomes considered severe. Nakamura et al. (2002) (361) described five pediatric cases of excessive pemoline ingestion. Overall, patients experienced a relatively benign course. Symptoms of pemoline toxicity occurred within 6 hours, lasted up to 48 hours, and were related to CNS and cardiovascular pharmacological effects, with tachycardia, hypertension, choreoathetoid movements, and hallucinations. Elevation of serum creatine phosphokinase (CPK) was also observed in 3 of 4 patients.

## ATOMOXETINE

Atomoxetine, approved by the FDA in January of 2003, is inherently interesting for a number of reasons. It is the first medication approved for the treatment of ADHD that is not a stimulant, the first medication specifically approved for the treatment of ADHD in adults, the first psychiatric medication that has been approved for use in children before adults, and the first of a new generation of selective norenergic reuptake inhibitors. The rapid increase in prescriptions written over its first year (more than 4 million written and more than 1 million children initiated into treatment) testifies to the many gaps and frustrations that practitioners face in the pharmacological treatment of youth and adults with ADHD, despite the long history and success of the stimulants. It is increasingly likely to be used as a first-line agent for newly diagnosed children with ADHD. The research into atomoxetine is far and away the most robust in pediatric psychopharmacology, as the number of children studied through industry-sponsored trials and the duration of longterm safety and tolerability trials are an order of magnitude greater than with any previous drug. At least 10 different RCTs of atomoxetine using multisite design have been done, and the cumulative number of children studied is around 5,000, some studied over 3 years.

### Pharmacokinetics

Atomoxetine is rapidly absorbed following oral administration and peaks in 1 to 2 hours. High-fat meals slow absorption slightly so that peak levels are delayed by an hour or 2, and the peak serum levels are about 10% lower. However, the total AUC and extent of absorption is unaffected by food. The serum half-life of this agent is relatively short, about 5 hours. Based on this observation, it was originally conceived that atomoxetine would

be administered as a twice-daily dose, hence the limited dosing formulations available currently. Later observations led to further single daily dose studies and in general, single daily administration is equally effective for the majority of patients. Atomoxetine is a substrate for the CYP2D6 hepatic enzyme and demonstrates linear pharmacokinetics. It does not itself inhibit or induce any hepatic enzymes, but CYP2D6 deficiency or inhibition will substantially increase its serum levels and extend half-life (362), though even poor metabolizers tolerate atomoxetine extremely well. The parent drug is hydroxylated to a metabolically active compound, which circulates at very low levels and is not clinically significant, before being excreted in the urine. Neither renal nor hepatic deficiency substantially increase risk of its administration.

### Pharmacodynamics

Inhibition of monoamine transporters for NE, serotonin (5 HT), and DA with dissociation constants ( $K_i$ ) of 5, 77, and 1,451 nanomolar, respectively, suggests good NE selectivity as well as potency. There is little to no activity at receptors of the serotonin, norepinephrine, dopamine, histamine, adrenergic or muscarinic type, and the adverse effect profile reflects this characteristic. Animal studies have suggested that extracellular dopamine is increased in prefrontal cortex (but not nucleus accumbens or striatum) via nonspecific monoamine uptake inhibition or stimulation of ventral tegmental NE neurons projecting to the cortex (363).

### Clinical Pharmacology

The impetus to study atomoxetine came from studies of secondary amine tricyclics in ADHD (see tricyclic section presented earlier). Spencer et al. (1998) (364) first explored atomoxetine in double-blind fashion in 22 adults with ADHD and found a robust response. Two subsequent early identical proof-of-concept 12-week studies (365) in 291 children randomized to either placebo, atomoxetine, or methylphenidate found highly significant effects ( $p < 0.001$ ) for atomoxetine over placebo on the clinician-scored parent-reported ADHD symptom rating scale. The study was not powered to detect differences in effect sizes between the drugs, but in this study no differences in primary outcomes measures were detected between them (366). Once-daily treatment was seen to be as effective as twice-daily dosing studies with an effect size of 0.71 as reported by parents, teachers, and clinicians. Further, parent diary ratings suggested that drug-specific effects were sustained late in the day following morning dosing (367). Many practitioners have found, however, that the overall effect size of atomoxetine is less than that of the stimulants in uncomplicated ADHD subjects. Preliminary evidence indicates that atomoxetine does not exacerbate tics and may

even be helpful in decreasing tics in those with comorbid tics and ADHD (368).

### Initiating and Maintenance

Dose response studies found that, in the pooled sample, 1.2 mg/kg/d and 1.8 mg/kg/d of atomoxetine were consistently associated with superior outcome in ADHD symptoms versus placebo, but they were not significantly different from each other (369, 370). Dose response curves are linear between zero and the target dose of 1.2 to 1.4 mg/kg/d, however. Thus, the recommended daily dose follows these guidelines with initiation at 0.5 to 0.8 mg/kg/d and increasing to target dose over several days to several weeks depending on tolerance. Because weight-adjusted doses provide reliable and similar blood level profiles at different weights and ages, weight-based dosing is an appropriate strategy at all ages. Abrupt discontinuation in both children and adults pooled from four large studies of atomoxetine did not appear to be associated with any acute discontinuation syndrome and was well tolerated although symptoms of ADHD worsened (371).

### Safety

All clinical studies have demonstrated good tolerability and safety with discontinuation rates due to adverse events generally very low (<5%) (367, 369). Cardiovascular effects were evaluated in a large group of children and adolescents and showed statistically significant but modest increases in diastolic blood pressure and heart rates consistent with its noradrenergic profile. These increases usually occurred early in treatment, stabilized, and returned to normal levels upon drug discontinuation. Corrected QT intervals (QTc) did not change from baseline, and routine EKG monitoring is not required (372). Routine laboratory monitoring of hematological, renal, hepatic, or thyroid indices and serum levels is not required, avoiding any need for blood tests.

While more than 2 million patients have taken Strattera since its approval, there have been two postmarketing cases (one adolescent, one adult) of severe liver injury. Based on these reports, the FDA issued a warning (December 2004) that is also included in the package insert. In both cases, liver function returned to normal after Strattera was stopped. Because of the rarity of this event, routine liver function assays are *not* recommended, but any sign of possible injury such as jaundice or malaise should be reported.

Common adverse events include sedation (the commonest side effect), abdominal discomfort, and decreased appetite. Other adverse events did not separate from placebo in pediatric studies but included insomnia, urinary retention, and dizziness in adults. Mood lability has also been observed anecdotally but is less common than with the stimulants. The apparent absence of dopaminergic activity in the nucleus accumbens and striatum predict little abuse liability and adverse effects of tics, consistent

with clinical experience. Based on baseline percentiles, there is an initial slight decrease in expected weight gain with a return to predicted growth rates with longer-term treatment. Effects on growth rates for height were even smaller (373).

## MOOD STABILIZERS: LITHIUM AND ANTICONVULSANTS

### Neuropsychopharmacology

This group of medications includes lithium, the older anticonvulsants sodium valproic acid (VPA), and carbamazepine (CBZ) and some relatively novel agents, including gabapentin, lamotrigine, tiagabine, oxcarbazepine, and topiramate. The anticonvulsants are used in the management of pediatric seizure disorders (374). While increasingly used for pediatric bipolar disorder, there is little controlled scientific evidence for anticonvulsant use in children with mental disorders, and their application stems largely from extrapolating evidence from the literature on adult mood disorders, which, in contrast, is extensive. Efficacy of the anticonvulsants in adults is reflected by several FDA indications for adults with bipolar disorder.

### Lithium/Valproic Acid/Carbamazepine

#### Lithium

Lithium is absorbed from the gastrointestinal tract at variable rates depending on the formulation of the tablet or capsule (IR versus extended release preparations). As a simple ion, lithium is distributed widely in body fluid and tissue and is not protein bound. The intracellular regulation of lithium is complex. Lithium does not undergo metabolism and is excreted renally. Because children and adolescents have higher relative body water volume and renal glomerular filtration rates compared with adults (375), studies show that lithium in children has a shorter elimination half-life and higher total clearance despite generally similar pharmacokinetics to adults (376). Moore et al. (2002) (377) used <sup>7</sup>lithium magnetic resonance spectroscopy (MRS) to measure in vivo brain lithium levels in nine children and adolescents and 18 adults with bipolar disorder. While serum and brain lithium concentrations were positively correlated, younger subjects had lower brain-to-serum concentration ratios than adults: 0.58 versus 0.92. Therefore it was suggested that children and adolescents may extrude lithium more effectively from neurons; therefore youth may require higher serum lithium concentrations than adults to achieve therapeutic brain lithium concentrations. Many formulations of lithium are available, including Lithium, Lithobid, and Eskalith CR, which vary in C<sub>max</sub> and AUC (378, 379).

### Valproic Acid and Carbamazepine

VPA is readily absorbed after oral ingestion, is significantly protein bound, and undergoes hepatic metabolism via mitochondrial beta-oxidation and CYP450 glucuronidation. Its metabolism may be accelerated with coadministration of CYP450-inducing agents (380). The clearance of valproic acid correlates with concentration of the unbound fraction and is age dependent, decreasing progressively from infancy to 14 years. For these reasons, the correlation between weight-adjusted dose, plasma concentrations, and efficacy is poor. Time to peak plasma concentration ( $T_{max}$ ) occurs within 3 to 4 hours after ingestion of Divalproex sodium delayed-release (DR), while the half-life ( $T_{1/2}$ ) is relatively short at 8 to 17 hours. These pharmacokinetic properties require that divalproex sodium DR be administered in a twice-daily dosing regimen. The FDA approved an extended-release (ER) formulation of divalproex sodium, and this once-daily formulation offers 89% bioavailability and 10 to 20% less plasma fluctuation compared to divided dose divalproex with maximum plasma concentrations ( $C_{max}$ ) occurring at 7 to 14 hours. In pediatric studies, Depakote ER produced plasma concentration-time profiles similar to those observed in adults (Abbott, Depakote prescribing information).

Absorption of carbamazepine is gradual and erratic following oral ingestion. CBZ is highly protein bound and is extensively metabolized in the liver, generating multiple metabolites including the toxic epoxide. Autoinduction (induction of CYP450 enzymes for which it is a substrate) occurs with continued use, with a subsequent reduction in half-life and doubling of clearance rate over the first 2 to 3 months (380). Both metabolic conversion of carbamazepine, as well as renal clearance, are much higher in younger children than in adults, so that its half-life is shorter. Oxcarbazepine (Trileptal) (OXC) is a closely related but different molecule from CBZ that yields different metabolites via primary reduction with no epoxide metabolite, reducing potential toxicity. Autoinduction does not occur, protein binding is low, and OXC pharmacokinetics are linear. Although the agent has minimal CYP450 activity, oxcarbazepine may induce CYP3A4/5 at a higher dose and inhibit CYP2C19 (Novartis, Trileptal prescribing information).

### Pharmacodynamics

#### Lithium

Molecular studies suggest that lithium affects neurotransmitter systems by altering intracellular signal transduction mechanisms such as phosphoinositide hydrolysis, adenylyl cyclase, G protein, glycogen synthase kinase-3 beta, and protein kinase C. Such mechanisms produce long-term changes in signaling patterns and levels of cytoskeletal protein phosphorylation, leading to neuroplastic changes (381). Long-term neurotrophic and neuroprotective effects of lithium are indicated by increases in human gray matter,

N-acetyl-aspartate concentrations, and other markers of neuronal viability. (382).

### Valproic Acid and Carbamazepine

Direct neuronal effects of valproic acid (VPA) include blockade of voltage-dependent sodium channels and increased calcium-dependent potassium conductance (374). Indirectly, metabolically mediated increases in GABA levels and altered DA and N-methyl D-aspartate (NMDA) activity may underlie its activity (380). Carbamazepine also blocks sodium-dependent channels but decreases depolarization-dependent calcium uptake (374). Inhibition of sodium channel activity appears to be the primary mechanism of anticonvulsant action for both CBZ and OXC (383) (Table 27.13).

### Pharmacotherapy

#### Mood Disorders

There is an extensive literature for lithium, VPA, and CBZ in adult mood disorders. Although anticonvulsant agents are increasingly being used in the management of juvenile bipolar disorder, controlled studies in this population are difficult to conduct. However, controlled trials are emerging, and treatment algorithm have been presented in an attempt to offer consensus guidelines to clinicians. Monotherapy with lithium, divalproex, and carbamazepine (in addition to atypical antipsychotics) are among first-line treatments for juvenile bipolar disorder (384).

Child psychiatrists should be aware of adult endeavors, such as the NIMH Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD), a long-term outpatient project that aims to discover which treatments are most effective for depression and mania, as well as prevention of recurrent episodes ([www.stepbd.org](http://www.stepbd.org)). Although these agents are generally studied individually in RCTs, monotherapy is the exception and not the rule. The propensity for pharmacotherapy that combines anticonvulsants or anticonvulsants and atypical antipsychotics has been similarly observed in pediatric bipolar samples (385, 386).

#### Lithium

In adults, lithium has shown efficacy in multiple controlled trials of acute mania, acute bipolar depression, and prophylaxis of adult bipolar disorder, and it is also the only psychotropic to demonstrate decreased suicidality (387–389). A pooled analysis on episode recurrence from 24 studies over 30 years found recurrence rates for those not on lithium averaged 18 times greater than those on lithium. In addition, recurrence rates for patients on lithium decreased fivefold from the 1970s to 1990s (390). Unfortunately, lithium is often inadequate as maintenance monotherapy; only 14% of 247 bipolar persons remaining on lithium achieved euthymia at 5 years, and approximately half achieved only partial improvement (391). Yet adjunctive antidepressant therapy in bipolar disorder

## TABLE 27.13

### CLINICAL PHARMACOLOGY OF ANTICONVULSANTS

	Carbamazepine	Gabapentin <sup>1</sup>	Lamotrigine	Oxcarbazepine	Topiramate	Valproic Acid
<b>Pharmacokinetic Parameters</b>						
T-Max (hours)	1.5 h (suspension) 4–5 h (tablet) 3–12 h (XR tablet)	2–3 h	2.2 h (single dose) 1.7 (multiple dose) 1.8 (single dose + VPA) 1.9 (multiple dose + VPA) 3–15 d	4.5 h (tablet) 6 h (suspension)	2 h	4 h without food, 8 h with food tablet; 3.3 h without food, 4.8 h with food (sprinkle capsule)
Steady state	Initiation: 3–5 wk; After induction: 2–4 d	1–2 d (normal renal function)	3–15 d	2–3 d	4–5 d (normal renal function)	2–5 d
Half-life (T 1/2)	25–65 h (initially) 12–17 h (chronic)	Renal-function-dependent; 5–7 h (normal renal function)	25 h (mean, monotherapy); 12.6 h (mean, LTG + enzyme inducer); 70. h (mean, LTG + VPA)	2 h (parent) 9 h (metabolite)	18–30 h (normal renal function) 59 h (impaired renal function)	5–13 h
Mechanism of excretion	>85% hepatic; major pathway: CYP3A4; active metabolite: CBZ epoxide	>95% renal excretion as unchanged drug	10% renal unchanged; >85% hepatic, major pathway: N-glucuronidation	>95% renal	70% renal unchanged (monotherapy)	>95% hepatic: glucuronidation (30–50%), $\beta$ -oxidation (40%), CYP (minor)
<b>Pharmacodynamic Parameters</b>						
Mechanism of action	Blocks voltage-dependent sodium channels but decreases depolarization-dependent calcium uptake	GABA binds to neuronal membranes glutamate synapse	Blocks voltage-dependent sodium channels, antigitamatergic and neuroprotective actions	Blocks voltage-dependent sodium channels	Modulates voltage-dependent sodium channels, potentiates GABA evoked potentials, and blocks the kainate/AMPA subtype of the glutamate receptor	GABA (to a lesser extent), blockade of voltage-dependent sodium channels and increased calcium-dependent potassium conductance
Dose range (mg/day)	10–35 mg/kg/day	30–60 mg/kg/d (t.i.d) <sup>1</sup>	LTG+enzyme-inducing AED w/o VPA: 0.6 mg/kg/d (initial), 5–15 mg/kg/d (maintenance); LTG+ AED regimin w/VPA: 0.15 mg/kg/d (initial), 1–5 mg/kg/d (maintenance)	Adjunctive Rx: 20–30 kg: 900 mg 30–40 kg: 1200 >40 kg: 1800 Monotherapy: 20–70 kg: 30–45 mg >70 kg: 23–30 mg increase by 10 mg/kg/wk	1–9 mg/kg/d <sup>1</sup> (b.i.d)	15–60 mg/kg/d (b.i.d-q.i.d)

depressive episodes has never been more effective than lithium monotherapy.

In pediatric populations, there are limited published controlled data in bipolar disorder to date. Several early studies of lithium demonstrating benefits in mood, aggression, and psychosis were methodologically limited, including small sample size and crossover design (392). These studies in pediatric bipolar disorder (393–395) reported findings similar to a larger open trial for acute mania in adolescents with bipolar disorder I (396), where approximately 50 to 55% of subjects met criteria for remission using the Young Mania Rating Scale (YMRS). In the only published RCT lithium trial, Geller et al. (1998) (397) completed a small, double-blind parallel group trial of lithium for adolescents with bipolar spectrum disorder and substance dependence. Using global measures, significant improvement was evident in 46% of the lithium-treated sample compared to 8% of the placebo-treated group. The mean serum lithium drug level for completing responders was 0.88 mEq/L.

### Valproic Acid and Carbamazepine

There have been no randomized controlled trials published to date using VPA or CBZ for pediatric bipolar disorder. Several open reports describe efficacy of VPA in bipolar youth, such as that by Papatheodorou (398). Oxcarbazepine and CBZ use in bipolar youth has also been reported, including case reports of efficacy in refractory childhood mania (399, 400). Comparative treatment trials using open-label lithium versus divalproex sodium (401) and randomized lithium versus divalproex versus CBZ but without placebo control (402) have been reported. The latter study suggested effect sizes of 1.06 for lithium (38% response), 1.63 for divalproex (53% response), and 1.00 for CBZ (38% response) in children and adolescents with bipolar I or II disorder. The majority of responders at the end of the continuation phase were on combination therapy (either a stimulant or a second anticonvulsant). Supporting this, a retrospective chart review of hospitalized bipolar preadolescents (403) found that by week 2, both lithium and VPA may be more efficacious than CBZ.

Multiple open and controlled trials of VPA in *adult* bipolar disorder show efficacy similar to lithium. Bowden et al. (2000) (404) compared the 1-year outcome of prophylaxis treatment with lithium, VPA, and placebo showing that VPA but not lithium was significantly better than placebo in preventing relapse. In a meta-analysis, Hirschfeld et al. (2003) (405) reported that oral loading of VPA leads to a more rapid antimanic effect compared with standard titration of divalproex, lithium, or placebo. Gyulia et al. (2003) (406) reported that divalproex-treated adults on maintenance therapy had less worsening of depressive symptoms than lithium-treated patients and reduced depressive episodes relapse. Rapid cycling or mixed mania has been suggested to be predictive of a good VPA response (380). Carbamazepine has demonstrated efficacy in RCTs in

adults with mania, comparable to lithium, but there is less evidence supporting its usefulness in treatment of bipolar depressive episodes and in maintenance therapy (380). Oxcarbazepine may be useful for adults with mood disorders as well. Open studies demonstrate mild to moderate improvement in refractory bipolar disorder, including decreased irritability and improvement in depressive symptoms (407–410).

### Aggression and Conduct Disorder

Expert consensus opinion supports the use of VPA, CBZ, and lithium in the management of aggressive adults with mental retardation (313). There are case reports (411), but no controlled trials of these agents in youth with MR. However, anticonvulsants, particularly VPA, have been found effective in the management of a range of neurobehavioral symptoms in patients with a history of brain injury (412–414).

Biederman et al. (1999) (415) presented compelling data in defining a dysphoric subtype of conduct disorder, noting that a positive response to mood stabilizers in levels of aggression in conduct-disordered children could be due to their antimanic effects, suggesting a comorbid bipolar disorder in some children with conduct disorder (CD).

There have been multiple short-term controlled trials of mood stabilizers, primarily with lithium, in inpatient and outpatient youth with CD, with mixed results overall (416, 417). For example, Malone et al. (418, 419), examined the effectiveness of lithium for aggressive conduct-disordered inpatients showing a significantly superior response in the lithium group (16/20) compared to the placebo group (6/20). More recently, Steiner et al. (2003) (417) completed a randomized controlled trial of VPA in youth with conduct disorder, demonstrating dose-dependent effects (53% response with high dose versus 8% response with low-dose VPA). The one published controlled trial of CBZ in aggressive youth did not find significant benefit compared to placebo (420).

### Pervasive Developmental Disorders

Anticonvulsants are commonly used in autistic spectrum disorders, due to the increased prevalence of epilepsy in these children. Open reports suggest improvement in social and behavioral domains in autistic subjects with epileptic discharges (421). They may also target underlying associated affective disorders (422).

### Initiating and Maintenance of Medication

Standard informed consent with parents or guardians and assent by the child or adolescent is the first step in initiating medication. A medical history of cardiac disease, thyroid disease (lithium), renal impairment, psoriasis (lithium, CBZ), liver disease (VPA, CBZ), blood dyscrasia (VPA, lithium, CBZ), and pregnancy (VPA, lithium, CBZ) are *potential* contraindications to initiation of a mood stabilizer. Baseline laboratory studies including complete

blood count (CBC), liver function tests (LFTs), electrolytes, thyroid stimulating hormone (TSH), urine, and, where indicated, pregnancy test, are recommended. An EKG to assess baseline intervals may be appropriate as well. Sexually active female patients should be counseled about the relationship between anticonvulsants and teratogenicity, and they should be assessed for baseline menstrual irregularities (VPA). Although rarely utilized as pharmacotherapy in infants and toddlers in child psychiatry, before initiating VPA, clinicians may perform screening tests, such as serum ammonium, amino acids, blood gases, lactate-pyruvate ratio, urinary organic acids, and free and total serum carnitine to rule out underlying metabolic disorders in children under the age of 2 years in order to decrease risk of fatal hepatotoxicity.

Lithium should be initiated at the lowest possible dose in children, and at 300 mg qhs in adolescents, depending on weight. Dosages are increased every 2 to 4 days, in increments of the starting dose, reaching the target dose in 2 to 4 weeks. Rapid titration could increase the incidence of adverse effects. Patients should be advised to maintain good hydration and cautioned regarding use of NSAIDs, such as ibuprofen, which may elevate lithium levels.

VPA should be initiated at the lowest possible dose in younger children (125 mg/d) and at 250 mg qhs in older children and adolescents, depending on weight. Dosages may be increased every 2 to 4 days, in increments of the starting dose, reaching a target dose in 2 to 4 weeks. Depakote sprinkle capsules (sodium valproate and valproic acid) are useful for children who are unable to tolerate valproate suspension, tablets, or capsules.

Carbamazepine should be initiated at the lowest possible dose in children, and at 200 to 300 mg/day in divided doses in adolescents, depending on weight (adult dose may be 200 to 600 mg divided twice a day). Dosages may be increased every 2 to 4 days, in increments of the starting dose, reaching a target dose in 2 to 4 weeks. Carbatrol is a new formulation composed of 25% IR beads, 40% ER beads, and 35% Enteric release beads (Shire Pharmaceuticals). Oxcarbazepine should be initiated at the lowest possible dose in children, and at 300 mg qhs in adolescents, depending on weight. The dose target is based on weight (900 mg/d in 20 to 29 kg; 1200 mg/d in 30 to 39 kg; 1800 mg/d in >40 kg).

### **Maintenance/Monitoring**

Practice guidelines and expert reviews in the adult and pediatric psychiatry literature provide guidance on the complex issues of medication monitoring and maintenance. APA guidelines for lithium monitoring suggest checking renal function every 2 to 3 months and thyroid function every 3 to 6 months in the first 6 months, and then every 6 to 12 months thereafter (423). Monitoring of lithium blood levels is indicated to achieve the narrow therapeutic and safety window of 0.5 to 1.2 meq/L. The

range of 0.6 to 0.8 meq/L may be most commonly utilized in adult practice (423). However, maintenance at a constant blood level may be more important than the level itself. By convention, lithium levels are drawn 12 hours after last dose, after reaching steady state or about 5 days after dose adjustment.

As most serious adverse effects with anticonvulsants occur in the initial 2 to 3 months, monthly blood screening (CBC, LFT) for the first 3 months has been recommended, followed by monitoring at three to six monthly intervals or as clinically indicated. Indications for anticonvulsant monitoring in children include: (1) at beginning of therapy to confirm serum levels are in the therapeutic range, (2) to monitor for noncompliance, (3) during growth spurts when serum levels may change unexpectedly, (4) during combined pharmacotherapy due to potential drug interactions, (5) symptoms and signs of toxicity, (6) patients with liver or kidney disease, and (7) disabilities that make evaluation of drug effect difficult (374).

Standard practice with VPA in adults typically includes safety monitoring of hematological parameters and liver function at a minimum every 6 months (423). Blood level monitoring in VPA is indicated to achieve the therapeutic and safety window of 50 to 125 ug/ml. Blood for VPA levels is usually drawn at trough, prior to next dose, and after steady state is reached or about 5 days after dose adjustment. Free plasma carnitine levels may be monitored and l-carnitine supplementation may be given if clinical symptoms suggest carnitine deficiency (e.g., weakness, lethargy, hypotonia).

APA guidelines for safety monitoring of CBZ suggest that CBC and liver function tests be drawn every 2 weeks in the first 2 months, and every 3 months thereafter (423). Blood level monitoring in CBZ is indicated to achieve the safe therapeutic window of 4 to 12 ug/ml. Carbamazepine levels are typically drawn at trough, prior to next dose, after steady state is reached or about 5 days after dose adjustment. Unlike carbamazepine, oxcarbazepine carries no black box warning regarding hematological adverse effect such as bone marrow suppression, and therefore no monitoring of hematological indices is indicated. Serum drug levels may be assayed to monitor compliance or make dose adjustments but have a lesser role than with CBZ. However, measurement of serum sodium may be appropriate if clinically significant adverse effects appear due to isolated reports of hyponatremia (424).

### **Safety**

#### **Side Effects**

Side effect profiles reported are based largely on adult experience with these agents. Side effects are common with lithium. Transient side effects such as gastrointestinal upset and tremor related to peak levels may be predicted, and may be noted more often if beginning treatment during a

depressed state versus a manic phase. Dose-related adverse effects include weight gain, gastrointestinal upset, benign increase in white blood count (WBC), lethargy, cognitive dulling, and impaired memory, acne, hair loss, edema, polydipsia, and polyuria. Lithium citrate may be better tolerated than the carbonate salt with respect to gastrointestinal upset. Benign EKG changes associated with repolarization may occur (423) such as T wave inversion or flattening. Cardiac toxicity (sinus node dysfunction) has been described in children receiving long-term lithium therapy (425). Longer-term effects include thyroid (hypothyroidism, hypoparathyroidism), kidney (impaired concentrating capacity), or bone (morphologic changes) disturbances with chronic use (423). Impaired thyroid function manifested by lower T4 levels has been associated with increased affective episodes, relapse, and depression (426, 427).

Dose-related adverse effects with VPA include sedation, weight gain, tremor, benign decrease in WBC and platelets, and gastrointestinal upset. Greater weight gain than that seen with lithium treatment (23 versus 16%) has been demonstrated with valproic acid treatment of bipolar adults at 1 year. In addition, rates of sedation, tinnitus, and hair loss were increased compared to lithium (404). VPA therapy may be associated with a transient elevation in liver enzymes in 15 to 30% of patients and rarely with fatal hepatotoxicity. Clinically significant and persistent gastrointestinal symptoms necessitate careful evaluation during the initial few months of valproate therapy (374). The majority of VPA hepatotoxicity has been observed in children younger than 2 years of age with prior neurological or medical conditions. Mitochondrial or metabolic diseases, such as blocks in carnitine metabolic pathways (leading to increased serum ammonia), VPA inhibition of beta-oxidation, and toxicity from VPA metabolites, may all be causative (428). However, Hirose et al. (1998) (429) reported that carnitine levels are unaffected by VPA in patients with epilepsy, without severe neurological or nutritional problems, and that a regular childhood diet provides sufficient amounts of carnitine. Pancreatitis has also been described in multiple case reports. Among 36 VPA-associated cases of pancreatitis (430), 9 patients (25%) were under 10 years old and 12 (33%) were between 10 and 20 years old. The association between VPA and polycystic ovarian syndrome (weight gain, hyperandrogenemia, and hyperinsulinemia) remains unclear (423), although Nelson-DeGrave et al. (2004) (431) reported a link between VPA and increased ovarian androgen biosynthesis. Adults using extended-release (ER) divalproex sodium reported significantly less frequent and severe adverse events when switched from divalproex sodium delayed-release (DR) formulations (432), perhaps due to smaller diurnal fluctuations and decreased formation of minor toxic metabolites (433).

Adverse effects of carbamazepine include reversible dose-related neurological symptoms such as fatigue, dizziness, ataxia, blurred vision, and cognitive dulling. In addition, rash, weight gain, mild reductions in WBC, platelets, sodium and thyroid hormones, and elevation in liver enzymes may all occur. Rare serious adverse effects include aplastic anemia, agranulocytosis, thrombocytopenia, liver or renal failure, cardiac conduction effects, and Stevens-Johnson syndrome, most often in the initial 3 to 4 months of therapy (374, 423).

Oxcarbazepine causes fewer overall adverse effects compared to carbamazepine, with the exception of hyponatremia (<125 mmol/L) (434), observed in about 2.5% of adults (Novartis). Although Holtman et al. (2002) (424) reported hyponatremia in 26% of a sample of 75 children with epilepsy, clinically relevant hyponatremia occurred in only one child. Adverse effects of oxcarbazepine include drowsiness, and neurological symptoms such as ataxia. About 25 to 30% of subjects with hypersensitivity to carbamazepine may experience adverse reactions to oxcarbazepine (Novartis, 2002).

### Overdose/Intoxication

Although lithium toxicity may occur at elevated serum levels, intoxication has also been described within the normal range of values. Neurological signs of toxicity include tremor, confusion, seizure, and coma. Cardiac dysrhythmia can also occur. In contrast, VPA possesses a wider margin of safety. In overdose, however, sedation, cardiac conduction block, and coma can occur, and deaths have been reported. CBZ toxicity presents with neurological effects, such as sedation, ataxia, seizure, and coma, as well as cardiac conduction disturbances (423).

### Drug Interactions

An extensive review of the safety and efficacy of mood stabilizers (VPA, Li, CBZ, Lamotrigine) in various combinations concluded that the safest and most efficacious mood stabilizer combinations appear to be anticonvulsants with lithium, particularly valproate plus lithium (435).

Agents that affect lithium clearance such as diuretics and NSAIDs may increase serum levels. Isolated case reports describe lithium neurotoxicity when administered with concomitant neuroleptics, CBZ, and calcium channel blockers (435). VPA drug interactions are related to its hepatic metabolism and protein binding. Coadministration of aspirin may decrease clearance of the unbound fraction of VPA and necessitate a decrease in the daily dose (436). VPA is unique in that it inhibits rather than induces hepatic enzymes and may therefore cause elevations in levels of concomitant medications, such as TCAs and CBZ. Notably, lamotrigine levels may be doubled with concurrent VPA administration (423), and skin rashes may occur with greater frequency or severity, so that great care is required when combining these agents.

Conversely, CBZ may increase the rate of VPA metabolism and reduce VPA levels (380). Isolated reports since 2002 also suggest an interaction between risperidone and VPA in youth, with protein-binding displacement yielding increased free VPA levels or alterations in VPA via cytochrome P450 2D6 interaction (437–439). However, Good et al. (2003) (440) found no significant difference in trough VPA drug levels with combination VPA and olanzapine or risperidone treatment in 45 subjects. Combined treatment with olanzapine and divalproex has also been associated with greater elevations of hepatic enzymes than with VPA monotherapy (441).

Carbamazepine can cause numerous potential drug interactions, due to its potent hepatic enzyme induction. Serum levels of concomitant medications, including neuroleptics, birth control pills, TCAs, lamotrigine, benzodiazepines, VPA, and prednisone, may be lowered, as well as CBZ itself, via autoinduction. CBZ has been shown not only to alter the metabolism of imipramine and its metabolites, but also its protein binding so that despite reductions in total TCA serum levels, the unchanged free fraction concentration is maintained (266). In addition, CBZ levels may be increased by concomitant medications, such as erythromycin, calcium channel blockers, fluoxetine, and VPA, via inhibition of CBZ metabolism (380). Notably, the CBZ epoxide/CBZ ratio (and toxicity) may be increased by metabolic inducers or by inhibition of carbamazepine epoxide conversion to carbamazepine diol (such as with VPA). Carbamazepine-epoxide, an active metabolite, may produce toxicity even at therapeutic carbamazepine levels (374). The effect of VPA on CBZ-E metabolism may be age dependent; in preschoolers, VPA is an inhibitor of CBZ-E metabolism (442). Finally, CBZ-associated hematological adverse effects must be considered when CBZ is used with concomitant medications. Oxcarbazepine may induce CYP3A4/5 at high dose and may inhibit CYP2C19; concurrent birth control pills may be less effective.

## LAMOTRIGINE/TOPIRAMATE/ GABAPENTIN

### Neuropsychopharmacology

There is a dearth of data regarding the efficacy of these agents in children and adolescents. Although information from adult studies may not directly extrapolate to pediatric populations, they may nevertheless inform our understanding of clinical use and safety.

### Pharmacodynamics

Ion channel effects (sodium channel blockade), antiglutamatergic, and neuroprotective actions may all contribute to the underlying mechanism of action of lamotrigine.

Although lamotrigine does not have robust GABA or monoaminergic actions, longterm lamotrigine treatment has been associated with significant elevations in central GABA concentrations (443).

Gabapentin is structurally related to the inhibitory neurotransmitter GABA, although it does not act directly at the GABA site. Studies of healthy adults have demonstrated acute increases in cerebral GABA concentrations following single doses of gabapentin (443). Gabapentin binds to neuronal membranes' glutamate synapse as well (374).

Topiramate modulates voltage-dependent sodium conductance, potentiates GABA evoked potentials, and blocks the kainate/AMPA subtype of the glutamate receptor (443). Like gabapentin, acute increases in cerebral GABA concentrations follow single doses of topiramate (443).

### Pharmacokinetics

Lamotrigine (LTG) is completely absorbed and undergoes hepatic metabolism and renal elimination. Metabolism is accelerated by drugs that induce CYP450 enzymes and inhibited by valproate. Although lamotrigine itself does not significantly affect the metabolism of other agents, increased CYP450 metabolism of LTG could increase formation of its reactive metabolite and increase the risk of rash (428).

Gabapentin is rapidly absorbed, but its absorption pathway becomes saturated at higher doses so that increasing the dose further may not yield a further increase in plasma levels. Clinical trials reported dose-dependent bioavailability ranging from 74 to 36% when the dose was increased from 100 to 1600 mg (444). Peak plasma levels occur in 1 to 3 hours. Gabapentin is not bound to plasma proteins and has a large volume of distribution, an elimination half-life ( $T_{1/2}$ ) of 5 to 7 hours, linear kinetics, and renal elimination.

Topiramate has low protein binding, little hepatic metabolism, and is excreted primarily unchanged by the kidney, with a half-life of around 24 hours.

### Pharmacotherapy

#### Mood Disorders

Lamotrigine may “stabilize mood from below” in that it may improve depressive symptoms in bipolar disorder, as demonstrated by its efficacy in controlled studies of *adult* bipolar disorder (445, 446). The US FDA has approved Lamictal for maintenance treatment of adults with bipolar I disorder; the first FDA-approved therapy since lithium for longterm maintenance therapy of bipolar I disorder. In youth, open studies in small samples of adolescents with refractory mood disorders have been positive (447).

Two 18-month, controlled trials compared lamotrigine, lithium, and placebo in the maintenance treatment of 1,315 manic or depressed adults with bipolar I disorder. Compared with placebo, lamotrigine and lithium significantly prolonged the time to intervention for a mood episode. Lamotrigine was mostly effective for depressive symptoms, whereas lithium was primarily effective against mania (448).

Gabapentin was not effective in two controlled trials of adult mania (423). In adults, the controlled data do not support the use of gabapentin either as an antimanic medication or as a mood stabilizer (449). However, numerous open-label studies and limited controlled trial data suggest an adjunctive role in the treatment of comorbid anxiety disorder or substance abuse (450). Only isolated case reports of gabapentin use in pediatric mood disorders can be found, and no conclusions regarding its potential benefit may be drawn at this time (451).

In adults, preliminary evidence from open trials of topiramate for acute and refractory mania is promising, but controlled evidence is lacking (449). Likewise, there are open-label reports of topiramate treatment of bipolar spectrum youth. One retrospective review of 26 patients with bipolar disorder treated for a mean duration of 4 months at a mean topiramate dose of 104 mg/day showed a response rate of 73% for mania (452). Pavuluri et al. (2002) (453) reported that topiramate plus risperidone controlled both weight gain and symptoms in preschoolers with mania.

### Anxiety Disorder

Gabapentin has been found effective in adults with anxiety disorder, with a meta-analysis showing an overall effect size of 0.78 (95% CI, 0.29 to 1.27) in social anxiety disorder (454), improvement in panic symptoms in severely ill patients in a RCT (455) case reports of benefit for generalized anxiety disorder (456), and insomnia in patients with PTSD (457).

### Miscellaneous Uses

Because of its effect in reducing weight, topiramate has been studied as an agent for weight loss (458) or stabilization in several populations including eating disorders such as bulimia (459). An open-label study of topiramate in patients with Prader-Willi syndrome reported weight loss or a reduction in weight gain, as well as improvements in mood, aggression, and obsessive-compulsive behaviors (460). Topiramate is *not* approved by the FDA as a weight loss treatment.

Gabapentin has been used successfully in multiple pain syndromes in adults, including trigeminal neuralgia, neuropathic pain, and postoperative pain. Analgesia has also been observed in open reports in pediatric patients (461, 462).

### Initiating and Maintenance of Medication

#### Initiation

Prior to initiation of treatment with lamotrigine, patients and their parents should be instructed that a rash or other

signs or symptoms of hypersensitivity (e.g., fever, lymphadenopathy) may herald a serious medical event and that the patient should immediately confer with their physician. Due to an increased risk of rash, the recommended initial dosing and dose increase guidelines should not be exceeded. With careful dose adjustments, the incidence of serious rash in youth given LTG has been reduced to about 1% (463). Nearly all cases of life-threatening rash have occurred within 2 to 8 weeks of initiation.

Dose increase regimens depend on whether lamictal is used as monotherapy or as adjunctive therapy, and on the particular second anticonvulsant being used (VPA or another). For adult patients not taking other anticonvulsants or other enzyme-inducing drugs, 25 mg daily for 2 weeks, followed by 50 mg daily for 2 weeks, followed by 100 mg daily for 1 week, and then 200 mg daily is recommended by the manufacturer (GlaxoSmithKline). In pediatric patients, lamotrigine should be initiated at 2 mg/kg/d as monotherapy or at 0.2 mg/kg/d if used with VPA and then titrated slowly at about monthly intervals (464).

Gabapentin should be initiated at the lowest possible dose in children (100 mg/daily), and doses intermediate to adult dosage in adolescents (initial adult dose of 300 mg twice a day is recommended), and then may be increased every 3 to 7 days, in increments of the starting dose, reaching a target dose in 4 to 6 weeks. Topiramate should be initiated at the lowest possible dose in children and doses intermediate to adult dosage in adolescents.

### Maintenance/Monitoring

Lamotrigine and gabapentin require neither baseline nor medical monitoring, other than diligence regarding emergence of a lamotrigine rash. Lamotrigine should be discontinued at the first sign of rash, unless the rash is clearly not drug related. Maintenance dose ranges from 1 to 5 mg/kg/d when used as adjunctive therapy with valproate, to 5 to 15 mg/kg/d when given as monotherapy (464).

With topiramate, baseline and periodic monitoring of HCO<sub>3</sub> levels are recommended, especially in youth with conditions that may predispose to acidosis. Evidence of hematuria and hypercalciuria should also be checked before and during topiramate therapy in these children (465).

### Safety

#### Side Effects

The most common ( $\geq 5\%$  incidence) side effects associated with lamotrigine in pediatric epilepsy trials were vomiting, nonserious rash, nausea, somnolence, dizziness, diarrhea, abdominal pain, ataxia, tremor, weakness, infection, and diplopia. Serious rashes requiring hospitalization have been reported, including Stevens-Johnson syndrome. In adult mood disorder trials, the incidence of these rashes was 0.08% (fewer than 1 per 1,000) in patients receiving lamotrigine as initial monotherapy and 0.13% (1.3 per 1,000) in patients receiving lamotrigine as adjunctive ther-

apy. However, in epilepsy trials the incidence of rashes with lamotrigine used as *adjunctive* therapy was 0.3% (3/1,000) in adult and 0.8% (8/1,000) in pediatric patients. In a cohort of about 2,000 pediatric epilepsy patients taking lamotrigine as *adjunctive* therapy, there was one rash-related death. Rash may be increased by concurrent administration of VPA or by exceeding the recommended initial dose or dose increase parameters.

In children with epilepsy, gabapentin (20 to 100 mg/kg/d) has been well tolerated as an anticonvulsant agent. The most common side effects associated with gabapentin therapy are somnolence, dizziness, fatigue, ataxia, nystagmus, and weight gain. There have been a few case reports of behavioral changes at higher doses consisting of tantrums, hyperexcitability, and outbursts of anger (464).

Adverse effects of topiramate include somnolence, dizziness, fatigue, nervousness, headache, diplopia, ataxia, speech difficulties, psychomotor slowing, nystagmus, paresthesia, impaired concentration, anorexia, sleep disorders, and anorexia with or without weight loss (466). Davanzo et al. (2001) (467) reported a child with refractory juvenile-onset bipolar disorder treated with topiramate (TPM) who experienced cognitive and academic deterioration 4 months after mood symptoms remitted. In adults, most of the commonly reported adverse effects were related to the central nervous system and observed with greater frequency at dosages of greater than 200 to 600 mg/day (468). No clinically significant abnormalities were observed in laboratory parameters or in neurological, electrocardiographic, ophthalmologic, or audiological tests (469). Chronic topiramate use may result in a distal tubular acidification defect, leading to an elevated risk of calcium phosphate nephrolithiasis (465). Others have reported that a metabolic acidosis (typically mild) may develop in adult patients over time (465, 470, 471). There is no apparent correlation between dose and acidosis. In December 2003, the prescribing information for topiramate was revised to include a warning that it may cause hyperchloremic nonanion gap metabolic acidosis (decreased serum bicarbonate). The incidence of markedly low bicarbonate in clinical trials ranges from 3 to 11%, compared to 0 to 1% for placebo.

### Drug Interactions

Lamotrigine's total daily dose and titration regimens vary according to whether it is used as monotherapy or as adjunctive treatment. Interactions with VPA were discussed earlier.

Topiramate has no significant effect on plasma levels of other anticonvulsants including carbamazepine and valproic acid. However, topiramate's inhibition of carbonic anhydrase and glutamine synthetase may cause hyperammonemia and encephalopathy (472). In addition, when topiramate is used concurrently with hepatic enzyme-inducing agents, its plasma concentrations are approximately 50% lower than when administered as monotherapy (473).

## ANTIPSYCHOTICS

### Neuropsychopharmacology

The use of antipsychotics in both adult and pediatric psychiatry has increased greatly since the introduction of the atypical antipsychotic agents. Goals for development of these atypical agents included equivalence in antipsychotic efficacy, less EPS and prolactin elevation, and broader efficacy for cognitive and "negative" symptoms. This section focuses mainly on the class of atypical antipsychotic drugs, which are increasingly utilized for more severe and treatment refractory conditions as well as first-line agents in juvenile bipolar disorder. Despite the broader scope of action and enhanced tolerability of the "atypicals," standard typical antipsychotics also retain clear indications in pediatric neuropsychiatry.

