Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

# Preface

The recent and rapid expansion of our knowledge of neurobiology and human nervous system development has resulted in considerable interest in the study of behavioral disorders associated with normal and “abnormal” brain maturation. Pediatric neuropsychiatry is an evolving clinical discipline devoted to the diagnosis and treatment of psychiatric or behavioral disorders in children and adolescents who have disturbances of brain function.

Our first attempt to systematize the discipline of pediatric neuropsychiatry culminated in the publication in 1998 of *The American Psychiatric Press Textbook of Pediatric Neuropsychiatry*. While this tome received critical acclaim, its comprehensiveness resulted in a volume that was quite large, relatively expensive, and thus inaccessible to some readers. Its publication also generated considerable correspondence from readers with appreciation for our efforts and suggestions for improvements to future editions.

*Pediatric Neuropsychiatry* takes to heart this advice and incorporates the very latest in neuroscience research in an updated and streamlined text designed for clinicians interested in brain-behavior relations. *Pediatric Neuropsychiatry* bridges the fields of pediatric medicine, pediatric neurology, pediatric neuropsychology, child and adolescent psychiatry, and clinical pediatric neuroscience, and emphasizes the relations between neuropsychiatric illness and the developing nervous system. This book is intended for health care professionals—child neurologists, child and adolescent psychiatrists, psychologists, pediatricians, and other clinicians—who desire to understand and ameliorate disturbed behavior associated with diseases of the brain through a comprehensive approach based on a thorough knowledge of contemporary neuroscience. *Pediatric Neuropsychiatry* endeavors to establish a link between the neurobiology of major psychiatric illness and the neurobiology of brain disorders that cause disturbed behavior in children and adolescents, and in so doing stimulate consideration of fundamental brain-behavior relationships as they evolve upon a backdrop of the developing nervous system.

*Pediatric Neuropsychiatry* is organized into four sections, each edited by one or more of the book’s editors or associate editors. The section editors have assembled an outstanding collection of world-renowned neuropsychiatrists, clinical neuroscientists, and scholars, who in turn have endeavored to produce chapters that impart clinically relevant information within the context of the very latest research in developmental neuroscience.

Section I, “Neuropsychiatric Assessment of the Child and Adolescent,” begins with an overview of normal and abnormal brain development, followed by two practical chapters on bedside, neuropsychological, and psychoeducational assessment of the pediatric patient; and three chapters on the role of advanced brain imaging technologies (computed tomography, magnetic resonance imaging, positron emission computed tomography, quantitative electroencephalography, and evoked potentials) in the evaluation of the child and adolescent. This section accomplishes the essential and fundamental task of defining the acceptable limits of “normal brain development” as assessed at the bedside and in the clinical neuroscience laboratory.

Sections II and III provide the clinical core of *Pediatric Neuropsychiatry* and focus upon the neuropsychiatric aspects of psychiatric and neurological disorders, respectively, in children and adolescents. The comprehensive chapters in these sections highlight the influence of the developing nervous system on the pathophysiology, neuropsychiatric manifestations, clinical course, treatment, and prognosis of psychiatric and neurological illness in the child and adolescent.

Section IV, “Principles of Treatment of Pediatric Neuropsychiatry,” emphasizes the special considerations that are essential for safe and effective treatment of neuropsychiatric disorders in children and adolescents. This final section features up-to-date chapters on neuropsychopharmacology, electroconvulsive therapy, genetic interventions, psychosocial and family therapies, educational interventions, and residential facilities. The section also includes a chapter on the special legal considerations that impact the provision of care for these patients. The discussions and recommendations for treatment are anchored as much as possible in a firm foundation of clinical neuroscience research.

## Acknowledgments

We thank the associate editors, David R. Rosenberg, MD, and Kytja K.S. Voeller, MD, for the amazing effort they devoted to *Pediatric Neuropsychiatry*. They join us in thanking each of the chapter authors for their impressive contributions—such quality work requires thought, time, and energy, all of which must be redirected from other pressing demands including those of managed care. Stacey Sebring, Lisa Kairis, and Charley Mitchell of Lippincott Williams & Wilkins provided much guidance and were always avail-

**x Preface**

able to assist with the many issues that invariably arise with a project of this scale. We are grateful that all of these collaborators—the associate editors, chapter authors, and LWW—shared our vision and made this text a priority.

We also acknowledge with special appreciation Mark Kelley, MD, and the Henry Ford Medical Group, as well as the Board of Trustees of Henry Ford Behavioral Health Services, all of whom understand and value the importance of art and science in the enterprise of clinical medicine. Fur-

ther, we acknowledge Creighton University, which in the Jesuit tradition of supporting educational efforts (particularly in the sciences), provided encouragement during the tasks of compiling this text. Finally, this project was ultimately made possible by the understanding, patience, and support of our families.

# Normal Development of the Nervous System

1

**Harvey B. Sarnat, MD FRCPC**    **Laura Flores-Sarnat, MD**

Embryology, the traditional term for ontogeny, has been the basis for understanding development for three centuries. Until recently, embryology was limited to descriptive morphogenesis, both macroscopic and microscopic. Two major advances, beginning in the late 1980s, continue to provide insight with new discoveries of importance almost daily. The first was the discovery of genetic programming as the basis of early development of the neural tube. The second was the recognition that neuroembryology cannot be restricted to the central, or even the central and peripheral, nervous systems, because the developing neuroepithelium and its derivatives, particularly neural crest tissue, induce and regulate the formation of many nonneural tissues. This phenomenon is well demonstrated in craniofacial development and its disorders associated with CNS malformations. Examples of the latter are the midfacial hypoplasia in many cases of holoprosencephaly and the hypertelorism that accompanies many cases of agenesis of the corpus callosum. These facial anomalies, previously recognized only as useful clinical diagnostic markers, can be explained in much more depth than ever before. The *New Neuroembryology* is, therefore, an integration of classical morphogenesis with molecular genetic programming and includes the induction of other tissues by the nervous system during embryonic and fetal life.

Maturation may be further defined by molecular genetics in terms of autocrine, paracrine, and endocrine influences of neurotrophins and other secretory molecules. Specific receptors on the plasma membranes of even “undifferentiated” neuroepithelial cells have been identified. The maintenance of mature neuronal and glial identity in the adult by many of these same genetic transcripts of fetal life provides a further basis for the continuity of development and maturity.

The new neuroembryology in no way invalidates or renders obsolete the classical meticulous observations of central nervous system (CNS) histogenesis, beginning with those of Santiago de Ramón y Cajal (1909–1911) and continuing to this day with ongoing major contributions by such distinguished neuroembryologists as Pasco Rakic, Miguel Marín-Padilla, Ronan O’Rahilly, and Fabiola Müller. Developmental neuropathologists, such as Paul Yakovlev, Reinhard L. Friede, Ellsworth C. Alvord Jr., Lucy Rorke, Margaret G. Norman, and Laurence E. Becker, also have contributed much by applying neuroembryological principles to the explanation of cerebral malformations. Without such a framework, molecular biology would consist of nothing more than a meaningless list of identified gene products. Modern neuroembryology thus encompasses classical embryology to demonstrate maturational change and molecular biology to provide insight into how and why such change occurs.

Embryological development is most readily understood as a sequence of distinct processes with considerable spatial and temporal overlap (Pinter and Sarnat 2004; Sarnat 1992a): (1) genetic patterning, the establishment of the axes of the neuroepithelium, and neural induction; (2) neurulation; (3) neural crest separation and migration; (4) neuroepithelial cell proliferation and differentiation; (5) apoptosis, or programmed cell death; (6) neuroblast migration; (7) axonal pathfinding; (8) membrane excitability; (9) dendritic sprouting and synaptogenesis; (10) biosynthesis of neurotransmitters; and (11) myelination.

An important additional principle of neuroembryology is *initial redundancy*. More neuroblasts are generated than are needed as mature neurons; surplus cells survive for a finite period and are then deleted through the mechanism

finite period and are then deleted through the mechanism of programmed cell death. Axonal collaterals are often numerous during development but later retract, so that diffuse projections become more specific. Transient synapses form that are later deleted. Finally, some cells of the immature brain are functionally important only during fetal life, after which time they disappear or change into another mature cell (e.g., cells that form the boundaries between embryonic segments of the neural tube; Cajal-Retzius neurons of the molecular layer of the cerebral cortex; radial glial cells of the cerebrum). Such cells provide transitional synaptic circuitry, and some contribute “pioneer axons” in long pathways to help guide the first permanent axons of those tracts (e.g., the subplate neurons that form the first descending fibers of the internal capsule before the appearance of pyramidal cell axons from deep cortical layers).

Although cerebral vasculature is not of neuroectodermal origin, the vascular supply and blood-brain barrier are intimately linked to many of the processes of neural development and should be recognized as important aspects of neuroembryology. The formation of the cranium, meninges, and other neural crest derivatives, including facial structures, is also closely associated with neural development, both normal and abnormal.

## EARLIEST EMBRYOGENESIS

---

### Cleavage and Blastulation

Even before the first mitotic division, the fertilized ovum shows a tendency toward axis polarity in the rotation and asymmetrical distribution of microtubules in its cytoplasm, producing animal and vegetal poles. The assembly of microtubules is encoded by a maternal gene and remains stable during cleavage (Gong and Brandhorst 1988); this gene is expressed by microtubule growth during mitotic spindle elongation (Shelden and Wadsworth 1990). The first mitosis yields a pair of daughter cells called *blastomeres*; each subsequent division doubles the number of cells. If the second tetrad of cells lies directly above the first, the arrangement is known as *radial cleavage*; if the second tetrad is rotated so that its cells are staggered above and between cells of the bottom tetrad, the arrangement is called *spiral cleavage*. Like all other vertebrates and some invertebrates, humans follow a radial cleavage pattern. The majority of invertebrates begin embryonic life with spiral cleavages; a few follow unique cleavages that are neither radial nor spiral. Most spiral cleavages are *determinate*: by the eight-cell stage, each cell is already programmed to form certain tissues and no others; for example, the cell of insect embryos forms all mesodermal derivatives, and selective removal of these cells is not compensated as the larva develops. Humans and other animals exhibiting radial cleavages are *indeterminate*: cells are not so rigidly programmed that others cannot compensate, and thus the destruction of one does not produce a defective embryo.

Further mitoses and an increased number of blastomeres produce a hollow sphere of cells, the *blastula*, which in birds and mammals is flattened into a bilaminar disk. The bottom sheet of the disk is known as the *hypoblast*, and the upper is called the *epiblast*. The hypoblast becomes endoderm, and the epiblast will form ectoderm, from which the neural plate and also the mesoderm will differentiate at a later stage. The *blastula* cavity, the *blastocoel* of spherical blastulas, is a potential space between the cellular sheets of hypoblast and epiblast. The *blastocyst* comprises the *embryonic disk* of the flat epiblast and hypoblast, together with the *trophoblast*, or peripheral epithelium, that forms the amniotic and chorionic membranes but is not part of the embryo proper. The blastocyst cavity is therefore not the same as the blastocoel. Both cellular proliferation and apoptosis occur in the blastocyst before and after implantation (Hardy et al. 1989).

## GASTRULATION

---

The next developmental stage in early ontogenesis, gastrulation, is the most crucial because it is during this stage that the body axes establish anatomic form and *induction*—the process whereby one layer of embryonic tissue influences another to cause the affected cells to differentiate in a direction other than that of the inducing cells—begins. Morphological development of the organism depends on normal gastrulation, and any error at this stage is lethal or produces gross defects.

In simple animals with a spherical blastula, such as the frog, gastrulation begins with a small dimple or invagination—the *blastopore*—at one site of the hollow ball of cells. The blastopore deepens, becoming not a hole in the blastula but an invaginated finger lined with surface cells protruding into the blastocoel. The new cavity formed within this finger is the *archenteron*, the lumen of the future gut. The archenteron compresses and eventually obliterates the earlier blastocoel.

## NORMAL DEVELOPMENT OF THE NERVOUS SYSTEM

---

Because the human blastula is flattened, the site of invagination appears as an elongated pair of parallel cellular ridges flanking a central groove. This ridged groove, the *primitive streak*, is the first morphological marker to define the dorsal surface of the embryo; it also establishes the rostrocaudal axis and bilateral symmetry. The day of gastrulation not only is a landmark of the establishment of the axes of the body, but also is the “birthday of the nervous system” because it is the first time that a neuroepithelium can be distinguished as a neural placode on each side of the primitive streak.

Classical embryology attributed great importance to the correlation of spiral cleavage with *protostomes* and of radial cleavage with *deuterostomes*; in *protostomes*, the site of the blastopore becomes the mouth, and in *deuterostomes*, it

## 4 Section I: Neuropsychiatric Assessment of the Child and Adolescent

of programmed cell death. Axonal collaterals are often numerous during development but later retract, so that diffuse projections become more specific. Transient synapses form that are later deleted. Finally, some cells of the immature brain are functionally important only during fetal life, after which time they disappear or change into another mature cell (e.g., cells that form the boundaries between embryonic segments of the neural tube; Cajal-Retzius neurons of the molecular layer of the cerebral cortex; radial glial cells of the cerebrum). Such cells provide transitional synaptic circuitry, and some contribute “pioneer axons” in long pathways to help guide the first permanent axons of those tracts (e.g., the subplate neurons that form the first descending fibers of the internal capsule before the appearance of pyramidal cell axons from deep cortical layers).

Although cerebral vasculature is not of neuroectodermal origin, the vascular supply and blood-brain barrier are intimately linked to many of the processes of neural development and should be recognized as important aspects of neuroembryology. The formation of the cranium, meninges, and other neural crest derivatives, including facial structures, is also closely associated with neural development, both normal and abnormal.

### EARLIEST EMBRYOGENESIS

---

#### Cleavage and Blastulation

Even before the first mitotic division, the fertilized ovum shows a tendency toward axis polarity in the rotation and asymmetrical distribution of microtubules in its cytoplasm, producing animal and vegetal poles. The assembly of microtubules is encoded by a maternal gene and remains stable during cleavage (Gong and Brandhorst 1988); this gene is expressed by microtubule growth during mitotic spindle elongation (Shelden and Wadsworth 1990). The first mitosis yields a pair of daughter cells called *blastomeres*; each subsequent division doubles the number of cells. If the second tetrad of cells lies directly above the first, the arrangement is known as *radial cleavage*; if the second tetrad is rotated so that its cells are staggered above and between cells of the bottom tetrad, the arrangement is called *spiral cleavage*. Like all other vertebrates and some invertebrates, humans follow a radial cleavage pattern. The majority of invertebrates begin embryonic life with spiral cleavages; a few follow unique cleavages that are neither radial nor spiral. Most spiral cleavages are *determinate*: by the eight-cell stage, each cell is already programmed to form certain tissues and no others; for example, the cell of insect embryos forms all mesodermal derivatives, and selective removal of these cells is not compensated as the larva develops. Humans and other animals exhibiting radial cleavages are *indeterminate*: cells are not so rigidly programmed that others cannot compensate, and thus the destruction of one does not produce a defective embryo.