### Pharmacokinetics

There has been little study of the pharmacokinetics of antipsychotic medications in children. Studies on the typical agent chlorpromazine and the atypical agent risperidone suggested faster metabolic rates compared to adults (473, 474). However, more recent studies found similar pharmacokinetics for olanzapine, quetiapine (475, 476), and ziprasidone (477) across age groups. Sallee et al. (2003) (478) performed a single-dose, open study of ziprasidone (0.2 to 0.3 mg/kg) in 24 youths with Tourette's or chronic tic disorder; mean AUC ranged between 457 and 247 ng·h<sup>-1</sup>·mL<sup>-1</sup>, with peak serum concentrations at 4 hours postdose.

Frazier et al. (2003) (479) studied clozapine (CLZ) (3 mg/kg) and its metabolites, norclozapine (NOR) and clozapine-N-oxide (NOX), in six youth with childhood-onset schizophrenia. NOR concentrations (410 ng/ml) exceeded CLZ (289 ng/ml) and NOX (63 ng/ml). In adults, NOR serum concentrations on average are 10 to 25% < CLZ. This difference between children and adults in the ratio of metabolites to parent compound may reflect greater activity of hepatic CYP450 isoenzymes 1A2 and 3A4. In addition, clearance varied up to 17-fold among individuals. Dose normalized concentrations of CLZ (mg/kg/d) did not vary with age and were similar to adult values.

### Pharmacodynamics

While traditional antipsychotics primarily cause dopamine type 2 (D2) receptor blockade to produce clinical effects, atypical antipsychotics possess mixed neurotransmitter effects, including 5HT receptor blockade and greater limbic selectivity. Within this class, 5HT/DA blockade ratio is greatest with clozapine, quetiapine, and olanzapine, followed by risperidone. The mixed neurotransmitter selectivity that distinguishes the atypical agents from

more typical agents is likely responsible for both fewer adverse effects (EPS) and their clinical efficacy including reduced negative symptoms and improved mood regulation.

The newest of the atypical agents (e.g., aripiprazole) may be considered dopamine system stabilizers. By interacting with multiple dopamine receptors, they enhance dopamine activity where levels are low (e.g., mesocortical region) and reduce activity where dopamine levels are in excess (e.g., mesolimbic region), while maintaining normal dopamine levels elsewhere (e.g., nigrostriatal region) (480). Dopamine type 1 (D1) receptor blockade in mesocortical regions may provide beneficial cognitive effects.

Two agents in the atypical antipsychotic class are ziprasidone and aripiprazole. The *in vitro* 5-HT<sub>2A</sub>/D<sub>2</sub> receptor affinity ratio of ziprasidone is higher than that of the other first-line atypical agents, and it has moderate affinity for both serotonin and norepinephrine reuptake sites (481). Clinically, this characteristic may be responsible for its antidepressant effects at lower doses and the activation sometimes seen in bipolar patients. At higher doses, the D<sub>2</sub> blockade is more apparent, so that moving up more rapidly to target doses will effect its antipsychotic properties more quickly. In animal models, ziprasidone also increases prefrontal cortical dopamine (482). Sallee et al. (2003) (478) performed an open study of ziprasidone (0.2 to 0.3 mg/kg) in 24 youths with Tourette's syndrome or chronic tics. This was the first human study to indicate that ziprasidone may cause both dopamine antagonism, supported by prolactin increase, and agonism, supported by an increase in spontaneous eye blink rates. Aripiprazole also displays properties of an agonist and antagonist in animal models of dopaminergic hypoactivity and hyperactivity, respectively. Given its partial agonism at 5-HT<sub>1A</sub> receptors (presynaptic) and antagonism at 5-HT<sub>2A</sub> receptors (postsynaptic), aripiprazole may be thought of as a dopamine-serotonin system *stabilizer* (483).

In addition to their DA and 5HT actions, atypical agents have varying antiadrenergic, anticholinergic and antihistaminergic effects. Alpha-adrenergic blockade causes hypotension, cholinergic blockade is responsible for side effects such as constipation, sinus tachycardia, blurred vision and dry mouth, and histamine blockade may cause weight gain and sedation (Table 27.14).

## Pharmacotherapy

Discussion of the therapeutic use of the antipsychotic medications is organized according to the primary clinical applications that are supported by controlled clinical trials. However, the clinical applications of atypical antipsychotics have become quite broad in pediatric care.

## Psychotic Disorders

Antipsychotic agents are recommended for treatment of the acute and stabilization phase of schizophrenia. The adult

literature suggests that atypical agents may also enhance neurocognitive function (484, 485) and improve negative symptoms associated with psychosis, although the effect size advantage over more typical agents may be small (486). Available studies, case reports, and clinical experience all suggest that patterns of response in youth are similar to that found in adults (487). Ongoing research efforts include the NIMH study of childhood-onset schizophrenia. Although little controlled data on the treatment of primary psychotic disorders in young children exists, the use of antipsychotic drugs is considered justified in early onset schizophrenia (487). Frazier et al. (2003) (479) reported the efficacy and safety of clozapine in youth with DSM-IV schizophrenia, during both open and double-blind trials of clozapine and haloperidol. These and other authors demonstrated that clozapine plasma concentrations may be positively correlated with response (488). An 8-week pilot study comparing the acute antipsychotic effect size of risperidone and olanzapine to that of haloperidol found that a majority of subjects treated with olanzapine (88%), risperidone (74%), and haloperidol (53%) all met criteria for positive response (489). Randomized controlled trials of antipsychotic drugs in psychotic disorders in youth include the more typical agents loxapine and haloperidol (490, 491).

Open trials of atypical agents have also demonstrated efficacy for olanzapine in the short-term treatment of adolescents with schizophrenia, schizoaffective, or schizophreniform disorders (492) and in a 1-year prospective open-label trial of childhood-onset schizophrenia (493), for risperidone in adolescents with schizophrenia (494) and for quetiapine in adolescents with selected psychotic disorders (495).

## Mood Disorders

RCTs of atypical agents have also shown benefit for adults with bipolar disorder. Unlike the typical neuroleptics, atypical agents show benefit for *maintenance* of treatment response and as adjunctive agents for depressive symptoms (496) in addition to controlling acute mania. Rigorous studies in this severely disturbed and likely heterogeneous pediatric population are hindered by ethical (placebo control) and nosological dilemmas. Despite this, controlled studies of juvenile bipolar disorder are under way, mostly with the atypical antipsychotic agents. In addition, treatment algorithms have been presented in an attempt to offer consensus guidelines to clinicians. Monotherapy with olanzapine, risperidone, and quetiapine (in addition to lithium, divalproex, and carbamazepine) are among the first-line treatments for juvenile bipolar disorder (384).

In a double-blind, placebo-controlled study of quetiapine in adolescent mania (452), 30 adolescent inpatients with bipolar I disorder received VPA with either adjunctive quetiapine or placebo for 6 weeks. The combination VPA + quetiapine treated subjects had significantly greater reduction in YMRS scores compared to VPA + placebo treated

5HT, Serotonin; CYP, Cytochrome P450; D, Dopamine; EPS, Extrapyramidal symptoms; H, Histamine; M, Muscarine; NMS, Neuroleptic malignant syndrome QTc. The beginning of the depolarization of the left ventricle is labeled Q (wave), and the ventricular repolarization is labeled T (wave). QTc is the interval corrected by a mathematical formula for heart rate. T-Max: time to peak plasma level.

subjects. Adjunctive augmentation trials include open-label olanzapine in manic children (497) and open-label olanzapine augmentation of lithium in bipolar psychosis (386). In the latter study, 43% of manic, psychotic adolescents relapsed when they discontinued the antipsychotic after 4 weeks of stabilization with adjunctive treatment. These

studies followed preliminary reviews of pharmacotherapy in childhood mania (498) and case reports of open-label atypical antipsychotic monotherapy in juvenile bipolar disorder. Rapid, robust improvement has been observed with risperidone and olanzapine (451, 499, 500) as well as quetiapine (476), including longterm safety and efficacy (501).

In adults, olanzapine has an FDA indication for both acute *and maintenance* bipolar monotherapy and may produce greater remission rates in acute manic or mixed episodes compared to standard agents, such as divalproex (502). In December 2003, the FDA approved the use of risperidone as monotherapy, or in combination with lithium or valproate, for the treatment of acute manic or mixed episodes of bipolar I disorder. Atypical antipsychotics may possess broad efficacy beyond their antimanic effects and have use in depressed phase bipolar disorder or even unipolar depression. Efficacy for quetiapine in psychotic depression has already been described in one report (503).

### Anxiety Disorders

The sum of evidence at this time points to the benefits of atypical antipsychotic augmentation of SSRIs for treatment resistant OCD in adults (504). In children, however, this subject is confusing. One case series on pediatric OCD found that symptoms progressively diminished with increase in dose of risperidone used for augmentation (505). However, there have been case reports of worsening of obsessive-compulsive symptoms with the atypical antipsychotic in adults (506–509) and children (510). Several authors also noted rapid resolution of OCD symptoms upon discontinuation of risperidone (510, 511). Others did not see OCD symptoms reemerge with risperidone rechallenge, yet others found that obsessions gradually diminished with continued treatment. Risperidone has greater relative dopamine blocking activity at higher doses (512). These observations add to a number of others that dopamine may be involved in the pathogenesis of OCD in some way (513, 514). At this time there is insufficient evidence to support the routine use of the atypicals in pediatric OCD unless there are comorbid tics.

### Pervasive Developmental Disorder/Mental Retardation

Following several decades of using the typical antipsychotics in children with pervasive developmental disorders and intellectual disabilities, atypical antipsychotics are now commonly used for behavioral problems in these children (515). Of the neuroleptics, haloperidol has been the most thoroughly studied with efficacy shown in both shortterm (516) and longterm (517) studies. Open trials have compared atypicals to typical agents, such as a parallel-group study of 12 children with autism treated with olanzapine or haloperidol (518). Five of six subjects in the olanzapine group and three of six in the haloperidol group were rated as responders.

The National Institute of Mental Health funded Research Units on Pediatric Psychopharmacology (RUPP) Autism Network completed an 8-week, double-blind, placebo-controlled study of risperidone in 101 children and adolescents with autism (519). In the risperidone group, 69% achieved a positive response for serious be-

havioral problems compared to just 12% in the placebo group ( $P < 0.001$ ). Besides risperidone, other atypical antipsychotics with demonstrated efficacy in open trials of autism or PDD include clozapine, olanzapine, quetiapine, and ziprasidone (520). A 3-year naturalistic study described 47% improvement in a sample of preschool children with PDD treated with risperidone monotherapy (521).

The efficacy of risperidone has also been demonstrated in children with subaverage IQs and severe disruptive behaviors in controlled trials (522, 523). In a follow-up extension study, risperidone was safe and well tolerated with positive effect maintained over 1 year (524).

### Tic Disorders/Tourette's Disorder

Atypical antipsychotics have been shown comparable to typical neuroleptics for tic suppression in studies in adolescents and adults. Two placebo-controlled studies and two randomized trials with active comparators have shown that risperidone is effective for the suppression of moderate to severe tics in children and adolescents with Tourette's syndrome (525, 526). Sallee et al. (2003) (478) suggested that ziprasidone may act primarily on the neocortex to dampen excitatory glutamatergic overdrive.

### Eating Disorders

Several reports describe open-label efficacy of olanzapine in the treatment of anorexia nervosa (527–529). In these medically and psychiatrically compromised populations, olanzapine may assist in mood regulation, distorted thinking, and ego function, as well as provide a shortterm boost in weight gain that often accompanies its use.

## Initiating and Maintenance of Medication

### Initiation

Use of antipsychotic agents requires adequate informed consent from the parent or the youth (depending on the legal age requirements or legal status). Special regulations may govern the prescribing of antipsychotics in children who are in state custody or foster care. In addition, documentation of target symptoms, baseline and follow-up laboratory monitoring, documentation of treatment response and side-effects—including EPS (Abnormal Involuntary Movement Scale) and weight gain—and adequate therapeutic trials of sufficient dosages over 4 to 6 weeks are all important (487).

The smallest dosage should generally be used for initiating antipsychotic medication in youth. Minimum effective doses for newer atypical antipsychotic medications across fixed-dose placebo-controlled studies in *adults*, defined by their equivalency to 100 mg/day of chlorpromazine, are 2 mg/day for risperidone, 5 mg/day for olanzapine, 75 mg/day for quetiapine, 60 mg/day for ziprasidone, and 7.5 mg/day for aripiprazole (530).

They should be used with caution in youth with a personal or family history of diabetes or hyperlipidemia due to metabolic adverse effects, as highlighted by the FDA. In 2004, the American Diabetes Association published a consensus statement recommending a baseline weight, height, waist circumference, blood pressure, fasting glucose, and lipid profile.

Clinical experience suggests that children with PDD spectrum disorders may be particularly sensitive to serotonergic agents. As such, low dosage and slow titration of atypical agents is indicated in this population, as with SSRI medications.

### Maintenance/Monitoring

Although clinical practice may vary, practice guidelines and expert reviews provide some guidance on the complex issues of medication monitoring and maintenance. The decision to lower dosages (to minimize side effects) or undergo medication-free trials must be balanced by the increased risk for relapse, particularly in psychotic disorders. In general, first-episode psychotic patients should receive maintenance psychopharmacological treatment for 1 to 2 years following an initial episode, due to risk for relapse (487). For mood disorders, treatment for 9 to 12 months beyond time to achieve remission is usual.

In 2004, the American Diabetes Association published a consensus statement suggesting follow-up monitoring of weight (4 weeks, 8 weeks, 12 weeks, quarterly), waist circumference (annually), blood pressure (12 weeks, annually), fasting glucose (12 weeks, annually), and lipid profile (every 5 years), noting that more frequent assessment may be warranted according to clinical status. For example, fasting serum insulin levels and HbA1C could be checked if morbid obesity is present to assess risk for type 2 diabetes. Melkersson and Dahl (2004) (531), in an extensive review, discuss preventative strategies for weight gain.

ECG monitoring is not routinely required, but in children QTc intervals should be checked for prolongation if other drugs that may also alter QTc are used concurrently or in overdose situations.

Clozapine is unique in the class of atypical agents, due to a "therapeutic window" and potentially severe hematological adverse effects such as bone marrow suppression. Based on emerging data for pediatric populations, it has been suggested that CLZ serum assays in youth be standardized to include CLZ + NOR metabolite rather than to CLZ alone (typically used in adults) due to their combined contribution to the overall effectiveness and side effect profile of CLZ in youth (479).

### Safety

There are ongoing efforts to acquire longterm safety data on the antipsychotic medications in youth, as they are applied

increasingly in mood and other psychiatric disorders. Although well tolerated in shortterm use, significant weight gain, extrapyramidal symptoms, and cardiac and metabolic effects may negatively skew the risk-benefit ratio of atypical agents over the medium to longterm.

For traditional antipsychotics, potency measured by degree of DA blockade correlates with adverse effects; high-potency agents such as haloperidol tend to produce EPS, whereas low-potency agents such as thioridazine and chlorpromazine have more anticholinergic side effects and sedation.

### Weight Gain

A review of an FDA postmarketing surveillance database on olanzapine found that the risk of complaints of weight gain was 4.3 times higher for children and 3.2 times higher for adolescents than for adults. Similarly, complaints of increased appetite were 24 times higher in childhood compared to adults (532). Increased weight gain may involve serotonergic, histaminergic, and adrenergic mechanisms (533) and, in reviews of adults, may be increased two- to threefold with administration of concomitant lithium or valproate (534). Management of this adverse event includes switching atypical agents or the discontinuation or addition of a targeted treatment. For example, Molindone may be uniquely weight neutral. Overall, treatment-induced obesity is a particularly challenging issue for practitioners. Familiarity with other management options, such as local weight-control behavioral programs for youth, may be helpful and associated with less frequent relapse than in adult populations (535).

### Metabolic

Thorough reviews of metabolic adverse effects such as hyperglycemia and hyperlipidemia may be found elsewhere (531). After the appearance of clozapine, the first atypical agent, reports of metabolic adverse effects, primarily on glucose and lipid regulation, are found in the adult literature. Noninsulin-dependent hyperglycemia has been observed with several of the atypical antipsychotics, primarily olanzapine and clozapine. Initially, elevated rates of diabetes (36% of 82 patients over 5 years) were described in small samples of adult patients treated with clozapine (536). In a 4-month study comparing the prevalence of diabetes in adults with schizophrenia (N = 38,000), atypical antipsychotic treated patients showed a greater prevalence than those treated with a typical neuroleptic (9% versus 6%). However, these authors suggested that atypical antipsychotics may hasten onset rather than cause the diabetes (537). On March 1, 2004, the FDA has asked manufacturers of atypical antipsychotic medications to add a warning statement to package inserts describing hyperglycemia, rarely extreme and associated with ketoacidosis or hyperosmolar coma and even death in patients treated with atypical antipsychotics ([www.fda.gov/med-watch](http://www.fda.gov/med-watch)).

Studies in pediatric populations ( $N = 175$ ) have also demonstrated significant weight gain with atypical agents (olanzapine, risperidone, quetiapine), as well as insulin resistance in children taking olanzapine. Insulin resistance was predicted by weight gain. Putative risk factors include increased premonitory weight and personal or family history of diabetes (538). However, impaired glucose tolerance and diabetes have also been found in certain psychiatric populations, such as schizophrenia compared to the general population (536, 539). In certain refractory cases, targeted drugs such as metformin to increase insulin sensitivity may have benefit. In one study, 15 of 19 children responded with weight loss (540).

Hyperlipidemia has also been observed with atypical agents, primarily olanzapine and clozapine. In a 2002, 4-year UK study of adult schizophrenics ( $N = 18,000$ ), a three-fold increase in triglycerides and cholesterol was found with olanzapine compared to more typical neuroleptics (541).

### Endocrine

Antipsychotic agents' dopamine blockade releases dopamine-induced tonic inhibition of prolactin secretion. Transient, dose-related increases in serum prolactin have been reported in adult schizophrenia (542), although serum effects may not be correlated significantly with adverse effects, such as acne, estrogen deficiency, galactorrhea, or decreased libido (543). The clinical significance of hyperprolactinemia outside of these adverse effects is unknown. Open-label treatment with numerous typical and atypical agents such as haloperidol, risperidone, and olanzapine has caused hyperprolactinemia in children (499, 544). A review of an FDA postmarketing surveillance database on the agent olanzapine found the risk of prolactin increase-related complaints to be 4.8 times higher for adolescents than adults (532). In one study, serum prolactin levels were shown to rise in the short term and then steadily decrease (545). Others have also demonstrated hyperprolactinemia in youth appearing within 4 weeks of beginning risperidone treatment and declining over time to within the normal range (524). Some of the newer agents in the class, ziprasidone and aripiprazole, have minimal chronic effect on prolactin concentrations in healthy adult males (546).

Expert opinion suggests that management of hyperprolactinemia includes assay of levels every 3 to 6 months, since serum prolactin often decreases over time. In refractory or symptomatic cases, medication may be considered if the atypical cannot be discontinued. Cohen and Biederman (2001) (547) successfully reversed hyperprolactinemia in four males (ages 6 to 11) with risperidone-induced increases (serum prolactin 57 to 129 ng/mL) with the dopamine agonist cabergoline. An alternative option is to switch drugs; for example, olanzapine reversed hyperprolactinemia in risperidone-treated females with schizophrenia (548).

### Motor

Extrapyramidal symptoms occur commonly in people taking antipsychotic medications, albeit less frequently with the atypical class. Meta-analysis (486) of data from more than 7,000 adult patients found the effect size of the difference to be 0.30 (i.e., 30% more extrapyramidal side effects with typical than atypical antipsychotics). Although there is little information, a review of the FDA postmarketing surveillance database on the agent olanzapine found a relatively low risk of EPS complaints across age groups, similar to prior reports (532). However, this same review found a fourfold increased risk of dyskinesia in children compared with adults. In a prospective, longitudinal study of haloperidol in 118 children with autism, Campbell et al. (1997) (549) reported that withdrawal dyskinesias (WD) developed in 40 (34%) children; 20 had more than one dyskinetic episode. A subgroup that remained longer in the study with a higher cumulative haloperidol dose evidenced a significantly higher WD incidence. Occurrence rates of tardive dyskinesia (TD) and multiple episodes of TD/WD were higher among girls. In an analysis of long-term risperidone treatment (0.02 to 0.06 mg/kg/day), 18% of a sample of 700 youth experienced at least one symptom of EPS during a 12-month period (545).

### Cardiac

Prolonged ECG QTc intervals have been associated with various medications, including the antipsychotics. The QTc interval reflects time occupied for combined depolarization and repolarization of the ventricles. Prolongation of the QTc via potassium channel blockade and delayed repolarization shortens the time that the heart is electrically at rest (isoelectric) and has been shown to be associated with torsade de pointes, a polymorphic ventricular tachycardia, and sudden death. QTc lower than 440 msec are considered normal, with values  $>500$  associated with significantly greater risk (550). The typical neuroleptic thioridazine, which blocks the potassium channel, has been found to cause torsade de pointes and sudden death, in contrast to tricyclic antidepressants, which block sodium channels associated with depolarization and thus increase QTc via another mechanism. A large retrospective cohort study of adult typical antipsychotic users ( $N = 481,744$ ) found a 2.4-fold increase in sudden death with doses greater than 100 mg thioridazine daily or the equivalent (551). Of the atypical agent class, several block potassium channels, primarily ziprasidone, although risperidone, olanzapine, and quetiapine also do to a lesser degree (550). ECG monitoring should be performed at maximum daily (peak) blood levels to best observe for cardiac conduction effects (550). Automated computer interpretations of ECGs should be followed by a cardiologist's review.

### Ocular

Beyond such risk factors as old age and diabetes, medications, particularly antipsychotics, have been associated with the development of cataracts. Although the typical

antipsychotics thioridazine and perphenazine have been associated with cataracts, no causal relationship has been determined. In preclinical studies, quetiapine was associated with increased rates of cataracts in puppies at doses four times the maximum human dose (prescribing information, quetiapine). However, in a survey of 620,000 persons taking quetiapine, a lower rate (0.005%) of cataracts was found than in the general population (552).

### Hematological Clozapine

Clozapine is available only through a distribution system that ensures appropriate WBC monitoring (Novartis). Clinical studies of clozapine in youth are limited. However, sialorrhea, tachycardia, sedation, enuresis, weight gain, and elevated hepatic transaminase concentrations have been reported. Side effects, including weight gain, have been shown to correlate positively with serum concentrations (479). Of more concern are potentially serious hematological adverse effects such as reduced neutrophil count. In the Frazier et al. trial (2003) (479), one 9-year-old female experienced moderate neutropenia. The higher NOR/CLZ ratio observed in these youth may increase vulnerability due to possible marrow toxicity of NOR (553). Alvir and Lieberman reported that patients younger than 21 years of age (and females) may be at higher risk for agranulocytosis (554).

### Neurological

Electroencephalographic (EEG) abnormalities have been demonstrated in adults using the typical antipsychotics. Among the new atypical class, the commonest abnormalities (47%) have been found with clozapine, while olanzapine and risperidone had lesser effects (555).

### Drug Interactions

Clozapine is metabolized primarily by CYP1A2, with additional pathways via CYP2C19, CYP2D6, and CYP3A4. Risperidone is metabolized primarily by CYP2D6 and to a lesser extent by CYP3A4. Olanzapine is metabolized primarily by CYP1A2 and to a lesser extent by CYP2D6. Quetiapine and ziprasidone are metabolized by CYP3A4. Although substrates for the CYP450 enzymes, at usual clinical doses these drugs appear not to significantly affect the metabolism of other medications (556).

Several case reports have appeared since 2002 regarding a possible interaction between risperidone and valproic acid in youth, suggesting protein-binding displacement to yield increased serum valproic acid levels or alterations in valproic acid levels mediated by a cytochrome 2D6 interaction (437–439). In response, Good et al. (2003) (440) retrospectively described their pediatric data (N = 45) using combination divalproex sodium with atypical antipsychotics finding no significant difference in trough divalproex levels with combination divalproex sodium and olanzapine or risperidone.

### Overdose

Scattered cases of antipsychotic overdose have been reported in youth. In a review of the current literature, Catalano et al. (2001) (557) suggested that special care may be indicated with pediatric cases of atypical antipsychotic overdose including intensive monitoring of potential respiratory or cardiac difficulties. Olanzapine overdose in a 12-year-old boy presented as opioid-like and was followed by complete recovery (558). Catalano et al. (2002) (474) presented the case of a 15-year-old girl who ingested 1,250 mg of quetiapine (21.6 mg/kg) in a suicide attempt and developed symptoms including tachycardia, agitation, hypotension, and unconsciousness. James et al. (2000) (559) described the epidemiology, clinical presentation, management, and outcome of phenothiazine and butyrophenone ingestions in children. Depressed levels of consciousness (91%) and dystonia (51%) were most common.

## MISCELLANEOUS AGENTS

### Benzodiazepines

Although possessing similar pharmacodynamic actions at GABA receptors, benzodiazepines (BZD) differ in their pharmacokinetics and metabolism, such as hepatic metabolic pathways, presence of active metabolites, T<sub>max</sub>, and half-life.

The study of benzodiazepines has been limited in pediatric populations and consists primarily of open-label small case reports or studies with variable or mixed samples of anxiety disorders. Open-label studies have demonstrated efficacy in overanxious disorder (560) and panic disorder (561, 562) using alprazolam (0.5 to 1.5 mg/day) and clonazepam (0.5 to 3.0 mg/day). Although controlled studies of alprazolam in overanxious youth (563) and clonazepam in mixed anxiety (564) disorders did not demonstrate significant differences over placebo, these were methodologically limited by small sample sizes. In one small, placebo-controlled study of alprazolam and imipramine in children with school refusal, Bernstein et al. (1990) (231) found no significant differences following treatment between groups in either anxiety or depressive symptoms. However, another placebo-controlled study found clonazepam effective for neuroleptic-induced akathisia, suggesting utility beyond primary anxiety disorders (565).

Adverse effects of BZDs such as sedation and behavioral changes may be particularly pronounced in neurologically vulnerable populations, as well as at either age extreme. For example, based on a literature review (566), behavioral side effects occurred in 13% of 446 individuals with mental retardation using benzodiazepines for psychiatric conditions, epilepsy, or other medical conditions. Children, including those with pervasive developmental delays or

autism, may be vulnerable to paradoxical behavioral agitation as well (567). Children hospitalized for accidental or deliberate benzodiazepine ingestion (568) experienced the following transient adverse effects: ataxia (87%), lethargy (57%), coma (35%), and respiratory depression (9%). BZDs should be initiated at the lowest available dosage, with gradual titration, particularly with agents with a longer half-life, such as clonazepam, allowing for its accumulation over several days. Adverse effects such as sedation tend to peak as steady state is being reached, and this may take a week or longer with clonazepam. Physiological tolerance may occur with the BZD class necessitating careful and gradual withdrawal. Withdrawal from short-acting agents such as alprazolam may be best achieved by switching to a longer-acting formulation such as clonazepam and then weaning gradually to enhance tolerance of discontinuation (Table 27.15).

### Buspirone

Buspirone, an azaspirone, may exert its effect via the dopaminergic or serotonergic system. The drug is rapidly absorbed with time to reach peak levels under 1 hour. It is extensively metabolized, with an elimination half-life of 2.5 hours and linear pharmacokinetics (569).

Adult-controlled studies have demonstrated efficacy in generalized anxiety disorder (570). Efficacy and safety of buspirone in pediatric samples have primarily been

observed in open studies of social anxiety (571) and anxiety disorders in children with PDD (572). In a sample of prepubertal psychiatric inpatients, it had limited benefit and caused increased aggression, agitation, and euphoria (573). Preliminary reports of benefit have also been presented in small open samples of ADHD (574, 575) and comorbid ODD (576).

In addition buspirone may facilitate antidepressant response, as suggested in the adult literature, via activation of presynaptic and postsynaptic 5-HT<sub>1A</sub> receptors and modulation of serotonin release (577). Only limited reports of SSRI augmentation with buspirone (for OCD) may be found in the pediatric literature (578).

### Alpha-2 Agonists

Clonidine, an imidazoline-derived agent, has agonist effects on central alpha-2-adrenergic receptors. Guanfacine is a longer-acting and more selective agonist than clonidine. Research in animal models demonstrates that too little alpha-2-receptor stimulation or too much alpha-1-receptor stimulation can impair prefrontal cortical function. Thus, agents that normalize NE prefrontal transmission may reduce impulsivity and enhance attention by improving prefrontal cortical behavioral control (579).

The alpha-2-receptor clonidine has been shown to be superior to placebo in ADHD in a number of randomized controlled trials, though methodological weakness limit

**TABLE 27.15**  
**USUAL DOSE RANGES FOR MEDICATIONS IN PEDIATRIC ANXIETY DISORDERS**

Drug	Starting Dose (mg)	Typical Dose Range (mg)
<b>First-Line Treatment</b>		
Citalopram	5–20 QD	5–60
Fluoxetine	5–20 QAM	5–80
Fluvoxamine	12.5–50 QHS	25–300
Paroxetine	5–10 QPM	5–60
Sertraline	12.5–25 QAM	25–200
Buspirone	5 BID	5–60
<b>Second-Line Treatment</b>		
Clomipramine	12.5–25 HS	25–150 (2–5 mg/kg/day)
Desipramine	10–25 QHS	10–250 (2–5 mg/kg/day)
Imipramine	10–25 QHS	10–200 (2–5 mg/kg/day)
Nortriptyline	10 QHS	10–150 (1–3 mg/kg/day)
Protriptyline	5–10 QHS	5–50 (0.5–2 mg/kg/day)
Clonazepam	0.125–0.5	0.125–3.0
Diazepam	1–2 HS	0.25–5.0
Lorazepam	0.125–0.5 BID	0.125–3.0
<b>Third-Line Treatment</b>		
Mirtazapine	7.5–15 HS	15–45
Venlafaxine	12.5–37.5 BID	25–300

their interpretation (588, part 1). Connor et al. (1999) (580) conducted a meta-analysis of 11 trials utilizing clonidine (0.10 to 0.24 mg/day) in children with ADHD. Across parent, teacher, and clinician ratings, positive findings were observed, with an overall moderate effect size of 0.58 and great variability depending on the methodology of individual studies. In one short-term controlled trial, clonidine was modestly effective in reducing irritability and hyperactivity in eight male children with autism (581). Two uncontrolled studies (1.5 to 3.2 mg guanfacine/day) found scattered and limited improvement in hyperactivity and inattention (582, 583). Open studies of alpha-2 agonists in a small sample of aggressive youth with childhood disruptive behavior disorders demonstrated improvement in opposition and conduct (584).

Clonidine (CLON) or guanfacine are considered first-line agents in tic disorders and Tourette's syndrome due to their modest efficacy and relatively benign profile compared to the antipsychotic agents. A multicenter, randomized, double-blind, 16-week clinical trial conducted in 136 children with ADHD and a chronic tic disorder (CLON alone, MPH alone, combined CLON + MPH, or placebo) showed efficacy of clonidine in tic disorders. Compared with placebo, the greatest benefit for comorbid children occurred with combined CLON + MPH ( $p < 0.0001$ ). Compared with placebo, tic severity lessened in all treatment groups in the following order: CLON + MPH, CLON alone, MPH alone (310). In addition, in an 8-week placebo controlled study of guanfacine (0.5 mg to 3 mg divided) in ADHD and tic disorder, Scahill et al. (2001) (585) found significant superiority of active drug over placebo in both ADHD symptoms and tic reduction. Based on open-label studies suggesting benefit for anxiety, arousal, and impulsivity, an ongoing RCT of clonidine for posttraumatic stress disorder is under way (586, 587).

Clonidine may be started as a single bedtime dose (0.05 mg) and titrated over 2 to 4 weeks to a total daily divided dose of 0.05 mg to 0.4 mg/day, with dose adjustments every 3 to 5 days. Clonidine's half-life is very short (3 to 4 hours) so that divided doses may be needed. It is often sedating and finds one of its most widespread uses as a hypnotic in hyperactive youth. Guanfacine has lower potency and a longer duration of action. Daily doses range from 0.5 to 4 mg/day, given on a schedule similar to that used for clonidine (588). Guanfacine and clonidine in children and adolescents have the common adverse events of sedation/lethargy and irritability (580, 589). Mood disturbances with longer-term use may also be noted. Sleep disturbances associated with ADHD may be improved with clonidine (590, 591), although clinical trials report sleep disturbance, such as awakening in the middle of the night (580).

Cardiac side effects (dysrhythmia, bradycardia, hypotension, first-degree heart block, nonspecific intraventricular conduction delay) associated with the use of clonidine in children have been reported (592, 593). Following the cases of four children who died, presumably while receiving

clonidine in combination with methylphenidate (MPH), Wilens and Spencer (1999) (358) critically summarized the literature. The authors acknowledged that clonidine can be associated with cardiovascular side effects in the context of coadministered sympatholytic agents or in the face of pre-existing myocardial impairment. Yet there were mitigating circumstances surrounding each of these cases, and there were insufficient data to declare any causal relationship. The American Heart Association has stated that ECG monitoring is not routinely required for clonidine treatment (328).

Physiological tolerance may occur, necessitating careful and gradual withdrawal to avoid rebound hypertension. A reasonable taper schedule could be reduction by 0.05 mg clonidine or 0.5 mg guanfacine each 5 to 7 days.

### Beta-Blockers

Beta-blockers, agents that block beta-adrenergic receptors, may be useful for adults in states of hyperarousal, such as panic, performance anxiety, aggression, and posttrauma. Beta-blockers differ in pharmacology, such as beta-selectivity and solubility; propranolol readily crosses the blood-brain barrier due to its lipid solubility. According to a *Cochrane Database of Systematic Reviews*, the best evidence for efficacy of beta-blockers is in the management of aggression in acquired brain injury (ABI) (594). Only one controlled trial of children with ADHD and comorbid conduct disorder has been reported (595), demonstrating modest efficacy for pindolol compared to MPH. A study of beta-blockers (propranolol) in adults with trauma suggests that they could mitigate or perhaps even prevent PTSD symptoms (596). Beta-blockers have anecdotally been usefully combined with stimulants to reduce systemic adrenergic adverse events such as tremor, for example, nadolol at 20 mg/daily. Lastly, there are case reports of pindolol used for treatment-resistant OCD.

Beta-blockers are generally well tolerated. In addition to bradycardia, adverse effects may include fatigue and bronchoconstriction, so that asthma may be a relative contraindication for their use. In these situations, using a selective beta-1 antagonist, such as atenolol or betaxolol, is recommended. Physiological tolerance may occur, necessitating careful and gradual withdrawal to avoid rebound hypertension.

### Novel Anticonvulsants

Tiagabine, a nipecotic acid derivative that enhances GABAergic activity by inhibiting GABA reuptake, is approved for adjunctive treatment of partial seizures in adults and children older than 12 years (597). Zonisamide, a sulfonamide derivative that blocks calcium channels and prolongs sodium channel inactivation, is approved as adjunctive therapy for partial seizures in patients aged 16 years and older (597). Both agents have only preliminary data in adult bipolar disorder (449) and none at all in pediatric psychiatry.

### Modafinil

Modafinil, an alerting agent that targets the hypothalamus and other sleep-regulating areas of the brain, is approved for the treatment of adult narcolepsy. Its pharmacokinetic properties have been reviewed (598). Modafinil may have utility for daytime somnolence in youth, suggested by a systematic chart review of 13 children (599). Care should be taken not to use modafinil for somnolence that may be the result of a sleep disorder such as obstructive apnea to avoid masking an underlying problem that requires a more specific intervention. According to commercial sales figures, sleep experts, psychiatrists, and generalists are increasingly prescribing modafinil for somnolence not caused by narcolepsy, such as found in depression and multiple sclerosis, as well as for ADHD (600). In one randomized, double-blind, placebo-controlled study of 24 children, Conners' Rating Scales ADHD total T scores for the modafinil group improved compared to control subjects ( $P = 0.04$ ). Ten of 11 treatment patients were reported as "significantly" improved, whereas 8 of 11 control subjects were reported as manifesting "no" or only "slight" improvement ( $P < 0.001$ ) (601).

### Nicotine/Acetylcholine

Nicotinic interactions with dopaminergic and glutaminergic systems may be important in cognitive function (602). Further, there may be genetically distinct subtypes of ADHD, so that attention problems could be responsive to receptor subtype selective nicotine agonists (603). Cholinesterase inhibitors may also be useful in ADHD. For example, five youth aged 8 to 17 years demonstrated improvement in ADHD with the acetylcholinesterase inhibitor donepezil (Aricept) (604).

### Opiate Antagonists

The opioid antagonist naltrexone has been studied in autism and specifically for self-injurious behaviors. This data suggest some positive effect on motoric overactivity but not on the core social deficits associated with autism (605). In a trial of 32 adults (7 with autism, 16 with autism and self-injurious behavior, and 9 nonautistic individuals with self-injurious behavior), naltrexone did not demonstrate efficacy for either self-injurious behavior or core autism symptoms. In fact, naltrexone increased the incidence of stereotypic behaviors, and at 50 mg/d, naltrexone-treated subjects were rated significantly globally worse than those on placebo (606).

### Alternative Medicines

Although widespread in their use, including in pediatric populations, studies of herbals, supplements, and other alternative medicine agents or techniques have significant

methodological limitations, including a general lack of standardization. Potentially useful agents such as omega-3/6 fatty acids, St John's wort, melatonin, and others are being studied with sponsorship by the National Center for Complimentary and Alternative Medicine (NCCAM) ([nccam.nih.gov](http://nccam.nih.gov)). As our knowledge base slowly expands regarding the efficacy of these agents, we are also increasingly aware of adverse effects and potentially clinically significant drug interactions (41), despite the public (and clinician) perception that these "natural" alternative remedies possess a benign safety profile.

### Calcium Channel Blockers

Many mood-disordered patients show increased intracellular calcium alterations during, and even between, depressive episodes, leading to the hypothesis that blockade of calcium influx may be clinically helpful. Hollister and Trevino (1999) (607) reviewed the literature for the use of calcium channel blockers (CCBs) in psychiatry and found 61 reports, including 17 controlled trials, all in adults. Most studies involved treatment of mania using verapamil but also included nimodipine. Results were mixed, but typically lithium and even placebo fared better than verapamil. Treatment for depression, schizophrenia, tardive dyskinesia, and dementia has largely failed to show justification for the use of CCBs. At this time, this class of drug has no indication in pediatric psychopharmacology.

## CONCLUSION AND FUTURE DIRECTIONS

In summary, we have seen an exponential growth in our evidence-based knowledge of pediatric psychopharmacology. The strongest evidence supports the use of stimulants in ADHD and SSRIs in OCD in children. Support for SSRIs in major depressive disorder and other anxiety disorders is substantial. The improved methodology, greater statistical power, and sheer number of psychopharmacology studies under way at this time should add greatly to our knowledge over the next decade. Areas of special interest are in the use of glutamate and NMDA receptor antagonists that promise to yield benefits over a range of clinical disorders. Neurobiological studies have implicated an intimate role for glutamate in the pathogenesis of OCD symptoms, mediated through glutamatergic innervation of caudate from prefrontal cortex as part of a cortico-frontal-striatal-thalamic loop (608). As such, the clinical value of glutamate antagonists in the treatment of OCD is being actively explored.

One possible etiological subtype of early-onset OCD, that is pediatric autoimmune neuropsychiatric disorder associated with streptococcus (PANDAS), has garnered much attention for its implication that antibiotic treatment may alleviate symptoms of tics and OCD through suppression of antibody-stimulating streptococci that indirectly cause

immune-mediated inflammation of basal ganglia structures (609). However, definitive evidence that antibody prophylaxis can reduce symptoms of OCD or prevent relapse is still lacking, despite some empirical evidence supporting this approach.

In the future, the use of sophisticated molecular genetic as well as functional, structural, and spectroscopic magnetic resonance imaging studies could lead to the development of pharmacogenetic and endophenotype studies to better craft pharmacotherapeutic interventions for children.

# Electroconvulsive Therapy in Pediatric Neuropsychiatry

*C. Edward Coffey, MD*

The past three decades have seen a remarkable resurgence of interest in electroconvulsive therapy (ECT). Indications have broadened; technical features are better understood, producing a safer and more effective therapy; and improved devices provide more effective electrical stimulation and better monitoring of seizures. What began as a treatment for adults, with emphasis on the elderly, is now finding an expanded application with adolescents and even children, including those with neurologic illness.

In this chapter, I review the history and clinical experience with ECT in children and adolescents; discuss guidelines and indications for its consideration; review physiological effects, treatment techniques, side effects, and patient attitudes; discuss theories of a mechanism of action; and call for greater flexibility in considering the use of ECT among children and adolescents with neuropsychiatric illness.

## HISTORY

ECT was apparently first given to a child around 1941 (Hemphill & Walter, 1941) and to adolescents (two teenagers) in 1942 (Heuyer & Bour, 1942), approximately 4 to 5 years after the first administration of ECT to an adult. In 1943, Heuyer and colleagues (1943) reported the administration of ECT to 40 adolescents and children with various psychiatric diagnoses and found the treatment safe as well as

effective for melancholia and (to a lesser extent) mania, but not for schizophrenia. In 1947, Bender (1947) reported that ECT improved the capacity of 96 of 98 children and adolescents with schizophrenia to deal with problems in living, and that treatment did not interfere with intellectual functioning or development, nor did it have any lasting effect on the electroencephalogram (EEG). In a follow-up of 32 of these patients, Clardy and Rumpf (1954) found that the effects of ECT were “temporary and resulted in no sustained improvement in the patterning of behavior” (p. 620).

These early reports were followed over the next several decades by additional case reports and small series involving scores of patients, which were reviewed by Bertagnoli and Borchardt (1990) and by Schneekloth et al. (1993). Despite numerous methodological limitations in these reports (Rey & Walter, 1997), ECT was found to be generally effective and free of serious side effects, including death. For patients with affective disorders or with catatonia, the results were described as “excellent” or it was stated that the subjects “recovered.” In adolescent patients with schizophrenia, ECT elicited transient reductions in symptoms; however, those with severe character pathology or substance abuse had poor outcomes. An exception to these generally positive findings was the survey by Guttmacher and Cretella (1988) of 10 years of ECT experience at Strong Memorial Hospital. Only one of their four patients improved, and “prolonged seizures” occurred in three of the patients. The marked limitations of this report have been discussed by Abrams (2002).

## CONTEMPORARY CLINICAL EXPERIENCE

The experience with ECT in adolescents and children has been limited by the philosophical view (now changing) that mental disorders in these age groups are largely caused by parenting and childhood psychosocial events, with biological contributions limited to a few conditions resulting from specific genetic defects or birth trauma. Perhaps because of this view, ECT has received scant consideration in textbooks of child and adolescent psychiatry. Consideration of ECT is also limited by concerns that seizures may damage the developing brain (Wasterlain, 1997; Camfield, 1997). An issue of *Lancet* carried a plea for a ban on the use of ECT in adolescents, arguing that adolescents cannot give informed consent for this treatment because they cannot competently assess the risks it poses to their learning and education (Baker, 1995). This negative public attitude toward the use of ECT in children and adolescents is also codified in legislation. In 1993, the Texas legislature banned the administration of ECT to persons younger than 16 years of age. Legislation in California (1974), Tennessee (1976), and Colorado (1977) prohibits the use of ECT in minors under 12, 14, and 16 years of age, respectively.

In a survey of the attitudes of child psychiatrists regarding the treatment of depression in young patients of various ages, 42% of the respondents opined that ECT was not useful in children, and 19% believed that ECT was not useful in adolescents for the treatment of psychotic depression, even when the condition was identical to that in adults (Parmar 1993). The respondents were unanimous, however, in their willingness to prescribe medications for these conditions.

In a 1978 survey of psychiatrists' attitudes toward ECT, only a small group felt that use of ECT in children and adolescents was acceptable, even in rare situations (American Psychiatric Association, 1978). A 1981 survey of child and adolescent psychiatrists in the United Kingdom revealed that less than 7% would consider using ECT in adolescents (Pipard and Ellam 1981). Ghaziuddin and colleagues (2001) surveyed a sample of members of the American Academy of Child and Adolescent Psychiatry (1998–1999) and found that the majority (70%) regarded ECT as a treatment of last resort. Yet, 54% indicated that they possessed minimal knowledge of ECT and 75% lacked confidence in providing a second opinion about ECT in children and adolescents. In a 2000 survey of the child psychiatrists in Australia and New Zealand, most (76%) approved of the use of ECT in adolescents (only 26% approved of its use in children), but only 41% felt confident about giving an opinion about its use if consulted (Walter & Rey, 2003b). The use of ECT in children and adolescents was not addressed in the 1985 National Institute of Mental Health (NIMH)-sponsored Consensus Development Conference on ECT (Consensus Conference, 1985). The American Psychiatric Association's Task Force on ECT did consider guidelines for the use of ECT in adolescents and children in both its 1990 (American Psychiatric Association,

1990) and 2001 (American Psychiatric Association, 2001) reports, as did the Royal College of Psychiatrists in its 1995 book, *The ECT Handbook* (Freeman, 1995). The American Academy of Child and Adolescent Psychiatry has recently issued guidelines on the use of ECT in adolescents (2004). These reports are discussed below.

### Electroconvulsive Therapy in Adolescents

Although there are no controlled data on the use of ECT in adolescents or children, since 1990 a growing clinical experience suggests that ECT may be very effective for adolescents with certain severe psychiatric illnesses (Table 28.1). Several of these reports represent methodological improvements over the earlier literature, with larger sample sizes, standardized diagnostic and outcome criteria, and more contemporary ECT technique. In general, the response rates (variously defined) to ECT ranged from approximately 50 to 90%, with higher rates for those patients with mood disorders or catatonia (Cohen et al., 1999; Ghaziuddin et al., 2002). These response rates are particularly noteworthy because almost all of the patients were severely ill (some had catatonia) and had failed to respond to multiple trials of medications and various psychotherapies. The number of treatments received was similar to that in adults.

Adverse effects from ECT were inconsistently sampled. In general, systemic side effects (headache, nausea, vomiting) were common, yet mild, transient, and responsive to symptomatic treatment. There were no fatalities. Prolonged or tardive seizures were described in some patients, but it remains unclear whether adolescents and children are at greater risk for such events than adults (Ghaziuddin et al., 2002; Walter and Rey, 1997).

Cognitive side effects (brief confusion, memory complaints) also appear to be common, mild, and temporary, but data are limited. Gurevitz and Helme (1954), examining cognitive and personality assessments in 16 children who had received bilateral sine-wave ECT, found no long-term impact on intellectual efficiency. Cognitive performance was reduced immediately after ECT but returned to baseline during the 5- to 27-month follow-up. Subjects' performance on simple cognitive and perceptual tests was unimpaired within 48 hours of the end of an ECT series. Two recent follow-up studies also provide encouraging findings. Cohen et al. (2000) assessed cognitive functioning in ten adolescents an average of 3.5 years after receiving successful bilateral ECT for severe mood disorders (nine were euthymic and one was mildly hypomanic), and compared the results to a group of psychiatric controls matched for age, gender, and diagnosis. There were no group differences on any of the measures, including the Mini-Mental State examination, the attention section of the Wechsler Memory Scale-Revised, and the California Verbal Learning Test. Although six of the ten patients treated with ECT complained of memory problems (Squire Subjective Memory Questionnaire) immediately after treatment, only one pa-

**SELECTED REPORTS OF ECT IN CHILDREN AND ADOLESCENTS SINCE 1990**

Study	Subjects	ECT Technique	Findings
Paillere-Martinot et al. 1990	<i>n</i> = 9, 15–19 years old; Dx: schizophrenia ( <i>n</i> = 2), delusional depression ( <i>n</i> = 4), delusional mania ( <i>n</i> = 3)	Sine waveform; Bitemporal X 9, 3X/week	Resolution of symptoms in 8 patients (89%); With continuation drug therapy (variable), 7 well at 3 months and 4 well at 6–12 months; Acute side effects: subjective memory disturbance (3), mania/hypomania (2), somnolence (2), headache (1)
Cook and Scott 1992	<i>n</i> = 5, all 17 years old, from Royal Edinburgh Hospital 1982–1992; Dx: schizophrenia ( <i>n</i> = 3), depression ( <i>n</i> = 1), bipolar depression ( <i>n</i> = 1)	Not described	Not described
Schneekloth et al. 1993	<i>n</i> = 20 (10B, 10G), 13–18 years old, from Mayo Clinic 1983–1991; DSM-III-R schizophrenia/schizophreniform/schizoaffective ( <i>n</i> = 10), depression ( <i>n</i> = 5), bipolar ( <i>n</i> = 4), “none” ( <i>n</i> = 1)	Pulse waveform; bitemporal ( <i>n</i> = 8), right unilateral ( <i>n</i> = 9), mixed ( <i>n</i> = 3); median 11.5 ECTs (range 8–21)	70% “improved”; “No residual adverse effects at discharge”
Kutcher and Robertson 1995	<i>n</i> = 16, 16–22 years old (mean = 19.6), over 8 years at Sunnybrook Health Science Center, Toronto; DSM-III-R bipolar mania ( <i>n</i> = 8) or bipolar depression with psychosis ( <i>n</i> = 8)	Pulse waveform; bitemporal (87% of treatments), right unilateral (13% of treatments) twice weekly for a mean = 10.4 ECTs (range 6–12)	Significant (70%) reduction in BPRS scores, and shorter length of stay than patients refusing ECT (74 vs. 176 days); 28% with “acute” side effects (headache, confusion, agitation, memory disturbance, vomiting)
Otegui et al. 1995	<i>n</i> = 29, 13–16 years old (median 15.1), Montevideo, Uruguay 1988–1995; DSM-III-R schizophrenia/schizophreniform/schizoaffective ( <i>n</i> = 18), impulsive-aggressive disorder ( <i>n</i> = 5), major depression with psychotic features ( <i>n</i> = 2), bipolar manic ( <i>n</i> = 1), obsessive compulsive disorder ( <i>n</i> = 1)	Pulse ( <i>n</i> = 13) or sine ( <i>n</i> = 16) waveform; bitemporal (100%); median 8.4 ECTs (range 3–13)	83% “improved”; No “complications were observed”
Ghaziuddin et al. 1996	<i>n</i> = 11, 13–18 years old (mean 16.3), over 3 years at University of Michigan; DSM-III-R major depression ( <i>n</i> = 9), bipolar depression ( <i>n</i> = 1), organic mood disorder ( <i>n</i> = 1)	Pulse waveform; right unilateral ( <i>n</i> = 3), bitemporal ( <i>n</i> = 2), mixed ( <i>n</i> = 6); thrice weekly for a mean 11 ECTs (range 7–15)	64% became euthymic (CDSR-R score ≤40); No change in MMSE; Acute side effects included headache (80%) and nausea/vomiting (64%)
Moise and Petrides 1996	<i>n</i> = 13 (11B, 2G), 16–18 years old (mean = 16.3), University Hospital Stony Brook, 1983–1993; DSM-III or III-R bipolar disorder ( <i>n</i> = 4), schizophreniform disorder ( <i>n</i> = 3), psychosis NOS ( <i>n</i> = 2), catatonia ( <i>n</i> = 2), schizophrenia ( <i>n</i> = 1), major depression with psychosis ( <i>n</i> = 1)	Pulse waveform; bitemporal ( <i>n</i> = 8), right unilateral ( <i>n</i> = 4), mixed ( <i>n</i> = 1); thrice weekly for a mean 10.9 ECTs (range 3–20)	10 (77%) responded (remission of presenting symptoms for at least 1 month post ECT); No “complications”
Cohen et al. 1997	<i>n</i> = 21 (12B, 9G), 14–19 years old (mean = 17), Pitie-Salpetriere, Paris, 1984–1995; DSM-III-R major depression with psychosis ( <i>n</i> = 10), schizophrenia/schizoaffective ( <i>n</i> = 7), mania with psychosis ( <i>n</i> = 4)	Sine waveform; bitemporal; thrice weekly for a mean 9.5 ECTs (range 3–15)	16 (76%) “improved”; 50% with mild side effects (headache, nausea, vomiting) or memory complaints
Hedge et al. 1997	<i>n</i> = 14, <16 years old (mean 12.4), NIMH Bangalore, India, 1990–1991; Dx: functional psychosis	Sine waveform; right unilateral; thrice weekly for 4–11 ECTs	13 (93%) “rated as markedly improved”

(continued)

**TABLE 28.1**  
(continued)

Study	Subjects	ECT Technique	Findings
Rey and Walter 1997	Review of 60 studies comprising 396 patients; 7–18 years old with various diagnoses (information was incomplete)	Information incomplete	Of 154 patients with adequate data, 81 (53%) showed “marked improvement or recovery” (63% with depression, 80% for mania or catatonia, and 42% for schizophrenia); “adverse effects appeared similar in type and frequency to those in adults”
Walter and Rey 1997	<i>n</i> = 42 (24 B, 18G) patients received 49 courses of ECT; 14–18 years old, state of New South Wales, Australia, 1990–1996; DSM-IV major depression ( <i>n</i> = 14 courses), major depression with psychosis ( <i>n</i> = 14 courses), schizophrenia ( <i>n</i> = 12 courses), schizoaffective disorder ( <i>n</i> = 4 courses), mania ( <i>n</i> = 3 courses), psychotic disorder NOS ( <i>n</i> = 2 courses)	Pulse waveform; right unilateral (90%), bitemporal (11%), mixed (26%); Thrice weekly for a mean = 9.5 ECTs (range 4–21)	51% with “marked improvement or resolution of symptoms”; “minor side effects” (e.g., headache, memory complaints, nausea and vomiting) occurred in 65% of courses and were transient
Duffett et al. 1999	<i>n</i> = 12 (8G, 4B), 12–17 years old, United Kingdom, 1996; Dx: depressive illness ( <i>n</i> = 8), manic illness ( <i>n</i> = 2), schizoaffective ( <i>n</i> = 1), and schizophrenia ( <i>n</i> = 1)	No information	Of 11 patients with data, 8 (73%) were rated as “improved or very much improved”; side effects not reported
Strober et al. 1998	<i>n</i> = 10 (7G, 3B); 13–17 years old, UCLA 1978–1996; RDC major depression ( <i>n</i> = 7) or bipolar depression ( <i>n</i> = 3)	Pulse waveform; right unilateral ( <i>n</i> = 2), bitemporal ( <i>n</i> = 1), mixed ( <i>n</i> = 7); Thrice weekly for a mean 12.1 ECTs (range 10–18)	60% “complete remission” and 40% “partial remission”; procedure was well tolerated, with headache in 50%
Bloch et al. 2001	<i>n</i> = 24 (15G, 9B); 13–19 years old, Shalvata Hospital, Israel, 1991–1995; DSM-III-R schizophrenia ( <i>n</i> = 15), schizo affective ( <i>n</i> = 4), major depression ( <i>n</i> = 4), bipolar depression ( <i>n</i> = 1)	Pulse waveform; bitemporal; 8–34 ECTs	58% “achieved remission”; “no serious adverse events”

All studies are retrospective.

BPRS = brief psychiatric rating scale; CDSR = children depression rating scale; RDC = research diagnostic criteria.

tient continued to complain of difficulty with memory at follow-up. Ghaziuddin et al. (2000) followed 16 adolescents for an average of 8.5 ( $\pm$  4.9) months after ECT. Although at 1 week after ECT the patients showed impairments in attention, concentration, verbal fluency, and verbal and visual delayed recall, their cognitive functioning had returned to pre ECT levels by the follow-up assessment (not every patient received every test).

Due to limitations in these reports, it is not possible to determine the relation of therapeutic response or cognitive side effects to technical parameters such as stimulus electrode placement and stimulus dosage.

### Electroconvulsive Therapy in Children

The experience with children has also been positive, if much more limited. Carr and colleagues (1983) described the successful use of seven right unilateral ECT treatments to

induce euthymia in a 12-year-old girl with medication-resistant mania and ventricular enlargement on brain computed tomography (CT) imaging. Black and colleagues (1985) described the successful treatment of a depressed 11-year-old boy with suicidal intent and severe head banging. The boy received 12 right unilateral ECT treatments, which resulted in remarkable improvement in his depressive symptoms. In the four cases reported by Guttmacher and Cretella (1988), the one patient who responded well was a 9-year-old boy. In another report, a 13-year-old prepubescent boy with depressive stupor was successfully treated with right unilateral ECT (Powell et al., 1988). This boy also exhibited dexamethasone suppression test changes that paralleled similar observations in depressed adults. More recently, Cizadlo and Wheaton (1995) described successful ECT (15 bilateral, then four right unilateral brief pulse treatments) in an 8-year-old girl in whom a severe catatonic stupor developed while she was taking antide-

pressant medication for DSM-III-R major depression; there were no observable deleterious side effects from the ECT. Hill and colleagues (1997) described two boys, 7 and 8 year olds, with DSM-IV mania, who responded well to brief pulse ECT (one received right unilateral electrode placement, the other both right unilateral and bilateral electrode placement). The treatments were associated with “minimal postictal confusion.”

### Electroconvulsive Therapy in Children and Adolescents With Associated Neurological Disease

In contrast to a growing literature on the use of ECT in adults with associated neurologic disease (Coffey & Kellner, 2000; Krystal & Coffey, 1997), there are only a small number of such reports in children or adolescents. An examination of the clinical descriptions of the “schizophrenic” children included in Bender’s (1947) study suggests that at least some of these patients may have had brain disease (e.g., “encephalopathy beginning by age 2 years”). Most of Bender’s patients were reported to have improved after sine-wave bilateral ECT. The successful use of ECT in three depressed patients with epilepsy has been reported, and in none was the experience described as adverse (Bender, 1947; Mansheim, 1983; Schneekloth et al., 1993). Indeed, the 17-year-old patient with epilepsy described by Mansheim (1983) also had meningomyelocele, hydrocephalus, and a functioning shunt, and responded to a course of seven right unilateral, brief pulse ECT treatments. Brief-pulse ECT was reported to be safe and effective in a male adolescent who had experienced a single spontaneous grand mal seizure immediately before the course of ECT (Schneekloth et al., 1993). As described previously, seven right unilateral brief-pulse ECT treatments produced euthymia in a 12-year-old girl with mania, a history of left posterior slowing on electroencephalogram (EEG), and enlarged lateral ventricles on brain CT scan (Carr et al., 1983). Depression was successfully treated with brief-pulse ECT in an adolescent with a septum pellucidum cyst (Schneekloth et al., 1993). Twelve ECT treatments lessened depressive symptoms in a 17-year-old girl with Kleine-Levin-Critchley syndrome (Jeffries & LeFebre, 1973). A 17-year-old girl with Down syndrome who had failed to respond to nortriptyline showed marked improvement in mood, behavior, and activities of daily living, and was actually able to return to school following 14 ECT treatments (Warren et al., 1989). Zaw and colleagues (1999) reported that brief pulse bifrontal ECT (13 treatments) was dramatically effective in treating severe catatonia in a 14-year-old boy with autism and depressive symptoms. Ghaziuddin and colleagues (2002) reviewed the effectiveness of ECT in adolescents and children with catatonia, and described the successful use of ECT for malignant catatonia in a 17-year-old girl with malignant neuroleptic syndrome (MNS). ECT was not effective in another adolescent with depression following traumatic head injury (Paillere-Martinot et al., 1990).

### Electroconvulsive Therapy Utilization in Adolescents and Children

In adults the use of ECT appears to be increasing, although there is dramatic variation in such usage (from 0.4 to 81.2 patients per 10,000 population) across regions of the United States (Hermann et al., 1995; Rosenbach et al., 1997). The limited data that exist for adolescents and children suggest that the rate of ECT use is low. According to data from the National Institute of Mental Health, of 33,384 patients receiving ECT in the United States in 1980, only 500 (1.5%) were between the ages of 11 and 20 (Thompson & Blaine, 1987). Approximately 0.3% of all patients receiving ECT in California between 1977 and 1983 were younger than the age of 18 (Kramer, 1985). Rey and Walter (1997) reviewed the use of ECT in the state of New South Wales, Australia (population approximately six million) between 1990 and 1995 and found that only 42 (0.93%) patients were younger than 18 years old. These authors found similar rates (1.53/100,000 adolescents) in a follow-up study of ECT use in New South Wales between 1996 and 1999 (Walter & Rey, 2003a). Among those patients who received ECT, there was an increase in the proportion of girls hospitalized involuntarily from 1990 to 1995 and from 1996 to 1999. Chung (2003) reviewed a central database of ECT use in all public hospitals in Hong Kong from 2001 to 2002, and identified 14 patients (9% of the total sample) between the ages of 15 and 19. Scott and colleagues (2005) reported that while 2.5 patients per 100,000 people younger than 18 years had received ECT in Edinburgh from 1993 to 1998, no patient younger than 18 had received ECT in the ensuing 5 years (1999 to 2004).

## THE PHYSIOLOGY OF ELECTROCONVULSIVE THERAPY

The physiology of ECT is well defined in adults. Because we have little information about any differences in physiological effect of ECT in children and adolescents, we infer the physiological effects from the available experience.

### Cerebral Physiology

In convulsive therapy, a chemical (flurothyl or pentylenetetrazol) or an electrical stimulus elicits a generalized cerebral seizure. There appears to be no difference in the efficacy of treatments using electrical or chemical induction, and no theory of the mode of action assigns specificity to the electrical stimulus. How ECT seizures are propagated is not well understood. Bilateral ECT appears to lead to seizure generalization via direct stimulation of the diencephalon, whereas seizures induced with unilateral stimulation may begin focally in the stimulated cortex and then generalize via corticothalamic pathways (Brumback & Staton, 1982; Staton et al., 1981).

During the initial tonic motor phase of the convulsion, EEG activity is variable, consisting of low-voltage fast activity with polyspike rhythms. EEG activity rapidly evolves into the hypersynchronous polyspikes and waves that characterize the clonic motor phase. These regular patterns begin to slow and eventually disintegrate as the seizure ends, usually terminating abruptly in a “flat” EEG (Weiner & Krystal, 1993).

During the ECT course, cumulative changes are observed in the interictal EEG. Increasing predominance of theta and then delta activity varies with the number and frequency of ECT treatments given in the course (Weiner & Krystal, 1993). The interictal EEG typically returns to baseline within 30 days of completion of the ECT course.

An ECT-induced seizure is associated with increases in cerebral blood flow, cerebral blood volume (resulting in a transient rise in intracranial pressure), and cerebral metabolism of oxygen and glucose (Bolwig et al., 1977; Broderson et al., 1973; Prohovnik et al., 1986). The transient increase in intracranial pressure is rarely of clinical consequence, but anticipation of this increase is the reason that ECT is proscribed in patients with intracranial space-occupying lesions. Postictally, cerebral blood flow and metabolism decrease and remain low for at least several days after the seizure, but then return to normal values. ECT induces a temporary functional increase in cerebrovascular permeability. Disruption in blood-brain barrier permeability also occurs (Bolwig et al., 1977). Such changes may account for the short-lived increase in T1 relaxation times observed on brain magnetic resonance (MR) imaging after ECT (Mander et al., 1987; Scott et al., 1990).

### Cardiovascular Physiology

ECT results in a marked activation of the autonomic nervous system, and the relative balance of parasympathetic and sympathetic nervous system activity determines the cardiovascular effects. Vagal (parasympathetic) tone, reflected in bradycardia or asystole, is sharply increased with the administration of the electrical stimulus. The cerebral seizure also activates the sympathetic nervous system, and this activation is expressed in increases in heart rate, blood pressure, and cardiac output (Webb et al., 1990). Peripheral sympathetic activation is manifested in piloerection and gooseflesh. Tachycardia and hypertension continue throughout the ictus but generally end with the seizure; these actions oppose the tendency to bradycardia and asystole. Shortly after the seizure terminates, there may be another period of increased vagal tone, possibly expressed as bradycardia and dysrhythmias, including the appearance of ectopic beats. As the patient awakens from anesthesia, increased heart rate and blood pressure may result from arousal (Welch & Drop, 1989).

The cardiovascular responses occurring during ECT combine to produce an increase in myocardial oxygen demand and a decrease in coronary artery diastolic filling time. Transient electrocardiogram (ECG) changes in the ST

segment and the T waves may develop in some patients, although the relationship of these changes to myocardial ischemia is unclear. No corresponding increase in cardiac enzyme levels accompanies the ECG changes (Braasch & Demaso, 1980). A study that used echocardiographic monitoring during and after ECT reported transient regional heart-wall motion abnormalities more often in older adult patients with ST-T changes on ECG, suggesting the occurrence of a period of myocardial-demand ischemia in these patients (Messina et al., 1992).

## THE PRACTICE OF ELECTROCONVULSIVE THERAPY IN ADOLESCENTS AND CHILDREN

---

ECT is a complex medical intervention in which generalized seizures are repeatedly elicited under anesthesia. It requires the coordinated skills of a psychiatrist, an anesthesiologist, and trained nursing and support personnel in a facility equipped to ensure patient safety and optimal ECT technique. The standards of ECT practice in Western countries are well documented (Abrams, 1997; American Psychiatric Association, 2001; Fink, 1988; Freeman, 1995).

### Indications for Electroconvulsive Therapy

ECT has been developed and tested in the treatment of adults, and an extensive literature supports its use in adults of all ages, including the elderly (Abrams, 1997; American Psychiatric Association, 2001). ECT is an important treatment option, and may indeed be lifesaving, in patients with severely disturbed mood, suicidal ideation, agitation, restlessness, excitement, delirium, stupor, or catatonia. Not only do the mood aspects of these disorders respond, but psychosis, delirium, and abnormal motor activity (catatonia, parkinsonism, stupor), common accompaniments of the major mood disorders, also improve (Fink, 1993a).

Perhaps surprisingly, ECT is also a viable choice in patients whose thoughts have become so delusional as to interfere with normal living or whose despondency is accompanied by the vegetative turmoil of severe insomnia, anorexia, weight loss, inanition, perplexity, confusion, inability to concentrate, or “dementia.” Such behaviors may arise without a defined biological cause, as occurs in the major mood or bipolar disorders, or may be a feature of a systemic disorder such as Parkinson’s disease; they may also occur consequent to a cerebral stroke or result from metabolic or toxic derangement of brain functions. It is these abnormal behaviors, not the underlying pathology, that are the focus of treatment. For this reason, the decision to undertake ECT is defined not solely by the clinical diagnosis, the longitudinal history of malfunction, or the patient’s age, but rather by the dominant cross-sectional clinical features, their duration, and their severity. ECT has the broadest spectrum of therapeutic activity of any modern biological treatment in neuropsychiatry.

Illnesses characterized by a lifelong history without specific acute onset of a defined psychopathology are not indications for ECT. Patients with only “psychoneuroses,” situational maladjustments, character pathology, substance abuse, social pathology, or sexual identification syndromes are poor candidates for ECT. Although these caveats have been developed in the treatment of adults, it is likely that they are equally applicable to adolescents. None of the adolescents with only personality disorders in the Mayo Clinic sample responded to ECT (Schneekloth et al., 1993). The two nonresponders in the Stony Brook sample also had severe character pathology (Moise & Petrides, 1996).

There is also little merit in considering ECT unless the technical requirements for safe administration are available at the institution in which the patient is being treated, that is, trained and competent therapists and nursing personnel, knowledgeable collaborating anesthesiologists, modern technical equipment to induce and monitor seizures, established practice guidelines and privileging standards, and financial support to allow its use. The absence of such facilities in many state, municipal, and federal hospitals, as well as in many private and academic hospitals, is a principal impediment to the consideration of ECT (Hermann et al., 1995).

Given these considerations, both the American Psychiatric Association (2001) and the American Academy of Child and Adolescent Psychiatry (2004) have issued guidelines that specify indications for ECT in adolescents and children. Both organizations agree that adolescents and children must meet specific criteria regarding (1) diagnosis (specifically major depression, mania, schizoaffective disorder, schizophrenia, and neuroleptic malignant syndrome); (2) severity of illness (the patient’s symptoms must be severe, persistent, and disabling); and (3) failure to respond to an adequate trial of drug therapy (the American Academy of Child and Adolescent Psychiatry specifies that the patient must have failed two adequate drug trials). Both organizations allow for ECT earlier in the patient’s illness if the patient cannot safely take the medication, or if waiting for a response to the medication would endanger the youth.

### Pretreatment Evaluation

Once the patient’s treatment team has made the decision to treat with ECT, a consultation is required from at least one other psychiatrist (The American Psychiatric Association [2001] recommends the use of two additional consultants for children younger than the age of 13). This preECT evaluation should be performed by an individual privileged to administer ECT and experienced in the treatment of adolescents and children. The goals of the preECT evaluation are to (1) determine if ECT is indicated, (2) establish baseline measures of efficacy and cognitive side effects, (3) optimize the treatment of any active medical problems, (4) initiate the process of informed consent, and (5) begin preparation of the patient and family for the procedure

(Coffey, 1998). Of course, findings from the preECT evaluation should be documented in the clinical record.

The indications for ECT in adolescents and children were discussed previously. These indications are identified through a thorough and detailed neuropsychiatric history, interview, and examination. The historical review should include a review of the adequacy of previous pharmacologic and psychosocial treatments, as well as response to prior courses of ECT. A thorough mental status examination establishes the presence of signs of the mental disorder. Handedness is assessed for its relevance to the decision to use unilateral ECT with nondominant placement. A minority of left-handed patients and patients with mixed dominance may have language localized to the right hemisphere, an issue of importance when one is determining the nondominant hemisphere for unilateral treatment.

Most patients are referred for ECT after failing to respond to psychotropic medications, and the decision to try ECT is made while these medications are still being actively prescribed. An evaluation of such medications is required for optimal ECT (Fink, 1994; Kellner, 1993). Generally, all psychotropic medications are discontinued prior to ECT. Lithium taken in proximity to ECT has been linked to an increased incidence of delirium and seizures, and the customary practice is to discontinue lithium therapy. If the practitioner considers concurrent lithium to be beneficial, dosages are usually not given in the 24 hours before each ECT treatment so that lower serum lithium levels can be sustained during the seizure. Because some authors (e.g., Kellner, 1993) have described an impairment of seizure efficacy when benzodiazepines are administered, these drugs are usually discontinued before a course of ECT. An exception to this rule has recently been described in the management of patients with persistent or recurrent catatonia (Petrides et al., 1995). When benzodiazepine use is continued during ECT, adjustments are made in energy dosing and electrode placement to ensure adequate treatments.

Antidepressant medications are frequently discontinued prior to ECT, mainly because there is little evidence of synergism. Some practitioners are concerned that tricyclic antidepressant drugs may alter cardiac functions, especially in the elderly, and therefore discontinue antidepressant drugs in ECT patients with a history or evidence of cardiovascular disease. Anesthesiologists may be concerned that recent exposure to monoamine oxidase inhibitors (MAOIs) will interfere with the action of succinylcholine. Studies by El-Ganzouri and colleagues (1985), among others, find no basis for such concern, and ECT may be administered safely in the presence of MAOIs or even when their use has only recently been discontinued.

Antipsychotic medications may be continued, as there is evidence suggesting synergism of ECT with these drugs (Klapheke, 1993).

Objective data are essential for determining the outcome of the course of ECT. Baseline affective and cognitive status should be documented. The HAM-D or the Montgomery-

Asberg Depression Rating are standardized assessment instruments that are often used at intervals throughout the ECT course. Cognitive testing should focus upon memory and new learning ability. More extensive neuropsychological testing may be indicated in patients with certain neurologic illnesses. The American Academy of Child and Adolescent Psychiatry (2004) specifies that memory function should also be assessed “at an appropriate time after ECT treatment (usually between 3 to 6 months).”

Although ECT is among the safest medical treatments that require general anesthesia, the procedure does produce temporary, robust changes in cerebral and cardiac physiology, as described previously. As such, a thorough medical history and physical examination should be performed that focuses upon these two organ systems, as well as upon the pulmonary, dental, and musculoskeletal systems. A personal or family history of complications from previous anesthesia should be noted. Although there are no absolute contraindications to ECT, serious disease of the cardiovascular, central nervous, pulmonary, or musculoskeletal systems will require optimal treatment prior to ECT, and the ECT technique may need to be modified. Adjustments may be required in some medications (e.g., insulin, anticonvulsant medications). Consultation with anesthesia personnel is important because the provision of general anesthesia is associated with some (albeit small) medical risk. Indeed, an anesthesiologist experienced in ECT may also serve as the “medical” consultant and can greatly facilitate the medical evaluation of patients with systemic illness. Additional consultation from other specialists may occasionally be required. A limited laboratory evaluation is sufficient for most patients (ECG, serum potassium). All girls should have a pregnancy test unless pregnancy is not possible.

Initiating the process of informed consent is an essential element of the preECT workup. The consent process should include the patient and the family, and should provide information about the indication for ECT, the efficacy of ECT for that indication, alternative treatments to ECT, a description of the ECT procedure, expected routine side effects, less common side effects, and any condition that raises the risk of the procedure. Various written and video materials can facilitate the educational process. Written informed consent must be obtained, and The American Psychiatric Association’s Task Force on ECT (2001) provides a model consent form which is an excellent template. The requirement that minors provide consent before receiving ECT varies by state, and practitioners must consider individual state laws governing the age at which a person can consent to psychiatric treatment and to ECT or surgical (i.e., anesthesia) procedures. In some states, the ages of consent may differ for the two procedures. If the patient is too young to give consent or is incompetent, a guardian provides consent. Surrogate (parental or guardian) consent is acceptable for non-competent patients in some states; in others, however, a court proceeding is mandated.

Finally, the preECT evaluation affords the clinician an opportunity to establish important interpersonal relationships with the patient and family which are additionally therapeutic as well as personally rewarding to the clinician.

### Electroconvulsive Therapy Procedure

In the United States, ECT is commonly administered as a series of single treatments on alternate mornings. Many adults now receive ECT on an outpatient basis, and this setting may be appropriate for many adolescents and children who meet appropriate criteria. The American Academy of Child and Adolescent Psychiatry (2004) recommends however, that ECT be administered to adolescents (and presumably children) on an inpatient basis. ECT is typically administered in either a special treatment suite or the recovery area of an operating room suite. Patients should have nothing to eat or drink for at least 8 hours prior to treatment.

In our experience with adolescents, we have found a remarkable equanimity and acceptance of ECT procedures by our patients once the need for the treatment is established and the procedures explained. Their physical tolerance of the procedures and rapid recovery from anesthesia allows them to participate in daily activities, including school classes, shortly after each treatment session.

The standard technique requires the establishment of a patent intravenous line. Electrodes for stimulation and for monitoring of the seizure are applied according to the appropriate technique. The medication sequence includes anticholinergic premedication (glycopyrrolate or atropine) to prevent vagal-mediated cardiac slowing (if indicated), followed by an anesthetic to induce amnesia (usually methohexital) and succinylcholine for muscle relaxation. Throughout the procedure, the patient is ventilated with 100% oxygen. Heart rate, blood pressure, and blood oxygen saturation are also monitored.

Once the patient is asleep and relaxed, a specially designed bite block is inserted into the mouth to protect the teeth from injury during jaw clenching as the electrical stimulus is applied. A predetermined electrical stimulus (see subsequent discussion on electrical stimulus dosing) is delivered, and, typically, a generalized seizure lasting from 30 to 90 seconds ensues. The seizure is monitored by observing brain electrical activity via EEG, and motor manifestations of the seizure via a blood-pressure cuff at the ankle (typically the right) inflated above systolic pressure to prevent access of succinylcholine to that extremity. Ventilatory support is continued until the patient breathes spontaneously, and further recovery is provided in a supportive environment. In addition, because the use of succinylcholine may be associated with an increased risk of malignant hyperthermia in children, patients should be monitored closely after each treatment for fever, muscular rigidity, and delirium (Welborn, 1996). The entire procedure takes approximately 20 minutes, and patients are often able to shower, dress, and have breakfast within an

hour of the time of treatment. The American Academy of Child and Adolescent Psychiatry (2002) recommends that patients be monitored for 24 hours after an ECT treatment for the occurrence of tardive seizures.

A typical ECT course consists of six to 12 treatments, although occasional patients may require fewer or more treatments to achieve a full response. ECT is discontinued when the patient has achieved maximal clinical improvement or when side effects outweigh any further beneficial effects of the treatment. Special attention is given to continuation/maintenance treatment with either medication or ECT (see subsequent discussion on this topic).

### Electrical Stimulus Dosing

The ECT stimulus should be delivered with a contemporary brief pulse, constant current device. Seizure threshold (the minimum amount of energy required to elicit an ECT seizure) increases with age (Coffey et al., 1995a; Sackeim et al., 1987); it is lowest in adolescents and children. Recent data in adult samples suggest an interaction of electrode placement, stimulus dosage, stimulus parameters and clinical efficacy so that threshold and barely suprathreshold stimulus intensities are clinically ineffective with unilateral nondominant electrode placements (Sackeim et al., 1993). Although ongoing studies are seeking to assess the parameters of this interdependence, data in adult samples suggest that stimulus dosages at multiples of four times or more of seizure threshold may be required to maximize the efficacy of unilateral ECT (McCall et al., 2000; Sackeim et al., 2000). Treatments with bilateral electrode placement, on the other hand, demonstrate less dependence on the strength of the electrical stimulus, so that stimulus dosing just above seizure threshold appears adequate for treatment efficacy.

Stimulus dosing is particularly important when unilateral nondominant electrode placement is selected. Some practitioners assess the seizure threshold by administering initial stimulations at a very low dosage and then increasing the dosage in a stepwise manner until a satisfactory seizure is elicited (Coffey et al., 1995a). This procedure is encouraged by the American Psychiatric Association Task Force on ECT (2001) and by the American Academy of Child and Adolescent Psychiatry (2004). However, such a procedure may be of limited usefulness in children and adolescents if the minimum stimulus dosage on the ECT device is at or above the seizure threshold in these age groups. My practice with adolescents is to estimate seizure threshold using a dosing titration protocol, then set the stimulus dosage for subsequent treatments at 1.5 times threshold for bilateral electrode placement and at 4 times initial seizure threshold for unilateral nondominant electrode placement.

As noted previously, the ECT seizure is monitored to ensure that it has ended and to estimate its therapeutic "adequacy." An adequate seizure may be defined as one that has a motor duration of at least 25 seconds and an EEG duration of more than 30 seconds, with well-defined periods of spike

and spike-and-wave ictal activity, and that terminates in a precise end point. If motor convulsion durations are less than 25 seconds, the EEG fails to show periods of defined spike and spike-and-wave activity, or the termination is imprecise, ECT is immediately repeated with higher stimulus dosage. Newer ECT devices provide quantitative estimates of these (and other) ictal EEG indices, but their routine clinical utility is limited at present by their sensitivity to EEG artifacts, variation in EEG lead placement, and inter- and intra-individual variation in the ictal EEG (Krystal, 1998).

Seizure threshold may rise during the course of treatment (Coffey et al., 1995b; Sackeim et al., 1987). As such, upward adjustments in stimulus dosage may be required to maintain efficacy. If an inadequate seizure is elicited, inductions are immediately repeated at a higher electrical dosage until an adequate seizure is obtained.

Occasionally, seizures persist beyond 180 seconds; such seizures are defined as "prolonged." They can be terminated by an intravenous bolus of methohexital or diazepam that is readministered if termination does not occur within 30 seconds and repeated at 30-second intervals until the seizure is clearly terminated.

### Electrode Placement

The choice of stimulus electrode placement is complex. Unilateral nondominant ECT is associated with fewer cognitive side effects in adults, but unless stimulus dosing and electrode application are carefully prescribed and other medications restricted, treatment efficacy may be impaired with this placement. Bilateral (bitemporal) ECT may be more reliably effective in adults, but may be associated with greater cognitive side effects. The American Academy of Child and Adolescent Psychiatry (2004) recommends commencing with unilateral nondominant electrode placement given its favorable side effect profile, and switching to bitemporal placement if the response is not satisfactory. Treatment may begin with bitemporal electrode placement if the patient is critically ill and requires an urgent response. Potentially promising alternative electrode placements such as bifrontal (Baline et al., 2000), have not been studied in adolescents and children.

### Continuation/Maintenance Treatment

Major depressive disorders are increasingly recognized as chronic, relapsing conditions (see Chapter 13). Some studies in adults with major depressive disorder have found 6-month relapse rates as high as 50% for patients initially responsive to antidepressants who are subsequently withdrawn from the medications (Prien & Kupfer, 1986). Relapse rates following successful pharmacotherapy are substantially reduced by continuation of antidepressant medication at full dosage (Frank et al., 1990). Similarly high rates of relapse have been noted in adults following ECT response when no form of follow-up therapy was given

(Jarvie, 1954). The risk of relapse after successful ECT is particularly high (especially in the first 4 months following ECT) in patients who were resistant to medication or who displayed psychotic symptoms during their index episode of illness (Grunhaus et al., 1995; Sackeim et al., 1993).

The American Psychiatric Association Task Force on ECT (2001) has defined *continuation therapy* as the “. . . provision of somatic treatment over the 6-month period after the onset of remission.” Somatic treatment beyond 6 months that seeks to maintain euthymia is by convention defined as *maintenance treatment*. The usual clinical practice is to place patients with mood disorders on continuation therapy after a successful course of ECT, either with pharmacotherapy or with ECT. Recent controlled data suggest that continuation pharmacotherapy with nortriptyline and lithium is superior to nortriptyline alone, which is in turn superior to placebo in preventing relapse of major depression in adults who have responded to a course of ECT (Sackeim et al., 2001). We have less data to guide the choice of continuation pharmacotherapy after successful ECT for bipolar depression (a mood stabilizer plus an antidepressant are typically used), mania (a mood stabilizer plus possibly an antipsychotic are typically used), or schizophrenia (an antipsychotic is typically used).

Relapse rates remain high after successful index ECT, even in patients on continuation pharmacotherapy. As such, some practitioners recommend continuation therapy with ECT, particularly in patients with psychotic depression or those who were resistant to medication during the index episode. An evolving literature in adult samples indicates that continuation ECT (typically administered on an outpatient basis) is safe and effective in the prevention of depressive relapse following successful “index” ECT (American Psychiatric Association, 2001). Continuation/maintenance ECT typically involves single treatments administered on an ambulatory basis, initially at weekly intervals and then gradually reduced in frequency to every 4 to 8 weeks, as the patient’s symptoms allow. The increased interval between treatments results in fewer cognitive side effects than during an “index” course of ECT; and this has led to the suggestion that bilateral electrode placement may be more acceptable for continuation/maintenance ECT. The logistical factors in ambulatory ECT are defined in the report by the Task Force on Ambulatory ECT of the Association for Convulsive Therapy (Fink et al., 1996).

There are no controlled data that assess the relative merits of continuation pharmacotherapy and continuation ECT. As of this writing, a four-site study is underway comparing the efficacy of continuation therapy with ECT versus lithium plus nortriptyline, after successful index ECT in depressed adults.

Based on the experience in adults, the American Academy of Child and Adolescent Psychiatry (2004) recommends continuation pharmacotherapy after successful ECT, although it acknowledges there may be a role for ECT in some cases. Although there are no controlled data in

adolescents to inform these decisions, I recommend considering continuation ECT in those patients who were resistant to medications during the index episode.

## ADVERSE EFFECTS AND THEIR MANAGEMENT

---

### General Issues

The safety of ECT compares favorably with that of treatments requiring brief general anesthesia. ECT mortality in adults is reported as approximately 0.2 to 1.0 deaths per 10,000 patients (or approximately one per 80,000 treatments), about the same as mortality from general anesthesia for minor surgery (American Psychiatric Association, 2001; Kramer, 1985). Although there are no mortality data specifically for children and adolescents, the mortality risk from brief general anesthesia in this age group appears similar to (if not even lower than) that in healthy adults (Motoyama, 1996).

As noted previously, systemic side effects such as headache, nausea, and vomiting, are common during and shortly after the postECT recovery period. Headache may occur in as many as half of all patients, and although its etiology is not known, its throbbing character suggests a vascular mechanism. Nausea may affect up to 20% of patients, and may be secondary to headache or its treatment with narcotics, or as a side effect of the anesthesia. Generally, these symptoms are mild, transient, and quite responsive to symptomatic treatments. If these problems recur, prophylactic therapy may lessen their recurrence or severity. Some patients complain of muscle soreness after ECT, which is likely secondary to fasciculations induced by the depolarizing muscle relaxant. Symptoms tend to diminish after the first treatment (assuming muscle relaxation is adequate), but persistent soreness can be treated successfully with simple analgesics such as aspirin or acetaminophen.

Some patients experience an agitated emergent delirium immediately after a seizure on awakening from anesthesia. Such experiences are more often seen in the first or second treatment of a series and are readily treated with intravenous benzodiazepines (Fink, 1993b).

### Cardiovascular Effects

As described previously, ECT results in a brief period of increased cardiac workload. This hemodynamic response should be well tolerated by the healthy older child or adolescent. If the presence of a preexisting heart condition raises a concern about such tolerance however, pharmacological blunting of the hemodynamic response may be indicated. The primary issues of concern are bradycardia, tachycardia, hypertension, and ventricular arrhythmia. Anticholinergic premedications (atropine, glycopyrrolate) are used to prevent vagally-induced bradycardia. Stimulus

dosage titration to determine a patient's seizure threshold requires the administration of subconvulsive stimuli, which produces a vagal surge unaccompanied by the sympathetic outflow associated with a seizure. Such titrations require the routine use of anticholinergic premedication, especially in children, in whom resting vagal tone may be higher than that in adults (Welborn, 1996).

Clinically significant hypertension and tachycardia during ECT may be attenuated by short-acting intravenous adrenergic blockers such as labetalol or esmolol (Howie et al., 1990; Stoudemire et al., 1990). Beta-adrenergic blockers have anticonvulsant effects; their use during ECT may theoretically limit the intensity of the ECT seizure and, in turn, its therapeutic potency. Alternative treatments include sublingual nifedipine, hydralazine (an  $\beta$ -adrenergic antagonist), nitroglycerin (sublingual, transdermal, or intravenous), or the ganglionic blocking agent trimethaphan camsylate (Arfonad) (Maneksha, 1991; Petrides et al., 1996). Indiscriminate use of antihypertensive medication may lead to severe hypotension, and we do not routinely attempt to blunt cardiovascular responses to ECT in physically healthy patients unless such responses are extreme or are clearly associated with signs of cardiovascular compromise.

### Cerebral Effects

There is no evidence that ECT causes structural brain damage (Devanand et al., 1994; Weiner, 1984). Carefully controlled, prospective brain-imaging studies in adults with follow-up durations up to 6 months have revealed no changes in brain structure after a course of ECT (Coffey, 1987; Coffey et al., 1991). Neuropathological studies in animals, including cell counts in regions thought to be at highest risk, have failed to find evidence of brain damage when seizures are induced under conditions approximating those used in standard clinical practice (i.e., when seizures are spaced, relatively brief, and modified by oxygenation and muscle relaxation). Furthermore, studies of the pathophysiology of seizure-induced structural brain damage in animals indicate that the conditions necessary for injury are not met in the modern practice of ECT.

Although it has been suggested that the developing brain may be more prone to the harmful effects of seizures, there are no data to support this contention as it applies to ECT. Indeed, an extensive clinical literature indicates that children and adolescents may sustain even multiple symptomatic seizures (e.g., secondary to toxic metabolic etiologies) without showing residual brain effects. Children with some types of epilepsy (e.g., Rolandic, absence) may eventually "outgrow" their epilepsy without demonstrating residual adverse cerebral effects. Finally, among the case descriptions of children and adolescents who have received ECT, there are no reports of brain injury from the treatment.

There are no reported cases of intracerebral hemorrhage with ECT or of ischemic stroke during ECT treatment.