Further mitoses and an increased number of blastomeres produce a hollow sphere of cells, the *blastula*, which in birds and mammals is flattened into a bilaminar disk. The bottom sheet of the disk is known as the *hypoblast*, and the upper is called the *epiblast*. The hypoblast becomes endoderm, and the epiblast will form ectoderm, from which the neural plate and also the mesoderm will differentiate at a later stage. The *blastula* cavity, the *blastocoel* of spherical blastulas, is a potential space between the cellular sheets of hypoblast and epiblast. The *blastocyst* comprises the *embryonic disk* of the flat epiblast and hypoblast, together with the *trophoblast*, or peripheral epithelium, that forms the amnionic and chorionic membranes but is not part of the embryo proper. The blastocyst cavity is therefore not the same as the blastocoel. Both cellular proliferation and apoptosis occur in the blastocyst before and after implantation (Hardy et al. 1989).

### GASTRULATION

---

The next developmental stage in early ontogenesis, gastrulation, is the most crucial because it is during this stage that the body axes establish anatomic form and *induction*—the process whereby one layer of embryonic tissue influences another to cause the affected cells to differentiate in a direction other than that of the inducing cells—begins. Morphological development of the organism depends on normal gastrulation, and any error at this stage is lethal or produces gross defects.

In simple animals with a spherical blastula, such as the frog, gastrulation begins with a small dimple or invagination—the *blastopore*—at one site of the hollow ball of cells. The blastopore deepens, becoming not a hole in the blastula but an invaginated finger lined with surface cells protruding into the blastocoel. The new cavity formed within this finger is the *archenteron*, the lumen of the future gut. The archenteron compresses and eventually obliterates the earlier blastocoel.

### NORMAL DEVELOPMENT OF THE NERVOUS SYSTEM

---

Because the human blastula is flattened, the site of invagination appears as an elongated pair of parallel cellular ridges flanking a central groove. This ridged groove, the *primitive streak*, is the first morphological marker to define the dorsal surface of the embryo; it also establishes the rostrocaudal axis and bilateral symmetry. The day of gastrulation not only is a landmark of the establishment of the axes of the body, but also is the “birthday of the nervous system” because it is the first time that a neuroepithelium can be distinguished as a neural placode on each side of the primitive streak.

Classical embryology attributed great importance to the correlation of spiral cleavage with *protostomes* and of radial cleavage with *deuterostomes*; in *protostomes*, the site of the blastopore becomes the mouth, and in *deuterostomes*, it

becomes the anus. This distinction may be less important in evolution than was previously thought, however (Willmer 1990). The primitive streak elongates through cellular proliferation at one end, designated caudal, while its other end, designated rostral, becomes enlarged as *Hensen's node*, also sometimes called the *primitive node* or *primitive knot*. A shallow depression on the surface of Hensen's node, the *primitive pit*, corresponds to the original blastopore. Cells from the surface of the primitive streak move inward and laterally to form the *mesoderm*. The classical embryological notion of three germ layers—ectoderm, mesoderm, and endoderm—that acquire identity during gastrulation is an oversimplification; molecular genetic studies suggest that this distinction of germ layers may be an outdated concept (Willmer 1990). Neural crest tissue contains the primordia of both ectodermal and mesodermal derivatives. Cells of the neural tube may be experimentally induced to change their fate to mesodermal differentiation (Bronner-Fraser 1995). Myogenic genes influence neural as well as muscle development (Tajbakhsh and Buckingham 1995).

## NOTOCHORD FORMATION

The notochord is an unsegmented transitory embryonic structure, regarded as mesodermal in origin, that helps establish body axes. It is the principal inductor of the overlying neural plate to form the neural tube. The notochord also induces formation of the sclerotomes, the precursors of the vertebral bodies.

The notochord itself undergoes considerable embryological development before it is ready to serve as an inductor. It originates from Hensen's node as a solid cellular strand or column, the *notochordal process*, that grows rostrally between the ectodermal and endodermal layers of epiblast and hypoblast until it reaches a small oval of columnar endodermal cells known as the *prochordal plate*. This plate acts as a barrier to further growth of the notochordal process. The point of attachment of the prochordal plate to the epiblastic ectoderm is the *buccopharyngeal membrane*, the site of the future mouth. The primitive pit extends into the notochordal process to create a tubular lumen, the *notochordal canal*. The primitive streak shortens as the notochordal process elongates. The ventral surface of the notochordal process then fuses with the underlying endoderm and degenerates. The remaining dorsal half of the notochordal process forms a flattened, grooved, elongated plate that remodels itself into the solid cylinder of the "mature" notochord. Mesodermal tissue grows between the notochord and the endoderm and also between the notochord and the neural plate dorsally, but this intervening tissue—the *mesenchyme*—does not impede the transport of secretory induction molecules (e.g., the gene product of *Sonic hedgehog* [see discussion later in this chapter]) from the notochord to the neural plate. The notochord also secretes other diffusible molecules, including trypsin, to repel migratory cells of the neural crest (Pettway et al. 1990). The mesenchyme forming the sheath of the notochord even-

tually contributes to the formation of the meninges—in particular, the dura mater and tentorium cerebelli. The cranial leptomeninges are mesencephalic neural crest derivatives, but the spinal leptomeninges are derived from paraxial mesoderm.

## GENETIC PATTERNING AND NEURAL INDUCTION

The genes that program development of the nervous system consist of a specific series of deoxyribonucleic acid (DNA) base pairs linked to small proteins known as *transcription factors*. A common structure of many transcription factors is the *basic helix-loop-helix* (bHLH), a configuration so primordial in evolution that it first appears in bacteria (Boncinelli et al. 1988). The ribonucleic acid (RNA) transcript translates a peptide, a glycoprotein, or other molecules that mediate induction or serve as trophic factors.

In situ hybridization is a method that allows histological identification of individual cells in which a precise nucleic acid sequence or a product of that sequence is expressed. This method involves the "hybridization" of a nucleic acid probe with a specific target nucleic acid to be recognized within the tissue section and represents a histochemical extension of the older method, liquid phase hybridization. Two single-stranded nucleic acid molecules recognize each other and form hydrogen bonds of complementary base pairs: DNA-DNA, RNA-RNA, or DNA-RNA duplexes. The most common application of in situ hybridization in studies of the developing nervous system is in the detection of specific messenger RNA (mRNA) molecules that are expressed only at precise times and in specific cells during embryogenesis. DNA or RNA probes used for in situ hybridization must be linked to a *reporter*, a means of making the localization within the tissue detectable. The traditional reporters—autoradiographic labels—are now seldom used and have largely been replaced by nonisotope reporters. These include biotin (vitamin H of the B complex), which binds with high affinity to the glycoprotein avidin and may then be demonstrated histochemically as a colored precipitate (the avidin-biotin method). Alternative methods use digoxigenin and enzyme-labeled reporters such as tyrosine kinase, alkaline phosphatase, 3-glucuronidase, or horseradish peroxidase, which may be demonstrated in tissues by either fluorescence or light microscopy (Tecott et al. 1994).

The three main classes of hybridization probes in current use are complementary DNA (cDNA), RNA (riboprobes), and oligonucleotide probes (for a limited segment of the RNA molecule; these require dependence on published nucleic acid sequences). The cDNA probe is double stranded, and the insert (the region complementary to mRNA) is usually contained within a plasmid or bacteriophage. Riboprobes are single-stranded RNA molecules produced from cloned cDNA that was previously introduced into a specifically designed plasmid transcription system. RNA-RNA hybrids are more stable than corresponding DNA-RNA

hybrids, but riboprobes are “stickier” than DNA probes and produce a higher degree of nonspecific binding to tissue; this nonspecific background may be reduced by posthybridization treatment with ribonuclease.

*Induction* is the process whereby one type of embryonic tissue influences another, causing the affected cells to differentiate in a direction other than that of the inducing cells. Induction often takes place between germ layers, as when the notochord (mesoderm) induces the floor plate of the neural tube (ectoderm). Induction may also occur within a germ layer; for example, the optic cup (neuroepithelium) induces the overlying surface ectoderm to form a lens placode and cornea rather than simply more epidermis.

Induction was discovered in 1924 by Hans Spemann and Hilda Mangold, who showed that in newts the dorsal lip of the gastrula was capable of inducing the formation of an ectopic second nervous system when it was transplanted to a different region of a host embryo. This dorsal lip of the amphibian gastrula is homologous with the primitive node (Hensen’s node) in avian and mammalian embryos, and transplantation of this node yields similar results. The regulatory gene *Cnot*, with major domains in Hensen’s node, the notochord, and the prenodal and postnodal neural plate, is probably responsible for this induction (Stein and Kessel 1995).

*Neural induction* is the maturation of nervous system structures in response to signaling molecules secreted in the vicinity by other tissues of either mesodermal or ectodermal origin. It is the receptors in the membrane of the induced cell, not the inductive molecule that determines the specific type of tissue that the affected cell will become. These membrane receptors are responsive to the effects of the inductive molecules only during a precise period of time known as the *competence* of the induced cell. A gene called *Notch* regulates the competence of response to more specific inductive cues in the CNS and in many other embryonic tissues (Fortini and Artavanis-Tsakonas 1993). Some mesodermal tissues (e.g., smooth muscle of fetal gut) may act as mitogens on the neuroepithelium by increasing the rate of cellular proliferation (Fontain-Perus 1993), but this phenomenon does not represent true neural induction because the proliferating cells do not differentiate. Some regulatory genes, such as *Wnt-1* (see discussion later in this chapter), also have mitogenic effects (Dickson et al. 1994).

## ORGANIZER GENES AND HOMEBOXES

In all vertebrates and most invertebrates, the fundamental body plan is established early in embryonic development and is defined by bilateral symmetry and axes of polarity—cephalocaudal and dorsoventral gradients of differentiation and growth. The radial symmetry exhibited by some invertebrates, such as sponges, coelenterates (e.g., sea anemone, hydra, jellyfish), and echinoderms (e.g., starfish), often is secondarily achieved or represents an exceptional

alteration of early programming (Sarnat 1992a). From a phylogenetic perspective, the fundamental body plan became firmly established in the Cambrian Period, 570 million years ago, although various other body models have been discovered in long-extinct multicellular organisms dating from the earlier Ediacara Epoch (Seilacher 1984). Bilateral symmetry as a body plan is more ancient than previously thought. A simple marine invertebrate with a bilaterally symmetrical body, named *Vernanimalcula*, from the pre-Cambrian period of 580-600 million years ago, recently was discovered in Guizhou Province, China, from microfossils with excellent preservation (Bottjer 2005).

*Organizer genes* are the earliest to be expressed in ontogenesis. They continue to regulate polarity and body axes beyond the gastrula state; they also establish growth gradients as embryonic cells multiply. The transcription products of these genes may be expressed in several differentiating organ systems but not necessarily in all; some of these products are integral to neural development.

The early formation of the neural plate is accomplished not only by mitotic proliferation of neuroepithelial cells but also by conversion of surrounding cells to a neural fate. In amphibians, a gene known as *achaete-scute (XASH-3)* is expressed very early in the dorsal part of the embryo from the time of gastrulation and acts as a molecular switch to change the fate of undifferentiated cells to become neuroepithelial rather than surface ectodermal or mesodermal cells (Turner and Weintraub 1994). Inhibitor genes also play a major role in controlling cell fate; some cells differentiate as specific types because they are inhibited from developing as others.

Each gene of the developing nervous system has a specific site of expression along the rostrocaudal and dorsoventral axes. Some genes determine the patterning of particular segments of the neural tube, such as the midbrain. A dorsal or ventral gradient of expression may or may not be associated with influence on adjacent regions. A *dorsalizing* gene not only has a dorsal distribution of expression but will also cause ventral regions of the neural tube to differentiate as dorsal regions if the influence of *ventralizing* genes is insufficiently expressed. This principle is well demonstrated in the development of the somite, in which the sclerotome normally lies ventral to the myotome and dermatome; implantation of ectopic floor-plate cells next to the somite in chick embryos causes ventralization of the somite, so that excessive amounts of sclerotome (cartilage and bone) and insufficient amounts of myotome (muscle) and dermatome (dermis) are formed (Brand-Saberi et al. 1993; Pourquie et al. 1993). The floor plate in this case functions as a ventralizing inductor of the mesodermal somite, and the gene product probably responsible is one known as *Sonic hedgehog*, which also exerts a ventralizing effect in the neural tube (see “*Sonic Hedgehog [Shh] Family*,” on page 9). Genes have often been assigned bizarre names, and vertebrate and invertebrate homologues may have similar but not identical names even if their nucleotide sequences are identical.