Nonetheless, many clinicians fear the consequences of ECT in patients with cerebral disease and have described various intracranial processes as risk factors. Intracranial mass lesions and increased intracranial pressure are the most prominent of these purported risk factors. However, several cases of safe and effective ECT in adult patients with brain tumors have been described in which ECT was necessitated by the patients' mental state, and these case experiences provide guidelines for such treatment (Fried & Mann, 1988; Greenberg et al., 1988; Malek-Ahmadi & Sedler, 1989; Zwil et al., 1990). Patients with functioning intracranial shunts may also be treated safely, provided that normal intracranial pressure is maintained (Coffey et al., 1987; Mansheim, 1983). Subdural hematomas require evacuation prior to ECT (Abrams, 1997).

### Cognitive Effects

The cognitive side effects of ECT include acute postictal confusion/delirium, and interictal impairments in attention, concentration, and memory (American Psychiatric Association, 2001). Other neuropsychological functions are generally unaffected by ECT. These ECT side effects have not been systematically studied in adolescents and children. In adults, the severity of these effects varies with age, electrical stimulus waveform, electrode placement, stimulus dosing, and frequency of treatments (Abrams, 1997; American Psychiatric Association, 2001; Fink, 1979). The cognitive side effects of the procedure in adults, and likely in adolescents and children as well, may be minimized by modern use of brief-pulse currents, selective electrode placement and stimulus dosing, and varied frequency of treatments.

Most patients experience disorientation immediately upon awakening during the postECT recovery process (Calev et al., 1993; Summers et al., 1979). The duration and severity of this disorientation is particularly sensitive to age, being extended in the elderly but remarkably short (e.g., 1 hour or less), in our experience, in adolescents. Impairments in attention and concentration are also common after a course of ECT, but are typically mild and resolve shortly after completion of the treatment.

ECT selectively results in anterograde and retrograde amnesia, particularly for episodic memory. Such effects are generally mild. The former typically resolves within weeks of completing the treatments, while the time course for resolution of the latter is often more gradual. Any residual memory gaps are usually mild and limited to the period of illness and treatment. Although it has been feared that children and adolescents may be at greater risk for these cognitive side effects as a result of the relative immaturity of their brains, no studies or case reports exist that support such a concern. Indeed, in my experience, the remarkably rapid recovery of adolescents after each treatment and their resistance to the development of measurable cognitive side effects make it unlikely that such concerns have merit. As discussed above, the studies by Ghaziuddin and colleagues

(2000) and Cohen and colleagues (2000) of follow ups ranging from 8 months to 3.5 years, provide additional reassurance that the cognitive effects of ECT in adolescents are similar to (and no worse than) those in adults.

With additional ECT treatments, the EEG shows progressive slowing of frequencies, increased amplitudes, and well-defined burst formations during interictal recording (Fink, 1979; Fink & Kahn, 1957). These manifestations are sensitive to age, being more common in the elderly. Such EEG slowing may be associated with confusion, disorientation, and impairment of immediate recall. Generally with adolescents, such interictal confusion is rare, despite marked slowing of EEG frequencies.

## PSYCHOSOCIAL ISSUES

In addition to its biological effects, ECT elicits strong intrapsychic and interpersonal responses. It should not be surprising that a treatment involving passage of an electrical current through a patient's head while asleep is perceived as powerful and mysterious. ECT arouses fears and fantasies in patients, parents, family members, and peers alike. Patients may feel quite vulnerable as they lie partially disrobed on a stretcher, waiting for treatment to commence, and this experience can raise issues of trust and personal bodily autonomy, especially in patients with a history of trauma. These fears can be minimized by providing ongoing education, ensuring that the treatment team members are well known to the patient and are experienced in ECT, and by paying careful attention to the anxieties and concerns of the patient and family.

Patient attitude surveys in adults have found that although ECT is typically poorly understood, the experience is not considered frightening (Benbow, 1988; Cowley, 1985; Fox, 1993; Hughes et al., 1981; Pettinati et al., 1994; Pettit, 1971). In fact, in the experience of some patients, it has been regarded as no more upsetting than a trip to the dentist (Malcolm, 1989). Similar studies are badly needed in the young.

## MECHANISM OF ACTION OF ECT

Despite considerable research, the mechanism of action of ECT remains a mystery. ECT produces a number of changes in brain chemistry, endocrinology, and electrophysiology. Current hypotheses of the mechanism of action of ECT focus on changes in hypothalamic neuroendocrine status (Fink, 1990), changes in brain neurotransmitters (these are similar but not identical to those seen with antidepressant drug therapy) (Nutt et al., 1993), or increases in seizure threshold (Sackeim, 1999) over the course of the treatment. It remains unclear however, whether any of these neurobiological changes accounts for the clinical effects of ECT, or whether they represent merely epiphenomena.

## OTHER BRAIN STIMULATION THERAPIES

A number of other brain stimulation therapies are currently under investigation for treatment of mood disorders in adults, including rapid transcranial magnetic stimulation, deep brain stimulation, and magnetic seizure therapy (Lisanby, 2002). Vagus nerve stimulation has recently been approved by the FDA for treatment-refractory depression in adults; there are no data on this procedure in children and adolescents with mood disorders.

## CONCLUSION

A growing clinical experience suggests that ECT may be an effective treatment for severe mood disorders and other selected psychiatric disorders in adolescents and possibly children. These response rates are particularly noteworthy because almost all of the patients were severely ill (some had catatonia) and had failed to respond to multiple trials of medications and various psychotherapies. Recent guidelines from the American Psychiatric Association (2001) and the American Academy of Child and Adolescent Psychiatry (2004) now endorse the use of ECT, although there remains an emphasis (unnecessarily restrictive?) on its role as a treatment of "last resort." The improved safety of contemporary ECT constitutes a compelling argument for its increased consideration in the treatment of adolescents with acute mental illness, especially when the illness is severe enough to require hospital care and is complicated by psychosis, inanition, suicidality, catatonia, delirium, or stupor.

An urgent need exists for more research on the efficacy, side effects, treatment technique, and mechanism of action of ECT in children and adolescents. We also need studies that clarify the attitudes and experiences of patients and their parents to the experience of ECT. Equally compelling is the need for education to promote a heightened understanding of ECT by child and adolescent psychiatrists.

# Genetic Evaluation,

# Counseling, and

# Treatment

29

**Carol E. Anderson, MD**

Information from the Human Genome Project (Venter et al., 2001; Sachidanandam et al., 2001) is being applied in virtually all medical subspecialties to study, understand, diagnose, and treat human disorders. Initial application of linkage analysis and positional cloning was successful in identifying the gene alterations (genotype) responsible for over 1,000 single gene disorders (most often ones with a secure *phenotype*, a change or changes observed on examination, radiograph, or biochemical testing that allow diagnosis reflecting the effects or manifestations of the changed genotype or genotypes.) Single gene syndromes including complex, heterogeneous phenotypes, such as breast cancer (Miki et al., 1994; Wooster et al., 1995) or colorectal cancer (Nishisho et al., 1991), offer insights into the pathogenesis of these disorders. With knowledge of the interaction of multiple genes to result in genetic susceptibility (as well as the environmental triggering factors) comes the possibility of presymptomatic measurement of genetic susceptibility, with subsequent manipulation of contributing molecular and environmental factors. However, the ability to perform such measurement and manipulation carries a heavy price of responsibility and raises difficult questions about the future role of gene testing and therapy in the treatment of human disease.

The first part of this chapter provides a brief overview of the history of genetics and introduce some of the various molecular biological techniques used in genetic research. The next section outlines the known categories of inheritance, including examples of the disorders associated with

each. An approach to clinical genetic evaluation and genetic counseling is outlined. In the final section of the chapter I introduce current approaches to the treatment of genetic disorders, and touch briefly on the future possibilities of gene therapy in neuropsychiatry.

## HISTORY OF GENETICS

The history of genetics as a scientific discipline is only a little more than a century old. Gregor Mendel published his studies of breeding in peas in 1866. Based on his observations, he suggested that discrete *elements*, or *genes*, explain the inheritance of traits from generation to generation (Mendel, 1866/1965). In the early 1900s, these concepts were rediscovered and applied to understanding the inheritance of human characteristics. It was only as recently as 1956 that techniques for visualizing human chromosomes confirmed that the normal human diploid number was 46. Lyon's (1968) hypothesis regarding X-inactivation allowed a better understanding of the role of the one remaining active X chromosome in development. The introduction of special banding techniques in the 1970s permitted a more detailed analysis of portions of specific chromosomes, and somatic cell hybridization began to enable the mapping of human genes.

Since Watson and Crick in 1953 first proposed the structure of DNA as the basis of inheritance, a proliferation of molecular techniques based on the *one gene-one protein*

model has allowed for the identification and manipulation of individual genes as well as the elucidation of their structure, function, and pathology. It is estimated that the human genome contains approximately 30,000 genes. McKusick's *Online Mendelian Inheritance in Man* (OMIM) surpassed 10,000 entries in December, 1998, and included over 14,000 entries in January, 2004. Only a small proportion of human disorders have been fully understood at the gene level. The following section briefly reviews some of the techniques used to identify and study genes.

## MOLECULAR BIOLOGICAL TECHNIQUES

Techniques in molecular biology are based on our understanding of how deoxyribonucleic acid (DNA) underlies inheritance. At the heart of the Watson–Crick hypothesis was the precept that complementary strands of DNA form the basis of DNA replication, transcription, and translation into protein. Following the rules of base pairing (i.e., adenine pairing with thymine and cytosine with guanine), DNA polymerase adds bases to the template of each of two parental strands to form two identical offspring strands. In transcription, the DNA serves as a basis for the formation of messenger RNA (mRNA, in which uridine takes the place of thymine). The single-stranded mRNA contains sequences that are translated into protein (exons), together with intervening sequences (introns) that are spliced from the mRNA before nuclear transport and subsequent translation into a protein on the ribosomes. The genetic code involved in the translation of the mRNA sequence into protein is the three-nucleotide unit (codon) that specifies insertion of a particular amino acid in sequence into the protein. Thus, for example, AAA or AAG in genomic DNA specifies phenylalanine. The AUG codon for methionine is part of the initiation sequence of every mRNA molecule. The ACT codon in genomic DNA functions as a stop signal. There are numerous transcriptional, translational, and posttranslational controls on the process by which a gene or sequence of nucleotides specifies a protein. Whereas a mutation or change in the DNA sequence in the coding region may result in an altered protein product, with possible loss or gain of function of that protein, mutations in the regulatory regions may alter the quantity of protein made.

### Recombinant DNA Technology

Because the Watson–Crick rules describe how base pairs hybridize, a complementary sequence of DNA, called a *probe*, can be used to show whether a given gene is present in a sample of DNA. Hybridization with the gene sequence of interest can be indicated by radioactive labeling of the probe. If the mRNA for a given protein can be isolated and purified, reverse transcriptase can be used to generate that protein's cDNA (complementary DNA) molecule. This probe will hybridize only with the translated (not the genomic)

sequences, including both the exons and the introns. If a probe for a protein is available, the gene for that protein product can be cloned and introduced into a bacterial species, where it can be produced in quantity, allowing subsequent characterization or manipulation. This procedure is the basis of recombinant DNA technology. The probe is used to identify which colonies of the bacteria carry the desired gene, so that they can be selected and grown in quantity. The gene can be sequenced to determine the exact order of bases, and this sequence of bases can then be compared with sequences of other known genes in computer databases to look for homology. The sequencing procedure is illustrated in Figure 29.1, which shows how a point mutation yields a protein with altered function, resulting in disease.

### Southern Blotting

Molecular techniques have made possible the diagnosis of many genetic disorders. One such technique, Southern blotting, is based on digestion of DNA by restriction enzymes.

**Figure 29.1** An autoradiograph of a portion of two DNA-sequencing gels. Each gel is produced according to the method of Sanger: DNA is added to each of four tubes, together with enzyme, reaction mixture, and a radioactive label specific for one of the four nucleic acids (guanine, adenine, thymine, or cytosine). DNA sequences are terminated at each position occupied by the nucleic acid studied in that tube, and a label is attached to the terminal nucleic acid position. After electrophoresis, the gel is exposed to x-ray film. For comparison, the normal sequence from a portion of “control” hexosaminidase is shown at left to illustrate a point mutation in the “mutant” sample shown at right. An adenine-to-thymine change is illustrated.

Source: Figure courtesy of Eugene Grebner, PhD, and Jerzy Tomczak, DVM, Tay-Sachs Laboratory, Jefferson Medical College, Philadelphia, PA.

More than 100 of such restriction enzymes have been characterized. These endonucleases cleave DNA at specified base-pair sequences, termed *recognition sites*, generating DNA fragments whose lengths are determined by the distance between recognition sites. After separation of the fragments according to length on gel electrophoresis, the DNA is transferred to a nitrocellulose filter. With radioactively-labeled probes, the fragments containing the gene (or portion of the gene) are shown by autoradiography. A decrease in size (deletion) or an increase in size (insertion or duplication) of the gene can be determined in this way.

### Polymerase Chain Reaction Analysis

Another revolutionary technique, which requires relatively small amounts of biological material and greatly speeds analysis, is polymerase chain reaction (PCR) analysis. Knowledge of the base sequence in the region around the DNA of interest is required. Oligonucleotide probes complementary to the two ends of the sequence to be amplified must be constructed. Each probe hybridizes and then acts as a primer for a thermophilic DNA polymerase that uses nucleotide precursors to produce two copies of the sequence to be amplified. Successive cycles (determined by temperature changes) of denaturation, annealing (primer hybridization), and synthesis result in orders-of-magnitude amplification of the sequence of interest in less than a day. Direct visualization of the PCR-amplified sequence by ultraviolet fluorescence yields rapid results.

### Linkage Analysis

If a mutation of interest alters a specific restriction site, Southern blotting, or PCR analysis can be used to show the difference in length that results after restriction enzyme digestion. In instances where the mutation is not known, linkage analysis will identify other inherited variations in nearby restriction sites to indirectly indicate whether a DNA segment of interest is present. Because alteration of the restriction sites results in sequences of varying length after digestion with the appropriate restriction enzyme, and because these restriction-length patterns are inherited according to Mendelian modes, such restriction fragment length polymorphisms (RFLPs) can be used as markers in linkage analysis. Variable-number tandem repeats (VNTRs) represent a special case of the RFLP category; these highly polymorphic markers have proved extremely useful in family studies. Finally, the sequencing of the human genome has made it possible to use single-nucleotide polymorphisms (SNPs) for linkage and association studies.

Linkage analysis is a tool used for gene mapping as well as molecular diagnosis. Such analysis is based on family studies and the physical presence of two loci located very close together on the same chromosome. Assumptions underlying linkage analyses include the gene model (e.g., single-gene, multifactorial), the mode of inheritance

(e.g., autosomal dominant, autosomal recessive, X-linked), and the penetrance. When loci are inherited together, they are said to be *linked*. The greater the distance between the two loci, the less linked they will appear, as the result of meiotic recombination secondary to formation of chiasmata, crossing over, and recombination. Thus, if the genes are on different chromosomes or are sufficiently far apart on the same chromosome, they will appear to assort independently in families and will not appear to be linked as they pass from one generation to the next. *Genetic distance*, the percentage of recombinants, is related to the physical distance between loci, but not in a one-to-one manner. Genetic distance is expressed in centimorgans (cM), where 1 cM represents 1% recombination.

Through linkage analysis, a marker with a known mode of inheritance can be used to locate another gene whose location was previously unknown. A *lod score* of 3 is usually required as proof of linkage (the lod score is a logarithmic expression; the logarithm of 3 means that the odds of linkage at a given distance between the two loci is 1,000 [10<sup>3</sup>] times greater than that of no linkage). Calculation of the lod score is usually performed by computer program and is based on the principle of maximum likelihood analysis. This kind of analysis (based on the known mode of inheritance) was used to locate the genes for Huntington's disease (see Chapter 21), cystic fibrosis, and neurofibromatosis. Linkage analysis has also been used in certain family situations for presymptomatic or prenatal diagnosis of disorders, such as Duchenne's muscular dystrophy or hemophilia A (Antonarakis, 1989).

Good reviews have been written on the statistical basis of linkage analysis (Ott, 1991) as well as on the difficulties in applying the technique to behavioral disorders (Gershon & Cloninger, 1994), because for complex human diseases there is not a simple mode of genetic inheritance and accurate categorization as to who is affected and who is not proves difficult.

The techniques described have been applied to dissection of DNA changes, especially as they relate to the etiology of human conditions; that is, genomics. An alternative but complementary approach is proteomics, the application of techniques such as two-dimensional gel electrophoresis or mass spectroscopy to the analysis of the gene products, proteins. Proteomics can be applied to analyze the response of cells in culture exposed to specific states, such as inflammation, drugs, or toxins, and to look at pathways and signaling networks involved in the response to those conditions. It is possible, based on genetic code, to work backward, from the protein of interest to identify the genes involved in the cellular response. For example, if it were possible to look at a patient's response to stress, differences might be discerned between patients with depression from those without. Thus, it is hoped that the joint disciplines of genomics and proteomics can be applied to understand the pathophysiology of many poorly understood human conditions.

## CATEGORIES OF INHERITANCE

Categories of inheritance include classical Mendelian modes (i.e., single-gene mutations), chromosomal mechanisms, multifactorial modes, and nonclassical mechanisms (i.e., mitochondrial mutation, genetic imprinting, and unstable repeat sequences).

### Classical (Mendelian) Modes of Inheritance

#### Single-Gene Disorders

A single-gene disorder occurs when there is a mutation from the wild type allele at one locus (on one or both members of a pair of chromosomes) that results in an observable phenotypic change. Inheritance of the phenotype generally follows the Mendelian rules of inheritance: autosomal dominant, autosomal recessive, or X-linked. Based on population studies, it is estimated that the incidence of single-gene disorders is between 2 and 3% by 1 year of age but is closer to 5% by age 25 years (Baird et al., 1988). These percentages do not include disorders with potentially later onset or identification, such as Huntington's disease, spinocerebellar ataxia, neurofibromatosis, and bipolar depression. Patients with single-gene disorders are those most likely to be referred to a genetics clinic for evaluation or counseling because of a family history of the disorder.

With *autosomal dominant* inheritance of a phenotype, one dose of the altered gene results in some degree of expression of the phenotype. Thus, a parent with one mutated copy and one normal copy has a 50% chance of passing on the mutated gene to any offspring. The expression is variable. In general, there are few human examples of homozygosity for autosomal dominant mutations. Where such homozygosity has been proven (as in the case of a double dose of the mutation for achondroplasia), the phenotypic effects are more severe than those resulting from a single copy of the abnormal gene. The gender of the individual does not determine whether he or she will receive the altered gene, although gender may affect gene expression. Autosomal dominant traits pass from generation to generation (so-called vertical transmission), affecting on the average about half of the offspring of any affected individual.

In contrast, *autosomal recessive* inheritance of a disorder requires two doses of the mutant allele for any phenotypic effect. A single dose of a gene (i.e., carrier status) may pass through many generations without two carrier parents having any affected offspring. Only when both parents are carriers is there a 25% risk that an offspring will inherit a double dose of the mutant allele. Thus, more than one sibling of either gender may be affected within the same generation (so-called horizontal inheritance) with no family history. The rarer the gene, the more likely it is that consanguinity, the sharing of genes identical by descent, is present. Hence, many of the metabolic disorders included in newborn screening were described in the inbred Amish and Mennonites (Morton et al., 2003).

Finally, in *X-linked* inheritance, the female carrier is in general less severely affected than the hemizygous males. For *X-linked recessive* traits, the female carrier is usually unaffected. Half of her daughters on the average will be carriers, and half of her sons will be affected. Thus, the trait may appear to skip generations but will always be inherited through the maternal side. In contrast to autosomal dominant inheritance, in which vertical transmission may also occur, there will never be male-to-male transmission in X-linked recessive inheritance. A male with an X-linked recessive disorder will have no affected sons, but all of his daughters will be carriers. *X-linked dominant* traits are occasionally seen in which female carriers are more mildly affected than the hemizygous males in the family.

#### Variability and Heterogeneity

Several key concepts in clinical genetics should give rise to caution in the interpretation of family histories.

It is important to realize that for any of the three major single-gene categories of inheritance, affected individuals may have a negative family history for the disorder in question. For autosomal dominant and X-linked inherited traits, there may be a new mutation (in general, such new mutations are correlated with advanced age in the father of the affected individual). For recessive disorders, a negative family history is common unless there is inbreeding.

Another reason that phenotypes may appear not to follow Mendelian rules of inheritance has to do with *variability of expression*. For dominantly inherited traits in particular, there may be great variability in the nature and severity of the symptoms of the disorder, even within a single family (where presumably all of the affected members carry the same mutation). When there is variation in age at onset, earlier age at onset is taken to be an indicator of greater severity.

Finally, because of *genetic heterogeneity*, one phenotype can turn out to be related to many different genotypes. Tuberous sclerosis provides an example of this genetic heterogeneity. Linkage of tuberous sclerosis (see Chapter 22) with chromosome 9 was initially reported in the United Kingdom (Fryer et al., 1987). A report of positive linkage with chromosome 11 then came from the United States (Smith et al., 1990), although this linkage has not been extensively confirmed. Subsequently, the majority of families studied have shown linkage with chromosome 16 (Kandt et al., 1992). No clear phenotypic differences are observed among the families showing linkage to the different loci, other than the concurrence of infantile polycystic kidney disease with tuberous sclerosis pointing to the chromosome 16 locus where these genes are contiguous. Thus, to conduct a linkage analysis to determine which locus is responsible for the phenotype in a given family, sufficient numbers of affected and unaffected informative individuals must be alive and willing to cooperate with the studies. Only then could linkage analysis be used; for example, in a prenatal diagnosis. Detection of

the putative allele would not allow prediction of the severity of the effects.

Another example of heterogeneity with even greater complexity is Alzheimer's disease. Only approximately 10% of Alzheimer's cases are inherited in an autosomal dominant fashion. There are no clear clinical differences between the familial and the sporadic cases. Furthermore, among the early onset familial cases, some are related to changes in an amyloid precursor protein (APP) gene on chromosome 21 (St. George-Hyslop et al., 1987) and others are related to a gene on chromosome 14 (St. George-Hyslop et al., 1992). Late-onset familial cases have been linked to chromosome 19 (Pericak-Vance et al., 1991), a finding that points to a possible role for the apolipoprotein E gene in sporadic cases of late-onset Alzheimer's disease (Corder et al., 1993). Familial cases constitute only a small portion, less than 10% of all patients with Alzheimer's disease, but they have contributed to understanding of the truly multifactorial majority of cases.

Occasionally, linkage analysis will demonstrate *allelic heterogeneity*; that is, different alleles within the same gene giving rise to slightly different phenotypes. For example, both the Duchenne and the Becker types of muscular dystrophy are linked to the dystrophin gene on the X chromosome. The Becker form of muscular dystrophy has a later onset and a milder course. Different areas within the gene represent deletional hot spots for the two disorders (Forrest et al., 1987; Monaco & Kunkel, 1987). Another gene in which linkage analysis revealed that different mutations or alleles gave rise to very different disorders is the L1 cell adhesion molecule gene (L1 CAM), which was found to be related to X-linked complicated spastic paraplegia, the MASA (mental retardation, aphasia, shuffling gait, and adducted thumbs) syndrome, and X-linked hydrocephalus associated with aqueductal stenosis (Fryns et al., 1991; Kenrick et al., 1996; Rosenthal et al., 1992; Vits et al., 1994). Apparently because of the extensive role of the L1 CAM in brain development, alterations in different areas of the gene give rise to a variety of developmental brain anomalies.

### Chromosomal Abnormalities

Chromosomes are the structures in which the genes are packaged. They are visible at the time of cell division. The normal diploid ( $2n$ ) number of human chromosomes is 46. Twenty-two pairs of chromosomes are designated *autosomes*, with the remaining pair (the X and the Y) constituting the *sex chromosomes*. In general, just as one member of each pair of genes is inherited from each parent, one member of each chromosome pair is inherited from each parent. It is a matter of chance which member of the pair is inherited.

It is estimated that approximately 1 in 200 live newborns will have a chromosome abnormality. The frequency is even greater in perinatal deaths, in which the rate of chromosomal abnormality ranges from 5 to 10%. The frequency of chromosome disorders in first-trimester

miscarriages is estimated to be approximately 50%. In general, chromosome disorders occur when there is either an excess or a deficiency of chromosomal material, both of which can arise either through a change in chromosome number or a rearrangement of chromosome structure.

*Changes in chromosome number* are of two types. In *polyploidy*, there is an abnormal multiple of the haploid number 23 (e.g., in triploidy, there are 69 chromosomes). In *aneuploidy*, the numerical deviation from normal is a discrete number of chromosomes. Deficiency of one chromosome (*monosomy*) is usually lethal; the most common monosomy compatible with survival is Turner syndrome (45,X). *Trisomy* refers to the presence of one extra chromosome; the most common live-born example of this deficiency is Down syndrome. The International System for Human Cytogenetic Nomenclature (ISCN) designation (Mitelman, 1995) for a male with trisomy 21 is 47,XY,+21.

Partial monosomy or trisomy can also arise by means of *structural rearrangements of chromosomes*, including deletion, duplication, translocation (reciprocal or Robertsonian), isochromosome formation, and inversion. Such rearrangements have been used to identify gene loci for single gene disorders such as Duchenne muscular dystrophy and neurofibromatosis, type I.

*Cytogenetics* is the study and analysis of chromosomes for structural abnormalities. Chromosomes are microscopically viewed in growing tissues where cells are dividing. For the sake of convenience, white cells from a heparinized blood sample are generally grown in tissue culture for diagnostic purposes. Colchicine is added to stop the process of mitosis at the metaphase stage. Hypotonic solution lyses the nuclear membrane, allowing the chromosomes from one cell to spread just far enough apart so that they can be stained, visualized with a microscope, and analyzed. Initially, chromosomes were homogeneously stained with Giemsa stain. With the development of special staining techniques in the 1970s, however, it became possible to evaluate chromosomes in greater detail. Pretreatment of the chromosome material with a protease (generally trypsin) allows for visualization of G-bands, and other stains identify different bands (e.g., Q-bands, R-bands, C-bands). *Preparing a karyotype* means arranging the pairs of chromosomes from one cell according to the lengths of the arms.

By standard G-banding, metaphase chromosomes contain between 200 and 550 bands. These bands allow for detailed analysis of rearrangements, but even the smallest visible deletion would involve 1 to 2% of a chromosome—anywhere from a few to 100 genes. In certain clinical situations in which a recognized multiple-malformation syndrome is suspected on the basis of a change involving one chromosome, *high-resolution chromosome analysis* is used to determine whether a *microdeletion*, that is, a deletion not usually detectable with standard G-banding, might account for the features observed in the affected individual. One of the best-known microdeletion syndromes is Prader-Willi syndrome, which is characterized by neonatal hypotonia,

small hands and feet, distinctive facial features, short stature, mental retardation, and central obesity secondary to hyperphagia. About half of cases of Prader-Willi syndrome are related to a microdeletion in the long arm of chromosome 15 (Ledbetter et al., 1981).

High-resolution analysis of prometaphase chromosomes (which contain between 500 and 1,000 bands) is more difficult than standard G-banding of metaphase chromosomes. For this reason, this technique is usually reserved for situations in which a particular deletion is suspected based on clinical evidence. The laboratory conducting the analysis is dependent on information about the patient to know where to look for a potential chromosomal abnormality.

In addition to prometaphase cytogenetic techniques, a new technique, *fluorescent in situ hybridization (FISH) analysis*, allows for definition of submicroscopic deletions or cryptic rearrangements. DNA probes for the critical region-specific genetic sequences are tagged with fluorescent dyes. When these FISH probes hybridize with the chromosome preparations, they confirm the presence or absence of the segment under the fluorescent microscope in cases where the deletions are too small to see even with prometaphase methods. Figure 29.2 depicts a standard G-banded chromosome preparation, which appears to be that of a normal

female (46,XX); however, in Figure 29.3, a FISH study of the same subject indicates the presence of two number-15 chromosomes with deletion of the Prader-Willi syndrome critical area.

Microdeletion syndromes are being studied in an attempt to determine which of the contiguous genes in the missing region contributes to the phenotype. Thus, for example, in a patient with a deletion of one copy of the Prader-Willi syndrome critical area, if the single remaining dose carries an altered recessive gene, such as the P gene for type II oculocutaneous albinism, the patient's syndrome will manifest oculocutaneous albinism secondary to the one copy of the altered gene (Hamabe et al., 1991). In this way, the identity of other deleted genes contributing to the mental retardation or behavioral phenotype in Prader-Willi syndrome may be uncovered. No clear neuropathological correlates of the hyperphagia and food-seeking behavior have been found, although such correlates have been sought in neuropathological studies of the hypothalamus. Individuals with Prader-Willi syndrome may display temper tantrums, compulsivity, and aggression with regard to food (Dykens & Cassidy, 1995).

The number of known microdeletion syndromes is continually expanding (Table 29.1). Although there is

**Figure 29.2** Standard G-banded human karyotype, with chromosomes arranged in pairs by size. The International System for Human Cytogenetic Nomenclature (ISCN) designation for this normal female karyotype would be 46,XX.

**Figure 29.3** A fluorescent in situ hybridization (FISH) study on a metaphase spread. The chromosomes look orange when viewed under the fluorescent microscope. Fluorescein-tagged probes appear yellow. The metaphase preparation has been hybridized with a mixture of two cosmid probes. One identifies 15q11q12, the Prader-Willi syndrome/Angelman's syndrome (PWS/AS) critical region. The other probe hybridizes to the 15q22 area to identify the fact that there are two number-15 chromosomes. The analysis reveals two number-15 homologues but only one copy of the PWS/AS critical region. This microdeletion was not visible on prometaphase spreads. (For color detail, see full color insert.)

theoretically no limit on the number of different chromosome abnormalities that can occur, syndromes defined by multiple cases have been catalogued in a number of comprehensive sources (Borgaonkar, 1991; DeGrouchy & Turleau, 1984; Gardner & Sutherland, 1989; Schinzel, 2001).

### Multifactorial Conditions

The term *multifactorial inheritance* implies not only that single-gene inheritance has been ruled out but also that the familial aggregation noted for a trait accords with a series of predictions that follow from the hypothesis of multiple genes interacting with environmental factors to produce the trait. Examples of such traits include height and dermatoglyphic ridge counts.

The multifactorial model was developed by Carter in the 1960s specifically to describe his observation that

*isolated birth defects* (i.e., a single malformation that is not accompanied by other malformations suggestive of a syndrome or other disorder with single-gene inheritance) aggregate in families. Examples of such isolated malformations include neural tube defects and cleft lip (with or without cleft palate), each of which has a population incidence on the order of 1 in 1,000. In general, once the first family member is affected, the risk of the defects occurring in close relatives will be much greater than that in the general population (depending on the degree of relationship, or the number of genes shared in common); that is, approximately 5% for first-degree relatives. More distant relatives (who have fewer genes in common as well as fewer shared environmental exposures) will have a risk that is slightly higher than the population risk. When the ratio of affected individuals is skewed toward one gender, the risk to relatives will be greater when the index

Note: If one of these microdeletion syndromes is suspected, the clinician must convey specific clinical concerns to the molecular cytogenetics laboratory so that the appropriate prometaphase studies, fluorescent in situ hybridization studies, or uniparental disomy studies can be initiated. It is also important to understand the heterogeneity of these conditions, because for some syndromes only a portion of truly affected patients will show any positive diagnostic results. In these instances, the clinician should clearly communicate to the family that a negative result does not rule out the syndrome.

individual is the less frequently affected gender, as in the example of pyloric stenosis, in which the male-to-female ratio is 5 to 1, and the risk to the offspring of affected females is greater than that to the offspring of affected males. The greater the number of family members affected or the more severe the defect, the greater the risk to relatives. Once a trait's pattern of occurrence has been shown to accord with multifactorial predictions in a given population, empirical, or observed, risk estimates may be used for members of that population.

In practice, because of the possibility of genetic heterogeneity, family histories and medical examination results must be inspected for associated abnormalities. Teratological exposures must also be assessed, because, for example, a mother on an anticonvulsant who has a child with cleft lip will be more likely in future pregnancies to have a similarly affected child if her exposure to the drug continues. Because adequate studies do not exist for all relationships in all populations, empirical estimates must be offered with caution, as the best estimates available, but not as certain as Mendelian risk estimates (Bartley & Hall, 1978).

One example of a behavioral disorder with familial aggregation that does not fit Mendelian modes of inheritance is schizophrenia (see also Chapter 10). Whereas the lifetime risk of schizophrenia in the general population is roughly 1%, the risk is ten times greater in siblings or offspring (but slightly lower in parents) of an affected individual. If more relatives are affected, the risk increases from 9 to 10% with one sibling affected, to 16 to 30% when both a parent and a sibling already have the disorder.

Twin studies have been used in the attempt to unravel the nature-versus-nurture question for schizophrenia. Monozygotic twins have 100% of their genes in common; dizygotic twins have, on average, 50% of their genes in common. Thus, if genes have an important role in the etiology of a disorder, one would expect to see a higher concordance in monozygotic than in dizygotic twins. Adoption studies of schizophrenia have also been conducted to further delineate the separate contributions of nature and nurture. The results of these studies have supported the role of genes (as opposed to shared environment) in the disorder, because the pattern of occurrence was found to be related more to the diagnosis in the biological parents than to that in the adoptive parents.

However, identifying the genes predisposing to schizophrenia raises difficult methodological issues. In general, linkage analyses depend on the initial assumptions as to mode of inheritance of a single gene. Efforts to search the genome for genetic markers in extended families have been undertaken in the attempt to identify genes that may contribute to the multifactorial category of schizophrenia. However, initial positive results (Sherrington et al., 1988) have not been replicated in subsequent studies (McGuffin et al., 1990). Not only may there be multiple susceptibility genes contributing to diagnoses in large families, but there are possible difficulties with diagnostic categories. For example, if one family member has the disorder according to the most rigorous criteria and another has a milder disorder that might be related, how should the latter case be classified? Is it possible that the more mildly affected individual will develop the full-blown syndrome over time? Linkage analysis is sensitive to misclassification of who is affected and who is not.

Some of these methodological difficulties might be overcome with population-based, collaborative studies in large numbers of nuclear families, but agreement regarding classification is a critical prerequisite to such research (Cloninger, 1994). Alternative statistical approaches to linkage analysis might also be used, including the affected sibpair approach, which is not as sensitive to misclassification errors associated with nonaffected individuals who subsequently develop the syndrome or disorder (Risch, 1990). Studies attempting to detect multiple simultaneous genetic effects or environmental triggers are also needed, given the compelling evidence for genetic susceptibility (Gershon & Cloninger, 1994). Perhaps it should not be surprising that complicated phenotypes such as

behaviorally defined neuropsychiatric disorders are so difficult to unravel. There are comorbid conditions that may affect different members of the same family, as in the overlapping predisposition to schizophrenia and bipolar disorder in the 22q critical region for DiGeorge/Velocardiofacial syndrome (Berrettini, 2003). Another multifactorial disorder is autism (Spence 2001) where speech delay maps to 7q, one of the several regions identified in genomewide scans contributing to autism. The search for putative genes is actively being pursued (Bonora et al., 2002).

### Nonclassical Mechanisms of Inheritance

Nonclassical mechanisms of inheritance include mitochondrial mutation, genetic imprinting, and unstable repeat sequences.

#### Mitochondrial Mutation

The finding of strictly maternal transmission of Leber's hereditary optic neuropathy led to the first documentation of inheritance due to a mitochondrial DNA (mtDNA) mutation (i.e., because mtDNA is transmitted via the egg, not the sperm) (Wallace et al., 1988). Table 29.2 provides a partial list of the classical mitochondrial disorders; for additional documentation of the variety of responsible mutations in mtDNA, the reader is referred to the new section on mitochondrial disorders in McKusick's *Mendelian Inheritance in Man* (12th Edition, 1998).

Human mtDNA is a small (16.5 kb), circular, double-stranded molecule that contains 13 structural genes for proteins involved in oxidative phosphorylation. Other genes coding for the balance of proteins involved in oxidative phosphorylation reside in the nuclear DNA. Body tissues vary in the extent to which they are sensitive to changes in energy metabolism secondary to oxidative

phosphorylation defects. Besides tissue-specific variation, there are also age-related effects. In fact, it has been suggested that cumulative oxidative damage to mitochondrial DNA contributes to aging in general. With reference to neurodegenerative diseases, it is hypothesized that changes in mitochondrial DNA could contribute to Alzheimer's disease and Parkinson's disease (Shigenaga et al., 1994). Interestingly, other systemic manifestations of mitochondrial disease may be depression (Johns, 1995) or autism (Graf et al., 2000; Pons, 2004).

#### Genetic Imprinting

Genetic imprinting occurs when the phenotypic effect of a gene mutation depends on which parent transmitted it. In classical Mendelian inheritance, phenotypic expression is the same regardless of which parent contributed the gene. However, animal models have provided evidence that in some instances the phenotype could depend on which parent contributed the altered gene; or, conversely, on which parent did *not* contribute a *normal copy* of genetic material.

One of the best-known human examples of imprinting is the critical region on the long arm of chromosome 15 (15q11q13), which, as previously described, has been found to be deleted in about half of patients with Prader-Willi syndrome. In all of these patients, the deletion occurred in the chromosome 15 inherited from the father, leaving a single copy of the genetic material inherited from the mother. Alternatively, if the deletion were inherited from the mother (leaving only one normal copy from the father), the offspring would be affected with a different disorder, Angelman's syndrome (formerly known as the "happy puppet syndrome") (Magenis et al., 1987).

Deletion of one copy of the critical region for these two syndromes can occur either *de novo* (as a result of a translocation) or by the mechanism of *uniparental disomy*, in which both members of a given chromosome pair are inherited from one parent, with no contribution from the other parent. Uniparental disomy for chromosome 15 has been observed for Prader-Willi syndrome and, less frequently, for Angelman's syndrome (Malcolm et al., 1991; Nicholls, 1993). If both copies of chromosome 15 come from the mother (i.e., none from the father), Prader-Willi syndrome results; conversely, if both copies come from the father (i.e., with none from the mother), Angelman's syndrome results. Cases have been reported in which a trisomy for chromosome 15 observed on chorionic villus sampling in the first semester had changed to uniparental disomy (i.e., secondary to the loss of the one copy of chromosome 15 from the father) by follow-up amniocentesis at 16 weeks, with the net result being Prader-Willi syndrome (Cassidy et al., 1992). Thus, for region 15q11q13, normal contributions from both parents are required for normal human development. The frequency with which genetic imprinting or uniparental disomy occurs, as well as the biological significance of these inheritance mechanisms, is under investigation.

Diabetes with sensorineural hearing loss	
Pearson syndrome	

### Unstable Repeat Sequences

The mechanism of unstable repeat sequences was discovered in relation to fragile X-linked mental retardation (see Chapter 8), the most common inherited form of retardation (affecting approximately one in 1,600 boys). A cytogenetic marker, an apparent fragile site at Xq27.3, was first described by Lubs (1969) in a family with X-linked mental retardation in which the affected males had the fragile site but the nonaffected males did not. Using the culture medium TC199, Sutherland (1977) clarified the role of low levels of folic acid and thymidine in induction of the fragile site. Subsequent experience with the fragile X marker showed it to be present in kindreds in which the males exhibited the phenotype described by Martin and Bell (1943); namely, moderate-to-severe retardation with long faces; prognathism; large, everted ears; and large testicles. The fragile X marker was not found in other forms of X-linked mental retardation. A number of features inconsistent with simple X-linked recessive inheritance began to be noted, such as transmission by normal males and an increased risk of retardation in the offspring of mentally impaired females (Sherman et al., 1985).

Cloning of the *FMR-1* gene allowed molecular techniques to be applied to elucidation of the mechanisms underlying the fragile site and enabled improved diagnosis of conditions related to this marker (Oberle et al., 1991; Verkerk et al., 1991). The basis for the fragile site turned out to be a GCC triplet repeat sequence that normally codes for a series of arginines in the EMR-1 protein. That sequence is inherited in stable form when there are fewer than 43 repeats. However, if the number of triplet repeats increases to the range of 50 to 70 (sometimes termed the *unstable range*, or premutation), instability during maternal meiosis results, usually with an increase in the number of repeats. Transmitting males with 50 to 70 repeats do not show any phenotypic effect or fragile sites, but their daughters have an increased risk of affected sons as a result of disruption of *FMR-1* gene function by even larger repeat sequences. When 200 or more GCC repeats are present, the fragile site may be seen. This increased number of repeats is termed a *full mutation*. *Somatic mosaicism*, the presence of repeat sequences numbering in the thousands in some tissues, is occasionally observed in affected males. In general, the size of the repeat sequence correlates positively with the severity of the developmental delay in affected males. Females do not show such a straightforward correlation, given lyonization (X chromosome inactivation in females) and the presence of another normal allele.

Interestingly, other diseases associated with unstable repeat sequences are also frequently related to neurological dysfunction. Besides the fragile X A site at Xq27.3, the fragile X E site nearby is apparently related to a milder form of retardation. Two other fragile sites (fragile X F and fragile X 16 A) are also related to increases in the number of CGG repeats and hypermethylation of the nearby CpG island, but these sites are not known to be associated with mental

retardation. Another category of unstable repeats is associated with six neurodegenerative disorders: Huntington's disease, spinobulbar muscular dystrophy, type I spinocerebellar atrophy, dentarubral-pallidoluisian atrophy, the allelic Haw River syndrome, and Machado-Joseph disease. All of these disorders are dominantly inherited, progressive neurodegenerative disorders with later onset (although one measure of their severity is age at onset, which can be as early as childhood). All are related to increased numbers of CAG repeats, with possible gain of function conferred on the gene product. Presymptomatic testing for Huntington's disease is now possible and consists of determining the number of CAG repeats. In contrast to the fragile X dynamic mutation, in which the instability occurs only during maternal meiosis, the instability in Huntington's disease occurs during paternal meiosis.

The phenomenon of *anticipation* (i.e., worsening phenotype with successive generations), which has been clinically reported in myotonic dystrophy, correlates with progressively larger expansions of a CTG repeat through the maternal line. The congenital form of myotonic dystrophy, characterized by expansion to more than 1,000 repeats, occurs mainly in the offspring of affected mothers (Harley et al., 1992; Hunter et al., 1992). Apparent anticipation has also been described in analyses of pedigrees for bipolar affective disorder (McInnis et al., 1993; Nylander et al., 1994), which suggests that repeat sequences may also have a role in that disorder.