Table 1.1 summarizes several of the important genes and gene families that program the nervous systems of all

**TABLE 1.1****PARTIAL LIST OF ORGANIZER GENES AND HOMEBOXES THAT PATTERN EARLY DEVELOPMENT OF THE MAMMALIAN NERVOUS SYSTEM**

Gene	Site(s) of Expression	Function(s)
<i>Lim-1</i>	Rostral progenitor cells	Head organizer, mesenchyme and neural placode
<i>twist</i>	Rostral progenitor cells	Head organizer, mesenchyme only
<i>XASH-3 (achaete-scute)</i>	Epiblast, neural plate	Induces neuroepithelial differentiation, mediolateral gradient
<i>Notch</i>	All embryonic cells	Determines competence of cells to respond to induction
<i>Delta</i>	All neural precursor cells	Antagonizes <i>Notch</i> ; prevents adjacent cells from undergoing neural differentiation
<i>Numb</i>	All embryonic cells	Antagonizes <i>Notch</i> during mitotic cycling
<i>Cnot (Xnot)</i>	Primitive node, notochord, prenatal diencephalon, postnodal neural plate caudal to hindbrain in a decreasing gradient	Responsible for specification of notochord and prechordal mesoderm; early induction of neural plate
<i>goosecoid</i>	Cells rostral to notochord	Induces prenotochordal mesoderm and forebrain
<i>Sonic hedgehog</i>	Ventral midline of neural plate and neural tube; posterior and distal limb buds	Mediates early induction from Hensen's node, notochord, and floor plate; exerts strong ventralizing polarity gradient; initiates differentiation of motor neurons
<i>HNF-3 (forkhead)</i>	Ventral neural tube	Patterns ventral midline of neural tube
<i>Islet-1,2</i>	Ventral neural plate	Promotes differentiation of motor neurons
<i>Hox-1.5</i>	Neural crest	Programs mesenchymal neural crest, thymus, parathyroids
<i>Hox-1.6 (Hoxa-1)</i>	r4 through r7	Contributes to rostrocaudal patterning and segmentation of hindbrain
<i>Hox-2.1</i>	r8, spinal cord	Contributes to rostrocaudal patterning and segmentation of hindbrain
<i>Hox-2.6</i>	Spinal cord to r6/r7 boundary	Contributes to rostrocaudal patterning and segmentation of hindbrain
<i>Hox-2.7</i>	Spinal cord to r4/r5 boundary	Contributes to rostrocaudal patterning and segmentation of hindbrain
<i>Hox-2.8</i>	Spinal cord to r2/r3 boundary	Contributes to rostrocaudal patterning and segmentation of hindbrain; regulatory axonal pathfinding at r3
<i>Hox-2.9 (Hoxb-1)</i>	r4 only	Contributes to rostrocaudal patterning and segmentation of hindbrain; cranial neural crest formation
<i>Hox-3.1 (Hoxc-8)</i>	Spinal cord (r8), especially brachial (cervical) region	Contributes to patterning of spinal cord
<i>Krox-20 (zinc finger)</i>	r3, r5	Regulates expression of <i>Hox</i> genes; myelination by Schwann cells
<i>Zic (zinc finger)</i>	r1	Programs differentiation and maintenance of cerebellar granule cells
<i>En-1 (engrailed)</i>	Midbrain, r1	Programs differentiation of midbrain, cerebellum, and rostral metencephalon (pons)
<i>En-2</i>	Midbrain, r1	Regulates differentiation of midbrain, cerebellum, and rostral metencephalon (pons)
<i>Wnt-1 (wingless)</i>	Midbrain, r1, lateral margins of neural plate of r3 to spinal cord; diffusely and weakly in forebrain	Maintains expression of <i>En-1</i> redundant with <i>Wnt-3</i> in hindbrain; mitogenic
<i>Wnt-3</i>	r3 through r8; Purkinje cells of cerebellum	Exerts dorsalizing polarity gradient for differentiation of hindbrain structures; maintains integrity of Purkinje cells
<i>Pax-2 (paired)</i>	r2 through r8 in ventricular zone adjacent to sulcus limitans; spinal cord; ventral half of optic up and stalk	Regulated by signals from notochord and floor plate; plays adjunctive role in segmentation of hindbrain; exerts dorsalizing polarity gradient
<i>Pax-3</i>	Spinal cord; Bergmann glia of cerebellum	Maintains integrity of Bergmann cells
<i>Pax-6</i>	Hindbrain; granule cells of cerebellum; forebrain; eye; pituitary; olfactory nasal epithelium	Maintains integrity of granule cells
<i>Dlx-1, 2, 3</i>	Forebrain	Provides positional information for somatotopic organization
<i>BF-1,2</i>	Forebrain, retina	Provides positional information for somatotopic organization
<i>Nkx-2.2</i>	Forebrain, neural tube	Induces forebrain compartmentalization; defines longitudinal columns of neural cells along entire neuraxis

Note: Genes are listed in general order of time of expression. r = rhombomere.

vertebrates. The gene locations of known human mutations causing specific CNS malformations are summarized in a recent table (Sarnat 2005). Homologues of vertebrate genes in the fruit fly *Drosophila* perform parallel though often more extensive functions in invertebrates, and gene products of the fly and the mouse are so similar that they can be experimentally interchanged to achieve the expected effect. Most of these genes are also functionally active in other systems of the body, such as in programming the gradient of anteroposterior differentiation of the limb buds.

Although *homeoboxes* and *regulator genes* overlap considerably with organizer genes and, in some of their expressions, could be dually listed under the “organizer” rubric, homeoboxes generally program the stage of CNS development subsequent to that in which the polarity gradients of the neural plate are established. Homeoboxes establish embryonic segmentation of the neural tube and invoke limits on cellular migration between successive compartments (Fig. 1.1); they initiate the differentiation of specific neuronal and glial cells and later help to maintain the morphological and metabolic identities of those cells even into adult life. These genes also provide for receptors on the cell membrane to receive specific inductive and neurotrophic molecules. From a molecular genetic perspective, homeoboxes consist of specific nucleotide sequences that encode a DNA-binding sequence, the *homeodomain* that is found in many transcriptional regulator proteins involved in development. Some human malformations are likely the result of failure of segmentation, with ectopic or deficient expression of homeoboxes to form normal neuromeres. Examples include congenital absence of the mesencephalon and metencephalon with cerebellar hypoplasia, probably due to an *EN=2* mutation (Sarnat et al. 2002) and perhaps the Chiari malformations (Sarnat et al. 2004a).

The evolutionary biologists and theorists of the late nineteenth century, led by Thomas Huxley in England, were constantly seeking “missing links” in evolution—between humans and great apes, between primates and other mammals, between mammals and reptiles, and, most perplexing of all, between vertebrates and invertebrates, whose bodies and central nervous systems differ so greatly that evidence of homology between structures often is elusive when one must depend solely on anatomic and histological examination. *Homeoboxes are the missing link*, because nucleic acid sequences *identical* to those that serve as segment polarity genes in larval arthropods and worms also program embryonic segmentation of the vertebrate brain (De Pomerai 1990).

*Homeoboxes* are restricted DNA sequences composed of 183 base pairs of nucleotides that encode a class of proteins sharing a common or very similar 60-amino-acid motif, the *homeodomain* (McGinnis and Krumlauf 1992). Homeodomains contain sequence-specific DNA binding sites and are components of larger regulatory proteins, the transcription factors. Homeoboxes, or homeotic genes, are classified into various families having a common molecular structure

and similar general expression in ontogenesis. A set of some 13 *Hox* genes determines the rostrocaudal gradient of differentiation of the neural tube and also creates *neuromeres*, segments that restrict cellular migration in the longitudinal axis (Keynes and Krumlauf 1994). A series of eight such segments, or *rhombomeres*, each of which forms predictable structures, has been identified in the hindbrain (Keynes and Lumsden 1990; Lumsden 1990). Rhombomeres are identified morphologically as a series of transverse ridges and ringlike constrictions at the dorsal or ventricular surface of the hindbrain. The eighth rhombomere is continuous with the spinal cord. Apparent segmentation of the spinal cord is

**Figure 1.1** Drawing of parasagittal section of a 3-day chick embryo to illustrate hindbrain rhombomeres (r1–r8) as a primary segmentation of the developing central nervous system. These compartments are mainly programmed by *Hox* homeobox genes. The spinal cord (sc) is really a caudal continuation of r8, and its segmentation is secondary, imposed by surrounding mesodermal somites. The midbrain (m) neuromere and diencephalic (d) and telencephalic (t) neuromeres are rostral continuations of the series; the forebrain actually consists of at least three distinct neuromeres. The cranial motor nerves (III–XII) are shown, but not the cranial ganglia. The exit points of branchial motor nerves (V, VII, IX) are in alternate rhombomeres, in register with the first three branchial arches (b1–b3). The entire cerebellum is derived from r1. (Reproduced from Lumsden A. *Trends in Neuroscience* 13:329–335, 1990. Copyright 1990, Elsevier Science, Ltd. Used with permission.)

actually a phenomenon of changes between somites adjacent to the spinal cord (Stern et al. 1991). The spinal cord does show distinctions in different regions, for example parasympathetic preganglionic neurons confined to the cervical and sacral regions and sympathetic neurons in the thoracolumbar region, and the presence of the column of Clarke, neurons of origin of the dorsal spinocerebellar tract, only at T1 to L2 levels, but these regional differences do not denote distinct compartments separated by neuromeric boundaries in embryonic life, hence are not true segments or distinct neuromeres.

In traditional neuroembryology the CNS is divided into two components, the brain and the spinal cord. However, the organization of the spinal cord is merely a continuation of fundamental brainstem architecture; molecular biology and comparative vertebrate neuroanatomy suggest that the spinal cord is nothing more than an elongated single rhombomere. It appears segmental only because of extrinsic groupings of nerve roots imposed by the primary segmentation of adjacent somites and of bony neural arches. A few intrinsic regional differences do occur, however, such as the autonomic relay nuclei of the intermediolateral columns and the column of Clarke for spinocerebellar relay.

The entire cerebellum is derived from rhombomere 1 (r1), though the deep cerebellar nuclei arise from r2. (Fig. 1.1). Each cranial nerve originates from a pair of sequential rhombomeres lying in register with an adjacent branchial arch. Thus, the neurons of the trigeminal nerve derive from r2 and r3, opposite the first branchial arch; the facial nucleus arises from r4 and r5, opposite the second arch; and the glossopharyngeal nerve emerges from r6 and r7, opposite the third arch. Furthermore, the rostral member of each rhombomere pair produces motor axons earlier than does the caudal member and contains the motor nerve root. The mesencephalic neural crest develops and migrates not only from the mesencephalic neuromere (r0), but also from r1 and r2' (the rostral half of r2, which together with r1, produces the metencephalon or rostral pons, in addition to the cerebellum).

The intermitotic to-and-fro movement of proliferating neuroepithelial cell nuclei within their own radial cytoplasmic processes, between the ventricular and pial surfaces, is active within rhombomeres but is reduced or absent at rhombomere boundaries. Although cells continue to divide at the ventricular surface at boundaries, their nuclei remain close to this surface throughout the cell cycle; this relative stasis and increased cell-cell adhesion contributes to the formation of barriers to cellular movement from one rhombomere to the next (Guthrie et al. 1991).

Certain genes are essential to segmentation of the neural tube and, if not expressed at the proper time, specific neuromeres fail to form (Sarnat and Menkes 2000). For example, agenesis of the midbrain and metencephalon (rostral pons) with cerebellar agenesis or hypoplasia may be caused by mutations in the WNT1, EN1 or EN2 homeobox genes (Sarnat et al 2004).

## FAMILIES OF REGULATORY GENES OF EARLY NEURAL DEVELOPMENT

### Fundamental Organizer Genes (*Notch*, *Delta*, *Numb*, *Lim*, *islet*, *twist*, *Cnot*, *gooseoid*)

These organizer genes establish the fundamental axes of differentiation and growth of the neuroepithelium from the time of gastrulation and also are important in determining cell fate, including to which germ layer a cell belongs. The expression of *achaete-scute* converts ectodermal cells to a neural fate (Turner and Weintraub 1994) and provides for neural induction and position along the mediolateral axis of the neural plate (Zimmerman et al. 1993). *Notch* regulates the competence of cells to induction. *Notch* is expressed in virtually all embryonic cells, in contrast to *achaete-scute* genes, whose expression is restricted to small territories from which neurons arise (Fortini and Artavanis-Tsakonas 1993). Neural precursors, by expressing the "antagonistic" gene *Delta*, inhibit neighboring *Notch* expressing cells from becoming committed to a neural fate. Interference with *Delta* activity results in overproduction of primary neurons; thus, commitment to a neural fate is regulated by *Delta-s-Notch* signaling (Chitnis et al. 1995; Henrique et al. 1995).

*Notch* is symmetrically expressed during the mitotic cycling of the neuroepithelial cell, and its gene products are concentrated on one side of the cell; an antagonistic gene, *Numb*, is associated with *Delta* and is expressed on the side of the cell opposite to *Notch* expression. The orientation of the cleavage plane or mitotic spindle, whether parallel with or perpendicular to the ventricular surface, determines the fate of the pair of daughter cells; if the cleavage plane is perpendicular to the ventricular wall, *Notch* and *Numb* are equally divided between the two daughter cells; if the cleavage is parallel, however, one cell inherits nearly all of the *Notch* and the other inherits nearly all of the *Numb*. One of these cells is at the ventricular surface and reenters the mitotic cycle; the other loses its attachment to the ventricle and becomes a postmitotic premigratory neuroblast (Chenn and McConnell 1995; Guo et al. 1996; Spana and Doe 1996). *Lim-1*, a gene generated in embryonic stem cells (undifferentiated progenitor cells), is the "head organizer." Mouse embryos homozygous for the null allele (inactivated *Lim-1*) lack anterior head structures, including the forebrain, although the remaining body axis and neural tube are normally formed (Shawlot and Behringer 1995). Although the earliest expression of *Lim-1* is in a small zone of the mammalian epiblast (i.e., dorsal lip of the amphibian gastrula) where the primitive streak forms (Shawlot and Behringer 1995), at a later stage *Lim-1* and *Zz'ra-3*, together with members of another family of organizer genes, *islet-1* and *islet-2*, define subclasses of motor neurons that segregate into columns in the spinal cord (Tsuchida et al. 1994). Motor neurons cannot be generated without *islet* genes (Pfaff et al. 1996) and *Sonic hedgehog* (discussed below). Another gene, *twist*, is equally essential for differentiation

of the cranial neural tube; in *twist-mill* mice, the cranial neural folds fail to fuse and there are defects in the head mesoderm and somites (Chen and Behringer 1995).

The gene *Cnot* (*Xnot* in the amphibian), first expressed in Hensen's node, is critical to notochordal identity and hence to induction of the floor plate and further development of the neural tube; a related gene, *gooseoid*, performs a similar programming function for the prechordal mesoderm, inducing the rostral neural tube to form the forebrain (Stein and Kessel 1995). A transition from *gooseoid* to *Cnot* expression may begin while cells are still in the epiblast stage but does not occur after cells assume a mesodermal identity.

### Sonic hedgehog (Shh) Family

*Sonic hedgehog* (*Shh*) is the name of an early gene of neural induction, the protein product of which is secreted by Hensen's node, the notochord, and floor plate ependymal cells in the ventral midline even before closure of the neural tube (Echelard et al. 1993); the floor plate cells are the first neuroepithelial cells to differentiate. *Hedgehog* (*hh*), the insect homologue of *Shh*, is a segment polarity gene. *Shh*, one of a family of four *hh* genes in vertebrates, is a regulator of polarity for induction of the ventral CNS and exerts a strong ventralizing influence on dorsal structures; it defines longitudinal columns of cells that are present along the entire neuraxis (Shimamura et al. 1995). *Shh* also programs a strip of posterior and distal mesenchyme on the developing limb bud that is closely associated with the overlying ectoderm (Echelard et al. 1993; Maden et al. 1991; Riddle et al. 1993). The *Shh* protein acts in a concentration-dependent gradient to induce different cell fates across a developing segment of limb bud or neural tissue. *Shh* is unique among the organizer genes in encoding not only a signaling molecule but also a protease required for its own processing (Peifer 1994). Retinoic acid (or its alcohol, retinol or vitamin A) induces *Shh* expression, but excess retinoic acid interferes with rhombomere segmentation in the otic region of r4 and the associated neural crest of r3-r5 by altering the transcriptional activity of *Hox-2.9* and *Krox-20* genes (Maden et al. 1991; Morriss-Kay et al. 1991; Schneider-Maunoury et al. 1993). Retinoic acid is synthesized by both the notochord and the floor plate (Wagner et al. 1990). *Shh* signals from the floor plate induce differentiation of motor neuroblasts. *Shh* is expressed in the ventral part of the forebrain as well as in more posterior regions of the neuraxis, despite the fact that the notochord and floor plate do not extend rostrally beyond the mesencephalic-diencephalic junction. The floor plate is itself induced by the notochord, probably through the synthesis of *Shh* protein and retinoic acid. *Shh* expression activates other important genes in both the CNS and the limb bud, including *Wnt-1* (Echelard et al. 1993) and *Hox* genes (Riddle et al. 1993). Similarly, in insects, *hh* is expressed concomitantly with the segment polarity genes *wg* (homo-

logue of *Wnt-1*) and *engrailed* (homologue of *En-1*) (Lee et al. 1992).

### Hox Family and (murine) Krox-20 (human EGR-2)

The primary family of homeobox genes for hindbrain segmentation, known as *Hox*, includes a bHLH transcription factor that encodes a 60-amino-acid homeodomain in the spinal cord and brainstem (Guthrie et al. 1992; Storey et al. 1992). The *Hox* family includes 38 members, which in vertebrates are organized into four gene clusters that are activated during gastrulation. *Hox-2* consists of a cluster of nine genes distributed on four different chromosomes (2, 7, 12, and 17) that specify the anterior limit of each rhombomere: *Hox-2.1* is restricted to the spinal cord; *Hox-2.6* is expressed in the spinal cord and extends rostrally to the boundary of r6/r7; *Hox-2.7* extends further rostrally to specify the boundary of r4/r5; *Hox-2.8* establishes the boundary of r2/r3; and *Hox-2.9* is expressed only in r4 and overlaps the domain of *Hox-1.6*, which includes r4 through r7. Although *Shh* from the floor plate induces initial motor neuron differentiation, *Hox-2* genes preserve their identity in the hindbrain (Kessel 1994). *Hox-2* genes also pattern migratory neural crest cells from r4, and *Hox-1.5* appears to program the formation of mesencephalic neural crest tissue as well as the thymus and parathyroid glands (Chisaka and Capecchi 1991; Hunt et al. 1991).

Another gene, *Krox-20* (mouse gene, same as *EGR-2* in the human), is one of the "zinc fingers" because of zinc-containing histidine and cysteine residues in its transcription factor, it is expressed in alternating rhombomeres, mainly r3 and r5; it is important in neural crest development and also regulates the expression of other genes, particularly those of the *Hox* family (Wilkinson and Krumlauf 1990). Retinoic acid antagonizes the expression of *Hox* genes and thus is considered to be another regulator (Kessel 1993). *Krox-20* (*EGR-2*) suppresses the formation of neural crest tissue. As this tissue forms in the dorsal region of r3 and r5, these neural crest primordia shift rostrally and caudally to join the neural crest forming in the adjacent rhombomeres, so that r3 and r5 appear to have no neural crest contribution.

### Pax (Paired) Family

Like *Hox* genes, the family of *paired* homeobox, or *Pax*, genes is also involved in the establishment of compartments and boundaries that segment the neural tube; in addition, *Pax* genes play a role in dorsal patterning and in establishing neuronal identity in the dorsal half of the neural tube (Chalepakis et al. 1993; Koseki et al. 1993; Stoykova and Gruss 1994). Regional expression of *Pax* genes occurs in response to signals from the notochord and floor plate (Goulding et al. 1993; Koseki et al. 1993). *Pax-2* is expressed in the ventricular zone in two compartments of cells on either side of the sulcus limitans along the entire rhomben-

cephalon and spinal cord; it is also expressed in the ventral half of the optic cup and stalk (Nornes et al. 1990). *Pax-6* is expressed in discrete regions of the forebrain and hindbrain, the eye, and the pituitary and olfactory nasal epithelium (Callaerts et al. 1997; Walther and Gruss 1991). *Pax-1* is expressed in sclerotome cells but only in the presence of an intact notochord (Koseki et al. 1993); it acts as a mediator of notochordal signals for the dorsoventral specification of sclerotomes that will form the ventral parts of vertebrae (Koseki et al. 1993). Signals from the notochord also regulate regionally specific *Pax-3* and *Pax-6* genes in the developing spinal cord (Goulding et al. 1993). These genes continue to be active in the adult CNS in maintaining cell identity and integrity: high levels of *Pax-6* are expressed by cerebellar granule cells, and *Pax-3* transcripts are associated with Bergmann glial cells (Stoykova and Gruss 1994). *Wnt-3* (discussed later), by contrast, is expressed in adult as well as fetal Purkinje cells and is modulated by presynaptic granule cells, presumably under the regulation of *Pax-6*, at the time of neuronal maturation (Salinas et al. 1994). More than one gene may be required for specific cellular lineage. Cerebellar granule cells are maintained not only by *Pax-6* but also by *Zic*, another “zinc finger” gene product (Aruga et al. 1994).

### Wnt (Wingless) and En (Engrailed) Families

The *Wnt* family is an important group of genes that program the secretion of cell-signaling or inductive molecules early in differentiation of the nervous system (McMahon 1992). Ten *Wnt* genes have been identified in the mouse embryo; the *Wnt* family is homologous with the segment polarity gene *wingless* (*wg*) in the fly. Each mammalian *Wnt* gene has a characteristic expression at particular sites in the rostrocaudal axis of the developing neural tube; of equal importance is the dorsoventral polarizing gradient that organizes the brain in the axis perpendicular to the longitudinal axis and exerts a strong “dorsalizing” influence that antagonizes the “ventralizing” induction effect of the notochord and floor plate. In the mouse, *Wnt* expression is strongly expressed in a domain nearly identical to that of the homeobox gene *En-1* (*engrailed* in the larval fly), throughout the midbrain and rostral half of the metencephalon in r1 (Joyner and Martin 1987). More caudally, *Wnt-1* expression is confined to the lateral margins of neural plate that later fuse in the dorsal midline with neurulation to become the medulla oblongata and spinal cord. *Wnt-1* is expressed weakly and diffusely rostral to the midbrain neuromere; *Wnt-7*, by contrast, is strongly expressed in the future diencephalon and telencephalon (Parr et al. 1993). The major domain of *Wnt-3* is the myelencephalon, in r3 through r8, where it possesses a strong dorsal polarizing gradient and induces cellular differentiation.

The limits of expression of *En* and *Wnt* genes change with maturation. Neither *En-1* nor *Wnt-1* is active in the mouse embryo before formation of the first somite, but, coincident

with the condensation of the first mesodermal somite, overlapping expression of *En-1* and *Wnt-1* is detected in the neuroepithelium just rostral to the preotic sulcus. By the three-somite stage, *En-1* and *Wnt-1* domains extend throughout the midbrain neuromere, and many individual cells coexpress the two genes (this is different from what occurs in the fly; however, in that species, a mosaic mixture of cells expressing either *En* or *Wnt* is present in each segment). By the six-somite stage, *Wnt-1* expression is more extensive in the longitudinal axis but is restricted to the dorsal region of the hindbrain and also is stronger dorsally than ventrally in the midbrain. By the 27- through 30-somite stages, *Wnt-1* is almost exclusively confined to the dorsal midline of the midbrain and is no longer detected in ventral regions (McMahon and Bradley 1990; McMahon et al. 1992).

### Diencephalic and Telencephalic Gene Families

Several homeotic genes—among them *Wnt-1*, *Dlx-1*, *Dlx-2*, and *Nkx-2.2*—are expressed in the developing forebrain, but their functions are incompletely defined (Bulfone et al. 1993; Figdor and Stern 1993; Price et al. 1992; Puelles and Rubenstein 1993; Salinas and Nusse 1992). *Nkx-2.2* also controls the patterning of longitudinal columns of neural cells along the entire neuraxis (Shimamura et al. 1995). Transcripts of *Cnot* are expressed in the epiphysis and ventral diencephalon at early stages; *gooseoid* is a gene similar to *Cnot* that is expressed only in the prenotochordal mesoderm for forebrain induction (Stein and Kessel 1995). The segmentation established in the hindbrain might also exist in the diencephalon, but the segments appear later and might represent functional units (Figdor and Stern 1993).

### Spinal Cord Gene Families

Ironically, the spinal cord remains the only region of the CNS for which no evidence yet exists of an intrinsic segmentation based on compartmental groupings of differentiating neurons (Lim et al. 1991). The *Hox-2.1* domain in the spinal cord is an earlier domain of the homeobox gene *Cnot* in the postnodal neural plate caudal to the primordial hindbrain (Stein and Kessel 1995). The apparent segmentation of spinal nerve roots is imposed by surrounding mesodermal structures that form the neural arches of the vertebrae and somites (Sarnat 1992a; Stern et al. 1991; Tosney 1988). The developing neural arches secrete keratan sulfate; this glycosaminoglycan is a strong repellent of axonal growth cones, which prevents the aberrant wandering of developing nerve roots.

## DISORDERS OF GENETIC PATTERNING OR NEURAL INDUCTION

Examination of the expression of homozygous mutant genes, or “knockout genes,” and the up regulation or over-

expression of individual genes can provide a great deal of insight not only into the functions of each of the genes but also into the redundancy of function that allows them to act as substitutes for one another. Researchers have bred and studied many experimental lines of mutant genetic mice with inactivated alleles of specific genes, some of which may relate to human malformations that are not easily explained by classical embryology. Abnormal or defective gene expression is a topic beyond the scope of this chapter.

## NEURULATION

---

The posterior neuropore is not located at the extreme caudal end of the developing neural tube. *Primary neurulation* involves closure of the neural tube at the dorsal midline between the rostral and caudal neuropores and results in formation of the brain and spinal cord to the sacral region. *Secondary neurulation* appears after closure of the caudal neuropore and results in formation of the caudal-most section of spinal cord, the conus medullaris and, in vertebrates with tails, the caudal segments. This part of the spinal cord, as well as other axial tail structures in the human embryo, derives from mesenchymal cells in the tail bud (Lemire 1969; Saraga-Babic et al. 1996). The caudal most segments of the spinal cord develop as a solid rod of neuroepithelial cells that secondarily forms a lumen by ependymal extension of the central canal rather than by closure of a sheet of cells to form a tube. In fishes, the entire spinal cord initially forms as a solid rod of cells rather than as a folded sheet.

Bending of the neural plate to form the neural tube requires both extrinsic and intrinsic mechanical forces (Marin-Padilla 1991; Schoenwolf and Smith 1990). Extrinsic forces are generated in part by the growth of mesodermal tissues flanking the neural plate that will form the somites. Removal of this mesoderm and of the endoderm lateral to the neural plate in the early chick embryo does not prevent neural tube formation but causes the neural tube to be rotated toward the side of the removed tissue (Alvarez and Schoenwolf 1992). Thus, although the mesoderm is important for maintaining the orientation of the neural tube, expansion of the surface epithelium provides the major extrinsic force that bends the neural plate (Alvarez and Schoenwolf 1992; Jacobson 1991). Neural plate cells are motile and attempt to crawl beneath the surface ectoderm along their common boundary, raising neural folds toward the dorsal midline, but the primordial epidermis also offers resistance to neural tube formation (Schoenwolf and Franks 1984). Growth of the embryo as a whole does not appear to be an important factor in neurulation, because neurulation proceeds at the same rate in anamniotes that grow (e.g., birds and mammals) and anamniotes that do not grow (e.g., amphibians) during this period (Jacobson 1991).

Intrinsic forces of primary neurulation begin with the notochordal induction of floor plate differentiation, which

establishes the longitudinal axis of the neural plate. The floor plate cells assume the shape of a wedge, narrow at the apex and wide at the base, to accommodate the nucleus, which no longer travels to and fro within the bipolar cytoplasm as it did during mitotic cycling. The wedged shaping of neuroepithelial cells during neurulation may not be as important as was previously thought, except perhaps at certain “hinge points,” and not all cells assume this shape (Schoenwolf and Franks 1984; Smith and Schoenwolf 1989). Also, ependymal cells do not completely line the ventricles or central canal of the spinal cord until long after neurulation is complete (Sarnat 1992a, 1992b). Adhesion molecules contribute additional intrinsic factors promoting neurulation. The selective expression of some regulatory genes, such as *Wnt-1*, at the lateral margins of the neural plate during neurulation probably plays an as yet undefined role in the intrinsic curling of the neural plate.

The neural tube closes in the dorsal midline first in the cervical region, with the closure then extending rostrally and caudally so that the anterior neuropore of the human embryo closes at 24 days and the posterior neuropore closes at 28 days, the distances from the cervical region being unequal. This traditional view of a continuous zipper-like closure is an oversimplification. In the mouse embryo, the neural tube closes in the cranial region at four distinct sites, with the closure proceeding bidirectionally or unidirectionally and in general synchrony with somite formation (Golden and Chernoff 1993; Juriloff et al. 1991). An intermittent pattern of anterior neural tube closure involving multiple sites has also been described in human embryos (Busam et al. 1993). In this closure, the principal rostral neuropore closes bidirectionally (O’Rahilly and Muller 1989) to form the lamina terminalis, the primordium of the forebrain (Sarnat 1992a).

Neurulation and the development of the central nervous system pose the question of the fundamental definition of “brain” and its distinction from a “cephalic ganglion.” A brain is a rostral, bilobed neural structure with internal architecture of gray and white matter, commissural fibers interconnecting the two halves, and in which the interneuron is the predominant neuron; it regulates the entire body. Ganglia, by contrast, may be rostral or occur anywhere else including the peripheral nervous system, are not bilobed, have no somatotopic internal architecture and no commissural fibers, and interneurons are sparse or absent, the neurons being almost exclusively primary sensory or motor neurons; ganglia subserve restricted segments, not the entire body (Sarnat and Netsky 2002).