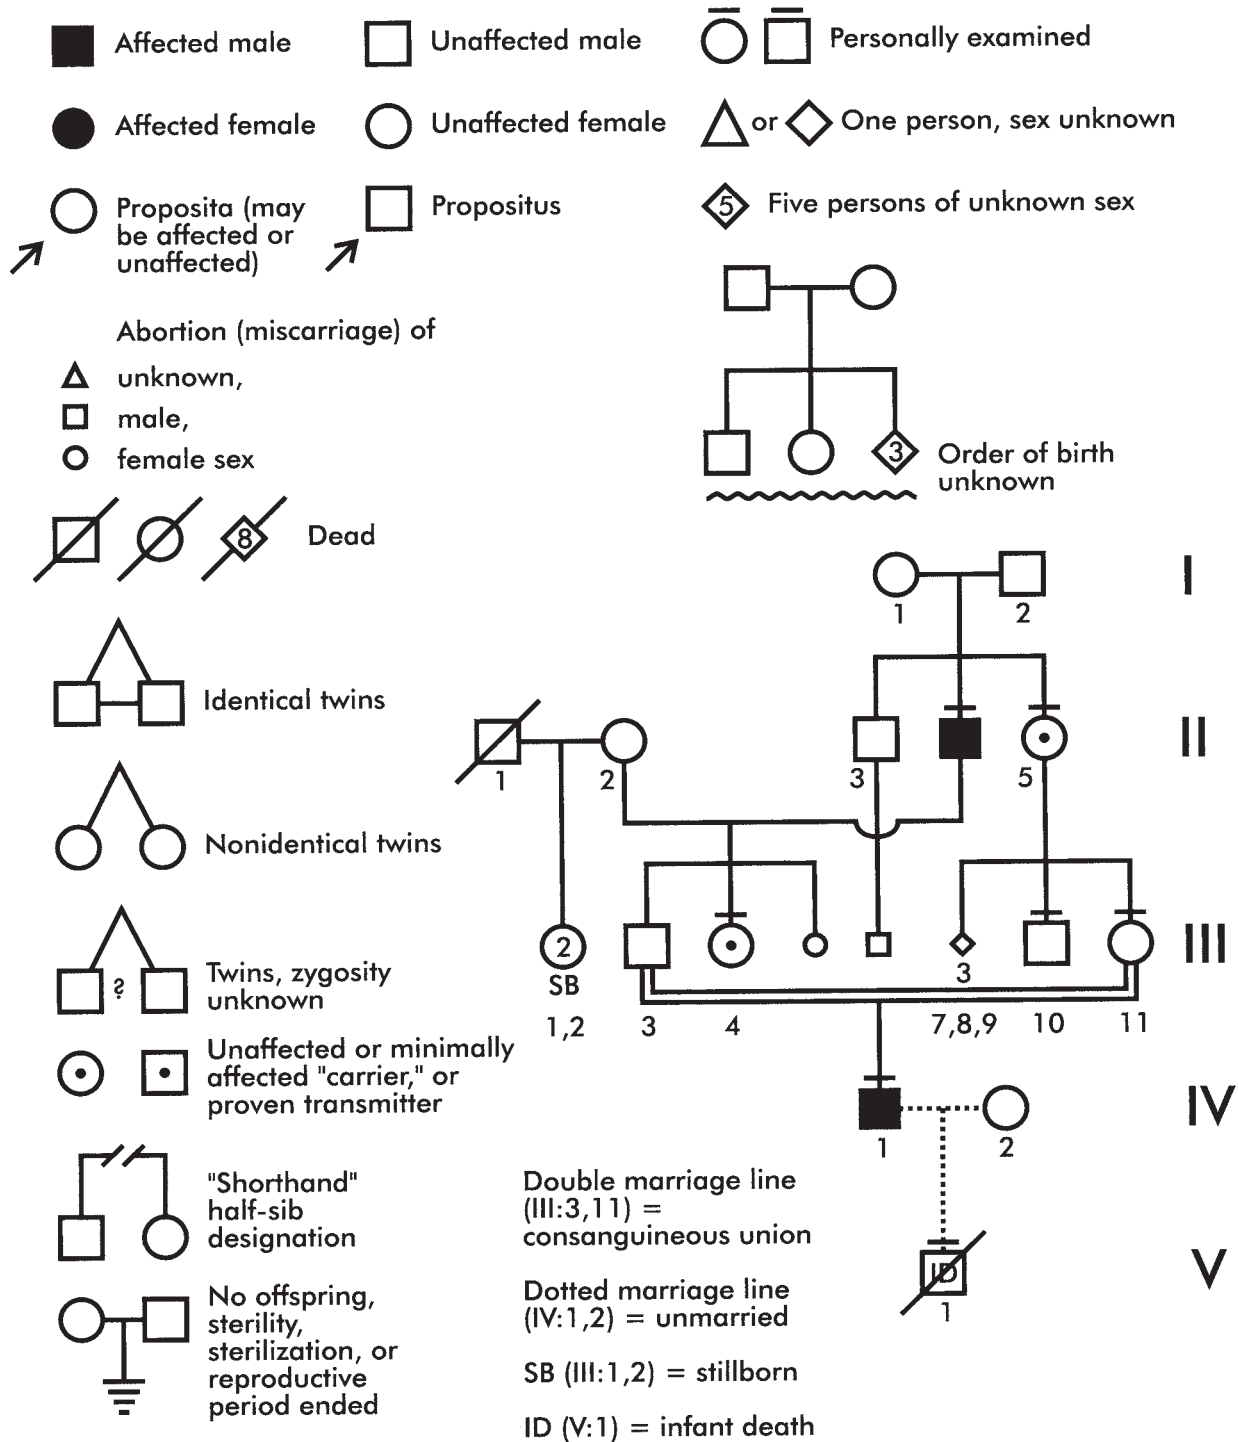

## CLINICAL GENETICS: GENETIC EVALUATION AND COUNSELING

Formal genetic evaluation of a family can be undertaken either at the family's request or upon referral by a physician. However, the timing of the evaluation—and, more importantly, of the counseling—should be considered carefully with regard to how circumstances may influence the family's ability to understand the information provided. For example, if a serious disorder has just been diagnosed in a family member, the ensuing emotions may make it difficult for the family to absorb and understand complicated information. On the other hand, if such a diagnosis is made during another family member's pregnancy, there may be urgency to providing information and helping the family to understand options. To evaluate the possible genetic basis of a disorder, complete information must be gathered, including a detailed medical history (prenatal, birth, and subsequent illnesses and events), a detailed general medical and neuropsychiatric examination, or documentation of such relevant evaluations, and appropriate laboratory testing.

Genetic evaluation always includes a family history. This analysis can be presented in shorthand form with the use of standard pedigree symbols (Bennett et al., 1995) (Fig. 29.4). In the genetic counseling situation, the individual

# Pedigree Symbols

**Figure 29.4** Pedigree symbols. Reprinted from "Instructions for Contributors." American Journal of Medical Genetics (Neuropsychiatric Genetics) 67:120, 1996. Copyright 1996, John Wiley & Sons, Inc. Used with permission.

seeking genetic information or testing, designated the “consultand”, is indicated with an arrow. The first affected family member coming to medical attention is called the *proposita/propositus*, *proband*, or *index case*. (Figure 29.4 is from a medical journal, where [in contrast to the genetic counseling situation] the *proposita/propositus* rather than the consultand is of primary interest and thus receives the arrow indicator.) A key indicates what each filled-in circle or square denotes. If additional family members are affected, these are indicated by filling in the appropriate squares or circles (depending on the sex of the individual).

The value of a pedigree depends on the completeness and care with which the information is gathered. The parents and siblings of the affected individual should be included, starting with the oldest individual on the left and proceeding to the youngest in each generation. Usually grandparents, aunts, and uncles are included as well. Deceased individuals are designated by a slanted line through the square or circle, with an indication of age at death and cause. This information may be important to determine whether that individual lived long enough to manifest a late-onset disorder. If age rather than date of birth is noted below the symbol for each person, the recorder will need to indicate the date that the pedigree was taken. Later adjustments can be made (births, deaths, changes in relationships, and new diagnoses) in subsequent visits.

Numbers within a circle, square, or diamond shape (indicating unknown gender) denote the number of unaffected siblings or offspring. It may be important to indicate whether individuals in the pedigree were ever formally assessed or tested for the condition under evaluation. Review of medical records may be necessary to verify the results, because the family member providing the information may not be aware of all the relevant details or tests performed.

The pedigree may include sensitive information not available to all family members (e.g., nonpaternity, infertility, or test results not meant to be available to insurance companies or employers). Thus, confidentiality should be respected and careful thought given to what information should be included.

Open-ended questions can be very helpful in eliciting information about more distant relatives who may not have been initially included in the pedigree. Opinions within the family regarding affected or unaffected individuals can be indicated as such. For example, family members may attribute an individual’s retardation to a “difficult birth.” This information can be included without prejudgment as to its validity. Also, related historical details, such as late language development, poor school performance, or behavioral difficulties, can be recorded without assigning diagnoses.

In a genetics clinic, it is often the genetic counselor who gathers information, including the pedigree, medical records, and the list of questions the family wants answered. Because correct diagnostic information is the cornerstone of accurate genetic counseling, the counselor may enlist the aid of a clinical geneticist for review of the

records, examination of affected family members, and, possibly, additional testing. In turn, the clinical geneticist may consult colleagues in other subspecialties for any help needed in interpreting the records.

The actual process of communicating risks and options to a family is complex and is influenced by many factors. The family members’ backgrounds, education, religious beliefs, and life experiences affect their questions and perceptions. If a medical diagnosis has been made in a family member, the family’s information may be limited to the problems exhibited by that individual. Some family members may not be familiar with the natural history, treatment possibilities, and range of outcomes for the disorder. The nature of the diagnosis, including whether it can be treated or prenatally diagnosed, may also influence the family’s feelings.

The psychological issues are many. The attitudes and perceptions of family members regarding the genetic condition may vary, depending on their relationship to the affected individual. For a parent, guilt related to a child’s diagnosis with a genetic disorder might be overwhelming, whereas a sibling may resent the amount of care and attention received by the affected child. If two parents or members of a couple disagree on important issues, such as the burden or severity of a particular disorder, the significance of the risks (high versus low), or the acceptability of prenatal diagnosis and termination of pregnancy, it may be hard for them to cope and to make decisions about future reproduction.

In general, the genetic counselor should strive to be nondirective, to be as clear as possible about risks and options, and to support the family in its response to the information provided and decisions regarding how this information might affect future plans for reproduction or testing. The goal is to promote autonomy, individual responsibility, and informed decision making. Follow-up can be critical in regard to providing reinforcement of the risk figures given (i.e., since many studies show that a large portion of families do not retain accurate information about recurrence risks) as well as clarification of other issues and communication of new information or testing results that may change the risk information provided or the options available. Additional family members may also need genetic evaluation, testing, or counseling.

Referral to family support groups may be helpful; information about such groups may be found online through the Alliance of Genetic Support Groups as well as in online websites offered by individual disease-specific support groups. Referral for individual psychological counseling, marital counseling, or family therapy may benefit some individuals.

The supportive role of the genetic counselor is emphasized in the definition of genetic counseling formulated by an ad hoc committee of the American Society of Human Genetics (Fraser 1974, p. 63):

[Genetic counseling is] a communication process which deals with the human problems associated with

occurrence, or risk of occurrence of a genetic disorder in a family. This process involves an attempt by one or more appropriately trained persons to help the individual or family to (1) comprehend the medical facts including the diagnosis, the probable course of the disorder, and the available management; (2) appreciate the way heredity contributes to the disorder and the risk of recurrence in specified relatives; (3) understand the options for dealing with the risks of recurrence; (4) choose the course of action which seems appropriate to them in view of their risk and their family goals, and act in accordance with that decision; and (5) make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder.

Efforts have been made to develop counseling models that integrate psychological, philosophical, and ethical principles (Kessler, 1979). Certainly there are ethical aspects to genetic testing, as, for example, regarding the testing of presymptomatic young people for late-onset untreatable disorders. Although there seems to be some consensus within the genetics community that persons younger than 18 years of age should not be tested for Huntington's disease (American Society of Human Genetics/American College of Medical Geneticists, 1995), situations exist in which the issue must be carefully considered. Despite the fact that most clinical geneticists eschew any eugenic approach, some clinicians acknowledge their desire to reduce the frequency of the Huntington's disease gene in the population and thereby prevent much individual suffering (Harper, 1984). Notwithstanding, all clinicians are troubled when recalling the complicity of geneticists in Nazi Germany in the sterilization of individuals with genetic diseases.

## TREATMENT OF GENETIC DISEASE

Progress continues in elucidating the metabolic basis of inherited disease (Scriver et al., 2001). The success of newborn screening and treatment for disorders such as phenylketonuria and beta-thalassemia illustrates how an understanding of the metabolic basis of a disorder can lead to effective therapy.

In the case of classic phenylalanine hydroxylase deficiency, modification of the infant's diet to control blood levels of phenylalanine prevents much of the brain damage that occurs with accumulation of substrate in the absence of effective enzyme. Screening programs for phenylketonuria that used careful follow-up have allowed identification of phenylketonuria variants, dihydropteridine reductase (DHPR) deficiency and impaired tetrahydrobiopterin (BH4) metabolism, that do not respond to dietary limitation of phenylalanine (Kaufman, 1985). In these disorders, cofactor therapy may be helpful, as has been the case in certain other metabolic disorders.

Another therapeutic approach for treating metabolic disease is providing a "somatic" source of the missing

enzyme; as, for example, with renal transplantation in cystinosis (Ehrich et al., 1991). Similarly, bone marrow transplantation for beta-thalassemia (Lucarelli et al., 1991) replaces the deficient hemoglobin with effective hemoglobin. Of course, there are many factors to consider with this type of therapy, such as financial costs, morbidity, mortality, the limited availability of human leukocyte antigen (HLA)-identical donors, and the age of the recipient. In southern Italy, the incidence of beta-thalassemia was reduced by the combined approach of population screening and prenatal diagnosis (Cao et al., 1981), as had been done for Tay-Sachs disease in the United States (Kaback et al., 1977). However, although a similar approach is theoretically possible for other metabolic disorders, the success of population-level programs depends on the public perception of the burden of the disease and whether families are willing to undertake prenatal diagnosis to prevent the disorder. The experience with cystic fibrosis suggests that many families do not find prenatal diagnosis (especially with consequent pregnancy termination) to be an acceptable preventive approach.

## Gene Therapy

For single-gene disorders in which the molecular pathogenesis is known, the strategy of inserting a normal gene (or appropriately modified nucleic acids) directly into the genome of the affected individual to correct the disorder has been actively pursued. Because the goal is to achieve gene expression in the correct intracellular location, attempts have been aimed at somatic modification rather than germline modification. Ethical guidelines have included the precept that gene transfer attempts should target significant medical illnesses only, not genetic characteristics that might be considered cosmetic or trivial. The first human gene therapy trial occurred in 1989. By the end of 1994, more than 80 clinical trials involving gene transfer (enlisting more than 200 participants) had been approved by the National Institutes of Health (NIH) Recombinant DNA Advisory Committee (RAC) (Ledley, 1995), despite opposition from some groups to recombinant DNA research of any kind. These trials focused not only on rare, single-gene disorders (e.g., cystic fibrosis, Duchenne's muscular dystrophy) but also on disorders as common as cancer, acquired immunodeficiency syndrome (AIDS), and arthritis. By the year 2004, over 900 clinical trials were either completed, ongoing, or approved throughout the world (Edelstein et al., 2004). Over 100 distinct genes had been transferred. Though most trials were found to be safe, some were discontinued because of side-effects and unforeseen risks. The entire approach to gene therapy was re-evaluated after the death of Jesse Gelsinger in 1999 in a phase I trial to treat his ornithine transcarbamylase deficiency. Research in gene therapy continues, with particular attention to the need for safety.

A variety of approaches to gene therapy have been used. One approach, which involves harvesting and cultivating cells from the affected individual, introducing the recombinant genes into those cells in culture, and then reintroducing the altered cells into the patient, has met with some success for disorders in which the deficiency affects mainly the cells in the bloodstream, such as adenosine deaminase (ADA) deficiency, the first genetic disease to be approved by the RAC for a gene therapy trial. ADA deficiency is particularly deleterious to the immune cells, especially the T-lymphocytes. It accounts for about one-half of the cases of autosomal recessive severe combined immunodeficiency. After the first affected child in a family is identified, subsequent siblings could be screened for the disease either prenatally or at birth. Previous therapy for the disorder involved repeated transfusions with irradiated blood, which provided enough ADA to temporarily meet the needs of the individual (adequate immune-system function can be achieved with less than the full normal levels of ADA). In a more recent therapeutic approach, the ADA gene was inserted into the blood of two affected patients by means of a retroviral vector. The genetically engineered cells were then reinfused back into the patients, thus bypassing the risks of autologous transfusion. The results were encouraging in that both patients subsequently responded to immunological challenges (Morgan & Anderson, 1993). Additional research is in progress.

For some disorders, simply achieving normal levels of a deficient protein is not enough to correct the underlying defect. For example, in cystic fibrosis, a double dose of the cystic fibrosis transmembrane regulator (CFTR) gene decreases chloride transport across epithelial cell membranes in the pancreas, lung, and sweat glands, resulting in the complex pulmonary and pancreatic symptoms characteristic of the disorder. However, to restore normal chloride transport and viscosity of secretions, the therapeutic gene must be introduced at the correct transmembrane position in the affected glands. Altered adenovirus sprayed in aerosolized form has been investigated in animal models, but the results were complicated by varying degrees of inflammatory response. An initial study that used a similar approach in a small number of cystic fibrosis patients was not markedly successful in incorporating the CFTR gene into nasal epithelial cells (Knowles et al., 1995). There was also considerable inflammatory response. However, continuing work on alteration of the virus and possibly even alteration of the immune response to the virus is in progress.

Animal models are not always entirely predictive of the human experience. The difficulties in transferring techniques from the laboratory to the bedside were illustrated in a study that attempted to transmit normal dystrophin into boys affected with Duchenne's muscular dystrophy by transplanting myoblasts. Whereas animal studies had demonstrated efficient incorporation of human myoblasts into mouse muscle, the boys in this study showed poor

incorporation of the myoblasts and little clinical improvement (Mendell et al., 1995). Although these preliminary attempts were not successful, their results should not be viewed as definitive; rather, such trials constitute an important part of the investigative process into the means of achieving successful gene incorporation into appropriate tissues. As these and similar efforts continue, longterm evaluation of the impact of such transfer approaches on participating human subjects is essential.

One of the great challenges in the treatment of neuropsychiatric disorders, assuming that the predisposing genes can be found and the pathogenesis understood, is crossing the blood-brain barrier. This barrier effectively protects the human brain from infection, but it also prevents direct transfer of viral vectors from the bloodstream into the central nervous system. Thus, for gene therapy of a disorder such as Tay-Sachs disease, efficacy would depend on targeting the tissue affected by the hexosaminidase deficiency. For multifactorial psychiatric conditions, vector therapies using conditional expression systems induced by the same environmental triggers that exacerbate psychiatric symptoms would be theoretically desirable (Sapolsky, 2003).

One "gene therapy" success story is the treatment of the nonneuronopathic form of Gaucher's disease. This most common form of Gaucher's disease is characterized by accumulation of lipid-laden white cells and platelets in the reticuloendothelial system, giving rise to enlargement of the liver and spleen. Targeting the deficient enzyme (glucocerebrosidase) by exposing the normally covered N-acetylglucosamine and mannose residues on the enzyme produces low but sufficient levels of enzyme in those cells. Use of a commercial product (Ceredase) in patients with type I Gaucher disease has resulted in decreased spleen size, increased platelet counts, and ultimately but very gradually, a decrease in bone pain (Barton et al., 1991; Beutler, 1991). Although the cost of the therapy is high, it represents a successful targeting strategy. Such innovation might ultimately be successful in bypassing the blood-brain barrier, although there is no way to predict how many years of research with animal models would be required to achieve that end. In addition, postnatal gene therapy would not be effective to addressing disorders that result from the interaction of multiple genes during development. Thus, it is only fair to be realistic with patients' families about the lack of imminence of such a breakthrough. As knowledge of the genetic contributions to neurologic and psychiatric disorders continues, however, it will be important for clinicians to become familiar with the knowledge gained by genetic epidemiologic and genomic research. Tools that have become available from the study of single-gene conditions, the human genome, and multifactorial conditions may be applied in creative ways first the understanding of the pathogenesis of pediatric neuropsychiatric disorders, but also hopefully to the prevention and treatment of such disorders.

# Psychological and Behavioral Interventions

30

**Robert T. Ammerman, MD    Mariah E. Coe, MD**

Historically, the prominence of behavioral and psychological interventions as frontline treatments of neuropsychiatric disorders in children has waxed and waned. In the 1950s and 1960s, the rise of behavior therapy was driven in part by the emergence of innovative therapies for mentally retarded and developmentally disabled children. Viewed as untreatable by most psychoanalysts, children with the significant cognitive limitations often associated with neuropsychiatric disorders were typically institutionalized and provided with few treatment options. For these children, behavior therapy offered new approaches for decreasing psychopathological behaviors that impeded integration into the community and allowed for the teaching of social, educational, and vocational skills that further enhanced mental health and overall well-being. Simultaneously, the corresponding emphasis on empirical demonstration of treatment effectiveness (which is one of the core tenets of behavioral therapy) called into question accepted approaches and contributed to the demand that these approaches also provide scientific evidence for their therapeutic impact. Accordingly, psychoanalytic and

psychodynamic models (some of which erroneously attributed certain developmental disabilities to parental dysfunction) and the overuse of nonspecific pharmacotherapeutic approaches fell into disfavor.

In the 1970s and 1980s, scientific investigations into the etiology of neuropsychiatric disorders delineated the neuropathological and genetic contributions to such conditions. New pharmacotherapies, which were developed in tandem with advances in cognitive neuroscience, further added to the armamentarium of the clinician. Moreover, neuropsychiatry matured quickly, growing beyond issues of localization of brain function and its clinical correlates to more sophisticated conceptualizations of neurological organization involving the interactions of neurological, physiological, and environmental systems. Indeed, the biopsychosocial model is now the only scientifically tenable approach to the design and implementation of comprehensive interventions in child neuropsychiatry and psychology.

Paradoxically, the biological revolution has contributed to a misperception that there is a conceptual dichotomy between somatic (e.g., pharmacotherapy, electroconvulsive therapy [ECT]) approaches to treatment and their psychological and behavioral counterparts. In some treatment settings, psychological and behavioral approaches to the treatment of child neuropsychiatric disorders are marginalized or are not integrated into the overall treatment plan. Likewise, in settings where behavioral interventions predominate (e.g., special education), neuropsychiatric

---

#### Acknowledgments:

This chapter was written with the partial support of Grant No. H133G000134 from the National Institute in Disability and Rehabilitation Research, U.S. Department of Education, Grant No. RO1 MH53703-05 from the National Institute on Mental Health, and by USPHS GCRC Grant #M01 RR 08084 from the National Center for Research Resources, NIH.

resources may be absent or tangential. Such disjunctive practices perpetuate the unjustified stereotypes of neuropsychiatrists as solely dispensers of medications and of the psychologists as unappreciative of neurological and genetic contributions to psychopathology.

Truly effective care of children with neuropsychiatric conditions can occur only in multidisciplinary, integrated treatment settings. Within these settings, interventions that have as their goals reduction of psychopathology and enhancement of skills that promote mental health and longterm adjustment should work in tandem. Scientific credibility and a strong linkage between etiological understanding and subsequent intervention are the common denominators of effective treatment, regardless of the clinician's therapeutic orientation or professional training.

In this chapter we present an overview of psychological and behavioral approaches to the treatment of neuropsychiatric disorders in childhood. These approaches are referred to as *child psychotherapy* or more generally, as *psychological interventions*. In keeping with the requirement of scientific credibility, we first review and consider research evidence for the effectiveness of child psychotherapy. Following a general survey of psychotherapeutic issues relevant to work with developmentally disabled children, we address principles and practices of behavioral assessment and treatment. We close the chapter with a discussion of family issues.

## EFFICACY OF PSYCHOLOGICAL TREATMENTS FOR CHILDREN AND ADOLESCENTS

What is child psychotherapy? How effective is it? What factors and characteristics are associated with positive outcomes? These questions have generated considerable debate over the past half-century and have been the subject of several reviews in the last decade (Kazdin, 2000). There is a consensus that research on child and adolescent psychotherapy is nascent in comparison with that on adult psychotherapy. However, there has also been a strong drive in recent years to take stock of the child and adolescent psychotherapy literature both to examine the overall effectiveness of such interventions and to identify mechanisms and moderators of positive outcome. The overall effectiveness of psychological interventions with children is relevant to pediatric neuropsychiatry in that, to the extent that such interventions have been empirically shown to be effective, they become viable treatment options for neuropsychiatric disorders as well.

### Critical Reviews and Meta-Analyses

The first question, What is psychotherapy? defies a simple answer. Kazdin (1991, 2000) has estimated that there are

more than 230 approaches to child psychotherapy, which he broadly defined as

An intervention designed to decrease distress, psychological symptoms, maladaptive behavior or to improve adaptive and psychosocial functioning. These ends are sought primarily through interpersonal sources of influence such as learning, persuasion, counseling, and discussion integrated into a specific treatment plan. The focus is on some facet regarding how clients feel (affect), think (cognition), and act (behavior). (Kazdin, 1991, p. 785)

Early reviews (e.g., Levitt, 1957) argued against the effectiveness of child psychotherapy relative to no treatment, although the literature on which these conclusions were based was scant and characterized by serious methodological limitations, including absence of control groups, unclear or poor delineation of subject populations, use of vague treatment protocols, failure to monitor treatment integrity, and application of inappropriate assessment strategies. In many of the investigations conducted to date there has been the lack of statistical power to detect significant differences between treatments (as opposed to between treatment and no-treatment control conditions). Since then, there has been considerable improvement in the methodological rigor of child psychotherapy outcome research, particularly in the last decade (Kazdin, 2003). Evidence for the effectiveness of child psychotherapy has emerged from meta-analyses of the expanded literature, which by conservative estimates includes over 1,500 controlled studies (Kazdin, 2003). The maturity of the field is further demonstrated by the dissemination of *empirically-based psychological treatments* for children by the American Psychological Association (Task Force on Promotion and Dissemination of Psychological Procedures, 1995).

The advent of meta-analysis (Mann, 1990) has permitted quantitative examination of treatment outcome research. In meta-analysis, studies are aggregated and rated according to predetermined criteria, and main effects across studies are derived. Specifically, each study is quantified in such a way as to generate an effect size, which is defined as the difference between the means of the treatment and control groups divided by the standard deviation of the control group. The effect size reflects overall treatment effectiveness and is used to delineate factors associated with treatment outcome (e.g., type of treatment, subject characteristics, contextual influences). The advantage of meta-analysis is that it is an objective approach to examining multiple studies rather than one that relies primarily on subjective judgment and opinion, as do more traditional reviews. However, meta-analysis is a correlation procedure and thus does not remove the effects of within-study methodological limitations; all studies have equal weight in a meta-analysis, regardless of their design limitations, although such factors can be empirically examined in meta-analyses (Wilson and Lipsey, 2001).

Meta-analyses conducted in the past decade (Casey and Berman, 1985; Durlak, et al., 1991; Weisz, et al., 1987;

Weisz, Weiss, Han, Granger, & Morton, 1995) have sought to determine the overall effectiveness of child and adolescent psychotherapy and to identify factors associated with positive outcomes. In the first of these meta-analyses, Casey and Berman (1985) examined 75 studies (published between 1952 and 1983) of psychotherapy outcome in children and adolescents 3 to 15 years of age. Specific goals of the meta-analysis were to determine (1) whether some forms of psychotherapy were superior to others, (2) whether the efficacy of psychotherapy varied as a function of the outcome measures used, and (3) which subject characteristics mediated outcome. Studies reviewed had an average sample size of 42 subjects at posttreatment, examined children who were primarily male (60%) with a mean age of 8.9 years, and included treatment durations averaging 9.5 weeks (range = 1 to 37 weeks). Behavior therapy was the treatment most often represented (56%); other studies evaluated cognitive behavior therapy (21%), client-centered therapy (28%), and psychodynamic therapy (9%).

The results of this analysis indicated an overall effect size of 0.71 for child psychotherapy (Casey and Berman 1985). In other words, the outcomes of children receiving psychotherapy were more than two thirds of a standard deviation better than those of subjects in a control condition. This effect size is consistent with results of meta-analyses of adult psychotherapy (e.g., Shapiro and Shapiro 1982; Stevens, Hyman, and Allen, 2000). Behavioral interventions were more effective than nonbehavioral ones (effect sizes of 0.91 and 0.40, respectively). No differences were found for play versus nonplay therapies, individual versus group approaches, parent-involved versus child-only interventions, or as a function of age. Treatment effectiveness was greater in children who displayed impulsivity, phobia, and somatic problems (these three symptoms were also most likely to be targeted in the studies that evaluated behavior therapy); problems of social adjustment were less responsive to treatment.

Casey and Berman's (1985) finding of superior efficacy for behavioral psychotherapy is consistent with the results of Shapiro and Shapiro's (1982) meta-analysis of adult studies. However, in their conclusions, Shapiro and Shapiro argued that the relative superiority of behavior therapy was tempered by the fact that behavioral and nonbehavioral treatment outcome studies tended to target different problems. Moreover, these authors contended that assessment measures used in behavioral studies were often directly linked to treatment targets, as opposed to the more global indices of functioning used in nonbehavioral studies. When these therapy-specific measures (which Shapiro and Shapiro believed led to an artificially inflated effect size for behavioral therapy) were excluded from the analysis, behavioral therapy was no longer superior to nonbehavioral interventions.

In a second meta-analysis, Weisz and colleagues (1987) examined 105 outcome studies (see Weiss and Weisz, 1990) of behavioral and nonbehavioral interventions with children and adolescents 4 to 18 years of age. Studies were selected only if they contrasted a treatment condition with

a nontreatment or minimal-treatment (i.e., attention) control condition. Like Casey and Berman (1985), the authors sought to examine overall treatment effectiveness as well as correlates of positive treatment outcome. However, contrary to the conclusions of Shapiro and Shapiro (1982), Weisz and coworkers (1987) argued that the direct link between assessment approaches and treatment targets in most behavioral evaluations does not necessarily represent a confounding factor in determining the effect size of behavioral versus nonbehavioral interventions. They pointed out that, for example, in the case of phobia, the most clinically meaningful indication of fear and its reduction is approach to the feared stimulus (a measure typically used to assess behavioral interventions for phobia). For such a condition, therefore, global measures of child adjustment would be tangentially rather than primarily relevant. In their meta-analysis, Weisz and associates (1987) distinguished between outcome "measures similar to the training procedures [that] are appropriate and necessary for a fair test of treatment success" (p. 546) and those assessments intricately linked to treatment, which were deemed "unnecessary."

Findings by Weisz and colleagues (1987) revealed a mean effect size of 0.79 for treatment-versus-control comparisons. Once again, behavior therapy was found to be more effective than nonbehavioral interventions (0.88 versus 0.44). This superiority remained when appropriate and necessary assessments were retained (0.93 versus 0.45), but it disappeared when all therapy-specific measures were eliminated. Overall effect size did not significantly change as a function of problem type (i.e., overcontrolled versus undercontrolled behavioral disorders). Children (ages 4 to 12 years) were more likely to improve than were adolescents (ages 13 to 18 years). Also, investigations that used nonclinical samples obtained findings equivalent to those that recruited subjects from clinics. Finally, treatment gains were likely to be maintained at 6-month follow-up.

In a third meta-analysis, Weisz and colleagues (1995) examined 150 studies published between 1967 and 1993 that were nonoverlapping with their previous meta-analyses. These included multiple presenting disorders (aggression, delinquency, anxiety, depression, somatic problems) treated with varying interventions (behavior therapy, relaxation, social skills training, cognitive therapy, insight oriented approaches). As in previous meta-analyses, child treatment exhibited sizable effects (0.71). Additional findings included a superiority of behavioral over nonbehavioral strategies, increased effectiveness in females over males, and greater effectiveness in adolescents over children (in contrast to Casey and Berman), and equivalent effectiveness with internalizing and externalizing disorders.

Although the body of literature on psychotherapy for children and youth with developmental disabilities is smaller than that for children with emotional and behavioral disorders, there is a growing consensus that a range

of treatments are potentially beneficial for this population as well. Prout and Nowak-Drabik (2003) reviewed 92 studies and case reports of psychological treatments for persons with mental retardation (26% of studies involved children and adolescents; 5% included mixed samples of children and adults). Although the methodological rigor of this sample was highly variable, expert ratings of treatment outcomes indicated moderate effects overall. An effect size of 1.09 was derived for 9 studies sufficiently controlled to permit meta-analysis. As with the aforementioned meta-analyses of the larger child treatment literature, behavioral treatments were superior to their nonbehavioral counterparts; although nonbehavioral treatments are infrequently used or studied in this population (Beail, 2003).

These meta-analyses yielded several important conclusions. First, psychotherapy is an effective intervention for a variety of social, emotional, and behavioral problems in children and adolescents with psychiatric disorders. Moreover, treatment effects are durable, being maintained at short-term follow-up. Second, behavior therapy is a particularly effective type of intervention. And third, similar effect sizes are found in meta-analyses of the child and the adult treatment literatures.

A frequent complaint among clinicians is that the experimental research literature has limited generalizability to actual clinical cases. There are potential limitations to evidence-based treatments (e.g., Levant, 2004), and, indeed, the limited outcome research in natural clinic settings (without the methodological control of laboratory studies) has yielded less positive results than have more empirically rigorous evaluations (although there is disagreement about the extent of differences between clinic-based and laboratory-based outcomes; see Shadish, Navarro, Matt, and Phillips, 2000). Weisz, et al. (1995) explored 10 hypotheses regarding why such disparities exist between laboratory and clinical findings. Their meta-analysis revealed that research treatment differed from clinic treatment in that clinical samples were more pathologically disturbed, research settings had superior resources, and behavior therapy (which is more likely to be part of research studies but less likely to be employed by the clinical community as a whole (Kazdin, 2000)) is more effective than nonbehavioral treatments. The analysis by Weiss and colleagues (1995) did not support other hypotheses (e.g., that recent research uses superior methodologies, research clinicians are superior to community researchers, research therapists receive more rigorous training, research psychotherapy is more circumscribed in terms of clinical presentations, research therapy is more highly structured). Although much work clearly remains to be done in bridging the gap between treatment provided in clinical settings and that provided in research evaluations (Weisz, et al., 1995), the evidence for the superiority of behavior therapy relative to alternative psychological interventions for children and adolescents is compelling.

### Guidelines for Empirically Supported Treatments

The emergence of an empirical foundation for psychological interventions in childhood disorders has spawned efforts to develop clinician guidelines and decision trees in selecting treatments for specific disorders (Herschell, McNeil, and McNeil, 2004). The American Psychological Association's Task Force on Promotion and Dissemination of Psychological Procedures (1995) established criteria for categorizing treatments as well established or probably efficacious based on multiple efficacy trials, clear procedural guidelines (i.e., treatment manuals), and independent replications. These, in turn, were applied to different childhood disorders and reviewed and summarized in a series of articles in *The Journal of Clinical Child Psychology* in 1998. Well-established treatments included behavioral parent training for Conduct Disorder, Oppositional Defiant Disorder, and Attention Deficit/Hyperactivity Disorder (ADHD); and modeling and reinforced practice for phobias. A number of additional treatments, all cognitive and behavioral in approach, were also identified as probably efficacious. These included, but are not limited to, cognitive behavior therapy for depression and anxiety, Multisystemic Therapy, Parent-Child Interaction Therapy for conduct problems, and behavior therapy for obesity. The establishment of these clinical guidelines reflects the maturing state of the still evolving literature on psychological treatments for childhood disorders.

The *American Journal on Mental Retardation* published results of an expert consensus panel on the treatment of behavioral and psychiatric disorders in persons with mental retardation (Rush and Frances, 2000). The purpose of this effort was to establish best practices in the treatment of children and adults with mental retardation. Guideline 3, Psychosocial Treatment, reports on consensus treatment recommendations based on severity of mental retardation, and type of disorder/behavior problem. The degree of consensus was high. Specifically, three psychosocial interventions consistently emerged as recommended or treatment of choice for a variety of disorders and behavior problems: applied behavior analysis (operant and classical conditioning procedures), managing the environment, and client and family education. It is noteworthy that, for most specific behavior problems in this population, several psychosocial treatments were recommended.

### PSYCHOLOGICAL TREATMENT IN NEUROPSYCHIATRIC DISORDERS

Although the meta-analyses described above suggest that behavior therapy and its derivatives are the psychological treatments of choice for neuropsychiatric disorders in childhood, basic principles of psychotherapy are applicable to this population as well. Indeed, the cornerstones of psychotherapy, establishment of a therapeutic alliance, em-

pathy, and unconditional acceptance; use of effective listening, are equally relevant to behavior therapy, despite the erroneous stereotype of behavior therapy as cold and overly clinical. Such relationship and process variables, although not viewed by behavior therapists as etiologically crucial or as the primary mechanisms through which treatment success is achieved, are nonetheless the sine qua non of positive outcomes (Beutler, et al., 2003).

Ironically, behavior therapy flourished in the 1960s because of its success with children who were thought to be poor candidates for psychoanalysis or other relationship-based interventions. This previously ignored population became the focus of a rapidly emerging and highly effective technology of behavior modification and change. Recently, however, there has been increased recognition of the emotional and interpersonal needs of neuropsychiatrically impaired children and youth. This awareness has occurred in tandem with (1) the acknowledgement that developmentally disabled children can exhibit a variety of psychopathologies, including internalizing disorders, in addition to the overt behavioral anomalies inherent to their primary disabilities; and (2) a greater appreciation for the diversity of developmental abilities and outcomes in children with neuropsychiatric disorders.

Accordingly, some authors (Harris 1995; Prout, Thompson and Douglas, 1998) have called attention to the importance of psychotherapeutic interventions with neuropsychiatrically impaired children and adults. A number of factors can undermine such children's self-esteem, self-efficacy, and sense of well-being (typically viewed as aspects of functioning that are targeted for change in psychotherapy). Relative ineffectiveness in one's environment, social isolation, and emotional abuse by peers are but some of the variables that can lead to anxiety, dysphoria, and demoralization. Communication limitations can interfere with obtaining needed social attention or tangible assistance, thereby contributing to frustration and learned helplessness. Dependence on others to provide for basic needs and the requirements of daily living can further engender feelings of helplessness and inferiority. Such feelings can intensify upon reaching developmental stages when independence and emancipation are expected (e.g., adolescence). Although these experiences will vary from child to child based on the type and severity of disability and the degree to which the child's family and other caregivers (e.g., educators, mental health professionals) are supportive and sensitive to the child's needs, they remain clinically significant features of the lives of virtually all children with neuropsychiatric impairments.

Harris (1995) has conceptualized psychotherapy in individuals with developmental disabilities from an attachment perspective. Attachment theory, first articulated by Bowlby (1969) and later expanded by Ainsworth (1969) and Sroufe and Rutter (1984), holds that establishment of the affective bond between infant and caregiver is the first and most important stage of social and emotional devel-

opment. Secure attachment emerges from reciprocal interactions of infant and caregiver, consisting of sensitivity to infant cues on the part of the caregiver and of socially reinforcing behaviors on the part of the infant. Insecure attachment, most often resulting from maladaptive parenting, can lead to avoidant, passive, or disorganized behavioral and emotional response patterns in infants. Insecure attachment in infancy, the crucial first stage of emotional and social development, is likely to lead to failure to master subsequent developmental challenges in these domains, even extending into adulthood.

Attachment is an especially relevant construct in neuropsychiatric disorders. Several features of these disorders interfere with the development of a secure attachment relationship. First, some neuropsychiatric disorders have social and interpersonal dysfunction as primary features of the diagnosis (e.g., autism). Second, central nervous system abnormalities inherent in many neuropsychiatric conditions may interfere with mechanisms responsible for the regulation of emotional processes (e.g., in head-injured youth) or other aspects of psychological and behavioral functioning (e.g., inattention, behavioral dysregulation, language disorders). Third, children with congenital abnormalities or early onset of neuropsychiatric conditions may exhibit characteristics that prevent formation of or undermine the attachment bond, or that are especially challenging for caregivers. For example, irritability, screaming, maladaptation to changes in routine or setting, or other behavioral sequelae of neuropsychiatric disorders in infants, can negatively affect the infant-caregiver relationship, particularly when the parent's ability to effectively identify infant cues and respond to them quickly and sensitively is already compromised (Ammerman and Patz, 1996). And fourth, social isolation and peer rejection interfere with socialization in neuropsychiatrically impaired children over and above the limitations imposed by the extent and severity of neurological dysfunction. Essentially, there are only a limited number of social and life experiences from which children may learn developmentally appropriate social and interpersonal skills. To the extent that attachment and subsequent socialization are undermined across the life span, neuropsychiatrically disturbed children are at increased risk for developing other forms of internalizing and externalizing disorders.

Some authors have argued that language-based psychotherapy is appropriate and potentially beneficial for persons with developmental disabilities if adaptations are made to simplify language, focus on more modest goals, and utilize strategies that are more effective given intellectual challenges (Prout, Thompson, and Douglas 1998). In conducting psychotherapy with individuals with developmental disabilities, Hurley (1989) has recommended six adaptations to the practices implemented with their cognitively intact counterparts: (1) use a directive approach, (2) involve family and caregiving staff in treatment, (3) alter the intervention to the individual's cognitive and developmental level, (4) recognize and acknowledge the individual's

interpersonal distortions and biases, (5) be flexible in selecting and applying interventions, and (6) assist the individual in accepting his or her disability. Treatment is facilitated by acknowledging the emotional and interpersonal needs of the child and by building into the treatment plan the means by which those needs can be met.

## PRINCIPLES OF BEHAVIORAL PSYCHOLOGY

Behavioral psychology has its roots in the early years of both experimental and clinical psychology. The application of classical conditioning paradigms found its early expression in the work of Watson (1924) and M.C. Jones (1924) in the treatment of childhood fears. Watson, in particular, is credited with establishing behavioral psychology's emphasis on empiricism and observable phenomena, a radical departure from the intrapsychic approach of psychoanalysis and the introspective tradition of early experimental psychology. Operant conditioning flourished under the leadership of its leading exponent and most prolific researcher, B.F. Skinner (1953). By the 1950s, experimental research with operant conditioning and classical conditioning paradigms had led, both directly and indirectly, to the design and evaluation of clinical interventions. Today, a considerable array of clinical procedures based on behavioral psychology is available to clinicians (Kazdin, 2001).

In this section we provide a brief overview of the basic principles of behavioral psychology. Many of these principles were originally identified in the laboratory with animal models, although their applicability to humans in general and to neuropsychiatrically impaired children in particular has been established. A thorough understanding of these principles is essential to the effective implementation of behavioral treatments. Indeed, a cookie cutter approach to behavior therapy, in which a series of techniques is indiscriminantly applied to targeted behavioral psychopathologies independent of a careful conceptualization, is unlikely to work. Instead, treatment should emerge from an understanding of the variables that cause and maintain maladaptive behavior patterns, as well as an appreciation for how environmental manipulations can alter these patterns.

### Operant Conditioning

Operant conditioning forms the basis of the majority of behavioral interventions used in pediatric neuropsychiatry. In operant conditioning, a behavior is followed by a consequence that either increases or decreases the probability that the behavior will occur in the future. *Reinforcement* increases the likelihood that a behavior will recur, whereas punishment decreases that likelihood. In *positive reinforcement* a pleasurable stimulus (e.g., praise, food) is presented, while in *negative reinforcement* an aversive stimulus is withdrawn

(e.g., escape from an unpleasant activity). Punishment consists of either the presentation of a noxious stimulus (e.g., yelling) or the removal of a pleasant stimulus (e.g., taking away a favorite toy). Temporal contiguity between the behavior and the consequence is critical: the interval must be short, often only a few seconds. Determining which stimuli are reinforcing or punishing is an empirical issue that can only be resolved by observing a stimulus' effect on the behavior (i.e., an increase or decrease in the probability of recurrence). *Intensity* of reinforcers and punishers is equally critical. Reinforcers that are intense and delivered to individuals in a relative state of deprivation will lead to a more robust and durable behavioral response. Likewise, if the individual is satiated, the effect of the reinforcer will be diminished. Punishers, too, must be intense in order to be effective. This phenomenon is one of the reasons that punishment is rarely used in clinical practice: ethical concerns preclude administration of aversive stimuli of sufficient intensity to significantly suppress an undesirable behavior. Moreover, the side effects of intense punishment are highly negative (e.g., pain, anger, anxiety, fearfulness).

Schedules of reinforcement pertain to the rules, or *contingencies*, under which reinforcers are delivered. In *continuous reinforcement*, a reinforcer is delivered each time a behavior occurs. *Intermittent reinforcement*, on the other hand, involves delivery of the reinforcer after the emission of more than one occurrence of the behavior or within a particular time frame. For example, ratio schedules require delivery of a reinforcer after a specific number of behaviors, and *interval schedules* dictate the delivery of reinforcers after a specific period of time has elapsed. Reinforcer delivery can be fixed (i.e., after every 10th response or after a 1-minute interval) or variable (i.e., after an average of every 10 responses or after an average interval of 1 minutes). Two variations of the above schedules of reinforcement are *differential reinforcement of other behavior* and *differential reinforcement of incompatible behavior* schedules, in which a reinforcer is delivered after an interval of time during which a particular behavior is *not* emitted. Differential reinforcement of other behavior and differential reinforcement of incompatible behavior schedules are widely used with neuropsychiatrically disturbed children who exhibit aggressive or self-injurious behaviors.