## NEURAL CREST SEPARATION AND MIGRATION

---

The neural crest is a tissue of such importance that some authors have even suggested that its status be elevated to that of a “germ layer,” equal to the ectoderm, mesoderm, and

endoderm. (Hall 2000) Neural crest is the means by which the embryonic neural tube induces many nonneural tissues, including most of the craniofacial structure (Carstens 2004; Hall 1999; Le Douarin and Kalcheim 1999). In addition, neural crest contributes much of the peripheral nervous system, particularly autonomic and somatosensory nerves and ganglia.

Incipient neural crest cells first appear at the lateral margins of the neuroepithelial placode on the day of gastrulation, but these cells are not yet “committed” to a specific fate. As the neural placode bends dorsally on either side to form the neural groove, and then the two sides meet in the dorsal midline and close to form the neural tube, the neural crest cells are those adjacent to the dorsal midline. Shortly thereafter they migrate along prescribed routes throughout the embryo to differentiate after reaching their final destination. They form neural structures of the peripheral nervous system—including neurons of the dorsal root and sympathetic ganglia, Schwann cells of peripheral nerves and chromaffin cells such as those of the adrenal medulla and carotid body. They also form structures of mesodermal origin, including blood vessels and melanocytes or pigment cells, blood vessels and membranous bones including the orbits, cranial vault, and most of the facial skeleton (Carstens 2004; Hall 1999; Le Douarin and Kalcheim 1999; Tan and Morriss-Kay 1985).

Neural crest cells migrate in a somewhat different manner from each part of the embryonic segmental neural tube, the neuromeres. The neural crest may be divided into three groups on this basis (Puelles and Rubenstein 2003). The *prosencephalic neural crest* migrates rostrally into the head as a vertical sheet of cells. The *mesencephalic neural crest*, which arises not only from the mesencephalic neuromere (i.e., future midbrain), but also from the first two hindbrain rhombomeres (neuromeres r1 and r2' or the rostral half of r2), migrates as streams of cells. The *rhombencephalic neural crest*, arising from the hindbrain and spinal cord, migrates as segmental blocks of cells (Bronner-Fraser 1994; Carstens 2004).

Though patterns of genetic expression in the hindbrain probably contribute to the segmental arrangement of neural crest cells, cellular migratory pathways also are guided by attractant and repulsant paracrine molecules secreted by surrounding tissues such as the otic capsule, the somites, and the vertebral neural arches (Jacobson 1991). In addition, neural crest cells possess integrin receptors for interacting with extracellular matrix molecules (Bronner-Fraser 1994). Changes in the distribution of extracellular matrix components during neural crest migration impose migratory guidance limits as well (Sadaghiani et al. 1994).

The neural crest consists of a series of overlapping cell populations that differ in their migratory pathways and fates. The precise origin of neural crest cells is a complex issue, because these cells form so many different mature structures, including some, such as facial bones, that ordinarily would be of mesodermal origin. Why neural crest precursors are so heterogeneous, why neural crest stem

cells with multiple potentials exist, and even whether stem cells arising from the neural tube are joined by surrounding cells from the mesodermal germ layer are not as well understood as the migratory pathways of neural crest cells (Selleck et al. 1993). Like other parts of the neural tube, neural crest tissue has a rostrocaudal gradient of differentiation. The fate of neural crest cells is not entirely predetermined; environmental factors may induce differentiation of different cells than ordinarily would have occurred. For example, although early migrating neural crest cells generally form dorsal root ganglion cells, when these early migrating cells are ablated, the late migrating neural crest cells that ordinarily form mesodermal structures will change their fate to become neurons. Furthermore, transplantation of early-migrating neural crest cells does not result in production of neurons under all conditions (Raible and Eisen 1996). Neurotrophic factors (e.g., neurotrophin-3 [NT-3]) also influence the fate of neural crest cells and are essential for survival of sympathetic neuroblasts and innervation of specific organs (El Shamy et al. 1996). NT-3 is the only neurotrophin needed by neurons of the myenteric plexus, but other neural crest derivatives require other factors. Nerve growth factor (NGF) was the first neurotrophin identified and was shown in dorsal root ganglia. Brain-derived neurotrophic factor (BDNF), ciliary neurotrophic factor (CNTF) and glial-derived neurotrophic factor (GNTF) all are associated with neural crest migration or differentiation (Sieber-Blum 1999).

The origin of neural crest is topographically unequal in the neuraxis. The streams of cells arising in the midbrain contributes to formation of the bony orbit, the connective tissue of the eye, the membranous bones of the face, the ciliary ganglion, part of the trigeminal ganglion, and the Schwann cells of nerves (Bronner-Fraser 1994; Le Douarin and Kalcheim 1999; Tan and Morriss-Kay 1985). In the hindbrain, the stream of migratory neural crest cells from r1 and r2 populates the trigeminal ganglion and mandibular arch; cells from r4 form the hyoid arch and the geniculate and vestibular ganglia; and those from r6 populate the third and fourth branchial arches and the associated peripheral ganglia (Bronner-Fraser 1994; Lumsden et al. 1991). Rhombomeres 3 and 5 appear to not generate neural crest cells, but the expression of *Krox-20* (human *EGR2*) only in r3 and r5 causes the neural crest cells of these segments to deviate rostrally and caudally and migrate with cells of adjacent rhombomeres (Bronner-Fraser 1994).

### Genetic Programming of Neural Crest

Many genes are essential to the formation of neural crest, but the most important are those having a strong dorsalizing effect in the vertical axis of the neural tube: *ZIC2*, *BMP4*, *PAX3*. Ventralizing genes of the vertical axis, such as *Shh*, inhibit neural crest formation, by contrast (Bronner-Fraser 1995). The gene *EGR2* (*Krox-20* in the mouse) is strongly

expressed only in rhombomeres r3 and r5 and in the neural crest cells from r5/r6 that migrate caudally around the otic vesicle (Bronner-Fraser 1994). This gene tends to suppress neural crest or cause their precursor cells to migrate to adjacent rhombomeres, rostrally and caudally, before migrating into the periphery. *Hox-1.5* and *Hox-2.9* regulate the premigratory and migratory neural crest cells from r4 (Chisaka and Capecchi 1991; Hunt et al. 1991). The gene *SLUG* (*Snail* in invertebrates) seems to be essential for later stages of neural crest differentiation, though it also can be detected in early stages of the neural placode, later regressing in expression and then re-expressed in stronger form. Other genes implicated in neural crest development include *OTX* (*EMX1, 2*), *PHOX*, *DLX*, and *TWIST*. The *PAX* and *MSX* families are of particular importance in craniofacial development associated with prosencephalic and mesencephalic neural crest migration (Bei et al. 2002).

### Relation of Neural Crest to CNS Malformations

Many genetically-programmed malformations of the brain are associated with facial dysmorphism that can now be understood in the context of a disturbance of neural crest. Holoprosencephaly is a prime example. The midfacial hypoplasia in many cases of holoprosencephaly was the basis for the DeMyer et al. (1964) frequently quoted statement, "the face predicts the brain." It became apparent that many children with even the most severe alobar form of holoprosencephaly had normal faces, however, and that some children with even the mildest lobar forms of this malformation had severe craniofacial dysgeneses. The reason for this disparity is the extent of the rostrocaudal gradient of expression of the defective gene(s) in holoprosencephaly, which may affect the mesencephalic neural crest in particular. If the gradient extends beyond the diencephalon to cause noncleavage in the dorsal midline of the mesencephalon, neural crest formation or migration is affected and defective development of midline structures of the face, with hypotelorism and absence or hypoplasia of the premaxilla and vomer bones, may result (Sarnat and Flores-Sarnat 2002). This embryonic midbrain involvement is not related to the severity of the forebrain noncleavage. The DeMyer statement was thus further specified as "the face predicts the rostrocaudal gradient of genetic expression that impairs mesencephalic neural crest," providing an explanation as well as a clinical observation. Finally, Carstens (2004) turned the DeMyer statement around in stating, "the brain predicts the face," indicating the primary role of the neural tube in craniofacial development.

Another example of neural crest defects associated with cerebral malformations is the hypertelorism that commonly accompanies agenesis of the corpus callosum. All birds and mammals have their eyes either on the side of the head or directed forward. The natural growth of the orbits is for the eyes to remain the lateral facial structures

that they are in the early fetus. Those animals that have their eyes directed forward (e.g., bears, cats, primates) have an extra bundle of connective tissue, the *intercanthal ligament*, that holds the orbits and periorbital soft tissues together as the face grows. This ligament is in the zone of prosencephalic neural crest origin. The owl provides further confirmation that it arises from neural crest. The owl is the only bird with eyes directed forward. The intercanthal ligament of the owl ossifies, unlike any mammal. The bone formed is membranous bone, which can only originate in neural crest or paraxial mesodermal; since paraxial mesoderm does not form at this rostral level, the presence of membranous bone can only be of neural crest origin.

The importance of the study of craniofacial clefts is that each cleft, indicating an absence of neural crest bone formation, is a marker of the site and timing of the neural crest migration from specific individual neuromeres of the embryonic brain (Carstens 2004).

### Relation of Neural Crest to Neurocutaneous Syndromes

Neurocutaneous syndromes are a diverse group of unrelated diseases, some with mendelian inheritance patterns (e.g., tuberous sclerosis complex and neurofibromatosis 1 and 2 as autosomal dominant traits) and others without evident inheritance patterns (e.g., Sturge-Weber syndrome; incontinentia pigmenti). Because the clinical and pathological expression of these diseases is so diverse, it is difficult to generalize about a common embryological origin. Because brain and skin are both of ectodermal origin, and because both tissues are affected in the neurocutaneous syndromes, the traditional view is that these are disorders of ectoderm. This interpretation is probably erroneous for two reasons: (1) organizer genes that program early development are expressed in many tissues and do not respect the traditional germ layers; some of these genes are likely defective in the various neurocutaneous syndromes; (2) neural crest induces not only neural structures of the peripheral nervous system, but also many mesodermal structures of the face, head, and body. A more rational explanation of a common embryology of the neurocutaneous syndromes is that they are all disorders of neural crest. For example, in neurofibromatosis 1, the most frequent, there are disturbances in growth in peripheral nerves (neural crest), melanocyte distribution in the dermis (neural crest), a high incidence of pheochromocytoma (neural crest), and an increased incidence of hypertelorism (neural crest). In addition, there are disturbances that are not of neural crest origin, such as the high incidence of optic nerve gliomas, but the *NF-1* gene is also a tumor suppressor gene and may act on nonneural crest tissues. Tuberous sclerosis complex is more problematic in this regard, because there is a cellular dysgenesis that involves almost every organ of the body in addition to failure of tumor suppression function and neural crest abnormalities, such as the angiofibromata of

the facial skin (“adenoma sebaceum”). In epidermal nevus syndrome (“linear sebaceous nevus of Jadissohn”), a midline pigmented or depigmented vertical line extends from the forehead onto the nose, clearly a prosencephalic neural crest abnormality of melanocyte differentiation.

This new concept of the embryology of neurocutaneous syndromes deriving from disturbances of neural crest formation or migration may lead to a reclassification of neurocutaneous syndromes as a category of “neurocristopathies,” with other categories that include aganglionic megacolon (Hirschsprung disease), Waardenburg syndrome, and familial dysautonomia (Riley-Day syndrome) (Sarnat and Flores-Sarnat 2005).

### NEUROEPITHELIAL CELL PROLIFERATION AND DIFFERENTIATION

Early cleavages of the fertilized ovum to form the blastula and gastrula involve a simple proliferation of blastomere cells cycling between mitotic (M-phase) and resting (S-phase) states, a process little different from bacterial DNA replication. As the neuroectoderm develops in the epiblast at postovulatory week 3 in the human embryo, it becomes organized as pseudostratified columnar epithelium, a sheet of bipolar cells all oriented so that one cytoplasmic process extends to the dorsal (future ventricular) surface and the other process extends to the ventral (future pial) surface. The nucleus of each cell moves to and fro within the cell’s cytoplasmic extensions. M-phase occurs at or near the ventricular surface and S-phase occurs at the other surface. The transitional periods between these two states are known as “gap phases,” G-1 when the nucleus moves distally toward the surface of the brain, and G-2 when it moves proximally toward the ventricular surface (Sauer 1935). During the normal cell cycle, S-phase always follows M-phase; the gap phases allow for adjustments to be made in the replication of DNA in G-1, and the sequence ensures that G-2 cells do not undergo an extra round of S-phase, which would lead to a change in ploidy as the chromosomes segregate in the dividing cell (Nurse 1994). In this way, errors may be corrected before the next mitosis, thus allowing for more plasticity than would the all or none principle of simple cell division. Mitoses continue to occur at the ventricular surface when the neural tube forms with the folding of the neuroepithelial plate. As the brain develops, other sites of mitotic activity include the external granular layer of the cerebellum and the olfactory epithelium, but these are specialized exceptions. A population of quiescent neuroepithelial stem cells in the subventricular region of the mammalian forebrain retains a proliferative potential for gliogenesis and perhaps for neuronogenesis even in the adult (Diener and Bregman 1994).

Disturbances of cellular growth and proliferation characterize several genetic disorders that primarily involve the central nervous system, including Proteus syndrome, tuber-

ous sclerosis, and hemimegalencephaly in multiple syndromes (Cohen 2001; Flores-Sarnat 2002; Flores-Sarnat et al. 2003). In many of these (e.g., tuberous sclerosis, hemimegalencephaly), the primary disturbance is one of cellular lineage, with abnormal individual brain cells expressing mixed glial and neuronal proteins (Curatolo 2003; Flores-Sarnat et al. 2003).

### FLOOR PLATE AND EPENDYMA

The floor plate is the first structure of the neuroepithelium to differentiate. This specialized ependyma, a longitudinal column of cells in the midline of the neuroepithelial plate, is induced by the notochord. Like the notochord, the floor plate extends from the caudal end of the neuroepithelium as far rostrally as the midbrain-diencephalic junction; in the diencephalon, the floor plate may transiently form but becomes incorporated into the infundibulum and hence cannot be recognized. Whether a transient floor plate exists briefly in the prosencephalon before “cleavage” into paired telencephalic hemispheres is uncertain, but, even in the absence of a demonstrable corresponding anatomic structure, ventral midline neuroepithelial cells probably serve a similar inductive function. The floor plate exerts a powerful ventralizing influence in the neural tube and, indeed, is a primary organizer of the histological structure of the spinal cord and brainstem (Yamada et al. 1991; Fig. 1.2). Like the notochord but unlike other ependymal cells that differenti-

**Figure 1.2** Transverse section of fully formed neural tube becoming spinal cord in a 6-week human fetus. The central canal is a large vertical slit whose wall consists largely of undifferentiated neuroepithelium. Dorsal horns and long tracts have not yet formed, but migration of motor neuroblasts is contributing to ventral horn formation. An ependyma is partially differentiated in the region of the roof plate and basal plate but not yet at the alar plate; the floor plate (fp) is well formed in the ventral midline. The floor plate is directly induced by the notochord and in turn induces many other structures, including ependyma and motor neurons; it exerts a strong ventralizing effect in the dorsoventral gradient. At this gestational age and earlier, the dorsal root ganglia (drg) are large structures lying lateral to the neural tube; they differentiate early from the neural crest after the latter separates from the paramedian dorsal neuroepithelium at the time of dorsal fusion. The dorsal root ganglia show neural crest migration. Hematoxylineosin. x40.

ate later, it secretes both retinoic acid and *Sonic hedgehog* glycoprotein. The floor plate induces differentiation of motor neuroblasts, although *Shh* from the notochord may also do this directly.

The adult ependyma is a simple cuboidal epithelial lining of the ventricular system with a function limited to the transport of fluid, ions, and small molecules between the cerebrospinal fluid (CSF) and the cerebral parenchyma. In the fetus, by contrast, the ependyma is a dynamic structure primordial to brain development (Sarnat 1992a, 1992c). A variety of metabolic and structural features distinguish fetal from adult ependyma (Sarnat 1992c).

Structurally, the ependyma differentiates in a precise spatial and temporal sequence in the human fetal CNS, beginning with the floor plate at 3 weeks' gestation and not completely covering the entire surface of the lateral ventricles until 22 weeks' gestation (Sarnat 1992b). The pseudostratified organization represents a continuation of the primitive neuroepithelial structure and gradually becomes thinned to a single layer of cells as the ventricles grow, although the size of the fetal ventricles relative to the mass of the brain is larger than at maturity. Once ependymal cells differentiate, they forever lose their potential for mitotic proliferation, so that the pseudostratified structure allows for the covering of a larger total ventricular surface area as the ependyma becomes a simple epithelium. The postnatal lengthwise growth of the spinal cord is accompanied by progressive narrowing of the central canal and the eventual obliteration of its lumen, because not enough ependymal cells are available to preserve the central canal's tubular shape.

Individual ependymal cells in the fetus have long basal processes that extend radially into the cerebral parenchyma, but these processes do not reach the pial surface in the telencephalon as they do in the brainstem and spinal cord. The processes and their ependymal cell bodies contain cytoskeletal structural proteins such as vimentin, glial fibrillary acid protein (GFAP), and certain cyokeratans; these proteins develop and regress according to a precise schedule, and none of them are expressed by adult ependymal cells. Basal processes are also absent from adult ependymal cells, except for a few small, specialized regions such as the infundibulum and the subcommissural organ. The apical (ventricular) surface of the ependymal cell has microvilli and is ciliated; cilia form early in the differentiation of ependymal cells while the cells are still arranged as a pseudostratified epithelium, and cilia are retained throughout life.

Functionally, the most important difference between fetal and adult ependymal cells is that fetal cells are *secretory* and adult cells are not. The products secreted by fetal cells include (1) glycosaminoglycans and proteoglycans, such as keratan sulfate, that strongly repel axonal growth cones, and (2) other molecules that attract growing axons, such as neton and S-100-beta protein (Kennedy et al. 1994; Sarnat 1992b). The basal processes of ependymal cells intermingle

with developing ascending and descending tracts. One function of the fetal ependyma is to guide the tips of growing axons along their intermediate trajectories (Snow et al. 1990). The influence may be positive or negative: floor plate processes attract and facilitate the passage of commissural fibers but repulse longitudinally growing tracts to prevent aberrant decussation (Bovolenta and Dodd 1990).

Another important function of the fetal ependyma is to arrest mitotic activity of the neuroepithelium. Because nearly all mitoses occur at the ventricular surface, differentiation of an ependyma precludes further cellular proliferation at that site; thus, it is advantageous for ependymal differentiation to be delayed in the fetus as long as possible to allow the requisite number of mitotic cycles to occur and to ensure production of an adequate number of neurons (Sarnat 1992c; Smart 1972).

The ependyma may play a role in transformation of radial glial cells to mature astrocytes, possibly through fetal ependymal secretion of S-100 protein (Sarnat 1992c). Finally, the fetal ependyma, like the adult ependyma, helps to regulate transport of fluid, ions, and small molecules between the CSF and the cerebral parenchyma. Whether the ependyma plays a role in the immune system in the brain is uncertain.

## NEURONS

All neurons of a homogeneous population have the same "birthday"—that is, they all differentiate together on the same embryonic day. Examples are the granular cells of layer 3 of the parietal cortex, neurons of various brainstem nuclei, and Purkinje cells of the cerebellum. An exception is the external granule cell of the cerebellum, which proliferates while spreading over the cerebellar cortex from the posterolateral part of the rhombic lip over several days. The external granule cell also is exceptional in being one of only two neurons capable of regeneration; destruction of most (but not all) of the external granule layer by irradiation or by cytotoxic drugs in rodents is followed by cellular proliferation and repopulation of the external granule layer of premigratory neuroblasts (Altman and Anderson 1972; Jones and Gardner 1976; Shimada and Langman 1970). The other neuron capable of regeneration is even more remarkable, because it is fully differentiated; the primary olfactory receptor neuron undergoes a continuous turnover even in adults, a process that is necessary because of its exposed site at the surface of the nasal epithelium and its vulnerability to destruction by upper-respiratory-tract infections. The sensory olfactory neuron is replenished by a population of stem cells at the base of the epithelium that differentiate and establish synaptic contact with target neurons in the mature olfactory bulb (Crews and Hunter 1994).

Among the earliest cells to differentiate within the neural tube after formation of the floor plate are the spinal mo-

tor neurons. These are induced by *Shh* gene products secreted by the floor-plate ependyma and the notochord. Differentiation of neurons in the hindbrain occurs first in the even-numbered rhombomeres and then in the odd-numbered segments (Keynes and Lumsden 1990).

How early a neuroepithelial cell is committed to differentiate into a particular type of mature neural cell and, specifically, which type of neuron it is fated to become—questions fundamental to the issue of cerebral plasticity and adaptability of the immature brain to adverse events in fetal life—continue to be highly debated among developmental neurobiologists. Two opposing schools of thought have emerged, each supported by some experimental evidence. The *predetermination hypothesis* presumes that undifferentiated neuroepithelial cells already have different genetic programs, so that their fate is fixed even before all mitotic cycles are completed. The *epigenetic hypothesis* presumes that nongenetic environmental events, such as altered afferent synaptic innervation and the metabolic milieu, may alter the fate of a neuroepithelial cell so that it becomes a different neuron than it would have become under other physiological conditions. In this regard, thalamic differentiation may be more highly programmed than cortical differentiation, and thalamocortical connections may be largely responsible for determining regional cortical specialization, including lamination and cell types (Bayer and Altman 1991). Dorsal and ventral neural tube derivatives can arise from a single precursor of a clone. If an ectopic notochord is homologously transplanted to the region near the roof of the neural tube, where its strong ventralizing influence is mixed with the normal inherent dorsalizing pattern, cells as diverse as dorsal root ganglion neurons and pigment cells of the neural crest, roof-plate ependyma, motor neurons, and floor-plate ependyma can all arise from the same clone (Artinger et al. 1995).

Cell fate has been examined by tagging individual neuroepithelial cells with isotopes, special dyes, or genetic markers introduced into the cell's DNA by retroviruses. Studies using this approach have demonstrated that at the onset of neuronogenesis, there is a heterogeneity of neural progenitor cells within the proliferative ventricular zone (Krushel et al. 1993). A single cell has progeny that differentiate into ependyma, glia, and neurons of several types. Yet separate sets of progenitor cells may give rise to the deep and superficial layers of cortex and may coexist as spatially segregated populations even though their waves of migration are not coincident (Crandall and Herrup 1990). Transplantation of fetal neuroepithelium into ectopic sites in the nervous system or into other embryos of a different gestational age demonstrates that the differentiation of neurons from the transplant may change. Transplanted neurons also selectively eliminate neurites unsuitable for the cortical area to which they are transplanted (O'Leary and Stanfield 1989). Autoradiographic data, by contrast, suggest that the unlaminated cortical plate is not a totally undifferentiated aggregate of identical cells and that lami-

nar specificity is at least partially programmed (Bayer and Altman 1991). Cell cultures of neuroepithelial cells produce uniform populations of maturing neurons or glial cells in some laboratories and mixed populations in others (Lois and Alvarez-Buylla 1993), although the conditions of the culture medium—for example, nutrients, cell density, exposure to cyclicadenosine monophosphate (cAMP)—may influence the phenotypic differentiation of the cells (Juurlink and Hertz 1985). Neurotrophic factors influence whether neural crest cells will develop in vitro as neurons or glia (Sieber-Blum 1999; Silver and Hughes 1974).

## GLIAL CELLS

Radial glial cells (Figs. 1.3 and 1.4) are among the earliest neuroepithelial cells to differentiate, and new radial glial cells proliferate mitotically until midgestation (Misson et al. 1988; Schmechel and Rakic 1979). Radial glial cells are identified in the human brain by their coexpression of the cytoskeletal proteins vimentin and GFAP (Roessmann and Gambetti 1986). After the radial glial cells' role in the guidance of migratory neuroblasts and glioblasts is complete, vimentin synthesis ceases, and the long radial process either is retracted or degenerates as the monopolar cell is transformed into a mature multipolar astrocyte that continues to express GFAP (Creutzfeldt 1977). Between 21 and 30 weeks' gestation, fascicles of radial glial fibers become clustered in the intermediate zone of the cerebral hemispheres (Gressens et al. 1992). The transformation of radial glial cells provides the bulk of the population of astrocytes in the deep corticallaminae and in the subcortical white matter at maturity, where as in the superficial cortical layers astrocytes are derived in the second half of gestation from radial migration of subventricular glioblasts and never became radial glia (Cameron and Rakic 1991; Gressens et al. 1992). Cortical radial glial cells transform themselves into astrocytes in vitro as well as in vivo (Culican et al. 1990). During development, there is a close correlation of the perivascular arrangement of astrocytes and the formation of endothelial tight junctions in the blood-brain barrier (Bertossi et al. 1993).

Some radial glial cells may be transformed into oligodendrocytes (Choi et al. 1983), but most oligodendroglia originate from the same pool of subventricular glioblasts that supplies most of the astrocytes (Goldman and Vaysse 1991; Kiernan and Ffrench-Constant 1993; Noll and Miller 1994). Cortical gliogenesis involves a progressively restricted sequence of progenitor cell pools genetically programmed and activated by growth factors and other molecules at the proper time, although astroblasts and oligodendroblasts may be of separate lineages (Kiernan and Ffrench-Constant 1993; Skoff and Knapp 1991). Oligodendrocyte progenitor cells migrate along the optic nerve from the chiasm (Kiernan and Ffrench-Constant 1993). Oligodendrocyte precursors originate from the ventral regions of

**Figure 1.3** (A) Radial glial fibers arch through the subcortical white matter and cerebral cortex of the temporal lobe in a 30-week human fetus. (B) These glial processes extend to the pial surface, where they form end feet with astrocytes of the subpial granular layer. (C) Radial glial fibers in the subcortical white matter (intermediate zone) are seen with migratory neuroblasts and glioblasts gliding along their surface as on a monorail. (D) Radial glial cells in the subventricular zone of the cerebrum. Each cell extends a long process centrifugally, the radial glial fiber. Ependymal cells in the fetus also have basal processes, but these are short and do not guide migratory neuroblasts; immature ependymal cells also express vimentin. Vimentin immunocytochemistry. A:  $\times 40$ ; B–D:  $\times 250$ .

**Figure 1.4** Drawing of a coronal section through the cerebral hemispheres of a 25-week fetus or preterm infant. The left side of the figure shows the normal position of radial glial cells in the subventricular zone and their processes spanning the cerebrum; the right side of the figure illustrates three potential sites where acquired lesions could destroy or interrupt the radial glial cell or its process or cause retraction of its end foot from the pial surface. Lesions at these sites arrest migrating neuroblasts and glioblasts and result in heterotopia and abnormal cortical lamination. Used with permission.)

the spinal cord (Noll and Miller 1994). Retinoic acid secreted by the floor plate acts as a mitogen for oligodendrocyte precursors but inhibits their maturation in early gestation, thus allowing migration and dispersal of these precursor cells to populate the developing white matter throughout the spinal cord, including the dorsal regions. Later in gestation, basic fibroblast growth factor exerts these same mitogenic and differentiation inhibiting influences, but retinoic acid now abolishes these effects (Noll and Miller 1994). Retinoic acid is thus a regulator of oligodendrocyte development. Extra cellular matrix molecules present in developing white matter tracts at the time of oligodendrocyte progenitor cell migration include laminin and the glycoproteins tenascin and thrombospondin.

Microglia of the CNS are not derived from the neuroepithelium, as are other glial cells; rather, these microglia are intracerebral macrophages of mesodermal origin and generally develop in parallel with the earliest sprouting of the intracerebralvascular system, at about 51 days' gestation. Some microglia may be demonstrated even earlier, at 38 days' gestation (Fujimoto et al. 1989); these early-developing microglia probably are needed to phagocytose

the cellular debris of apoptosis. In the developing cerebral cortex, microglia are more numerous, superficial to, and beneath the cortical plate than within it (Fujimoto et al. 1989). Additional microglial cells may enter the brain as transformed amoeboid macrophages from the blood after microcirculation is established, and this process may continue into adult life. Microglia also have anatomic articulations with pericytes—small, undifferentiated cells beneath the basement membrane of capillary endothelial cells of the brain—and pericytes may be the origin of some microglia (Monteiro et al. 1996). The differentiation of human fetal microglia is modulated in vitro by basic fibroblast growth factor (Di Pucchio et al. 1996).

The density of astrocytes in the term neonatal brain is about one sixth that in the normal adult brain and makes it more difficult for the neonatal brain to form dense gliotic “scars” in response to focal lesions. The development of glial cells has long been neglected because of the erroneous view that they serve no purpose except as the glue or the filler substance of the brain, but the complexities and functional importance of glia in the developing fetus, as well as in the mature organism, is being increasingly recognized (Jessen and Richardson 2001).