A final aspect of reinforcement is *fading*. In fading, the contingencies for delivering reinforcers are gradually shifted to require more responses (in ratio schedules) or a greater time interval (in interval schedules) between reinforcers. Fading creates a more durable response pattern and decreases the labor needed to deliver frequent reinforcers.

When the contingencies change so that a reinforcer is no longer delivered after a response, *extinction* will occur. The pattern of responding during extinction varies as a function of the reinforcement schedule previously in place. If responses were continuously reinforced, responding decreases quickly and eventually ceases. With intermittent reinforcement schedules, responding is more durable,

taking a longer time to drop off. Often, a significant increase in responding (i.e., an extinction “burst”) occurs when reinforcement is first withdrawn. For example, a preschooler’s tantrums that are reinforced by a parental attention may initially increase in frequency and intensity when the parent begins to ignore them.

Other important features of operant conditioning are *stimulus discrimination* and *generalization*. Discrimination describes the degree to which the individual distinguishes between specific features of the stimuli present in the setting where the reinforcer is delivered (e.g., a child is non-compliant with parents but not with teachers). Stimulus generalization is said to occur if the child is noncompliant in all settings in which demands are placed. When operant methods are used to increase positive behaviors (e.g., social initiation in a withdrawn child), generalization is desirable, that is, it is hoped that skills learned in the hospital unit will generalize to school and the playground. However, generalization rarely occurs unless it is specifically built into the treatment plan (Edelstein, 1989).

*Shaping* is the process by which complicated behaviors are taught by means of positive reinforcement. In shaping, *successive approximations* of the desired behavior are reinforced, with the criteria for receiving the reinforcer made progressively more stringent. In the case of the social withdrawal, a child may initially receive positive reinforcement for leaving his room in a hospital unit, then for gathering with other children, and finally for talking with them. Children with significant cognitive impairments will require a much finer breakdown of the behaviors to be subsequently shaped. A *task analysis* specifies the sequence of steps required to perform the targeted behaviors (e.g., brushing teeth). Task analyses are most often used with autistic and/or mentally retarded children.

## Classical Conditioning

Classical conditioning is a form of learning in which two or more stimuli become associated. It is generally viewed as a more passive form of learning than operant conditioning in that the targets to be altered are reflexive and autonomic responses rather than overt behaviors (operants). In classical conditioning, an unconditioned stimulus initially elicits an unconditioned response. For example, an individual may experience a traumatic event (unconditioned stimulus) and become extremely anxious (unconditioned response). A stimulus temporally contiguous with the unconditioned stimulus, referred to as the conditioned stimulus, subsequently elicits a conditioned response that is topographically similar to the unconditioned response. For example, the individual may experience anxiety in settings similar to those in which the traumatic event occurred. Therefore, classical conditioning involves the learned association between a conditioned stimulus and an unconditioned stimulus, which in turn leads to a conditioned response.

The conditioned stimulus must precede the unconditioned stimulus. Essentially, the conditioned stimulus alerts the individual that an unconditioned stimulus is coming. As in operant conditioning, the time interval between the conditioned stimulus and the unconditioned stimulus must be brief (i.e., 1 to 2 seconds). The only exception to this requirement is for *conditioned taste aversion*, in which the interval can be several hours. The conditioned response is strengthened by repeated pairings of the conditioned stimulus and the unconditioned stimulus. If the conditioned stimulus is intense, fewer pairings (or even only one pairing) will be needed to bring about a conditioned response. Presentation of the conditioned stimulus without the unconditioned stimulus results in extinction and a weakening of the conditioned response. Passage of time has little effect on the strength of the conditioned response. Stimulus discrimination and generalization (in which the conditioned response may be elicited by stimuli similar but not identical to the conditioned stimulus) also occur in classical conditioning.

Classical conditioning is important in the development or maintenance of several anxiety disorders, including specific phobias, posttraumatic stress disorder, social phobia, and obsessive-compulsive disorder. *Systematic desensitization* and *exposure* are two widely used behavioral interventions of anxiety disorders that are also based on classical conditioning. In pediatric neuropsychiatry, in which developmental disorders predominate, there are relatively fewer applications for classical conditioning. However, there has been a recent convergence of assessment and treatment approaches in the literatures on children with developmental disabilities and children with emotional and behavioral problems such that there is increasing overlap in implementation and outcomes (Clarke, Dunlap, and Stichter, 2002).

## Social Learning Theory

Unlike operant and classical conditioning, in which environmental factors predominate as determinants of behavior, social learning theory assigns a prominent role to cognition in the etiology of child psychopathology. *Modeling* is an important form of learning (Bandura, 1977) whereby children acquire knowledge by observing others. Attributions are also critical; self-efficacy, or the child’s belief that he or she is a competent person, promotes effective social behavior and is associated with overall well-being and mental health. The tenets of social learning theory are consistent with the cognitive focus of developmental psychopathology, developmental models of socialization and emotional regulation, and cognitive therapy. An important advance in social learning theory has been in our understanding of development of antisocial behavior in children and adolescents (e.g., Patterson, 1997). Because of its cognitive focus, social learning theory is less applicable to children with neuropsychiatric disorders who are non-verbal or cognitively limited.

## BEHAVIORAL ASSESSMENT AND TREATMENT

### Behavioral Assessment

Behavioral assessment operates under several assumptions. First, behavior is primarily controlled by environmental contingencies, and the functional relationship between environmental variables and specific target behaviors is the primary focus of assessment. Second, target behaviors must be operationally defined, observable, and measured reliably. Third, because behavior is likely to differ across settings, it is necessary to gather data from multiple venues in the child's life. And fourth, assessment and treatment are intricately linked, such that treatment plans should emerge from assessment data and should be periodically altered to reflect changes in patterns of behavior. Thus, unlike more traditional psychological assessments, in which measures are administered discretely before and after treatment, behavioral assessment is ongoing and continuous.

Behavioral assessment also takes into account the numerous factors that influence the child's clinical presentation (MacDonald, 2003). These factors include the child's physical health, genetic liability to psychiatric disorder, neurological impairment, family system, and growth and psychosocial development.

What is categorized under the rubric of behavioral assessment techniques has expanded greatly over the years. Originally, *direct observation of behavior* in the natural environment was the defining feature of behavioral assessment, and this method remains the cornerstone of data gathering. With this approach, target behaviors are operationally defined, clear criteria for their occurrence are stipulated, and exploratory samplings are conducted during which the behavior is measured. Behaviors can be counted (e.g., number of hostile verbalizations) and timed (e.g., number of minutes spent mouthing an object in a given hour), or a behavior can be recorded as having occurred or not occurred during a specific time interval (e.g., out of seat at any time during 5-minute intervals). *Antecedents* (events that precede the emission of the behavior) and *consequences* (responses to the behavior) are also recorded. Reliability checks are conducted to ensure that data are being collected in an accurate and consistent manner. Data are collected prior to (baseline) and during treatment.

Single-case experimental designs (Tervo, Estrem, Bryson-Brockmann, and Symons, 2003) are used to evaluate an intervention's effectiveness. Examples of such methodologies include the *alternate-treatments design* (A-B-A-B), in which the intervention is alternately introduced and removed, with the expectation that the behavior will change in the predicted direction as a function of the intervention, and the *multiple-baseline design*, in which the intervention is introduced sequentially across classes of behavior or across settings.

Observation can also be conducted in analog fashion; examples include simulated social interactions (role-play

tests) and clinician-directed parent-child interactions (i.e., asking a parent to place a demand on the child so that their interactions can be observed). Behavioral assessment also measures products of treatment, such as body weight (in a weight-loss program), physiological arousal (in an anxiety-reduction intervention), or number of items correct on a test (in a program for ADHD).

Most behavior therapists incorporate additional forms of measurement in their assessments, including self-report questionnaires, semistructured and structured interviews, symptom checklists, personality assessments, functional skills inventories, diagnostic interviews, cognitive and developmental functioning tests, and family functioning indices, to name but a few. This broadening of the definitions of behavioral assessment is viewed by most behavior therapists as a positive development in that it brings together approaches to data gathering that have as their common feature a reliance on empirical methods for instrument development.

### Behavioral Treatments

#### General Issues

Before specific behavioral interventions are addressed, we note several implementation issues critical to the successful outcome of behavior therapy.

First, behavior therapy involves considerable effort on the part of the clinicians and caregivers. Restructuring environmental contingencies requires the participation of parents, teachers, and others in the child's life. Indeed, the time commitment required may discourage families and clinicians from embarking on behavioral treatment plans. However, considerable evidence exists of the shortterm and longterm benefits of behavior therapy, and caregivers frequently underestimate the amount of time they already spend responding (usually without positive effect) to psychopathological behavior in their children.

A second issue is *consistency in carrying out behavioral interventions*. Behavioral programs are extremely sensitive to inconsistent implementation, which typically results in failure. For example, if a reinforcement program is administered correctly by the child's mother but incorrectly by the father, the intervention is likely to collapse. A general rule of thumb is that clinicians should enlist the active cooperation and involvement of caregivers before proceeding with the intervention. Toward this end, therefore, behavior therapy requires a partnership between families and clinicians. A corollary to this rule is that it is best not to begin a behavioral intervention until the family's active and full participation has been enlisted; otherwise, the plan will fail, and the family will attribute that failure to the specific intervention, thereby undermining future attempts by other professionals to use behavioral approaches.

A third issue is the ethical and legal imperative to *use the least restrictive intervention possible* when designing and carrying out treatments (Sprent and Jampol, 1997). This prin-

principle means that interventions should be as unintrusive as possible, provide maximum freedom and choice to the patient, and be conducted in settings that are open and uncontrolling. Failure in these settings justifies interventions that are more restrictive in nature, although it is imperative that such failure be well documented before alternative settings or treatments are pursued. In the case of behavior therapy, it is virtually universally recognized that positive approaches to behavior change are preferable to punishment, and that, should aversive interventions be used, a positive behavioral program should be part of the overall treatment package.

A fourth consideration is *concurrent implementation of behavior therapy with other treatments*. It is generally believed that behavior therapy is a less restrictive form of treatment than some kinds of pharmacotherapy and thus should be tried before medications are prescribed. In practice, however, the use of behavior therapy prior to pharmacotherapy is the exception rather than the rule. Although the underuse of behavior therapy can be partly attributed to lack of training in or appreciation of behavior therapy as an efficacious treatment on the part of mental health practitioners, it is also the case that severe psychopathologies, particularly those involving aggression or self-injury, often require multiple interventions, and that such combined interventions are more likely to lead to a rapid treatment response. Thus, concurrent use of behavioral and somatic treatments is often desirable. Although the literature on concurrent use of medications and behavioral treatments in children is sparse, preliminary evidence suggests that these approaches may have additive or synergistic effects (see Pelham, et al., 2000). There are few scenarios in which such combined treatments are contraindicated, except perhaps in the anxiety disorders (e.g., the use of anxiolytics in patients with specific phobias may interfere with extinction of conditioned anxiety).

## Behavioral Techniques

Specific behavioral interventions should emerge from the *functional assessment*, in which the antecedents and consequences of targeted behaviors are identified. Patterns of behavior are examined to establish contextual parameters in which the behavior is likely to occur. During this stage, potential reinforcers are also identified by observing the child and interviewing the child and caregivers. For children who are nonverbal or who have profound cognitive impairments, identifying an array of potential reinforcers can be quite challenging. Creativity is often required to generate toys, objects, smells, or tactile stimuli that might be reinforcing. *Reinforcement sampling* (Patel, Carr, Kim, Robles, and Eastridge, 2000) refers to the process whereby simple behaviors are shaped by introducing a variety of potential reinforcers in an effort to identify those stimuli with the strongest reinforcing properties. In this paradigm, potentially reinforcing stimuli are first presented to the child in an effort to determine their relative pleasantness

(approach) or unpleasantness (avoidance). To evaluate their strength, stimuli that appear to be reinforcing are then used to teach the child simple tasks. In this way, a menu of reinforcers is created that can be used in more complicated behavioral programming. Assumptions should not be made about what stimuli might or might not be reinforcing; social praise may mean little to an autistic child, and a neurologically impaired child may be overstimulated by physical touch and find such stimuli aversive.

For most children with neuropsychiatric disorders, it will be desirable both to decrease negative behaviors (i.e., aggression, defiance, noncompliance, inattention, self-abuse) and to increase positive behaviors (e.g., social initiation, social skills, recreational skills, problem-solving skills, self-control skills). Positive behavioral programming (Gresham, et al., 2004) encompasses behavioral interventions that are based on positive reinforcement and that are minimally restrictive in nature.

The first step in behavioral interventions is to *structure the environment*. The functional assessment will have revealed stimuli or settings in which the behavior problem is most likely to occur. Changes in these settings or in the child's routine may be the most effective (and certainly the least intrusive) way of reducing maladaptive behaviors. For example, many autistic children react negatively to changes in routine or transitions during the day. Ample advance warning about upcoming transitions, or ensuring that such changes are not abrupt and unexpected, may prevent negative reactions.

*Positive reinforcement* is the centerpiece of any behavior program. Positive reinforcement is not only a less restrictive intervention; in addition, because it has as its focus the learning of new behaviors, it has the potential to enhance the behavioral functioning of the child rather than simply suppressing an undesirable behavior. Reinforcing stimuli are identified through the functional analysis conducted during behavioral assessment as well as through reinforcement sampling. Behavioral interviews with the family and child (if possible) are also sources of information about reinforcing stimuli. Differential reinforcement of other behavior and differential reinforcement of incompatible behavior schedules are implemented to decrease aggressive or self-abusive behaviors; other reinforcement schedules are used when new behaviors are to be learned. With differential reinforcement of other and differential reinforcement of incompatible behavior schedules, reinforcement is delivered contingent upon a behavior's absence.

*Differential reinforcement of appropriate response* schedules target specific behaviors for reinforcement that are directly incompatible with the aberrant behavior and that serve to enhance the child's overall functioning. Initially, contingencies should be structured so that the child is highly likely to earn rewards. Effort on the part of the clinician, staff, and family is greatest at this point.

*Prompting, manual guidance, and shaping* are critical approaches in the early implementation stages of reinforcement

programs for teaching new skills and behaviors. As the child receives reinforcers and successfully adapts to the program, the contingencies are gradually made more stringent (*fading*). To promote *generalization* of learned behaviors to other settings or with other caregivers, the program is then expanded to these areas. Failure to actively promote generalization will likely result in rapid deterioration after discontinuation of treatment. Using reinforcers that are likely to occur in the child's natural environment is the best way to facilitate generalization.

For behavior problems that are reinforced in the child's natural environment (e.g., tantrums reinforced by parental attention), *extinction* is often employed. In this procedure, the reinforcing stimuli are withdrawn in the hope that the behavioral problem will decrease or disappear if it is not reinforced. As previously mentioned, a brief increase in intensity of the behavior (the extinction "burst") is to be expected when the reinforcing stimuli are first withdrawn. Extinction should never be the sole intervention used, for the simple reason that it is an approach that is almost impossible to implement consistently. Almost invariably, someone in the child's environment will inadvertently reinforce the negative behavior, thereby providing intermittent reinforcement and strengthening the behavior's resistance to extinction. Extinction is more likely to be effective if used in conjunction with other behavioral interventions.

For self-stimulatory or self-abusive behaviors, which are often controlled by internally-based reinforcers rather than environmental ones, *sensory extinction* is a variable treatment. In this procedure, the reinforcing aspects of the behavior are reduced or eliminated (e.g., a desk is padded with soft material for a child who head-bangs on that surface). Such an intervention can be quite effective in combination with differential reinforcement of other behavior, differential reinforcement of incompatible behavior, and differential reinforcement of appropriate response schedules. Under controlled conditions, extinction has been found to be an effective intervention. For example, Iwata and colleagues (1990) used extinction to treat hand biting, face hitting, and head banging in seven children and adolescents with mild to profound mental retardation. Withdrawal of reinforcing stimuli (e.g., escape from demand, attention) results in clinically significant reductions in self-injury.

*Functional communication* (e.g., Kahng, Hendrickson, and Vu, 2000) has recently emerged as a major treatment option for neuropsychiatrically disturbed children who are nonverbal or who have limited language abilities. This approach derives from the assumption that aggressive, self-abusive, and self-stimulatory behaviors occur partly as a result of frustration secondary to ineffectiveness in one's environment and problems in communicating needs and wants. Accordingly, teaching children alternative ways of communicating ("I need help" or "I want a break") by using assistive devices or sign language should reduce frustration and lead to decreases in aberrant behavior. Functional communication also teaches children alternative

ways (e.g., other than acting out) to escape aversive situations, thereby circumventing the negative-reinforcement contingencies that can maintain aggressive and self-stimulatory behaviors.

*Punishment paradigms* should be used only 1) when positive reinforcement methods have been tried and have failed, 2) in conjunction with positive reinforcement programs, 3) when the clinical consequences of the behavior problem are seriously detrimental to the child or others, and 4) after being appropriately reviewed by the treatment team or an independent body (e.g., human rights committee) (National Institutes of Health, 1991). Depending on the setting, state and federal regulations typically mandate extensive restrictions on the use of aversive approaches. *Response cost* is a relatively mild aversive procedure in which reinforcers are withdrawn contingent upon the emission of a targeted negative behavior. Essentially, it involves a penalty used in the context of a positive reinforcement program. Response cost procedures may bring about a more rapid treatment response; these have been found to be especially helpful in children with disruptive behavior disorders (Musser, Bray, Kehle, and Jenson, 2001). *Overcorrection* involves requiring the child to undo or correct (i.e., make restitution for) the damage resulting from an aggressive behavior (e.g., throwing objects) and then to carry out a series of steps (e.g., using the object appropriately) incompatible with the acting-out behavior (positive practice). *Time-out* is a procedure whereby the child is removed from a setting in which negative behaviors are being reinforced to an area where no such reinforcement is possible. The time-out may involve moving to the corner of a classroom away from the group (exclusionary time-out) or being isolated in a separate room with the door closed (seclusionary time-out). In most settings, types and durations of time-out are quite restricted. Time-out is most effective if it is quickly implemented, of short duration, used with behavior problems maintained by social reinforcers (which are absent in the time-out situation), and not in itself reinforcing (i.e., positively reinforcing by attracting attentions, or negatively reinforcing by allowing the child to escape an unpleasant task).

In general, punishment should be used sparingly. As previously noted, the side effects of punishment (e.g., fear, anger) are undesirable, and punishment procedures do not by themselves teach the child alternative behaviors. Moreover, these approaches are easily abused. The role of punishment in the treatment of neuropsychiatrically impaired children is still a matter of debate, however, and some advocate its use for cases of severe self-injury in which other interventions have been ineffective.

### Token Economy

Token economics emerged in the 1960s as an important approach to behavioral change in developmentally disabled and neuropsychiatrically disturbed children.

Essentially, a token economy is a system in which contingencies are established for the earning of objects or symbols that in turn are exchanged for reinforcers. The rules for earning, losing, and exchanging tokens, as well as the types of reinforcers that can be earned, are established by the clinician. Because the token economy is designed to influence groups of people, it is employed in closed and controlled settings such as classrooms, inpatient units, and group homes.

Tokens have no reinforcing properties by themselves; they usually consist of chips, paper cutouts, or points on a card. Williams, Williams, and McLaughlin (1989) noted that, to be effective, tokens should be easily dispensed, easy to carry and exchange, draw little attention away from the task at hand when distributed, and have an understandable exchange value. Tokens are secondary reinforcers, that is, they gain their reinforcing qualities by their association with primary reinforcers. To the extent that the primary reinforcers are salient and powerful, the tokens will also take on those features. As with all reinforcement programs, success is dependent upon establishing a menu of desirable reinforcing stimuli with which tokens are paired. If the child does not find the stimuli to be reinforcing, the token system will deteriorate and fail. Likewise, if the contingencies for earning tokens are too stringent and difficult for the child, motivation will decrease and the system will not work. If the child has several reinforcers from which to choose, the token system is more likely to be effective. Thus, a good economy has an array of reinforcing stimuli and allows the child to earn tokens readily.

Tokens are typically used for group management. For example, inpatient units may have a levels system whereby privileges are earned through points awarded contingent upon maintenance of self-control and participation in ward programs. There also exists a sizable literature documenting the use of token economies as primary treatment modalities (Martin and Pear, 2002). Indeed, token economies were originally developed to treat, rather than simply manage, behavior problems. Examples of treatment targets include social initiation, compliance, delusional verbalizations, and language acquisition.

Token economies have several advantages over other interventions. Tokens are effective reinforcers, and provision of a menu of reinforcers decreases the likelihood of satiation. Moreover, a token economy is a relatively less restrictive form of intervention, tokens can be paired with social reinforcers (e.g., praise) to enhance their reinforcing strength, and tokens can be used to promote generalization of learned behaviors to other settings.

Paradoxically, despite the demonstrated effectiveness of token economies, their use has decreased, and they are rarely established for reasons other than group management. A number of factors are responsible for this decline, including concerns about cost, the labor required to set up and maintain a token system, potential problems arising

from the use of extrinsic rewards for social behaviors, legal limitations on what can and cannot be administered to individuals contingently, and problems with generalization. However, token economies are cost effective, run smoothly when implemented properly, and can be easily manipulated to fade reliance on tangible reinforcers and promote generalization to other settings (Martin and Pear, 2002). For these reasons, they should be considered a viable and highly successful approach to behavior change.

### Summary of Behavioral Assessment and Treatment

It is clear that behavior therapy encompasses a series of approaches and techniques embedded within a theoretical conceptualization of how aberrant behavior originates and how it can be altered. Haphazard application of behavioral strategies in the absence of a careful case formulation is almost certain to fail. Rather, for behavior therapists, assessment and treatment are tightly woven together, each influencing the other in a dynamic manner.

Table 30.1 presents a summary (grouped by type of approach) of the behavioral interventions outlined in this section in order to articulate a step-by-step approach to behavioral assessment and treatment. It should be emphasized that the selection of appropriate interventions must arise from the assessment. Moreover, the choice of treatment may change as the ongoing assessment reveals new functional relationships and areas in need of intervention.

Assessment begins with the *behavioral interview*. This interview differs somewhat from other clinical interviews in that its primary goals are to identify factors relevant to behavioral intervention. Thus, in addition to gathering information on interpersonal, family, and school functioning, the behavioral interview focuses on specific parameters of problem behaviors (severity and frequency), antecedents and consequences of behaviors, settings in which the behaviors may be better or worse, skills that the child may have, and potential reinforcers that may maintain or increase negative behaviors or that may subsequently be used in a reinforcement program. From the beginning, then, information gathering focuses on features that will be incorporated into treatment.

Behavior therapists also employ *standardized assessments*, which are useful in comparing the child's behavior with that of relevant normative or control groups. Moreover, specific items on some standardized measures may lead to a better understanding of factors contributing to the behavior and controlling its expression. As in any clinical assessment, collection of information from multiple sources is imperative. Nonetheless, such measures are not integral to treatment selection and treatment effectiveness monitoring; rather, they supplement the behavioral measures articulated earlier in this chapter.

*Direct observation* is the cornerstone of behavioral assessment. Recording the occurrence and parameters of

**TABLE 30.1**  
**SUMMARY OF BEHAVIORAL ASSESSMENT AND TREATMENT APPROACHES TO BEHAVIORAL DISORDERS IN PEDIATRIC NEUROPSYCHIATRY**

<b>Assessment</b>		
<b>Steps</b>	<b>Approach</b>	<b>Objectives</b>
1.	Behavioral interview	Obtain information from patient, family, and other caregivers regarding frequency and severity of behavior problem, antecedents and consequences, stimulus control, social skills, coping skills, cognitive style, and reinforcers.
2.	Self-report and report by others	Using standardized instruments and checklists, gather information about behavior problems and overall psychosocial functioning.
3.	Direct observation	Directly monitor and record parameters of behaviors, and related variables of interest (e.g., antecedents and consequences).
4.	Functional assessment	Manipulate environmental factors to determine functional relationships between such factors and behavior.
5.	Additional assessments	Conduct additional assessments that may be etiologically important or have implications for treatment selection and effectiveness (e.g., neuropsychological evaluation, neuroimaging studies).
<b>Treatment</b>		
<b>Behavioral Intervention Approaches</b>	<b>Illustrative Strategies</b>	
Operant conditioning	Positive reinforcement programs, contingency management, token economy, skills training, relaxation training	
Classical conditioning	Systematic desensitization, flooding, other counterconditioning interventions	
Cognitive approaches	Cognitive therapy	

behavior problems in the environments in which they are exhibited is essential both for documenting the severity of these problems and for monitoring changes resulting from intervention. Direct observation also permits identification of antecedents, consequences, and environmental stimuli that may influence the behavior.

The *functional assessment* involves manipulation of environmental factors to observe their impact on the expression of behavior. In this way, the functional relationship between environmental variables and behavior can be ascertained, and changes can be made in those variables associated with an increase in aberrant behavior.

Finally, information gathered from *other assessment approaches* may be critical to understanding the etiology and treatment of behavioral disorders. *Imaging studies* may implicate specific neurological contributions. Likewise, *neuropsychological evaluations* may identify neurocognitive impairments and learning difficulties. Because such phenomena may interfere with learning, behavioral interventions may need to be adapted for optimal effectiveness.

## **FAMILY ADAPTATION AND INTERVENTION**

Historically, the family was viewed as the primary etiological influence in child neuropsychiatry and psychology.

Psychopathology and behavioral disturbances in children were attributed to dysfunctional family systems in general, and to inappropriate parenting practices in particular. Another widespread belief was that raising a child with a disability led to longterm family distress and, in some cases, psychopathology in family members. In other words, a disabled child results in a disabled family.

More modern research, however, has largely dispelled the myths that neuropsychiatrically impaired children necessarily emerge from dysfunctional families and that all families fail to adapt to childhood disabilities (Quittner and DiGirolamo, 1998). Instead, it is increasingly apparent that the etiologies of neuropsychiatric disorders are multi-determined and frequently involve processes that are out of the direct control of family members (e.g., genetic anomalies, neurological damage) (Schuntermann, 2002).

Most recently, research has started to track resiliency factors; those aspects of the family environment and interpersonal traits that increase the likelihood of positive adaptation. Resiliency, simply defined, is the presence of adequate social resources and coping strategies to allow the family to successfully adapt to the added strain of disability. In other words, the presence of positive family traits may more than compensate for the presence of family pathology in adaptation (Hastings and Taunt, 2002). This is not to say that dysfunctional family systems play no role in the etiology, maintenance, or exacerbation of child

psychopathology. On the contrary, a rich and growing scientific literature is documenting such relationships and evaluating effective treatments for children and their families (Henggeler, Schoenwald, and Pickrel, 1995). But current models of family adaptation to children with disabilities in general and neuropsychiatric disorders in particular, highlight the importance of mediating factors, both positive and pathological, as critical determinants of functioning. These variables shift in their relevance, intensity, and influence, resulting in changes in family responding over time. Adaptation, therefore, is best characterized as a continuous process, rather than static, and an interactive, reciprocal process rather than linear.

Although virtually all children with neuropsychiatric disorders can be said to place strain on the family, the manifestation of stressors will vary from child to child depending upon the neuropsychiatric impairment. Numerous features of the child's disability have been implicated in family adaptation, including functional limitations, impact on language, externalizing symptoms, additional time required to care for the child, depletion of tangible resources, and disruptions in routine. Strain, in general, is exacerbated by the lack of predictability that may accompany certain neuropsychiatric disorders, such as epilepsy and traumatic brain injury (Cohen, 1993; Franks, 2003). This lack of predictability manifests as everyday, daily hassles of living that are more important stressors than intermittent negative life events in producing strain on the family, as is the inability to establish and maintain daily routines due to the fluctuating demands of the disability.

Family and social support are primary resiliency factors, as they can buffer the impact of caring for a difficult-to-manage child regardless of the type of neuropsychiatric disability. A distinction is made between *social support* (in which the family has someone on whom it can rely for emotional and tangible assistance) and *social network* (the number of contacts with others). Social support, or *quality*, of interpersonal contacts, appears to be more important than social network, or *quantity*, of contacts, for psychological health (Perlesz, Kinsella, and Crowe, 1999), although the two are clearly related. Respite care is an important resource for giving parents a break from caring for their child as well as an opportunity to increase their social networks and to build supportive relationships outside of professional care systems.

Families of children with disabilities often have limited social networks as the result of the particular features of the child's disability. Others may not wish to associate with them because of the stigma of neuropsychiatric disorders, such as with seizures in epilepsy or the lowered cognitive functioning in a child with developmental delay (Ellis, Upton and Thompson, 2000; Melnyk, Feinstein, Moldenhouer, and Small, 2001). Both adults and children may experience difficulties in relating to or being around children that fail to reciprocate in social interactions; for example, the child with autism. The child with ADHD may be

impulsive and behave with other children in such a way that limits the ability to successfully make friends. Also, curtailed mobility of the child (e.g. wheelchair reliant) may limit access to social networks and more normative family activities and interactions.

Adding to family stress is the realization that, even with appropriate therapies and interventions, features of the disability may be present lifelong (Majovski, 2000; Perlesz, et al., 1999). When parenting a child without disabilities, parents recognize the time-limited nature of the child's lack of abilities, such as walking and talking. As children undergo normal development, these stressors subside; as when a child learns to walk, so increases the mobility of the family, or when a child learns to use language to make requests, relieving the parent of the responsibility of trying to ascertain the needs of and speaking for the child. Conversely, the families of children with neuropsychiatric disabilities may anticipate a lifelong responsibility for a child with restricted mobility or who lacks the cognitive functioning to successfully use language to express basic needs.

Children with less physically impairing disabilities may still place strain on the family in other ways. For example, children with ADHD are, overall, more impaired in educational settings. They are more likely to be suspended or expelled from school, to underachieve academically, and to be held back a grade than children without a disability. While these traits create longterm challenges for the individual as he or she moves into young adulthood, the family feels the strain during the childhood years; parents may spend considerable extra time in contact with school staff.

Other stressors in the family may also undermine adaptation. Financial hardship, family violence, inadequate housing, and neighborhood violence further add to family stress. Coping styles of individual family members and the family unit as a whole moderate the impact of stress and foster resiliency. Parents with effective problem-solving skills and optimistic cognitive styles are more likely to cope effectively with adversity or the daily stressors of raising a neuropsychiatrically impaired child. Families with limited cognitive abilities or few psychosocial resources will be less effective in coping with stressors (Sloper and Turner, 1993).

Family adaptation is also influenced by parental expectations and attributions. Excessively high expectations about the child's abilities, rigid beliefs about how children should behave, and erroneous attributions of a child's behavioral dysfunction to purposeful intent erode the parent-child relationship and contribute to family dysfunction. This effect points to the need for parental education about the particular disability as an intervention to aid in the family's successful adaptation to and parenting of a child with a developmental trajectory and pattern of behavior unique to their particular disability (Schuntermann, 2002).

Family adaptation is affected by features of the parent-child relationship. Failure of a child to establish a secure attachment with caregivers will negatively affect family adaptation. This is particularly challenging with

neuropsychiatrically impaired children, such as those with autism, who are less able to reciprocate in interpersonal relationships thus resulting in less attachment. Temperamental mismatches between a parent and a child with a disability may also be implicated in family distress. Parental premorbid functioning also contributes to family adaptation. Family functioning can be negatively affected by parental psychiatric disorder, particularly substance abuse and other disorders that lead to family instability (e.g., psychoses).

As is the case with psychological and behavioral treatment of children, family-based interventions should emerge from a comprehensive assessment. Numerous measures are available that can be used to assess aspects of family functioning (e.g., communication, rituals, relationships), social support, parental psychiatric status, and parents' attitudes toward their children. From this assessment, a range of intervention options can be constructed. Some families will require greater community resources, such as self-help groups or respite programs. Others will require extensive education about their child's disorder or will need instruction on child development and basic child care. Still others will require more intensive therapeutic intervention to remediate dysfunctional aspects of family interactions and relationships, including help in facilitating the adjustment of other children (without disabilities) in the family. In certain cases, it will be desirable for the parents to receive treatment for psychiatric disorders.

In order for behavioral interventions for children to be successful, parents must be partners in implementing these programs. *Parent training* involves instructing parents in how to implement behavioral programs for their children. Although parent training is essential for parents with deficient parenting skills, it is typically provided to all parents who are required to carry out behavioral interventions at home. An added therapeutic benefit of such training is that it empowers parents and families to actively work toward the remediation of the child's behavioral problems. Parents are taught specific behavioral skills (e.g., reinforcement, contingency contracting) to improve child management, reduce reliance on physically punitive strategies, and increase nurturing and relationship-enhancing behaviors. Although several widely used parent-training protocols exist (e.g., Baker, 1989), they all share several features. First, they are highly structured and didactic. Second, they involve the extensive use of in-clinic training with at-home practice. And third, they use behavioral training principles, including modeling of skills by therapists, practice through simulated role-playing and/or in-clinic analogs, and feedback provided to parents by therapists.

## SUMMARY

The comprehensive treatment of neuropsychiatric disorders in children requires an integrated approach that incorpo-

rates both psychological and somatic interventions. Assessment involves measurement of social, emotional, behavioral, cognitive, neurological, neurophysiological, and other medical domains of functioning. Although a variety of psychological interventions for behaviorally disturbed children are available, recent meta-analyses have supported the superior effectiveness of behavior therapy. Behavioral strategies have special relevance for children with developmental disabilities or neuropsychiatric impairments, including those with significant cognitive limitations.

Core features of psychotherapy (e.g., establishing a therapeutic alliance) must be altered to maximally benefit children and adolescents with developmental disabilities and neuropsychiatric disorders. Within the larger assessment of clinical psychopathology and child functioning, behavioral assessment is carried out to identify functional relationships that serve to maintain or exacerbate behavioral dysfunction. Interventions are developed on the basis of this assessment. Principles of learning are applied to increase social and other skills and to decrease maladaptive behaviors. Ongoing observational assessment provides data regarding the effectiveness of the intervention and guides needed alterations in the intervention. In general, treatments pursued should be the least restrictive possible and should incorporate interventions based on positive reinforcement. Treatment necessarily requires family participation, although some families will need additional intervention. Families with few social and psychological resources are those at greatest risk for maladaptive responses to raising a neuropsychiatrically impaired child.

# Interventions in

# Pediatric Neuropsychiatry

31

**Jeffrey A. Miller, MD** **Stephen Bagnato, EdD** **Carl J. Dunst, PhD**  
**Hillary Mangis, MEd**

Brain injury or malfunctioning occurs all too frequently in children and adolescents (Annegers, 1983; Frankowski, Annegers, and Whitman, 1985; Langlois and Gotsch, 2001; Moyes, 1980; Snow and Hooper, 1994). Two broad areas of science—the biological and the behavioral—have contributed substantially to our understanding of the causes and sequelae of brain disorders. Research in the neurosciences generally and in neuropsychiatry specifically has advanced our knowledge of brain–nervous system–behavioral disorder linkages, while research in neuropsychology, psychology, and education has enhanced our understanding of the behavioral manifestations of neurological impairments and of how environmental interventions can influence these behaviors in an adaptive manner. According to Mrazek and Haggerty (1994), there is an “increasing tendency within the biological and behavioral sciences to appreciate the complexity and interplay of genetic and environmental interactions” (p. 498). This renewed appreciation reflects an increased recognition of the environment’s vital role in influencing both brain functioning and the behavioral characteristics associated with brain disorders.

In this chapter we discuss a number of themes and critical elements of emerging best practice in one domain of environmental influence, psychoeducational interventions. Our purpose is not to describe in detail specific kinds of psychoeducational interventions; such detailed discussions can be found elsewhere (e.g., Cohen, 1991; Eslinger, 2002; Ewing-Cobbs, et al., 1986; Glang, et al., 1992; Semrud-Clikeman, 2001; Snow and Hooper, 1994). Rather, our intention is to present a framework that pediatric neuropsychiatrists can use to ensure that appropriate educational interventions are developed and implemented for children and adolescents with neuropsychiatric disorders. More specifically, it is our goal in this chapter to provide pediatric neuropsychiatrists with information they can use to bridge neuropsychiatric diagnoses with environmental interventions that have a high probability of producing positive, socially adaptive outcomes and to identify facilitators and inhibitors for success of these environmental interventions.

The chapter is divided into six sections. In the first, we briefly discuss the importance of both neurobehavioral markers and behavioral characteristics of neuropsychiatric disorders in children and adolescents and show how these markers and characteristics can inform the use of appropriate psychoeducational interventions. In the second section, we describe several assessment and classification systems used in psychology, special education, developmental disabilities, and related interdisciplinary fields. These systems are important because their purposes, functions, and methods differ from those of the system used almost exclusively by professionals in the neuropsychiatric community, the *Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition-Text Revision (DSM-IV-TR)* (American Psychiatric Association, 2000). In the third section of this chapter, we outline the characteristics of psychoeducational intervention approaches best suited for children and adolescents with neuropsychiatric disorders. These characteristics are ones that collectively define emerging best practice in terms of those psychoeducational interventions having the greatest potential to produce positive benefits. In the

fourth section, we address the broader-based context of physician–family–school relationships, including the current call for adoption of family-centered approaches to neurobehavioral problems. Family-centered interventions have emerged as a philosophy and approach for ensuring that family members are supported and meaningfully involved in the diagnostic and care processes so that they in turn can interact with their children in ways that support the children’s behavioral and developmental progress. In the final two brief sections intervention effectiveness research is examined and a case example provided in which the seven elements of psychoeducational interventions are highlighted.

## NEUROBEHAVIORAL MARKERS AND PATTERNS OF BEHAVIOR IN CHILDREN WITH BRAIN DISORDERS

Researchers in a number of basic science and applied fields (e.g., early intervention, developmental disabilities, developmental pediatrics, developmental neuropsychology, medicine, neuropsychiatry) have become increasingly interested in brain–behavior relationships and how those relationships influence behavioral and developmental outcomes in children with brain disorders (e.g., Johnson, 1993). Whereas neuropsychiatrists may focus on the particular mechanisms that lead to brain disorders, including the defining characteristics of specific types and subtypes of psychiatric or neurological conditions, psychoeducational interventionists focus primarily on the behavioral consequences of brain disorders and the environmental conditions best suited to promoting adaptive functioning in individuals with such disorders. Psychoeducational interventionists differentiate between the *antecedents* (i.e., risk markers) of specific kinds of disabilities and the behavioral characteristics that represent the *consequences* of these conditions. This distinction is an important one, because it is the latter (i.e., the *patterns of behavior* associated with a disability or impairment) that are the focus of psychoeducational interventions.

### Risk Markers

Problems accompanying brain injury or malfunction are often correlated with particular behavioral markers; that is, specific risk factors associated with the onset, severity, and patterns of particular neurodevelopmental problems or behaviors. For example, the onset of pervasive developmental disorders, including autism and childhood schizophrenia, is often preceded by signs such as unusual eye movements. According to Mrazek and Haggerty (1994), such signs *mark*, or identify the potential for, different kinds of problems or unfavorable outcomes. However, although for psychoeducational intervention a risk marker may indicate the *need for intervention*, it may not necessarily be the *target* of such intervention. Rather, as

indicated above, the consequences are the typical targets of psychoeducational interventions.

Specific risk markers have been found to be associated with both congenital and acquired brain injury and malfunctioning. For example, young children who subsequently manifest developmental delays and disabilities are often found to have had early disturbances in areas of self-regulatory functioning related to sleep patterns, feeding, attention/activity, arousal, sensory organization, coping with environmental changes, and control of emotional behavior (DeGangi, 1991; Neisworth, Bagnato, and Salvia, 1995). Many of these self-regulatory problems are also found in children who have been prenatally exposed to drugs, who have sustained subtle brain insults prenatally or postnatally, who have difficult temperament styles, or who have particular kinds of congenital syndromes (Bagnato and Campbell, 1993; Coie, et al., 1993; Drotar and Strum, 1991; Yeates, Ris, Taylor, 2000). Acquired brain damage, whether resulting from injury or disease, has been found to be correlated with various kinds of risk markers that can be used both in diagnosis and in decisions about the need for intervention (Snow and Hooper, 1994).

From a psychoeducational perspective, the importance of risk markers is rather straightforward. The presence of markers known to be associated with brain-related problems signals the need for interventions to prevent or deter the emergence of maladaptive functioning and to promote and enhance adaptive behavior and competence (DeGangi, 1991). In general, the more risk markers present, the higher the probability of adverse consequences and thus the greater the need for intervention. For example, intrauterine growth retardation is associated with as many as eight biological risk markers (Harel, et al., 1991) in addition to related physical and behavioral risk signs (Harel, et al., 1993). Similarly, children who have experienced brain trauma often manifest a number of symptoms and complications that collectively indicate the presence and severity of brain damage and the need for intervention (Semrud-Clikeman, 2001; Snow and Hooper, 1994).

### Behavioral Characteristics and Templates

As previously noted, combinations of risk markers and other neurobehavioral indicators are often used to diagnose brain disorders. Emerging evidence reveals that many neurological disorders are presaged by specific signs and markers, and that certain disorders are associated with specific clusters of behavioral characteristics (Hertzog, 1983; Miller and Ramer, 1990; Rourke, et al., 2002; Thompson, 1989; Whitney and Thoman, 1993). Although individuals with different disorders often manifest similar behavioral characteristics, it is nonetheless possible to construct neurobehavioral templates that can be used to differentiate disorders with similar presentations, to select the optimal targets and approaches for psychoeducational interventions, and to anticipate the emergence of intervention targets over the developmental

period. For example, Table 31.1 shows behavioral characteristics associated with four different brain disorders. Delineating such disorder-specific neurobehavioral characteristics is an important prerequisite to identifying and differentiating the antecedents from the consequences of the disorder (as previously emphasized, it is the latter that become the targets of psychoeducational interventions).

**TABLE 31.1**  
**PATTERNS OF BEHAVIOR ASSOCIATED WITH**  
**SELECTED BRAIN DISORDERS**

#### **Fragile X Syndrome**

Deficits in social play skills  
Gaze avoidance  
Repetitive motor behaviors  
Social communication deficits  
Hyperactivity/attention deficits  
Object mouthing  
Excessive tantrums  
Self-injury  
Hyperreactivity to new events

#### **Autistic Spectrum Disorder**

Absence of pretend play  
Imitative deficits  
Sensory hypersensitivities  
Poor adjustment to change  
Disorganized play  
Hyperactivity  
Self-stimulation  
Social communication deficits

#### **Rett Syndrome**

Normal development for first 6 months  
Head-growth decline  
Loss of purposeful hand skills  
Decline of neuromotor, language skills  
Stereotyped midline hand movements:  
    wringing/squeezing/clapping/tapping/mouthing/washing/  
    rubbing  
Breath holding  
Teeth grinding  
Facial tics  
Torso tremors  
Seizures/staring

#### **Early Brain Injuries**

Neuromotor deficits  
Sensory and affective hypersensitivities  
Response latencies  
Social communication deficits  
Motor planning problems  
Disorganized play routines  
Low physical endurance  
Poor goal-directed behavior  
Attention and memory deficits  
Easy frustration  
Variable alertness and awareness

Both researchers and practitioners have found early identification and specification of the behavioral clusters associated with particular brain disorders to be helpful in detecting problems, and designing and evaluating psychoeducational interventions (Bagnato and Neisworth, 1999a; Baumgardner, et al., 1995; Miller and Ramer 1990; Neisworth, et al., 1995; Rourke, et al., 2002). For example, among older individuals (8+ years to adult) with fragile X syndrome (Baumgardner, et al., 1995), researchers have identified a cluster of neurobehavioral characteristics—hyperactivity, stereotyped and self-injurious behavior, inappropriate speech, and coping difficulties—that have been used as the targets of psychoeducational interventions. Such behavioral templates can help practitioners to recognize behaviors that could be responsive to intervention. Also, the Temperament and Atypical Behavior Scale (TABS) (Neisworth, et al., 1999) uses an authentic assessment approach and parent–professional observations to identify clusters of related concerns which detect types of self-regulatory behavior problems in young children. The TABS identifies atypical aspects of temperament and self-control, and evidence-based interventions in four major behavior clusters: Detached; Hypersensitive/Active; Underreactive; and Dysregulated. The TABS is endorsed by the American Academy of Pediatrics for use by pediatricians in the early identification of behavior problems in infants, toddlers, and preschoolers. Several assessment systems useful for identifying intervention targets are briefly described in the following section.