## APOPTOSIS (PROGRAMMED CELL DEATH)

The number of cells generated in the fetal nervous system is 30% to 70% more than the number required at maturity. Surplus cells survive for a finite period, usually days to weeks, and then spontaneously undergo a cascade of degenerative changes and die. This physiological process of programmed cell death, or *apoptosis*, was discovered in 1949 by Hamburger and Levi-Montalcini, who demonstrated its occurrence in the spinal dorsal root ganglion of the chick embryo (Hamburger and Levi-Montalcini 1949). Many investigators subsequently confirmed that apoptosis occurs in all parts of the nervous system and, indeed, that it operates in most organ systems and in all animals, from the simplest worms to humans (Ferrer et al. 1990, 1992; Harris and McCaig 1984; O'Connor and Wyttenback 1974; Okado and Oppenheim 1984). The 120-day half-life of erythrocytes and the continuous turnover of intestinal mucosal cells are examples of apoptosis that continues throughout life. In the fetal nervous system, however, the process is unique in that most differentiated neurons do not regenerate if lost.

Apoptosis differs from cell death by necrosis (due to ischemia, hypoxia, toxins, or infections) in several important morphological details. In neural cell apoptosis, the sequence begins with shrinkage of the nucleus, condensation of the chromatin, and increased electron opacity of the cell, followed by disappearance of the Golgi apparatus, loss of endoplasmic reticulum, and disaggregation of polyribosomes; final events are formation of ribosome crystals and breakdown of the nuclear membrane (O'Connor and Wyt-

tenback 1974). Mitochondria are preserved until late in apoptosis, whereas they swell and disintegrate early in cellular necrosis. Phagocytic microglial cells remove the debris of apoptotic cells, but lymphocytes and other inflammatory cells do not appear.

Programmed cell death is genetically patterned, as is the case with other early developmental events, but it is more complex than most such events because there does not appear to be any gene or gene combination that initiates the cascade; on the contrary, apoptosis appears to be programmed into every cell but its *expression is blocked* by the genetically-regulated secretion of trophic factors by other cells in the vicinity that preserve metabolic integrity. Nerve growth factor and basic fibroblast growth factor block cell death and preserve the identity of various cell lineages in the nervous system (Diener and Bregman 1994; Gomez-Pinilla et al. 1994; Pittman et al. 1993). Many other trophic factors are also essential for cellular survival. Table 1.2 lists four prominent neurotrophic factors and their specifications for preserving the integrity of various types of neurons.

Not all programmed cell death is an early embryonic event; motor neurons of the cervical spinal cord of the rat continue to show apoptosis in the early postnatal period (Nurcombe et al. 1981). Neural cell apoptosis is a biphasic process; early apoptosis involves undifferentiated or incompletely differentiated neuroepithelial cells, whereas late apoptosis involves well-differentiated neurons or glial cells. In one popular analogy, necrosis is compared to “death by murder,” whereas apoptosis is likened to “death by neglect,” because the cell’s death is caused not by a toxin but by a deficiency of atrophic factor needed to preserve its integrity.

Apoptosis may be either accelerated or retarded by metabolic “environmental” factors, such as the circulating thyroxine level; fetal hypothyroidism delays apoptosis, and fetal hyperthyroidism enhances it. Neurotoxic excitatory amino acids such as glutamate and aspartate may trigger or accelerate apoptosis (Page et al. 1993). Lactic acidosis, high concentrations of ammonia, electrolyte and calcium imbalances, and many other transient metabolic aberrations may accelerate apoptosis.

Other environmental factors that affect apoptosis involve synaptic relationships. An inverse relationship exists between the rate of apoptosis of spinal motor neurons and synaptogenesis. On the afferent side, neurons that fail to be innervated because of loss of presynaptic neurons degenerate; an example of “transsynaptic degeneration” is what occurs in the lateral geniculate body as a consequence of lesions of the optic nerve. On the efferent side, motor neurons degenerate if they fail to match with target muscle fibers. Removal of a limb bud of a developing embryo results in accelerated loss of motor neurons at the corresponding spinal cord level. The ectopic grafting of a supernumerary limb bud close to a natural limb bud requires innervation by the same pool of motor neurons and causes apoptosis to be retarded or stopped, resulting in an increased number of motor neurons on that side.

In addition to the well documented apoptosis involving differentiated or maturing neurons and glial cells, some undifferentiated neuroepithelial cells also undergo physiological cell death, but the factors that select these short life cycles are less well understood (Homma et al. 1994). The mechanism may involve activation of the immediate early protooncogene *c-fos*, which is also expressed in regions of cerebral infarction (Gonzales-Martin et al. 1992; McLean et al. 1994; Page et al. 1993).

## NEUROBLAST MIGRATION

Few, if any, neurons in the mature human brain are ultimately located in the same site where they began their differentiation. Neurons shift position, often migrating over long distances, to form three-dimensional relationships with other neurons with which they must establish synaptic circuitry. The migration of neuroblasts is a precise and orderly process and is intimately associated with specialized fetal glial cells with long processes that serve as guides (Sidman and Rakic 1973; Figs. 1.3 and 1.4). In a few spe-

cialized foci, such as the olfactory tract, some neurons may follow axonal guides of others; however, the great majority of neuroblasts slide to their destinations on the outer surface of radial glial fibers. Neurotrophins also play an important role: NT-3 is required for olfactory tract migration and, if defective, results in arrhinencephaly as in holoprosencephaly, though hypoplastic, rudimentary, unmigrated olfactory bulbs may be “fused” to the entorhinal cortex in carefully examined microscopic sections (Sarnat and Flores-Sarnat 2001).

The radial migration of periventricular postmitotic neuroblasts in the cerebrum is regulated in part by the specialized Cajal-Retzius neurons of the initial marginal zone of the early cerebrum, which later becomes the molecular layer or layer 1 of the cerebral cortex when the developing cortical plate from radial migrations forms in the middle of the molecular zone. Cajal-Retzius neurons are mature neurons that form a preplate plexus prior to the first wave of radial migrations. They synthesize GABA and other neurotransmitters, including several calcium-binding proteins such as calmodulin and parvalbumin, and also express several genes that both mediate radial migration and organize

the cortical plate; these genes include *reelin*, *LIS1* and *DS-CAM*. Cajal-Retzius neurons form the first intrinsic cortical circuits, forming synapses with neurons of layer 6 (the first to migrate radially) and later with all cortical layers (Sarnat and Flores-Sarnat 2002). At the end of cerebral development, the Cajal-Retzius neurons become sparse in the molecular zone with growth of the brain but do not disappear; their function in the adult brain is unknown.

In the cerebral hemispheres, the radial glial cell bodies are in the subventricular zone, and their processes extend to the pial surface radially. Groups of postmitotic premigratory neuroblasts migrate together in waves throughout the subcortical white matter (i.e., the intermediate zone) to the surface of the cortical plate; each subsequent “wave of migratory neuroblasts completes its journey superficial to the preceding one, so that the deepest layer of the neocortex is formed by the first migratory wave, and the most superficial neurons in layer 2 are the last to migrate. The inverted arrangement of six-layered neocortex is not the pattern followed in the three-layered paleocortex (hippocampus) or the laminated superior colliculus, however. In these trilaminated cortices, the outermost layer represents the earliest rather than the latest migratory wave. In the cerebellar cortex, Bergmann glial cells in the Purkinje cell layer extend radial processes to the surface and guide the migratory external granule cells to their mature position in the interior of the folia.

In addition to the columnar radial migrations along glial fibers from the subventricular zone to the cortical plate, tangential migration occurs within the intermediate zone (i.e., the future subcortical white matter); a minority of migratory neuroblasts turn to travel perpendicularly to the radial glial fibers for a net effect of tangential dispersion of clonally related cortical neurons (DeDiego et al. 1994; O’Rourke et al. 1992). Time lapse confocal microscopy of living slices of cerebrum demonstrates that these horizontal cell movements are three times faster than radial migrations, suggesting that nonglial substrates such as tangential axons guide this cellular movement (O’Rourke et al. 1992, 1995). The validity of these observations of horizontal migration in the subcortical white matter has been confirmed by other techniques, including retroviral labeling to trace clonal allocation of neuroblasts (Walsh and Cepko 1988) and radioisotope marking of premigratory clones of neuroblasts (O’Rourke et al. 1995). Tangential migrations are not limited to the cerebrum; they also have been documented in the developing optic tectum of the midbrain (Gray and Sanes 1991) and near the surface of the medulla oblongata, where neuroblasts migrate in the subpial region along circumferential axons and perhaps are also guided along the leading processes of other tangentially migrating cells (Ono and Kawamura 1989). Horizontal migrations occur in the developing cerebellar cortex as well (Hager et al. 1995). Even in the spinal cord, longitudinal and tangential migrations serve to disperse and mix different clones and generations of postmitotic neuroblasts (Leber and Sanes 1996).

The signals that mediate neuroblast migration are incompletely understood. The ependyma may play a role in the regulation of radial glia, but this speculation is not well documented. The mechanism of actual migration is uncertain. The neuroblast travels along the radial glial process as if it were a monorail, but the identity of the molecules attracting the migratory neuroblast surface, their location, and the role of adhesive substrates on the radial glial process are unresolved questions. Glycoproteins, including lectin, tenascin, and thrombospondin, may be important in this regard (Bartsch et al. 1992; Lehman et al. 1990; O’Shea et al. 1990). By contrast, S-laminin, a component of the basement membrane, acts as a chemical barrier to cell migration (Porter and Sanes 1995). The plasma membrane of the radial glial cell itself shows a complex dynamic and topographic flow that facilitates cell migration, as is demonstrated in Bergmann glial cell guidance of cerebellar external granule cells (Komuro and Rakic 1995). Genetic programming of neuroblast migration is of primordial importance and regulates many of the other factors that influence this migration (Mochida and Walsh 2004).

Although most neuroblast migration is complete by midgestation, some neuroblasts continue to migrate past this time, perhaps until 34 weeks. In the second half of gestation, most of the post mitotic neuroepithelial cells in the subventricular zone or periventricular “germinal matrix” are glial precursors, and these glioblasts also migrate toward the cerebral cortical surface. After migration is complete, the radial glial cell retracts its process and becomes a mature astrocyte.

Gyri and sulci form in a predictable sequence to enlarge the surface area of the cerebral cortex without concomitantly increasing the volume or mass of the brain (Chi et al. 1977). By 20 weeks’ gestation, only the rudimentary primary fissures are formed—the sylvian and calcarine fissures and the early appearance of a Rolandic fissure. The secondary and tertiary gyri develop with further maturation of the cortex and additional radial migration of glioblasts and are fully formed by term. Convulsions of the cerebral cortex thus develop during the phase of glioblast, not neuroblast migration. The forces responsible for gyration of the cerebral cortex are predominantly intracortical rather than subcortical (Richman et al. 1975). They are related more to neurite growth and expansion of the neuropil between cortical plate neurons and to enlargement of the neurons of the cortical plate than to cellular migration.

Neuroblast migration to the cerebral cortex may be divided into three phases, with different genes regulating each and, consequently, mutations of each of these genes resulting in different malformations with arrested migration in different stages. The earliest stage is the initiation of migration from the periventricular region (i.e., the embryonic subventricular zone). The second stage is the centrifugal journey through the subcortical white matter to reach the cortical plate. The third stage is the organization of the

## 22 Section I: Neuropsychiatric Assessment of the Child and Adolescent

cortical plate and lamination of the cortex (Mochida and Walsh 2004; Pinter and Samat 2004).

### AXONAL PATHFINDING

The outgrowth of a single axon precedes the formation of the multiple dendrites and is one of the first events marking the maturation of neuroblast to neuron, sometimes beginning during the course of neuroblast migration. The tip of the growing axon, termed the *growth cone* by Ramon y Cajal (1909–1911), is neither pointed nor blunt, but rather a constantly changing complex of cytoplasmic fingers, the *filopodia*, enclosed by a membrane that forms veils or webs between the filopodia. Microtubules, filaments, and mitochondria fill the cytoplasm of the filopodia.

Axons must be guided to their destinations, which are often a great distance from the cell body. Three mechanisms are involved in this guidance (Oakley and Tosney 1993; Tessier-Lavigne et al. 1988):

1. *Cell-cell interactions.* Molecular signals generated by the target cell induce the growth cone to form a synapse. This mechanism is effective only as the axon approaches to within 1 to 2 mm of the target.
2. *Cell-substrate interactions.* Molecules known as *integrins* bind the cell to an extracellular protein matrix such as fibronectin or laminin. Such substrates serve as adhesive surfaces for growth cones, allowing them to pull themselves along, but might also provide some directional cues as attractants or repellants.
3. *Chemotactic interactions.* Secretory molecules may release powerful attractants or repellants to keep the axon aligned along an intended course of intermediate trajectory; growth cones are exquisitely sensitive to certain chemical and grow toward or away from these molecules.

An example of a repellant molecule is *keratan sulfate*. This glycosaminoglycan is secreted by many tissues of the fetal body at sites where nerves are not wanted: the epiphyseal plates of growing bones, the epidermis (to prevent nerves from growing through the skin), the notochordal sheath, and the developing neural arches of the vertebrae (to segment and guide nerve roots from the spinal cord) (Oakley and Tosney 1993). The segmental somites are important early guides of neural crest cellular migration and also of axonal projections peripherally (Tosney 1988). Within the CNS, fetalependymal cells synthesize keratan sulfate partly to prevent axons from growing into the ventricles of the brain but also to prevent aberrant decussations of long tracts and wandering of axons toward the wrong targets (Sarnat 1992c). The dorsal median raphe that separates the dorsal columns of the two sides in the dorsal midline of the spinal cord is composed of ependymal roof-plate processes that secrete keratan sulfate at the time when the axons of the dorsal columns are ascending. The raphe repels growth

cones that might otherwise decussate (Bovolenta and Dodd 1990; Snow et al. 1990). However, the effects of such repellant molecules are selective. Keratan sulfate secreted by the floor plate and by the dorsal median septum of the midbrain allows the passage of commissural fibers of local interneurons but repulses axons of longitudinal tracts. The floor plate also repulses axons of developing motor neurons, so that they extend into spinal roots only on the same side as the soma (Guthrie and Pini 1995). The commissural axons are actually facilitated in their traversal of the midline septa of ependymal processes by other selective attractant molecules known as *netrins* (Kennedy et al. 1994; Keynes and Cook 1995), but netrins may be bifunctional and may also act as chemorepellants in other sites (e.g., for trochlearaxons) (Colamarino and Tessier-Lavigne 1995; Keynes and Cook 1995). Another family of proteins, the semaphorins/collapsins act mainly as growth-cone repellants both in neural tissue (including the floor plate) and throughout the body in nonneural tissue (Dodd and Schuchardt 1995). Some axons are initially drawn toward the floor plate, perhaps through long-range chemoattraction by a netrin, but then are repelled locally by a semaphorin as they approach the midline and are forced to turn and proceed in another direction. Thus, although the midline septa of ependymal processes act as chemical barriers, they are not the physical barriers to axonal passage that they appear to be in histological sections. Nerve growth factor and S-100  $\beta$  protein are examples of other growth-cone attractants secreted by ependymal and perhaps other cells of the immature CNS.