## **FUNCTIONAL ASSESSMENT AND CLASSIFICATION SYSTEMS**

Professionals who work with children and adolescents with or at risk for neurodevelopmental disorders often employ functional approaches to assessment that directly link assessment with intervention practices. The term “functional” is used in this chapter to refer to the ability to perform various functions within the context of real life situations. Functional assessment and classification systems are especially useful from a psychoeducational perspective because they rely on methods that directly lead to the selection of intervention targets and approaches. Such systems are used to ascertain specific capabilities of children and adolescents rather than global indices such as behavioral traits, intelligence, or personality, because it is these capabilities that constitute the targets of psychoeducational interventions.

Functional approaches to assessment and classification often used with children and adolescents with brain disorders include the *International Classification of Functioning, Disability and Health* (ICF) (World Health Organization, 2001); the Adaptive Behavior Assessment System-Second Edition (ABAS-II) (Harrison & Oakland, 2003) that closely aligns with the American Association on Mental Retardation classi-

fication system (American Association on Mental Retardation, 2002); Functioning After Brain Injury (FABI) (Smith, et al., 2004), and the System to Plan Early Childhood Services (SPECS) (Bagnato & Neisworth, 1990). Each of these systems includes methods for ascertaining the presence and severity of neurodevelopmental disorders. More importantly, each system assists in identifying intervention targets and approaches for effecting behavioral and developmental change. That is, because these assessment systems emphasize identification of the behavioral consequences of disorders and disabilities, they contribute to decisions and practices that can be used to strengthen existing competencies and to promote acquisition of new, adaptive capabilities.

### International Classification of Functioning, Disability, and Health (ICF)

*The International Classification of Impairments, Disabilities, and Handicaps* (ICIDH) (World Health Organization, 1980) was originally created to emphasize behaviors associated with specific disorders and the behavior-environment relationships that account for variations in behavioral functioning. More specifically, the ICIDH assessed (1) how diseases, injuries, and disorders result in impairments in behavioral functioning; (2) how these impairments translate into disabilities in terms of incapacity to perform specific activities; and (3) how both impairments and disabilities influence outcome in terms of impeding the affected individual's access to social, economic, and other opportunities. Complimentary to the *ICD-10th Revision* (World Health Organization, 1992) and part of the World Health Organization Family of International Classifications (WHO-FIC), the ICF (World Health Organization, 2001) has replaced the ICIDH. The ICF is designed to describe how health conditions impact individuals' lives. It covers a variety of domains within each of four components: body functions and structures, activities and participation, environmental factors, and personal factors. A domain "is a practical and meaningful set of related physiological functions, anatomical structures, actions, tasks, or areas of life" (World Health Organization, 2001, p. 3). The first component covers mental functions and body structures and includes domains such as mental functions and the nervous system. This first component is used to describe changes to the individual as a result of disease or injury. The next two components (activities and participation; environmental factors) are most relevant to setting functional goals for psychoeducational interventions and examining environmental facilitators or inhibitors to their success. The activities and participation domains are learning and applying knowledge; general tasks and demands; communication; mobility; self-care; domestic life; interpersonal interactions and relationships; major life areas; and community, social and civic life. The environmental domains, organized from the individual's most proximal environment to the most global, are products and technol-

ogy; natural environment and human-made changes to environment; support and relationship; attitudes; and services, systems and policies. The last component, personal factors, includes internal influences not part of the health condition such as gender, habits, and past life events. Personal factors, however, are not coded in the ICF.

The system allows professionals to determine and classify the severity of an individual's behavioral problems in functional terms and to grade the impact of those problems on the individual's performance and social integration. Also, there is a strong focus on individual and environmental strengths that facilitate successful adaptation. The ICF includes methods for assessing behavioral changes resulting from interventions and for evaluating the potential for recovery in several neurodevelopmental domains of functioning.

### Adaptive Behavior Assessment System-Second Edition

*The Adaptive Behavior Assessment System-Second Edition* (ABAS-II) (Harrison and Oakland, 2003) is a norm-referenced, cross-informant assessment system that closely aligns with the 10 adaptive skills areas specified by the *Diagnostic and Statistical Manual of Mental Disorders-Fourth Edition-Text Revision* (DSM-IV-TR) (American Psychiatric Association, 2000) and the current guidelines for the diagnosis of mental retardation from the recently revised *Mental Retardation: Definition, Classification, and Systems of Support-Tenth Edition* (American Association on Mental Retardation (AAMR), 2002). The skill areas assessed using the teacher and parent forms of the ABAS-II are communication, community use, functional preacademics, school/home living, health and safety, leisure, self-care, self-direction, social, and work. For younger children, motor skills replaces work skills. Difficulties identified in each area represent functional goals for psychoeducational intervention.

The ABAS-II also assesses the three clusters of adaptive skills identified by the American Association on Mental Retardation (2002) for the diagnosis of mental retardation. Historically, the AAMR emphasized assessment of intellectual functioning and two aspects of adaptive skills: personal independence and social responsibility (Harrison and Oakland, 2003). These aspects of adaptive skills have been revised by the AAMR to cover conceptual (money concepts and academic skills), social (responsibility and social competence), and practical (activities of daily living and occupational skills) adaptive skills. The skill areas measured by the ABAS-II can be organized into these three general aspects of adaptive functioning. This organization is important to plan and monitor psychoeducational interventions, as well as to make the diagnosis of mental retardation. Currently, according to AAMR, two criteria are used for making a diagnosis of mental retardation: the individual must concurrently demonstrate significant limitations in intellectual functioning and in adaptive behavior as

expressed in conceptual, social, and practical adaptive skills. More importantly, because intellectual and adaptive strengths and weaknesses are assessed for the individual in the context of specific community and cultural environments, such assessment can lead directly to identification of the kinds of individualized supports, educational interventions, and instructional practices that are needed to promote a child's competence.

### Functioning after Brain Injury

The Functioning After Brain Injury (FABI) (Smith, et al., 2004) is a clinical performance measure for traumatic and nontraumatic pediatric brain injury, suited for both inpatient and home aftercare settings. It was designed to align closely with the *International Classification of Functioning, Disability and Health* (ICF) (World Health Organization, 2001). The FABI is the successor to the *Pediatric Evaluation of Disabilities Inventory* (PEDI), a standardized, norm-referenced instrument designed to provide a functional appraisal of the capabilities of young children with sensory, neuromotor, brain-related, and other types of developmental problems (Haley, et al., 1992). The FABI allows assessment of the following major domains: Physical Activities, Cognitive/Behavioral Activities, and Readiness for Community Functioning. Each domain has several dimensions. The scales are designed to identify intervention targets and assess behavioral outcomes from treatment as well as other important predictors. First, the system uses an algorithm to predict expected levels of functioning at discharge based on a combination of injury-related and personal factors (comparable to the ICF). Second, it was devised to be amenable to correlational study with biochemical markers of severity to determine signs closely indicative of brain recovery.

### System to Plan Early Childhood Services (SPECS)

The SPECS employs collaborative team assessment and a decision-making format that links assessment information directly with intervention targets and approaches (Bagnato and Neisworth, 1990). This system is designed for use with young children between 2 and 6 years of age, who have, or who are at risk for, developmental delays or disabilities. This functional assessment system integrates data from multiple sources and settings across occasions and instruments to enable a team of parents and professionals to profile a child's needs in 19 functional domains. It also includes procedures that lead to consensus about the severity of neurodevelopmental problems. Additionally, the SPECS generates information that aids in decision making about appropriate intervention modes and team collaboration regarding the specific details of an intervention plan, including the intensities of intervention, in the following behavioral and developmental areas: early education,

adaptive needs, behavior therapy, speech/language therapy, physical therapy, occupational therapy, vision and hearing services, medical services, and transition services.

Although these four approaches differ in their purposes and methods of assessment and classification, they share several common features: (1) they emphasize the identification of behaviors that establish the presence of a disorder or disability; (2) they specify those aspects of behavior that become the focus of psychoeducational interventions; (3) they inform practice in terms of influencing which procedures, methods, and supports will be used to effect change in positive, socially adaptive functioning; and (4) they provide a repeatable metric for assessing outcomes of psychoeducational interventions.

### KEY ELEMENTS OF PSYCHOEDUCATIONAL INTERVENTIONS

Children and adolescents with congenital or acquired brain disorders are most likely to benefit from psychoeducational interventions that are characterized by an integrated functional approach to promoting adaptive capabilities (i.e., emphasize the acquisition of practical life skills in the context of daily living) (Bagnato and Mayes, 1986; Bagnato and Neisworth, 1985). Such intervention strategies differ from traditional educational approaches, in which various school personnel (e.g., regular and special education teachers, speech/language therapists, occupational and physical therapists, nurses) tend to perform their respective functions in an isolated, nonintegrative manner. The importance of an integrated approach derives from the fact that interventions are more likely to be functional and implemented *consistently* across settings and people when they are implemented collaboratively (Anderson, et al., 1993). An integrated intervention approach is especially important for working with two special populations: (1) children with congenital brain disorders, who need a range of interventions in order to receive optimal benefit; and (2) children and adolescents reentering school after traumatic brain injury, who require creative, flexible, individualized, and ever-changing psychoeducational interventions to help them navigate this difficult process (Ylvisaker, Feeney, Maher-Maxwell, et al., 1995; Ylvisaker, Feeney, & Mullins, 1995).

Psychoeducational intervention approaches are characterized by the following seven principles and elements: (1) functional intervention goals, (2) a developmental perspective on change, (3) functional assessment/intervention linkages, (4) functional instructional strategies, (5) functional contexts and settings, (6) integrated support services, and (7) collaborative teamwork. Collectively, intervention practices characterized by these features increase the likelihood that psychoeducational interventions will have optimal benefits (see Bagnato and Mayes, 1986; Bagnato and Neisworth, 1985, 1999b; Dunst, 2002; Dunst, et al., 2002; Neel and Billingsley, 1989; Wellman, 2001).

### Functional Goals

According to Wolery (1989), functional intervention goals are those that (1) are immediately useful, (2) enable a child to be as independent as possible, (3) allow the child to learn other, more complex skills, (4) allow the child to function in the least restrictive environment possible, and (5) enable family members and others to more easily care for the child. Neel and Billingsley (1989) have similarly noted that functional goals are ones that permit a child to have greater control over environmental events and consequences.

White (1980) made a useful differentiation between behavioral form and behavioral function that has important implications for developing psychoeducational goals: *form* refers to the observable behavior to be taught, whereas *function* refers to the effect of the behavior on the child's social and nonsocial environments. According to Wolery (1996), "for some goals, the form (behavior) is important, as in the case of self-feeding; for other goals, the effect is more important, as in the case of initiating social interactions with peers or requesting a drink" (p. 505).

Generally, functional instructional goals are ones that specify observable and purposeful behaviors across many major developmental domains or behavioral areas: cognition, preacademic/academic, motor, language, social communication, and self-regulatory behavior. For example, the goal of getting across the room with decreasing reliance on others might be an appropriate one for helping an individual in a wheelchair to increase his or her independence, whereas the goals of communicating personal needs and initiating social interactions might be appropriate for helping a child acquire better communication skills.

### Developmental Perspective

A developmental perspective of psychoeducational interventions maintains that the form and function of behavior change across time. Such change is, in part, a result of the reinforcing consequences of an individual's acquisition of socially adaptive competencies (Dunst and McWilliam, 1988). In contrast with adults, children have not mastered fundamental developmental milestones of normal development. So, as the child recovers competencies lost due to a disability the child must concurrently achieve normal developmental competencies making for additional challenges that must be considered for intervention planning (Dennis, 2000; Thomson and Kerns, 2000). Accordingly, the goals of psychoeducational interventions must be ordered (sequenced) and promoted in a manner that permits progressively more complex socially adaptive capabilities to be acquired over time as well as meet the vicissitudes of development, thus enabling a child to become involved in or to reenter a variety of environments. Consequently, psychoeducational interventions are most likely to be effective if they have sequential functional goals, link the child's assessed capabilities with these goals and methods, include

procedures for monitoring improvement as a function of intervention type, and modify strategies and practices in response to behavioral and developmental change in the child (Bagnato and Campbell, 1993; Bagnato and Mayes, 1986; Bagnato and Neisworth, 1985; Dennis, 2000).

### Assessment/Intervention Linkages

A functional approach to assessment and intervention directly links assessment information with the selection of intervention plans and instructional goals and practices. That is, the information obtained by gathering assessment data leads to a better appreciation of the environmental conditions, situations, and contexts that will optimize the socially adaptive benefits resulting from psychoeducational interventions (Miller, Tansy, and Hughes, 1998). Unlike traditional assessment methods, which tend to focus on a child's level of functioning in terms of an intelligence (IQ) or social quotient (SQ) or some other global index, functional assessment methods examine the form and function of behavior across and within settings and environments, with particular emphasis on the environmental conditions associated with variations in behavioral form and function. For example, the SPECS (Bagnato and Neisworth, 1990) pools assessment information from multiple informants (e.g., parents, teachers, therapists) to reach a consensus about a child's capabilities, determines intervention needs and selects appropriate priorities, and monitors progress toward desired goals. The approach to functional behavioral assessment for individuals with disabilities by Miller et al. (1998) employs a similar approach of directly linking eight domains of functioning (affective regulation/emotional reactivity, cognitive distortion, reinforcement, modeling, family issues, physiological/constitutional, communicate need, and curriculum/instruction) with instructional goals and methods.

### Functional Instructional Strategies

According to Neel and Billingsley (1989), "increasing control over the environment is the major goal of instruction" (p. 15). The achievement of this goal draws upon a number of different methods and procedures for promoting a child's acquisition of socially adaptive competence. Although functional instructional strategies may deploy any number of different intervention practices, all share one feature: they contribute to change in the form and function of socially adaptive capabilities as a result of the experiences and opportunities afforded the child (McClellan, Wolery, & Bailey, 2003).

Wolery (1996) has described a useful framework for examining how differences in the form and function of a child's behavior might lead to different intervention approaches. For example, when behavioral form is adequate but function is limited (e.g., a child has a rich topography of gestures but does not use them for communicative

purposes), the emphasis of instruction would be to “teach new functions using existing forms and promote maintenance of existing functions” (Wolery, 1996, p. 506). In contrast, when behavioral function is multiple but form is limited (e.g., a child uses only hand gestures to communicate a variety of needs, desires, and wishes), the focus would be to “teach new forms for existing functions and promote maintenance of existing forms” (Woolery, 1996, p. 506). It should be readily apparent from these examples that a child cannot be fitted to one instructional method; on the contrary, instructional practices must fit and match the child’s unique learning needs.

Although the term *instruction* has generally been used to refer to techniques employed by a teacher or therapist to teach a child specific behavioral goals and objectives, the term in a broader sense refers to any practices that contribute to changes in the form or function of a child’s socially adaptive capabilities. Such practices include direct teaching, responsive teaching, programmed instruction, making available materials that evoke desired behavior, scheduling activities in ways that increase behavioral responding, arranging the environment so that it facilitates adaptive behavior, and providing access to different environmental settings and conditions, all of which, either individually or in combination, can be used to promote and enhance behavioral competence and developmental change.

Regardless of the particular methods employed, effective psychoeducational interventions share certain key features (Wolery 1996):

1. Promote student participation in classroom activities and routines, as well as independence and mastery of the environment.
2. Address functional goals many times throughout the student’s day.
3. Address as many goals as possible within the same activities and routines.
4. Use a functional goal-by-activity/routine framework (matrix) to determine which goals can be addressed in which activities and routines.
5. Adapt the student’s activities and routines as necessary to promote acquisition of identified goals and behaviors.
6. Monitor (i.e., evaluate) the effects of the instructional practices used to achieve identified goals/outcomes so that appropriate changes and/or modifications can be made as needed.

Instructional practices that adhere to these guidelines are more likely to produce desired effects and developmental changes in both the form and the function of behavior. When deciding among instructional practices that equally meet Wolery’s (1996) criteria, Brown, Odom, and Conroy (2001) recommend that the most appropriate interventions are ones that are (1) effective for children with similar markers or behaviors (i.e., evidence-based); (2) efficient (i.e., least demanding on service providers); and (3) normalized (i.e., authentic and naturalistic to the individual’s environment)

## Functional Settings and Contexts

Because of the importance of the environments in which children and adolescents must learn to function adaptively and independently, instructional settings and contexts deserve to be considered as a separate element of psychoeducational interventions (Neel and Billingsley, 1989; Wolery, Bashers, and Neitzel, 2002). Functional instructional practices are ones in which instruction occurs in the settings and contexts that a child directly experiences in daily living. That is, functional instruction must occur in environments that have meaning to the child, not in isolated or contrived locations that bear no resemblance to real life settings (Ware, 1990). This principle is especially relevant for instructional support services, which we describe next.

## Integrated Instructional Support Services

Instructional support services, including sensory, communication, and neuromotor therapies, for children with neurological or other developmental disorders have traditionally been provided in a pull-out fashion. For example, physical therapy for a child with cerebral palsy may be offered once weekly in a 45-minute session in a school building therapy room or a hospital-based clinic. These kinds of pull-out services, however, are costly, and their effectiveness is as yet undetermined. Moreover, these approaches often disrupt one of the most important predictors of a child’s learning potential: time on task (i.e., engagement in functional learning activities/environments) (Greenwood, 1991; McWilliam and Bailey, 1992; Rosenshine, 1978). Finally, because they occur apart from classroom routines, pull-out services do not address generalization of specific functional skills (e.g., Cole, et al., 1989; Giangreco, 1986, 2000).

Instructional support services include communication, speech/language, physical, occupational, and other kinds of therapies and supportive interventions (e.g., adaptive equipment and augmentative devices) (Ried, et al., 1995) that are used integratively and that adhere to the previously identified key features of functional instructional strategies. Thus, psychoeducational and support service personnel must communicate and work together on an ongoing basis if this kind of integration is to become a reality (Weist, et al., 2003).

## Collaborative Teamwork

The likelihood that these first six key elements of psychoeducational interventions will be operationalized in a consistent fashion is increased considerably if collaborative teams are used to identify functional goals and settings and to implement instructional practices (see Bagnato and Mayes, 1986; Bagnato and Neisworth, 1985, 1999b; Campbell, 1987; Miller, et al., 1998; Walther-Thomas, Korinek, and McLaughlin, 1999; West and Cannon, 1988). Appropriate team members include school

personnel, other professionals working with the child and his or her family (e.g., neuropsychiatrists), the child's parents, and, when appropriate, the child himself or herself. Collaborative teamwork encourages consensus decision making, flexible judgments regarding the child's capabilities, and identification of the most creative and appropriate ways to deliver services. Further, Walther-Thomas and colleagues (1999) identified the features supportive of collaboration including shared leadership, family involvement, cohesive school vision, comprehensive program planning, provision of adequate resources, sustained implementation, and ongoing performance evaluation and improvement. In order for collaborative team efforts to work and the identified functional goals to be attained, team members must be flexible and define their roles in terms of what is best for the child. In many instances, achieving the necessary flexibility may require staff members to function in a consultative rather than a direct service capacity and to use a transdisciplinary team model in which all team members integrate their knowledge and expertise into a more functional instructional approach (Campbell 1987; West and Cannon, 1988). These properly distributed professional responsibilities allow for opportunities for all team members to contribute to the well-being of the individual and to have ownership in the process of treating children with disabilities (Walther-Thomas, et al., 1999).

All of these key components of psychoeducational interventions are implemented in the context of broader based environmental influences, several of which we describe next.

### PHYSICIAN–FAMILY–SCHOOL RELATIONSHIPS

Building strong physician–family–school relationships can be accomplished by bringing together the knowledge, competence, and expertise needed to inform psychoeducational practices and to ensure that other needed supports and resources are available to children and adolescents with brain disorders. According to ecological theory (Bronfenbrenner, 1979, 1992), different settings (e.g., hospital, school, home) and people within these settings are characterized by different degrees of linkages and levels of reciprocal relationships, respectively. In settings in which relationships (linkages) are strong, information sharing and collaboration among participants are more likely to occur in ways that serve supportive functions. For example, parents' knowledge and understanding of their child can help inform both neuropsychiatric and psychoeducational practices; neuropsychiatric expertise can inform psychoeducational practice and vice versa; and both neuropsychiatric and psychoeducational knowledge and expertise can be supportive of parents' efforts to care for their child with a brain disorder.

Two emerging systems practices (described below) hold special promise for forging and strengthening physician–family–school relationships. The first of these, school-based health clinics/school-linked services, specifically aim to promote integration of educational, medical, mental health, therapeutic, and other kinds of services and supports. Such integration has the explicit purpose of bringing important resources to bear on the development and implementation of interventions for children with brain-related and other kinds of developmental disabilities. The second of these promising practices is family-centered interventions, which specifically aim to promote the flow of different kinds of resources in ways that strengthen the family. Such systems interventions are premised on a new larger body of evidence indicating that social-support networks involving reciprocal transactions among network members are associated with positive effects in multiple areas of child, parent, and family functioning (Dunst, Trivette, and Jodry, 1997).

### School-Based Collaboration

The basic argument for instituting school-based collaboration is that it will result in increased access to treatment. School-based collaboration offers promise in bridging the gap between service need and service utilization (Ambruster and Lichtman, 1999). Hacker and Wessel (1998) list seven qualities critical for effective school-based collaboration: (1) clarification of roles and redefinition regarding integration and collaboration, (2) strong leadership, (3) emphasis on shared ownership of the program, (4) training, (5) continued education, (6) creative compromise, and (7) mutual respect and support.

Several innovative service-delivery projects have recently been instituted to facilitate school-based collaboration among medical, educational, and mental health professionals. An example of school-based collaboration is HealthyCHILD (Collaborative Health Interventions for Learners With Differences) (Bagnato, 1999; Bagnato, et al., 2004), a school-linked developmental health care service serving young children (0 to 8 years) with chronic health conditions, neurodevelopmental disabilities, or behavioral health (e.g., self-regulatory behavior) problems and their families in public school settings.

The predominant mission of HealthyCHILD is to plan, deliver, and monitor the impact and outcomes of a transagency model for providing developmental health care resources and support in naturalistic school or agency environments such as early childhood classrooms and family child care settings. In the context of these naturalistic environments, resources and support are provided to teachers, parents, and their children with developmental delays/disabilities, chronic medical conditions, and challenging behaviors (e.g., extremes in temperament and problems in social and self-regulatory behaviors). This program began as a collaborative effort involving a major children's hospital, an urban public

school system, a university-based psychiatric facility, a county mental health department, and a number of primary care pediatricians and family practitioners. HealthyCHILD uses a mobile, transdisciplinary team composed of a teacher, a psychologist, and a pediatric nurse practitioner, with consultation from a developmental pediatrician, who collectively provide direct support to children, parents, and teachers, and programmatic consultation and mentoring to personnel in public school settings, Head Start programs, early intervention programs, and early care and education centers. A developmental health care plan serves as the protocol for generating consensus goals by the family, teachers, and allied health professionals and for forging supportive linkages between the primary care pediatrician and the school staff. For example, the nurse, psychologist, teacher, and parent collaborate to produce individualized interventions for delivering health care services on-site in the classroom setting for children with asthma, diabetes, seizure disorders, and various neurodevelopmental disabilities including fragile X syndrome, Autism Spectrum Disorder, and Traumatic Brain Injury. The interventions target jointly the medical and developmental conditions and the impact on the functional early learning needs of such children, as well as the priorities of the families.

The HealthyCHILD model demonstration program research was funded originally by federal and foundation research grants from the U.S. Department of Education, Office of Special Education and Rehabilitative Services (OSERS), School-Linked Services for Better Outcomes competition, (1994 to 1998, PR award HO23D40013) and the Jewish Healthcare Foundation of Pittsburgh (1995 to 1997). The evidence-based practices for the HealthyCHILD model were established during this phase (Bagnato, 1999) and undergo current research and refinements with each new interagency contractual venture beyond the original research phase.

Currently, HealthyCHILD is administered by the Early Childhood Partnerships program of Children's Hospital of Pittsburgh and the UCLID Center at the University of Pittsburgh and is directed by one of the authors, S. J. Bagnato, with a full-time transagency coordinator. It has evolved into a school-linked or agency-linked developmental health care consultation venture funded by contracts with school districts, early intervention programs, and Head Start grantees across Pennsylvania and in West Virginia. Currently, HealthyCHILD employs one full-time nurse, three psychologists, 12 full-time developmental health care consultants, and one full-time interagency liaison to coordinate and deliver collaborative support services to nearly 4,000 children and families and over 300 teachers and staff under six interagency contracts. Bagnato (2001) studied the service quality and behavioral outcomes for children served under the HealthyCHILD model during the 2000 to 2001 school year. Results indicated that service providers showed significant increases in their skill level to work with

children with medical and behavioral difficulties, increases in the level of support they were provided through the model, and increased opportunity to team with professionals from multiple disciplines in the service of the children. Children served under the HealthyCHILD model showed significantly increased social skill acquisition and decreased behavior problems (Bagnato, 2001).

In another example of a school-based collaborative project, Costello-Wells and colleagues (2003) developed a multisite, school-based mental health center called InteCare. The focus of the Indianapolis coalition of four mental health clinics is building on the strengths of the family by allowing them to search for expectations and discover their own possibilities. This approach is in contrast to focusing on the weaknesses that tend to overwhelm individuals, families, and service providers. In this program, the psychiatrist conducted initial evaluations; led clinical staffings with psychologists, nurses, and therapists; reviewed treatment plans; prescribed medication; and reevaluated clients progress quarterly. Qualitative data from the study found that school-based collaboration resulted in greater parental involvement in school and their children's education, less reports of problematic behaviors, lower incidence of children running out of medicine, improved support for personnel, and family reports of feeling more comfortable with receiving treatment from the school rather than services in a traditional outpatient setting.

### Family-Centered Care

Although historically the idea of family-centered care can be traced to the early 1960s, its potential value was more recently articulated in 1987 by then-Surgeon General C. Everett Koop at a conference jointly sponsored by the American Academy of Pediatrics and the U.S. Department of Health and Human Services. In the report of the proceedings of this conference (Koop, 1987), Dr. Koop described new ways to improve both access to health care and related services and the quality of life of children with special healthcare needs. The contents of this report in part formed the basis for a new approach to delivering health care, education, and early intervention services to children and adolescents with medically related and other developmental problems, one based in the community and centered on families.

An emphasis on a family-centered approach to service delivery has emerged in the federal special education law *Individuals With Disabilities Education Act* (IDEA, 1997) (see Chapter 32). Many children served by the neuropsychiatrist will be covered under IDEA since medical conditions and traumatic brain injury are qualifying conditions. In IDEA, professionals are expected to recognize the family's expertise, guide and facilitate the family's understanding of and adherence to IDEA, and provide family training (Miller & Gallagher, 1997).

Dunst (2002) has defined family-centered care as: beliefs and practices that treat families with dignity and respect; individualized, flexible, and responsive practices; information sharing so that families can make informed decisions; family choice regarding any number of aspects of program practices and intervention options; parent–professional collaboration and partnerships as a context for family-program relations; and the provision and mobilization of resources and supports necessary for families to care for and rear their children in ways that produce optimal child, parent, and family outcomes (p. 139)

Shelton and colleagues (Shelton, 1999; Shelton and Stepanek, 1994; Shelton, Jeppson, and Johnson, 1987) developed eight elements of family-centered care that operationalize a philosophy of care for use in day-to-day practices across a variety of programs, settings, and situations (see Table 31.2). Both individually and collectively, intervention strategies that incorporate these elements of care increase the probability that other kinds of interventions (e.g., neuropsychiatric and psychoeducational) will have *value-added benefits*; that is, outcomes produced beyond those attributable to more traditional clinical practices.

Dunst and colleagues (Dunst and Trivette, 1996; Dunst, et al., 2002), for example, summarize evidence indicating that professional helpgiving practices that foster family choice and decision making and the active involvement of parents in helping relationships produce better outcomes, compared with traditional clinical practices. This result seems to be the case because family-centered care brings to bear supports and resources from many sources to flexibly and responsively deliver an array of individualized services to children and adolescents and their families. Unfortunately, family-centeredness has

only taken hold in early childhood intervention programs and has yet to extend into elementary and secondary settings (Dunst, 2002).

## EFFECTIVENESS OF PSYCHOEDUCATIONAL AND SYSTEMS INTERVENTION

The methods typically used to ascertain the effectiveness of psychoeducational interventions are quite different from those used by medical researchers (i.e., double-blind clinical trials). Psychoeducational evaluation methods include studies that contrast different interventions designed to produce similar effects, compare different features of the same intervention, and examine those conditions of specific interventions that produce desired effects, as well as the processes that contribute to the implementation of intervention practices as planned and intended (Eslinger & Oliveri, 2002). Studies of this kind were cited throughout earlier sections of this chapter.

Studies examining the effectiveness of psychoeducational interventions in children with disabilities or those at risk for poor outcomes and their families currently focus on questions of the following sort: To what extent do specific aspects of interventions have similar or different effects on children and families differing according to child or family characteristics, or both? These second generation studies differ from first generation studies, which were concerned with questions about efficacy (e.g., did the intervention work?). This shift has occurred because second generation but not first generation research *directly* informs practice in the ways described in this chapter. Thus, if we know which

**TABLE 31.2**  
**KEY ELEMENTS OF FAMILY-CENTERED CARE**

- Incorporate into policy and practice the recognition that the family is the constant in a child’s life, while the service systems and support personnel within those systems fluctuate
- Facilitate family/professional collaboration at all levels of hospital, home, and community care:
  - care of an individual child
  - program development, implementation, evaluation, and evolution
  - policy formation
- Exchange complete and unbiased information between families and professionals in a supportive manner at all times
- Incorporate into policy and practice the recognition and honoring of cultural diversity, strengths, and individuality within and across all families, including ethnic, racial, spiritual, social, economic, educational, and geographic diversity
- Recognize and respect different methods of coping and implement comprehensive policies and programs that provide developmental, educational, emotional, environmental, and financial supports to meet the diverse needs of families
- Encourage and facilitate family-to-family support and networking
- Ensure that hospital, home, and community service and support systems for children needing specialized health and developmental care and their families are flexible, accessible, and comprehensive in responding to diverse family-identified needs
- Appreciate families as families and children as children, recognizing that they possess a wide range of strengths, concerns, emotions, and aspirations beyond their need for specialized health and developmental services and support

aspects of an intervention produce what kinds of effects with what kinds of children and families under what conditions, we can be specific about making informed, empirically-based recommendations. The pursuit of data and supporting evidence, both direct and corroborative, about intervention effectiveness for children with specific aptitudes or characteristics is just emerging and an is need of further study.

With respect to first generation studies, a number of meta-analyses have been conducted examining the effectiveness of various psychoeducational interventions. In a summary of these meta-analyses Forness (2001) found that interventions such as mnemonic strategies, reading comprehension strategies, behavior modification, and direct instruction consistently evidenced large effect sizes. Interventions found to have medium effect sizes included cognitive behavioral therapy, psychotherapy, stimulant medication, computer-assisted instruction, and peer tutoring. Based on these findings, Forness (2001) concluded that best practices “include monitoring students’ progress and providing positive consequences for improvement; teaching cognitive-behavioral self-management; and, at least in the case of children with ADHD, considering a systematic course of stimulant medications” (p. 194).

#### CASE EXAMPLE

This case involves Amy, an 8-year-old girl with a complicated medical history including congenital heart failure and seizure disorder. She had to be resuscitated twice during her first weeks of life and a pacemaker was implanted. She has taken antiepileptic medication since approximately 3 years of age after experiencing several generalized tonic-clonic seizures. Most recently, she underwent surgery to repair a vertebral arteriovenous fistula. Educationally, Amy’s current teacher is quite rigid and does not reinforce her successes. Children in her class have begun teasing her with respect to academic failures by calling her stupid. She becomes easily frustrated and upset when she does not do well on academic tasks. Her parents are divorced and her father is only peripherally involved. In fact, visits to the father often exacerbate her adjustment problems. Her mother appears to lack confidence in parenting and becomes frustrated with Amy quite easily.

Cognitive testing revealed that Amy’s verbal reasoning ability is in the low average range, perceptual reasoning ability is in the below average range, working and long-term memory are in the below average range, executive functions such as the ability to shift mental sets are in the well below average range, basic reading and reading comprehension were at grade level, spelling was at grade level, and mathematics skills were well below grade level. Taken together Amy has relative strengths in verbal reasoning

and language-based academics. However, the significance of these strengths would be moderated if one adopts a developmental perspective on change. That is, although she has a relative strength in language-based academics, her cognitive functioning is at best within the low average range. As a second grader, the level of challenge with respect to language-based academics is relatively low. She will need to be closely monitored through the developmental period to ensure that her reading and writing skills do not begin to lag significantly behind her age-mate peers as academic expectations increase. Overall, test results indicate she has significant difficulties in memory, executive control, and mathematics. Adaptive testing using the ABAS-II (Harrison and Oakland, 2003) (described previously) indicated that Amy has significant functional difficulties in the areas of home/school living, self-care, self-direction, and social functioning. These areas of difficulty fall within the practical and social domains of the ABAS-II.

Difficulties in the cognitive areas of memory and executive control, the academic areas of mathematics, and the adaptive functioning areas of home/school living, self-care, self-direction, and social function are the consequences of Amy’s conditions and therefore are the targets for intervention. Interventions are then planned for Amy and her environment to promote adaptive functioning with respect to each of the intervention targets. Further, the psychoeducational interventions are implemented in an integrated manner in which the neuropsychiatrist leads a team of professionals that conduct or supervise interventions in the school, home, and community.

The neuropsychiatrist involved Amy’s mother in both the planning and intervention stages to ensure that she could help monitor consistency of treatment across settings and to directly improve her ability to care for Amy. The psychoeducational intervention plan also included members of the school instructional support team so that Amy’s services were not dependent on a single school professional, namely the teacher. Rather, the school psychologist, counselor, nurse, teacher, and special education teacher were included at the planning and intervention stages. School personnel worked with the parent so that both settings (home and school) would become more responsive to Amy’s needs and to indications that she was struggling. Specific psychoeducational interventions recommended for Amy included direct instruction in metacognitive strategies such as mnemonics, note-taking, and listening skills to increase memory and reduce cognitive demands. She was provided with individual counseling using cognitive-behavioral techniques in school to help with her coping, frustration tolerance, and social functioning. Her mother and teacher were informed and educated about these cognitive-behavioral techniques so they could be practiced in the home and in the classroom. Amy was provided itinerant support in the classroom for mathematics. Her teacher was provided with classroom management techniques to help reduce the impact of teasing on Amy. Finally, through a partnership between the neuropsychiatrist and the primary physician her antiepileptic medication and general physical health continued to be monitored.

## CONCLUSION

In this chapter we have described the major features of functional psychoeducational approaches to intervention and practice for children and adolescents with neuropsychiatric disorders, and have placed these practices within the broader context of two different but complementary systems-level interventions, school-based services and family-centered care. Our goal is to provide professionals with a framework for understanding the key characteristics of effective psychoeducational interventions in pediatric neuropsychiatry, which they can use for informing these children and adolescents and their families about what they should look for in obtaining effective educational and related services. Consequently, the contents of the chapter, and especially the seven principles and elements described in the key elements of psychoeducational interventions section of this chapter, can be used as a checklist for determining the appropriateness of educational practices used with children and adolescents with brain disorders. At a minimum, emerging best practice psychoeducational interventions are ones that focus on the form and function of behavior, as well as the environmental conditions that contribute to optimal, socially adaptive outcomes. To the extent that neuropsychiatrists incorporate these elements in their treatment recommendations to family members and other professionals, they will make a major contribution toward bettering the lives of children and adolescents with brain disorders and disabilities.

# Selected Legal Issues

32

*Peter S. Latham, JD*     *Patricia H. Latham, JD*

It is important that medical and legal professionals understand enough of each other's disciplines to ensure that both provide the best professional services of which they are capable. It is our intent in this chapter to foster such an understanding.

Specifically, in this chapter, we provide a legal overview of various pertinent laws, discuss standards for determining whether a disorder is covered under each of the laws, address entitlements under the laws, explain documentation requirements from a legal perspective, discuss the professional report, and provide an overview of the concept of confidentiality under the law.

## BASIC PRINCIPLES

### The Constitution

The government of the United States of America is a limited one. It has those powers expressly granted it by the United States Constitution and no others. The Tenth Amendment to the United States Constitution provides:

The powers not delegated to the United States by the Constitution, nor prohibited by it to the states, are reserved to the states respectively, or to the people.

The powers of the federal government may be exercised through legislation which is authorized by, and enacted pursuant to, specific provisions of the Constitution. As a result, the federal legal rights accorded individuals with disabilities must be found in the Constitution of the United States, or those statutes which Congress has enacted pursuant to its provisions. There are three relevant Constitutional provisions: the Commerce Clause, the Spending

Clause, and the Fourteenth Amendment. Disability legislation must be authorized by one or more of these provisions in order to be valid. Each of these laws, and the Constitutional provisions which authorize them, will be discussed next. In contrast, the states have all powers *not* specifically delegated to the federal government. These powers are, in many cases, far broader than the federal ones and permit states to enact legislation which the federal government cannot.

### The Statutory Overview

To protect individuals with disabilities, Congress enacted three key federal statutes: the Rehabilitation Act of 1973 (RA) (1), the Education for All Handicapped Children Act, now called the Individuals with Disabilities Education Act (IDEA) (2), and in 1990, the Americans with Disabilities Act (ADA) (3).

The ADA and RA are civil rights statutes that outlaw discrimination but do not necessarily provide funds for the activities mandated by them. The IDEA goes beyond the civil rights objective of a ban on disability-based discrimination; it provides funding for the provision of a free appropriate public education to students whose needs are such that they require special education and related services to learn. What follows is an overview of these laws. Each statute is discussed in greater depth subsequently.

### The Rehabilitation Act of 1973

The Rehabilitation Act of 1973 (RA) made discrimination against individuals with disabilities unlawful in three areas: (1) employment by the executive branch of the federal government, (2) employment by most federal government contractors, and (3) activities that are funded by federal subsidies or grants. The last mentioned category includes all public elementary and secondary schools and most post-secondary institutions. The section of the statute that prohibits discrimination in grants and other forms of financial

---

This chapter has been adapted and updated by the authors from their texts, including *Learning Disabilities and the Law*, published by JKL Communications.

assistance was numbered 504 in the original legislation, and the Rehabilitation Act is often referred to simply as Section 504. Other sections, for example, create a limited requirement for affirmative action in the hiring of individuals with disabilities by the executive branch of the federal government and most federal government contractors.

The RA applies to state agencies, local governmental agencies, and private firms because those entities have agreed that it should apply. Agreement to the terms of the Rehabilitation Act is required in order to receive federal financial support and funding. The courts have given the nondiscrimination provisions of Section 504 a broad reach by finding the existence of federal financial support and funding in circumstances in which the interpretation of receipt of such funding is far from immediately obvious.

The RA is authorized by the Spending Clause of the United States Constitution which provides that "The Congress shall have Power to lay and collect Taxes. . .to. . . provide for the. . .general Welfare of the United States. . ." (4). Under this authority the federal government provides funding for good purposes, such as education, which it could not provide directly itself. It accomplishes this through the use of grants, which are much like contracts. Any contract, by definition, requires the agreement of the parties, and so the question becomes, what have the states agreed to when they receive grants authorized under the Spending Clause? Sometimes states are found to have agreed to waive immunity to suits by private parties. On the other hand, the Supreme Court has held that the States have *not*, for example, agreed to accept liability for punitive damages for violations of the RA (see *Barnes v. Gorman* (2002) (5)). Nor have they agreed to liability for violation of the myriad of regulations issued pursuant to the RA in suits brought by private parties (see *Alexander v. Sandoval* [2001]) (6). However, the RA does clearly prohibit states from engaging in intentional discrimination against persons with disabilities and that states are not immune from private suits based upon intentional discrimination.

### **The Individuals With Disabilities Education Act**

In 1975, the Congress enacted a statute titled the Education for All Handicapped Children Act. That statute, now called the Individuals with Disabilities Education Act (IDEA), which was reauthorized in December, 2004, provides funds to state and local elementary and secondary schools for the education of children with disabilities. It provides for a free appropriate public education (FAPE) and represents a unique approach to civil rights in that the IDEA provides at least a part of the funds which enable these school systems to comply with federal disability-based civil rights laws. Comparable financing does not exist for compliance with race-based and gender-based civil rights laws. Under the IDEA, the school is responsible for identifying and evaluating students with disabilities, who by reason thereof, need special education and related services and then, for providing to them such edu-

cation and services under an Individualized Education Program (IEP). These services are to be provided in the least restrictive environment (LRE), appropriate to the needs of the child. In other words, to the extent appropriate in terms of the needs of the child, the child should be integrated with other children, with and without disabilities, and still receive special services. This is sometimes referred to as inclusion. A child found ineligible under the IDEA still may be eligible for services under Section 504 of the RA.

The IDEA is authorized by the Spending Clause. The states have validly consented to its provisions.

### **The Americans with Disabilities Act of 1990**

In 1990, the Congress enacted the Americans with Disabilities Act (ADA). This Act extended the concepts of Section 504 to (1) employers with 15 or more employees (Title I), (2) all activities of state and local governments, including but not limited to employment and education (Title II), and (3) virtually all places which offer goods and services to the public, termed "places of public accommodation" (Title III). In addition, ADA standards apply to employment by the Congress.

Two constitutional provisions authorize the ADA. First, Titles I and III are authorized by the Commerce Clause, which provides that Congress has the authority "To regulate Commerce. . .among the several States. . ." (7). Title II is authorized by the Fourteenth Amendment which provides in pertinent part that:

No state shall make or enforce any law which shall. . .deprive any person of life, liberty, or property, without due process of law; nor deny to any person within its jurisdiction the equal protection of the laws. . . .

Note that the Fourteenth Amendment applies to states and not to the federal government. The Fifth Amendment applies to the federal government and contains the prohibition against deprivation "of life, liberty, or property, without due process of law. . . ." While the Fifth Amendment does not contain the equal protection guarantees, in practice, the Fifth Amendment has been interpreted to include it. Note also that the Fourteenth Amendment provides for the enactment of implementing legislation.

The Fourteenth Amendment prohibits only intentional discrimination. For this reason, the Americans with Disabilities Act of 1990 is limited in its application to states. We will discuss intentional discrimination further in this chapter.

### **Social Security**

The Social Security Act, in Titles II and XVI, provides for the payment of benefits and Supplemental Security Income (SSI) to disabled persons. To obtain SSI benefits, an individual must (1) be disabled and (2) have income and resources that do not exceed the prescribed maximums (8).

Entitlement must be established through the presentation of evidence supported by acceptable medical sources (e.g., appropriately qualified medical personnel). The validity of many of the claims for SSI benefits is decided on the basis of evidence presented by the treating sources (i.e., by those actually treating the patient). Other forms of evidence are medical reports and results from consultative examinations. The content of medical reports is specified by regulation. Essentially, a medical report is one that involves all the elements of a standard examination in the applicable medical specialty (9). The Social Security Act is authorized by the Commerce Clause.

### State Law

Most states have enacted laws prohibiting discrimination against individuals with disabilities. Their coverage, in some cases, exceeds that of the federal statutes we will be discussing. The laws of each state should be consulted in dealing with any particular issue.

Children and adults also may be entitled to services under state statutes authorizing the furnishing of social services and education to individuals with disabilities. In *Mullins v. North Dakota Department of Human Services* (10), individuals with attention-deficit/hyperactivity disorder (ADHD) were held to be developmentally disabled persons entitled to social services under statutory language similar to that used in the federal statutes and regulations. In reaching this decision, the court disregarded an administrative manual used by the state agency that, while purporting to provide administrative guidance, in fact narrowed the class of potential recipients.

In *In re Richard M.* (11), the Supreme Court of New Hampshire ruled that a brain injury resulting from an automobile accident may result in a "specific learning disability" under a state statute providing for social services for the developmentally disabled. The court also held that a state regulation limiting the application of the term *developmental disability* to those individuals with onset of the disability before age 18 years was invalid under the statutory definition. (It should be noted that the New Hampshire statute in question used the IDEA definition of disability.)

### WHO IS A QUALIFIED INDIVIDUAL WITH A DISABILITY?

The Rehabilitation Act or the ADA may apply when a *physical or mental impairment* exists that *substantially limits a major life activity*. In order to obtain the protections of the Rehabilitation Act or the ADA, a patient is required to establish that the Rehabilitation Act or the ADA applies and that he or she (1) is an "individual with a disability," (2) is "otherwise qualified," and (3) was denied a job, education, or other benefit by reason of that disability (12).

### Impairments Covered

The Rehabilitation Act or ADA apply to any "individual with a disability," which includes one who "has a physical or mental impairment which substantially limits one or more of such person's major life activities" (13). The term "individual with a disability" includes individuals with ADHD, specific learning disabilities, autism, other neurological impairments, and neuropsychiatric disorders that substantially limit a major life activity. Alcoholism is covered, but current illegal drug use is not. A recovering drug user who has been drug free for a reasonable period is, in all likelihood, covered as having an impairment under the ADA. Conditions such as left-handedness and lack of familiarity with the English language are not covered, even though they may interfere with learning and working.

### Substantially Limits

The impact of the impairment must be severe enough to result in actual substandard performance or in significant restriction of the manner in which a major life activity is performed. The regulations use the term "substantially limits," by which is meant that an individual *either* (1) is "[u]nable to perform a major life activity that the average person in the general population can perform" or (2) is "[s]ignificantly restricted as to the condition, manner or duration" of the major life activity in question, when measured against the abilities of the "average person in the general population" (13).

Who is the average person, and what is the general population? How do you measure the severity of an impairment? Do you consider the beneficial effects of coping strategies and medication? The Supreme Court addressed these questions in a series of cases.

Prior to 1999, most courts held that, under the ADA, the severity of an impairment is to be measured *without* considering the effects of a person's coping strategies, medication, or prosthetic devices. In *Sutton v. United Air Lines, Inc.* (1999) (14), the Supreme Court rejected those cases.

Karen Sutton and her twin sister, Kimberly, had "severe myopia," which was *correctable* to "20/20 or better" with glasses or contact lenses. Without these, however, both sisters "effectively" could not "see to conduct numerous activities such as driving a vehicle, watching television or shopping in public stores." Nonetheless, the sisters applied to United Airlines for employment as commercial pilots. They were rejected because United's policy required 20/20 vision without the corrective effects of glasses or contact lenses. They sued under the ADA and, having lost at trial and on appeal, petitioned the Supreme Court which affirmed the dismissal of their case. The Supreme Court concluded that Congress never intended the ADA to protect, as disabled, those who, like the sisters, were able to "function identically to individuals without a similar impairment," when employing "mitigating measures such as medicines,

or assistive or prosthetic devices." The Court reached the same result with respect to medication (*Murphy v. United Parcel Service, Inc.* (1999) (15), and compensatory strategies (*Albertsons, Inc. v. Kirkingburg* (1999)) (16).

### Major Life Activities

An impairment must substantially limit a "major life activity" before it can be considered a "disability" under the law. The major life activities are considered to be "caring for oneself, performing manual tasks, walking, seeing, hearing, speaking, breathing, learning, and working" (17). The Equal Employment Opportunity Commission (EEOC) has added: *thinking, concentrating, and interacting with others as well as sleeping* to the list of major life activities its investigators will recognize. Whether, and to what extent, the courts will agree with the EEOC is uncertain. Note: Some courts hold that reading and writing are separate major life activities, but these appear to be minority views. It should be noted that the regulations specify that learning and working are major life activities, and these are the ones that most concern us. However, working is treated differently from all other major life activities for purposes of considering whether an individual with an impairment is substantially limited thereby. To be considered to represent a substantial limitation on *working*, the individual's impairment must bar him or her from significant *classes* of jobs, not just from a *particular* job. Only disabilities with the former (and broader) impact are considered to substantially limit working. *Whitlock v. Mac-Gray, Inc.* (18).

Under the ADA, the impairment must *substantially limit* a major life activity. In *Toyota Motor Manufacturing, Kentucky, Inc., v. Williams* (2002) (19), the United States Supreme Court considered the level of severity required. That case involved a suit by an automobile assembly worker who experienced pain in her neck and shoulders and was eventually diagnosed with carpal tunnel syndrome and other disorders. However, while her carpal tunnel syndrome limited her "ability to perform the range of manual tasks associated with an assembly line job," it did not limit her ability to perform isolated, nonrepetitive manual tasks over a short period of time, such as tending to her personal hygiene or carrying out personal or household chores. She was placed on "a no-work-of-any-kind restriction" by her treating physicians. Toyota then terminated her employment, and she sued under the ADA, claiming that she was disabled because she was substantially limited, among other things, in the major life activities of performing manual tasks and working.

The United States Supreme Court ruled that Williams was not an individual with a disability because she could not meet the "demanding standard for qualifying as disabled" created by the ADA. It ruled that to be "substantially limited" in a "major life activity":

an individual must have an impairment that prevents or severely restricts the individual from doing activities that are of central importance to most people's daily lives. The impairment's impact must also be permanent or long-term.

Applying this reasoning to the case at hand, the Supreme Court noted that repetitive work with hands and arms extended at or above shoulder levels for extended periods of time, "is not an important part of most people's daily lives." Williams' ability to perform household chores, bathing, and brush her teeth were, because these "are among the types of manual tasks of central importance to people's daily lives, and should have been part of the assessment of whether [Williams] was substantially limited in performing manual tasks." The case was then returned to the court of appeals for further proceedings.

Lower federal courts have applied similar reasoning in cases involving the ADA and RA. One case, involving a public high school student with learning disabilities, ADD, and epilepsy, is *Costello v. Mitchell Pub. Sch. Dist.* (20). The court found that the student was not substantially limited in any major life activity compared to the general population. While the student may have had a more difficult time learning compared to her peers, any limitations she had did not prevent her from moving to the next grade level. Note, however, that the application of state law may produce radically different results. California, for example requires only that an impairment limit participation in a major life activity. Proof of substantial limitation is not required (21).

### Otherwise Qualified

Under both the Rehabilitation Act and the ADA, an "individual with a disability" must be one who is "otherwise qualified." An "otherwise qualified" individual is one who, although possessed of a disability, would be eligible for the education, job, or program benefit, with or without, a reasonable accommodation. It should be noted that in public elementary and secondary schools, a student is presumed to be qualified for public education. Thus, it is not necessary to prove that the student is otherwise qualified.

The RA and ADA requirement that an individual with a disability be otherwise qualified will exclude many individuals with neuropsychiatric impairments from educational programs and the workplace because it is difficult to show that one is both substantially limited in a major life activity such as learning and is also qualified for the educational program or job. The facts that prove substantial limitation also show a lack of qualification. Conversely, a person whose neuropsychiatric impairments do not disqualify him or her is unlikely to be considered disabled under federal law. In *Robertson v. Neuromedical Center* (22), for example, the Fifth Circuit upheld the termination of a neurologist with ADHD. Holding that there was no duty to accommodate Robertson in his medical practice, the Court found that he was not otherwise qualified to practice medicine, because he was a threat to the "basic medical safety" of his patients, saying:

Robertson posed a 'direct threat' to the health and safety of others in the workplace. Robertson's short-term memory

problems had already caused various mistakes to be made in patients' charts and in dispensing medicine. Most significantly, Robertson voiced his own concerns about his ability to take care of patients, stating that it was only a matter of time before he seriously hurt someone.

### The Central Dilemma of the ADA

The ADA and RA pose a central dilemma: to prove that one has a disability under the ADA/RA, one must show an impairment which both substantially limits a major life activity but (despite its severity) does not render one unqualified for the job or educational program. A great many plaintiffs with neuropsychiatric conditions find that they are either: (1) qualified, but not disabled or (2) disabled, but not qualified.

## THE RIGHT TO BE FREE FROM DISCRIMINATION

Illegal discrimination exists in two senses, intentional discrimination and a refusal to accommodate. Intentional discrimination is illegal whether done by governmental or private entities. Refusals to accommodate are illegal only when done by private parties. We will consider each below.

### Equal Protection and Intentional Discrimination

The Fourteenth Amendment provides in part that "No state shall. . . deny to any person within its jurisdiction the equal protection of the laws. . . ." In the context of disabilities, equal protection of the laws is denied when intentional discrimination occurs. Intentional discrimination consists of a baseless and unlawful difference in the treatment of individuals by reason of their race, gender, or disability characteristics. Whether a difference in treatment is unlawful depends on whether it has a rational basis. Distinctions based on race or gender are *presumed* to have no rational basis and are, for all practical purposes, unlawful. *Nevada Department of Human Resources v. Hibbs*, (U.S.S.C. 2003) (23).

Differences in treatment on the basis of disability may or may not have a rational basis; it all depends on the facts of each case. There is no presumption against different treatment. (See *City of Cleburne, Texas v. Cleburne Living Center, Inc.* (1985) and *Kimel v. Florida Bd. of Regents* (2000) (24)) For example, it would be unlawful for a government to bar African Americans or females from employment as bus drivers. There can be no reason for such a distinction. However, a prohibition against the employment as bus drivers of persons who lack the ability to see has a rational basis even though it involves a difference in the treatment accorded persons with a disability. Under the Constitution, there is no duty to provide individuals with disabilities accommodations, reasonable or otherwise. Failure to provide accommodations does not constitute intentional discrimination.

In *University of Alabama v. Garrett* (2001) (25), the United States Supreme Court said:

States are not required by the Fourteenth Amendment to make special accommodations for the disabled, so long as their actions towards such individuals are rational.

In *Garcia v. S.U.N.Y. Health Sciences Ctr. of Brooklyn* (26), the court held that a medical student dismissed from a state university could not maintain a suit for monetary damages against the university under either the ADA or Section 504 of the RA, unless the university violated the Fourteenth Amendment by committing intentional discrimination (not simply failure to accommodate a disability), and, as to Section 504, unless the state knowingly waived its sovereign immunity from suit when it accepted federal funds. In *Garcia*, the court found that the state had not waived its sovereign immunity.

However, where the discrimination by a state government is intentional, both the Constitution and the ADA, as well as the RA, provide available remedies. In the case of *Olmstead v. L. C.* (1999) (27), the Supreme Court held that the ADA's "proscription of discrimination" may require placement of persons with mental disabilities in community settings rather than in institutions. The persons in question were two women, both of whom were mentally retarded. In addition, one of the two, L.C. suffered from schizophrenia, and the other, E.W., a personality disorder. Community placement, found the Court, is "in order when the State's treatment professionals have determined that community placement is appropriate, the transfer from institutional care to a less restrictive setting is not opposed by the affected individual, and the placement can be reasonably accommodated, taking into account the resources available to the State and the needs of others with mental disabilities." The Court considered the applicability of these rules:

"Unjustified isolation, we hold, is properly regarded as discrimination based on disability."

L.C. and E.W. were entitled to liberty, the maximum reasonable freedom, under the Fourteenth Amendment. Anything less was illegal segregation. In this case, the discrimination consisted of intentional segregation and violated the Fourteenth Amendment as well as the ADA.

In the context of elementary and secondary public education, it is often meaningful access to education. In *Padilla v. School District No. 1* (28), the Court held that the parents had alleged facts which, if true, would constitute a valid claim of intentional discrimination. The facts follow. Between 1992 and 1997, a school district failed to provide a special education student "with the behavioral programming, augmentative communication, and tube feeding services identified in her IEP." The school district also repeatedly "placed her in a windowless closet, restrained in a stroller without supervision," contrary to her IEP. During one of these incidents "she tipped over and hit her head on the floor, suffering serious physical injuries, including a skull fracture and exacerbation of a seizure disorder, which kept her from attending school

for the remainder of the term.” Being locked in a closet and physically abused deprives one of access to education.

In *Davis v. Monroe County Board of Education* (1999) (29), the United States Supreme Court considered what types of access deprivation might be actionable. The Court noted that the “most obvious example” of deprivation “would thus involve the overt, physical deprivation of access to school resources.” Conduct which prevented “students from using a particular school resource—an athletic field or a computer lab, for instance” would give rise to liability. It “is not necessary, however, to show physical exclusion to demonstrate that students have been deprived. . . of an educational opportunity.” Conduct “that is so severe, pervasive, and objectively offensive, and that so undermines and detracts from the victims’ educational experience, that the victim-students are effectively denied equal access to an institution’s resources and opportunities,” is actionable. Note that, while the Court was discussing sexual harassment, the same principles apply in the area of disabilities. (See *Gebser v. Lago Vista Independent School Dist* (30) and *Rees v. Jefferson School District*) (30a). Intentional discrimination must also be proved under the RA (see *Alexander v. Sandoval*) (31). Following *Sandoval*, the Court was careful to point out that its rulings were not based on regulations. In *Jackson v. Birmingham Board of Education*, 544 U.S. \_\_\_ (2005), the court held that a private party may sue a school that receives federal funds in a case in which the private party (a male coach) alleges acts of retaliation against him for reporting discrimination against girls on a girls’ sports team “based on sex.” Following *Alexander v. Sandoval*, the court refused to base its holding on the Department of Education’s regulations. The court said:

We do not rely on regulations extending Title IX’s protection beyond its statutory limits: indeed, we do not rely on the Department of Education’s regulations at all, because the statute itself contains the necessary prohibition.

### Due Process and Intentional Discrimination

The test of what constitutes intentional discrimination is different when due process is concerned. The Fourteenth Amendment also provides that “No state shall. . . deprive any person of life, liberty, or property, without due process of law. . . .” That is because due process requirements apply when the government seeks to require something of the individual. In *Tennessee v. Lane*, 541 U.S. 509 (2004) (31a), the U. S. Supreme Court considered Title II of the ADA in a case involving the issue of physical access by persons with paraplegia to the courts. The Court ruled in a 5–4 decision that private parties could sue states for monetary damages under Title II of the ADA where fundamental due process rights, such as access to the courts, are at issue. Applied in this manner, the ADA “is congruent and proportional” to the congressional “object of enforcing the right of access to the courts.” Put another way, if a court has the authority to take actions against individuals by holding them liable,

then due process requires that those subject to the courts have the ability to use them effectively. For this reason, the United States Supreme Court held the ADA to be constitutional as applied in *Lane*, but not in *Garrett* (25).

### Duty to Accommodate

Intentional discrimination consists of a baseless and unlawful difference in the treatment of individuals by reason of their race, gender, or disability characteristics. In the ADA/RA, the concept has been expanded to include a refusal to provide reasonable accommodations. For example, the ADA provides with respect to employment that “No covered entity shall discriminate against a qualified individual with a disability because of the disability of such individual. . . .” Discrimination is defined to include “not making reasonable accommodations to the known physical or mental limitations of an otherwise qualified individual with a disability. . . .” (32). Similar prohibitions are applicable to places of public accommodation, including private schools.

It should be noted at the outset that states and their agencies, including public educational institutions are barred only from engaging in intentional discrimination. There is no duty to provide reasonable accommodations in the public classroom. Reasonable accommodations are alterations in *nonessential* testing requirements (33), delivery of course materials (34), or job requirements (35) that will enable a child or adult with a disability to perform the *essential* or *fundamental* tasks involved. Modifications that would require alteration of the fundamental nature of a test, course of study, or job or that would cause an undue hardship are not reasonable and are not required (36) (see *Zukle v. Regents*) (37).

The requirement for reasonable accommodation affects virtually all educational institutions, regardless of whether they are elementary, secondary, or postsecondary, in three principal areas:

- Testing (for admissions, evaluation of academic performance, and graduation)
- Delivery of course materials
- Nonacademic benefits of school or college life (e.g., sports, dormitory living)

The bases for these common requirements vary, depending on whether the educational institution is public or private, elementary or postsecondary. Special education and services in *public* elementary and secondary education are governed by the IDEA (38). The Rehabilitation Act and ADA also apply, but in many cases their coverage is less comprehensive than the IDEA’s coverage (39).

Accommodations in *private* elementary and secondary education are governed only by the Rehabilitation Act and the ADA. Accommodations in postsecondary institutions, including colleges, graduate schools, and institutions that prepare individuals to take entrance examinations and

professional licensing examinations or that administer such examinations, are governed by the Rehabilitation Act and the ADA (40). As previously noted, the Rehabilitation Act would not apply unless the school receives federal funding, and the ADA would not apply to religiously controlled schools.

Examinations must be structured in such a way that their results “accurately reflect the individual’s aptitude or achievement level or whatever other factor the examination purports to measure” (41).

In general, entrance and other examinations may not reflect “the individual’s impaired sensory, manual, or speaking skills” unless (1) the purpose of the test is to measure those factors and (2) the measurement of those factors has a valid educational purpose. Testing that relies on a single criterion is unlawful where that criterion can be shown to be an inaccurate predictor of performance and the use of that criterion has no compelling justification.

Examinations are generally required to be modified (1) in the “length of time permitted for completion” and (2) in the “manner in which the examination is given” (42). Auxiliary aids and services must be provided. Modifications are not required where they will alter the fundamental nature of the course or pose an undue hardship. The U.S. Department of Education has stated that in making undue hardship determinations, the primary consideration will be the size and budget of the institution in comparison with the cost of the requested aids, and not the amount of tuition paid by the student (43).

An educational institution must provide equal access to classroom and other educational materials. This duty is described in the regulations as an obligation to provide auxiliary aids and services (44). The auxiliary aids and services must “recognize individual communications needs” and must provide “contemporaneous communication” of the entire educational experience, including class participation, being offered. Their selection is to be guided primarily by a consultative process with the student and not just made unilaterally by the institution (45).

The requirement for reasonable accommodation generally applies in the workplace as well. Again, *nonessential* testing and job performance requirements must be modified. Modifications that would require fundamental job alterations or undue hardship are not required. These requirements apply to federal executive (46) and congressional (47) branch employment, federal funding recipients (48), federal government contractors (49), state and local governments, and most private employers.

## THE RIGHT TO EDUCATIONAL ASSISTANCE—IDEA

Thus far we have discussed the right to be free from discrimination by reason of disability. However, some impairments are sufficiently serious that more proactive measures

are required. In the case of education, these measures are contained in the Individuals with Disabilities Education Act (IDEA). The IDEA applies to “children with disabilities,” which the *United States Code Annotated* (U. S.C.A.) defines as children:

(i) with mental retardation, hearing impairments including deafness, speech or language impairments, visual impairments including blindness, serious emotional disturbance, orthopedic impairments, autism, traumatic brain injury, other health impairments, or specific learning disabilities; and

(ii) who, by reason thereof, need special education and related services (50).

It should be noted that to be eligible, a child must (1) have a listed disability and (2) “by reason thereof, need special education and related services.”

The IDEA has been interpreted to cover ADHD under the categories of “specific learning disabilities,” “other health impairments,” and “serious emotional disturbance.” (See Chapter 11 for discussion of ADHD.) Mood disorders, schizophrenia, anxiety, and other psychiatric illnesses could be covered under the emotional disturbance category. (See Chapter 13 for discussion of mood disorders, Chapter 14 for anxiety disorders.) Autism and Asperger’s Syndrome are also covered.

The IDEA is implemented by the *Code of Federal Regulations* (12), which repeats the terms of the U.S.C.A. definition. The disability definitions in the IDEA are interpreted to be consistent with those that appear in the regulations issued under the Rehabilitation Act and the ADA. For example, the IDEA’s definition of “specific learning disability” governs the interpretation of the term “specific learning disability” as it appears in the regulations issued under the Rehabilitation Act and the ADA (13).

The special education and related services are delivered by means of an *individualized education program* (IEP), which reflects agreement between the school district and the parents as to the specific services that will be delivered during the academic year. Failure to agree triggers a requirement for a due process hearing whose purpose is to create an IEP based on evidence from a variety of sources, including classroom teachers, parents, and professionals.

The IDEA applies only to those disorders and impairments that are sufficiently severe to require special education and related services. Many states give great weight to a “2-year” rule-of-thumb for assessing the impact of a learning disability. Specifically, they refuse to find that a child needs special education and related services unless the child is 2 years behind in his or her academic progress. Thus, a child who puts forth a Herculean effort to perform at grade level in achievement may in effect work his or her way out of qualifying for special education and related services. In some states, the applicable state law may bring about a result more favorable to students with learning disabilities. For example,

Massachusetts requires special education services to develop successfully each child's educational potential. Many states have used a "severe discrepancy" test in deciding whether a specific learning disability exists. The 2004 IDEA, 20 U.S.C. §1414(b)(6)(50a), provides that "when determining whether a child has a specific learning disability. . . a local educational agency shall not be required to take into consideration whether a child has a severe discrepancy between achievement and intellectual ability in oral expression, listening comprehension, written expression, basic reading skill, reading comprehension, mathematical calculation, or mathematical reasoning." The local educational agency may, of course, consider such a discrepancy as a factor in its assessment.

Special education and related services are delivered under the IDEA by means of an IEP, which reflects agreement between the school district and the parents as to the specific services that will be delivered during the academic year. As noted earlier, failure to agree triggers a requirement for a due process hearing whose purpose is to create an IEP based on evidence to be supplied from a variety of sources (e.g., classroom teachers, parents, professionals) (51). Services must be delivered in the *least restrictive environment* appropriate to the needs of the child.

An issue currently of concern is the exclusion for misconduct of elementary and secondary public school students with behavioral and mental impairments. Children with disabilities who are receiving services in public school under the IDEA may not be expelled or suspended for more than 10 days for misconduct arising out of their disabilities, except if maintaining the student in the current placement is substantially likely to cause injury, in which case proper procedures must be followed. Generally, rather than exclude the student from the school program, the school should use the IEP process to determine what additional services may be appropriate to address the disability-related behavior.

A suspension for more than 10 days constitutes a change in placement and triggers a notice and the right to a due process hearing. During these proceedings, the child remains in the original placement. Students who bring firearms to school are treated differently. Such students may be suspended for up to 45 days and may be maintained in an interim placement pending completion of any hearings requested by their parents. Even when a child is excluded from a program because of misconduct, the child is entitled under the IDEA to continuing services.

Students with disabilities who are receiving services under Section 504 of the Rehabilitation Act are also entitled to procedural safeguards in the event of misconduct. However, in contrast with the IDEA, Section 504 has been interpreted to permit the school to cease providing educational services during periods of disciplinary exclusion from school.

## THE RIGHT TO CARE: SOCIAL SECURITY

---

The Social Security Act (SSA) provides for financial support to certain persons with disabilities. To obtain SSI benefits, an individual must have 1) a qualifying disability and 2) income and resources that do not exceed the prescribed maximums (52). A child's disability is measured in terms of what would disable an adult. In other words, a child's ability to function as other children of the same age do must be impaired to a degree comparable to that required of adults. Other statutes provide for *social services* to individuals with disabilities. Individuals with disabilities are also covered by the Fair Housing Act (53).

The SSA (54) applies when a *physical or mental impairment* exists that *effectively precludes* an individual from working and/or caring for himself or herself. A *disability* for purposes of SSI is "the inability to do any substantial gainful activity by reason of any medically determinable physical or mental impairment which can be expected to result in death or which has lasted or can be expected to last for a continuous period of not less than 12 months" (55). The degree of impairment required by this test is greater than that required by the Rehabilitation Act and the ADA.

The following impairments are those specifically covered for children:

- Multiple-body-system impairments, which include "acquired disorders" that create "significant interference with age-appropriate major daily or personal care activities" (56).
- Organic mental disorders ("abnormalities in perception, cognition, affect, or behavior associated with dysfunction of the brain") (57).
- Neurological impairments, including seizure disorders (58).
- Mental retardation, defined as "dependence on others for personal needs" and as having a "valid verbal, performance, or full scale IQ of 60 through 70" accompanied by "impairment imposing additional and significant limitation of function" (59).
- Autistic disorder and other pervasive developmental disorders (60).
- ADHD (61).
- "Developmental and emotional disorders of newborn and younger infants" (62).

## THE RIGHT TO PROTECTION: CRIMINAL AND CIVIL COMMITMENT

---

### Criminal Justice System

A disability such as schizophrenia may constitute an *excuse* that requires a finding of *not guilty by reason of insanity*. A disorder may preclude a witness from testifying when its sever-

ity is such that the individual is not a *competent* witness. A disability may be a factor that reduces the severity of an offense for which an individual may be convicted. A disability also may require a lesser or a modified sentence or may influence the approach to rehabilitation.

Two cases may serve as examples of the increasing interplay between disability-based requirements and the criminal law.

In a case involving a motor vehicle accident, *Jackson v. Inhabitants of Sanford, Me* (63). Jackson, the plaintiff, had been jailed for operating a motor vehicle while under the influence of alcohol or drugs. The evidence of his alleged alcohol-based or drug-based impairment consisted of certain physical difficulties, including partial paralysis and slurred speech. However, Jackson succeeded in establishing that these conditions resulted not from alcohol or drug use but from a prior stroke. The court held that the Town of Sanford, Maine, was liable for discriminatory arrest in violation of Title II of the ADA.

In *State v. Woody* (64), the defendant had been arrested for driving under the influence of alcohol. The principal proof against him was his blood alcohol results. However, the court held these test results inadmissible because the arresting officer had not provided the defendant, who was deaf, with a qualified sign language interpreter from the human resources department at the time the tests were made, as required by state statutes.

The right to adequate physical and mental *health treatment* in prison is evolving. Suffice it to say that although the *existence* of such a right is theoretically established (i.e., by the Eighth Amendment's prohibition against cruel and unusual punishment), the *scope* of that right is disputed, and the enthusiasm with which it is recognized by correctional institutions varies (65). The applicability of the Rehabilitation Act (because of federal law enforcement moneys) and the ADA (because of Title II, which prohibits disability-based discrimination by state and local governments) may lead to improved care.

The right to *education* for children and adolescents who would be entitled to it under the IDEA were they not incarcerated stands on a more substantial footing. In general, the IDEA requires such education, and the various jurisdictions have made progress in implementing these requirements.

### Civil Commitment

Involuntary civil commitment involves compelling individuals with mental illnesses or mental impairments to receive care and treatment. States have various standards for involuntary commitment, one of which is *danger to self or others*. Over the past 20 years, there has been increasing recognition of the importance of less restrictive alternatives to long-term institutional care. Most states provide for an initial commitment period for observation. An individual may not be held beyond that initial period without a hear-

ing. Longer-term commitment without periodic review is unlawful (66). Usually, commitment is to an inpatient institution. Sometimes, involuntary outpatient commitment is an alternative option.

Almost all states have voluntary admission procedures under which an individual may initiate admission for treatment. Minor children with parents or legal guardians have less due process protection than adults. The United States Supreme Court has held that an admitting physician's determination is sufficient for children to be committed to state hospitals by their parents (67).

### Treatment Approaches and Legal Rights

Patients in institutions have legal rights, which may include legal rights to treatment and habilitation, to basic necessities, to refusal of treatments, and to treatment in the least restrictive environment. The courts have held that patients with mental disabilities have a constitutional right to treatment and habilitation (68). Competent individuals have the right to refuse medication for psychiatric conditions, although such medication may be forcibly administered in an emergency situation. In the case of persons who are ruled incompetent to stand trial, antipsychotic medication may be forcibly administered, consistent with due process (69).

The law governing electroconvulsive therapy (ECT) in most states is that before ECT can be administered, the individual, when competent, must give knowing and voluntary consent. In one case, a court honored the declaration of a patient, made prior to her incapacity, withdrawing her consent to further ECT (70). (See Chapter 28 for discussion of ECT.)

The United States Supreme Court has established a restrictive institutional liability standard. Generally, for liability to be imposed, it must be demonstrated that a "substantial departure from accepted professional judgment, practice, or standards" occurred (71). A federal court in Pennsylvania has held that the professional judgment standard should be applied in an action brought by the U.S. Department of Justice under the Civil Rights of Institutionalized Persons Act (CRIPA). The Department alleged that residents of an institution for persons with mental retardation were deprived of adequate basic and medical care and were unduly restrained. The court found that most of the institution's practices, while not necessarily the most desirable practices, did meet minimal constitutional requirements (72).

### DOCUMENTATION

Individuals with neuropsychiatric disabilities or their parents or guardians seek evaluations for a variety of reasons. Increasingly, evaluations are sought to determine eli-

gibility for benefits, services, or accommodations under a number of laws. Documentation of the disability is vital to establishing eligibility. Ordinarily, documentation is based on history, testing, and personal interview and medical examination.

### Components of Documentation

#### History

Compilation of a personal history can be of critical importance in making well documented diagnoses and recommendations. The following areas ordinarily should be considered:

- Obstetrical history
- Developmental history
- Medical history
- School history
- Family history

The patient and his or her family are an essential source of information. However, when disorders such as ADHD and learning disabilities and other psychiatric disorders are at issue, the individual's early family and school experiences may be highly relevant from a clinical viewpoint. When possible, interviews with family members, schoolteachers, and medical advisers can be invaluable in confirming the existence of these disabilities. Additionally, school and medical records can provide important information.

#### Testing

The purpose of IQ testing is to measure intelligence. Psychoeducational testing is undertaken to assess the individual's proficiency in performing academic tasks, and neuropsychological testing is undertaken to assess the functioning of relevant brain regions.

Results from prior testing can be useful. However, because certain disorders, such as ADHD, may lessen in severity or impact with age, a childhood diagnosis of ADHD may not in itself be persuasive when one is attempting to document an adolescent or adult case of that disorder. Similarly, some learning disabilities may have a lessened impact in adulthood because of compensations developed over the years and the greater freedom adults have in selecting activities that are a good match. Therefore, in order to be persuasive, the testing and evaluations undertaken should be recent enough to be clearly relevant to the individual at his or her present stage of life. Recent testing and a prior record of these disabilities are, when occurring together, highly persuasive.

The same is true of school records. A record of accommodation in elementary school, by itself, is probably insufficient evidence to establish the existence of an adult disability and entitlement to accommodations. When combined with results from recent testing, however, such a record is highly persuasive.

#### Personal Interview/Medical Examination

The patient is, of course, the focus of the evaluation. The personal interview and medical examination are of fundamental importance in arriving at well-documented diagnoses and recommendations. (See Chapters 3 and 4.)

#### Sufficiency of the Documentation

Determining how much testing and evaluation is enough is a matter of professional judgment and depends on the use to which the results will be put. At one end of the spectrum is the individual who has sought testing to gain self-knowledge and treatment recommendations. In such a case, the amount of documentation is simply that which a responsible medical practitioner would require in order to make a diagnosis, prescribe medication, and select appropriate additional treatment. At the other end of the spectrum is the individual with disabilities who has sought testing in connection with the assertion of a legal right. A school or employer might be resistant to the request for accommodations or services. Probably the best strategy is to proceed on the assumption that the individual may one day desire to request accommodations or services, even if they are not needed now, and to provide appropriate documentation.

#### Reasonableness of the Documentation

Determining the amount and type of documentation that is reasonable is a medical and legal exercise. The medical professional documenting a neuropsychiatric disability may have to function both as a scientist and as an advocate. Essential medical terms in documentation and their corresponding legal terms under the Rehabilitation Act and the ADA are presented in Table 32.1. Testing, observation, medical examinations, and interviews support the diagnosis. When the purpose of the diagnosis is to assist an individual in obtaining services or academic adjustments in school or accommodations in the workplace, the diagnosis must also support the legal finding that the patient is

<b>Medical</b>	<b>Legal</b>
Diagnosis	= Impairment
Impact	= Substantially limits a major life activity compared to the average member of the population, considering all the beneficial and negative effects of strategies, coping mechanisms and medication
Recommendations	= Reasonable accommodations for an otherwise qualified individual

“otherwise qualified” (although this is presumed in public elementary and secondary school) and is an “individual with a disability” as those terms appear in the law.

As a practical matter, then, the medical practitioner must “document” the patient’s disability by presenting that amount of evidence necessary to persuade the individuals with whom the practitioner is dealing, or, in the event that more formal proceedings become necessary, by proving entitlement by “a preponderance of the evidence.” This legal language means essentially that the practitioner’s evidence must be more convincing than that of his or her “opponent.” Since the practitioner can never know for certain when he or she will be called on to support the patient’s case with testimony, the documentation should be developed with care.

The practitioner may testify as an expert witness. Under the *Federal Rules of Evidence*, he or she may be “qualified as an expert by knowledge, skill, experience, training, or education” to do so (73). As such, the practitioner may offer testimony concerning “scientific, technical, or other specialized knowledge,” provided that it will “assist” the judge or jury “to understand the evidence or to determine a fact in issue” (74). The practitioner’s opinion may be based on “facts or data in the particular case,” which are “those perceived by or made known to” the practitioner “at or before the hearing.” The “facts or data need not be admissible in evidence” if they are “of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject” (75).

## Documentation of the Disability in a Report

### Elements of Documentation

Using as an example the Rehabilitation Act and the ADA, we noted that persons with impairments that substantially limit a major life activity are considered “individuals with disabilities” under those laws. To obtain their protections, an individual may be required to *document* his or her disability. There are three basic elements to proper disability documentation: (1) diagnosis, (2) impact evaluation, and (3) recommendations.

A *diagnosis* is what its name suggests: an *authoritative* opinion by one qualified to assert it, concluding that a specific disability is present. Legally speaking, the diagnosis also establishes the existence of an *impairment* under the Rehabilitation Act and the ADA. Some courts appear to prefer diagnoses that refer to the current edition of the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders*, now in its fourth edition (DSM-IV) (76).

An *impact evaluation* demonstrates how the diagnosed *impairment* affects the individual. Legally speaking, it must show that in the individual case the impairment *substantially limits a major life activity*, such as learning or working, compared to the average member of the population. It must consider the positive and negative effects of pros-

thetic devices, medications, and compensatory strategies employed by the individual, together with an assessment of the impact of the impairment on the individual’s day-to-day tasks. In this regard, it must also address the question of whether and to what extent the impairment was life long.

*Recommendations* suggest reasonable accommodations appropriate for the individual.

### The Report

The professional’s findings are set forth in a report, which usually consists of at least three sections:

- Introductory material
- Fact section (describing history, interview, medical examination, and testing)
- Opinion section (setting forth diagnosis, evaluation of impact, and recommendations)

### Some Dos and Don’ts

The medical professional’s report is central to the patient’s future. A well-supported and well-reasoned report can persuade the school, college, or employer with which the practitioner is dealing. The report can make further advocacy and litigation unnecessary. A poorly reasoned and unsupported report can lead to a refusal to grant the patient’s request and may increase the chances of a dispute and possibly litigation. Here are a few common errors to avoid.

- *Writing the report for the wrong purpose.* A patient may want an evaluation and report for (1) self-knowledge, (2) the development of skill-building strategies or compensatory strategies, or (3) requests for benefits, services, or reasonable accommodations. It is important that both the practitioner and his or her patient know which purpose is intended.
- *Including inaccurate information to avoid offending the patient.* Accuracy can be painful. As a compassionate professional, the practitioner may want to minimize the severity of a disorder so that the patient will not feel discouraged. Such kindness can be harmful, however. In one case, a competent psychologist, having concluded that an auditory processing problem lay at the root of a patient’s academic problems, hastened to add that no learning disability was present. This comment was as harmful as it was kind, for the report suggested that certain of the patient’s academic problems did not result from a disability. Consequently, the university in question had no duty to provide certain of the reasonable accommodations requested.
- *Providing raw data with no explanations.* When writing a report dealing with benefits, special education, services, or reasonable accommodations, the practitioner is writing for a *legal* as well as a *scientific* purpose. The practitioner should remember that his or her medical conclusions support corresponding legal conclusions, as shown in

Table 32.1. Thus, the practitioner must explain the significance of the raw data in terms of the purpose of the report.

- *Including irrelevant information.* A report written for the development of *personal strategies* must necessarily focus on those strategies. An emphasis on those strategies may not be appropriate in a report in which the purpose is to discuss reasonable accommodations. A discussion of certain personal strategies may mistakenly convey the impression that reasonable accommodations would not be necessary if more effective personal strategies were followed. The use of effective personal strategies is not required by law; provision of reasonable accommodations is so required.
- *Using an obsolete edition of a textbook or test.* The practitioner should be sure that he or she cites to the most current edition of the *Diagnostic and Statistical Manual of Mental Disorders* and uses the most current edition of the tests he or she administers. At best, the use of an earlier edition or of superseded texts or tests can sharply diminish the credibility of one's work; at worst, it could, under certain circumstances, constitute malpractice. In a North Carolina case, for example, a psychologist's professional license was revoked for a number of professional deficiencies, including that in one case his professional opinions were based on test results from an obsolete (and inappropriate) intelligence test (77).
- *Misjudging when legal advice is appropriate.* An attorney's advice often is not necessary. However, when the practitioner is uncertain as to whether the report is legally sufficient, or when he or she anticipates opposition to the recommendations in the report, legal complications are probable, and the patient may benefit by consulting with an attorney.

## Confidentiality

Confidentiality may be a major concern for individuals with disabilities. There are several sources of requirements that define when and on what terms confidential information must be protected. Generally, information is public unless its dissemination is *prohibited* by one or more of the following:

- Contract
- Constitutional law
- Statutory provisions and their implementing regulations
- Court decisions

Of these, two that are important for pediatric neuropsychiatrists are contractual agreements and state law statutory provisions applicable to the practice of neuropsychiatry in a particular state.

Arrangements with patients and their families as to confidentiality should be clear and, of course, adhered to in a professional manner.

States have laws that require confidentiality for information furnished to certain professionals. These laws carry with them criminal penalties for unauthorized disclosure. Violations, by professionals, of these laws may also be punished by suspension or revocation of professional licenses. Each state has its own definition of the classes of professionals whose patient–client communications are considered privileged. Virtually all states recognize as confidential communications made to clergy, medical doctors, and lawyers. Psychologists are frequently also included. However, professionals who are not listed in the statutes of a particular state but who perform functions similar to those of listed professionals may *not* be covered. Thus, in *Thompson v. State* (78), the court held that communications made to a “crisis intervention specialist” were *not* protected under a statute creating a psychotherapist–patient privilege.

The psychotherapist–patient privilege is not absolute. Cases have upheld the duty of a psychiatrist, when the patient is a danger to another, to use reasonable care to protect an intended victim. The privilege did not block enforcement of subpoenas issued to psychiatrists during an insurance fraud investigation in which the requested information pertained to patient identities and treatment lengths (79).

Federal laws provide confidentiality protections for children and adults with disabilities. The IDEA provides for confidentiality of school records concerning students with disabilities (80). Regulations provide that these records may be retained permanently by the school unless the parents request that the records be destroyed. The only records that need not be destroyed following such a request are the student's name, address, and telephone number; grades; attendance record; grade level completed; and year completed (81).

At the college level, the IDEA does not apply, but protections are provided by the Family Educational Rights and Privacy Act (FERPA), also known as the Buckley Amendment, which was passed in 1974. It affords students the right to have access to their educational records, requires their consent to release of records to third parties, and allows them to challenge information in their records. The FERPA applies to all colleges that receive federal funds. However, FERPA can no longer be enforced by private law suits. The Supreme Court has ruled that the states have not agreed to liability for suits by private parties to enforce the confidentiality provisions of the Family Educational Rights and Privacy Act of 1974 (20 U.S.C. § 1232g; FERPA (81a)). (See *Gonzaga University v. Doe* (2002)) (82). The only remedy left for disappointed students and their parents are the administrative remedies available from the Department of Education.

Statutes and regulations establish rules of general applicability. On a showing of necessity, courts may authorize or prohibit the release of records based on the factual necessities of the case.

## SUMMARY

The task of the medical professional has broadened in recent years to include advocacy on behalf of patients who wish to use medical information to support legal claims. To accomplish this purpose, the medical professional must understand, in general terms, what legal elements have to be proven, how the medical facts may assist in this demonstration, and what information should be contained in the files of patients who are asserting legal claims and may therefore be subject to disclosure in the course of potential litigation.

# Index

## A

Abbreviated Injury Severity Scale (AISS), 508, 516

abducens nerve palsy, 567

Aberrant Behavior Checklist, 203

abilities, development, 33

abnormal behaviors, 31

abnormal development patterns, 68–69, 69

absence seizures, 460–461

absorption of drugs, 589–590

academic achievement. *see also specific diagnoses*

assessment, 81

brain tumors and, 566

of children born prematurely,

487–488

tests of, 80

accidents, substance abuse and, 334

Accutane. *see* retinoic acid (Accutane, isotretinoin)

*N*-acetyl aspartate/creatine ratios, in ADHD, 224

*N*-acetyl aspartate (NAA), 201, 269

acetylcholine, 637

*achaete-scute* (*XASH-3*) gene, 6, 9

Achenback Child Behavior Checklist, 171

Achenback Teacher Rating Scale, 216

achievement tests, 45

acquired brain injuries, 231

acquired epileptiform aphasia, 68, 122, 463–464. *see also* Landau-Kleffner syndrome

action selection, psychopathologies, 89

activation/switching, 604, 609, 612

active sleep, 35

activity levels, 33, 33, 41

acute disseminated encephalomyelitis, 389

acute dystonic reactions, 432

acute lymphoblastic leukemia, 578

acute stress disorder, 287–288

acute subdural hematomas, 528–529

adaptive behavior

after traumatic brain injuries, 535

assessment of, 704–705

behavioral therapy and, 689

description, 34

family, 696–698

functional instructional strategies, 706–707

school success and, 45

*Adaptive Behavior Assessment System-Second Edition* (ABAS-II), 703, 704

adaptive development, 39–42

adaptive functioning

assessment of, 152

in blind children, 402

tests of, 81

Adderall, 613, 617

adenoma sebaceum, 15

adenosine deaminase (ADA) deficiency, 682

adenotonsillectomy, 369, 371

adenylosuccinase deficiency, 128

adjustment disorder with anxiety, 288

adolescence

acetylcholine levels, 591

brain maturation, 101

cognitive development, 46

development during, 45–47

drug use, 322

emotional development, 47

neurodevelopment, 45–46

pharmacodynamics during, 590

physical development, 45–46

socialization in, 46–47

stages of, 45

tasks of development, 47

adolescents

alcoholic, 324–325

with bipolar disorder, 264

blindness in, 398

common drugs used by, 328–330

depression and, 266

dyslexic, 351

electroconvulsive therapy in, 656–658, 659

insomnia, 377

neuropsychiatric assessments, 49–73

normal anxiety, 286

patterns of substance use, 328

adrenocorticotrophic hormone (ACTH), 296

adults

brain weight, 49

children compared with, 49–50

dyslexic, 351–352

EEG activity, 137

ERP waveforms, 138

affective disorders, 655

affective switching, 604

age factors, TBI recovery, 531

age-related brain atrophy, 332

Agency for Healthcare Research and Quality (AHRQ), 591

aggressive behaviors, 332, 391, 623

agoraphobia, 291

Ainsworth, Mary, 39

alarm, mature CNS, 293

*Albertsons, Inc. v. Kirkingburg*, 718

alcohol idiosyncratic intoxication, 330

alcohol use

acute effects, 328, 330

in adolescence, 47

maternal, ADHD and, 229

alcohol use disorders (AUD)

age-related brain atrophy and, 332

brain activation in, 325

chronic effects, 330

community studies, 321

long-term effects, 331

alcoholism, 325, 717

alertness, biological rhythms, 367

Alexander, Duane, 347

*Alexander v. Sandoval*, 716, 720

alexia, neuroimaging in, 354

all-terrain vehicle injuries, 526

allelic heterogeneity, 673

Alliance of Genetic Support Groups, 680

alpha-2-agonists, 635–636

alpha activity, EEG, 137

alpha-melanocyte stimulating hormone, 308, 308

alpha methyl tyrosine, 173

alpha values, EEG, 142

alternate-treatments design, 692

alternating hemiplegia of childhood, 128

Alzheimer's disease, 673

amantadine, 538

amblyopia, 488

American Academy of Child and Adolescent Psychiatry (AACAP)

on electroconvulsive therapy, 661

guidelines for pediatric depression, 272

mood disorder evaluations, 264

schizophrenia practice parameters, 205