The cytoskeleton plays a central role in axonal guidance. The internal organization of actin filaments and microtubules changes rapidly within the growth cone before large scale changes in growth-cone shape are seen, and these changes are evoked by local environmental molecules, which stabilize local changes of cytoskeletal polymers in the growth-cone (Tanaka and Sabry 1995). Although microtubule assembly in the growing axon is required for the axon's extension in forming pathways, drugs that inhibit or disrupt microtubule assembly appear not to impede the process of assembly and grow that the axonal tip, a finding that refutes the hypothesis that the growth cone is the principal site of microtubule assembly (Yu and Baas 1995). Local electrical fields within the neural tissue may play an additional minor role in orienting axons within their trajectories, perhaps by altering receptive properties of the growth-cone membrane to neurotransmitters and molecules that attract or repel (Erskine and McCaig 1995).

Finally, or perhaps first of all, homeobox genes are involved in the regulation of axonal growth as well as earlier stages of development. A gene expressed early in neuronal differentiation, *TOAD-64* (turned-on-after-division, molecular weight 64 kDa), is strongly expressed by its protein transcription product in growth cones and is down regulated after axonal projection is complete; mutations in this gene result in aberrations in axonal out growth in the

mouse and also in the simple roundworm *Caenorhabditis elegans*, in which *TOAD-64* is identified as the gene *unc-33*, with an identical nucleotide sequence (Minturn et al. 1995). Overexpression of *Hox-2* reverses axonal pathways from r3 (Kessel 1993). Boundary regions between adjacent domains of regulatory gene expression influence where the first axons will extend (Wilson et al. 1993). The establishment of intersegmental connectivity by short axons precedes the development of long ascending and descending tracts (Oppenheim et al. 1988). Initial tract formation is also associated with the selective expression of certain cell adhesion molecules and their regulatory gene transcripts (Chedotal et al. 1995).

## MEMBRANE EXCITABILITY

Two features distinguish mature neurons from all other cells: (1) an electrically polarized and excitable membrane and (2) secretory function. Muscle cells have excitable membranes but do not secrete; endocrine and exocrine cells are secretory but have electrically neutral membranes.

The development of electrical polarity of the cell membrane is a maturational feature that marks the transition from neuroblast to neuron. This maturational process depends on the development of ion channels for  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ , and  $\text{Ca}^{++}$  as well as the means for delivering continuous energy production to maintain a resting membrane potential, the  $\text{Na}^+/\text{K}^+$  adenosine triphosphatase pump (Spitzer 1981). Although the importance of glial cells for ion transport in this regard is incompletely understood, it is thought that astrocytes may play a substantial role in regulation of the cerebral microenvironment in the developing and the mature brain (Walz 1989).

## DENDRITIC SPROUTING AND SYNAPTOGENESIS

Dendrites sprout only after the axon of the neuron begins its projection. The branching pattern of dendrites and the formation of spines on these dendritic arborizations upon which synapses form are varied and characteristic for each type of neuron. In the cerebral cortex, synaptogenesis always occurs after migration of the neuron to its mature site is complete, but in the cerebellar cortex, the external granule cells project bipolar axons as "parallel fibers" in the molecular layer and form synapses with Purkinje cell dendrites before migrating to their mature site in the interior of the folium.

Afferent nerve fibers reach the cerebral cortex even before the cortical plate becomes laminated. The first synapses are axodendritic and form both superficial to and deep within the cortical plate, between the Cajal-Retzius cells of the molecular zone and the pyramidal cells of layer 6, the latter representing the earliest wave of radial neuro-

blast migration from the subventricular zone. However, most of the dendritic arborization and synaptogenesis in the cerebral cortex occurs during the third trimester of gestation and in early infancy, a circumstance that renders this developmental process vulnerable to toxic, hypoxic, ischemic, and metabolic insults in the postnatal period, particularly in preterm neonates.

An excess of synapses is generated, and many of these synapses are later deleted with the retraction of redundant collateral axons. In addition, transitory neurons (e.g., the Cajal-Retzius neurons of the fetal cerebral cortex) form temporary synapses that function for a time and then disappear as the transient neuron undergoes apoptosis.

When an axonal terminal reaches a dendritic spine and cell-cell contact is achieved, a chemical synapse usually forms rapidly. It has been proposed that some "promiscuous" neurons secrete transmitters even before contacting their targets, thus inducing an overabundance of synapses which then undergo additional electrical activity dependent refinement (Haydon and Drapeau 1995). Dendritic spines determine the dynamics of intracellular second-messenger ions such as calcium and very likely provide for synaptic plasticity by establishing compartmentalization of afferent input based on biochemical rather than electrical signals (Koch and Zador 1993). Neurotrophins play an important role in the modulation of synaptogenesis as selective retrograde messengers (Thoenen 1995). Transsynaptic signaling by neurotrophins and neurotransmitters also may influence neuronal architecture such as neurite sprouting and dendritic pruning (Greenough 1984; Lipton and Kater 1989). Prostaglandins and their inducible synthetase enzymes (e.g., cyclooxygenase-2) are expressed by excitatory neurons at postsynaptic sites in the cerebral cortex and hippocampus; they modulate *N*-methyl-D-aspartate (NMDA)-dependent responses such as long-term potentiation and show a spatial and temporal sequence of expression that is demonstrated immunocytochemically in the fetal brain. This expression is highly localized to dendritic spines and reflects functional rather than structural features of synapse formation (Breder et al. 1995; Kaufmann et al. 1996; Lerea and McNamara 1993; Williams et al. 1989). Thus, prostaglandin signaling of cortical development, and synaptogenesis in particular, may be mediated through dendrites, and the same is likely for neurotrophin signaling (Thoenen 1995).

In addition to the axodendritic and axosomatic synapses, a few specialized sites in the developing brain show dendrodendritic contacts, such as those on the spines of olfactory granule cells (Shepherd and Greer 1989).

The electroencephalogram (EEG) is probably the most reliable and accessible noninvasive clinical measure of the functional state of synaptogenesis in the cerebral cortex of the preterm infant. The maturation of EEG patterns involves a precise temporal progression of predictable changes with increasing conceptional age and includes the development of sleep/wake cycles.

## BIOSYNTHESIS OF NEUROTRANSMITTERS

The synthesis of secretory products is the function of neurons, and the beginning of this metabolic process denotes the adequacy of the organelles and the maturity of the nerve cell. The number of ribosomes in the cytoplasm of maturing neurons is large if the secretory product is a peptide, such as somatostatin or substance P, or if the product requires the continuous synthesis of protein enzymes of synthesis or degradation, such as those involved in the metabolism of acetylcholine and the monoamines. Nonsecretory neuroblasts have few ribosomes.

Neuropeptides are sometimes synthesized in immature nerve cells but not in mature cells. An example is the peptide substance P, which is present in high concentrations in the cerebellum at 16 to 18 weeks' gestation but is almost undetectable in the cerebellum at term or thereafter; in the second half of gestation, granule cells begin the synthesis of glutamic acid and Purkinje cells produce gamma-aminobutyric acid (GABA) as their neurotransmitters. At this time, the neuropeptides synthesized earlier, in the first half of gestation, probably function more as trophic factors than as synaptic transmitter molecules. Neuropeptide secretory products may coexist with other transmitters, such as acetylcholine and amino acids, in both the fetus and the adult. Cajal-Retzius neurons of the fetal cerebral cortex appear to synthesize both acetylcholine and GABA (Sarnat and Flores-Sarnat 2002).

Neurotransmitters that persist at maturity appear in a predictable sequence during development: serotonin is detected in the fetal brainstem earlier than norepinephrine and dopamine, whereas acetylcholine and GABA do not appear until later. Endorphin is found in high concentrations much earlier than substance P, enkephalin, and the hypothalamic hormonal peptides (Lagercrantz 1984). Endogenous glutamate release in the cerebellar cortex produces a dramatic increase in the tonic NMDA receptor channel activity during granule cell migration and synaptogenesis, an effect which suggests that transmitters contribute to the maturational process and are not just end products of maturation (Rossi and Slater 1993).

Equally important to the maturation of secretory capacity of neurons for the biosynthesis of neurotransmitters is the development of specific receptors for each of these molecules on the cell and dendritic membranes of the neurons with which the axons synapse (Rho and Storey 2001; Simeone et al. 2003, 2004).

## MYELINATION

The velocity of conduction of a depolarization wave along an axon is important because the transsynaptic propagation of an impulse depends on its temporal summation of generator potentials. Myelination greatly increases the

speed of conduction, but myelin is not essential for the integrity or function of many small nerves, such as most of those of the sympathetic nervous system. If a hypothetical axon, whether central or peripheral, conducts 50 impulses per second without myelin and 200 impulses per second with myelin, synaptic block will occur if 100 impulses per second is the critical threshold to release enough quanta of neurotransmitter to trigger the next neuron. For this reason, immature infants without sufficient myelination do not simply move and think more slowly; rather, they have functional synaptic block in many polysynaptic pathways of the brain.

As with other aspects of nervous system development, myelination cycles (i.e., the time of onset and termination of myelination) are specific for each pathway and are precisely time linked. The proximal and distal portions of most pathways myelinate at the same time, but some pathways (e.g., the corticospinal tract) myelinate in rostrocaudal progression. Some cycles are short; the medial longitudinal fasciculus of the brainstem begins myelination at 24 weeks' gestation and completes it at 28 weeks. Others are long; the corticospinal tract begins myelination at about 38 weeks' gestation and is not fully myelinated until 2 years of age. Postnatal myelination is first seen in the forebrain in the thalamus, corona radiata, and posterior limb of the internal capsule at 1 month of age. Myelination is then seen in the optic radiations to the occipital poles at 3 months, the anterior limb of the internal capsule and the radiation to the precentral gyrus at 6 months, the parietal and frontal deep white matter at 8 months, and the white matter of the temporal lobe at 12 months (Brody et al. 1987; Kinney et al. 1988). Myelination in the corpus callosum begins at age 4 months postnatally and finishes in midadolescence. The last pathway of the brain to myelinate is the association bundle connecting the prefrontal cortex with the ipsilateral temporal and parietal lobes, which finally completes its myelination cycle at 32 years of age (Yakovlev and Lecours 1967). These very late cycles require further study and documentation.

Most studies of myelination are based on the staining of postmortem brain tissue with luxol fast blue or other traditional myelin stains (Brody et al. 1987; Gilles 1976; Kinney et al. 1988; Rorke and Riggs 1969; Weidenheim et al. 1992). Newer techniques of histopathological examination use gallocyanin histochemistry, antibodies to myelin basic protein (Bodhiredy et al. 1994; Hasegawa et al. 1992), and special stains that detect myelination more precisely with polarized light or fluorescence microscopy (Miklossy and Van der Loos 1991). In the living patient, T2-weighted magnetic resonance images are a valuable and reliable means of semiquantitatively assessing myelination in the various tracts, fiber bundles, and white matter (Barkovich et al. 1988; Dietrich et al. 1988). When one is comparing studies, care must be taken to ensure that technical conditions in each are the same; for example, results obtained with a 0.5-T magnet will differ from those obtained with a

1.5-T magnet. Although tables of myelination cycles generated by magnetic resonance imaging (MRI) differ somewhat from those based on tissue examination at autopsy in fetuses and infants, the general sequence of myelination of the various tracts correlates well. Conventional T1- and T2-weighted sequences of MRI show that brain maturation proceeds sequentially, from central to peripheral, from inferior to superior, and from posterior to anterior areas (Barkovich et al. 1988). Compared with conventional MRI, newer techniques of quantitative MRI are potentially more sensitive, less subject to subtle changes in myelination and less open to variable interpretation (Steen et al. 1994).

Early onset of myelination is not always associated with early maturation of myelin (Kinney et al. 1988). On the other hand, an early adult pattern of white matter myelination on MRI has been reported in infants as young as 10 months of age (Dietrich et al. 1988).

Myelination depends both on the normal differentiation and maturation of oligodendroglial cells and on the availability of the lipids needed to form the complex compounds of myelinated membranes. The sequence of proteins and lipids incorporated into myelin may be quantitatively measured by the biochemical study of white matter at autopsy, and the normal sequence of myelination in the human fetus differs from the abnormal sequences in individuals with metabolic diseases involving myelin (Kinney et al. 1994). Like other developmental processes of the nervous system, differentiation of oligodendrocytes from precursor cells and programming of myelin formation are under genetic regulation (Topilko et al. 1994; Yu et al. 1994). The *Krox-20* "zinc finger" gene has been identified as playing an important role in the process of myelination by Schwann cells in the peripheral nervous system (Topilko et al. 1994). *PMP22/gas3*, another gene that programs a proteolipid protein, encodes an axonally-regulated Schwann cell protein that is incorporated into myelin; this gene is the target of mutations both in a mouse model of defective myelination and in human Charcot-Marie-Tooth disease type 1a, the most common form of inherited peripheral neuropathy (Lemke 1993). Whether these same genes are active in CNS myelination is not yet known.

In addition to their role in forming myelin sheaths or enveloping unmyelinated axons in both the peripheral and central nervous systems, oligodendrocytes express nerve growth factor and may secrete other molecules that stimulate the growth of axons (Byraven et al. 1994). The number of axons per Schwann cell or per oligodendrocyte becomes reduced with maturation, from as many as 55 to as few as 1 to 4 unmyelinated axons per Schwann cell from midgestation to birth; only rarely does a Schwann cell ensheath more than one myelinated axon (Hasan et al. 1993).

Myelination as an important parameter of the normal functional maturation of the brain is a clinically measurable index of delayed cerebral maturation (Dambaska and Laure-Kamionowska 1990; van der Knaap et al. 1991).

## VASCULAR DEVELOPMENT

The development of both the major cerebral arteries and the microvasculature of the brain have an additional influence on cerebral development. Acquired ischemic episodes during fetal life, such as maternal shock, and congenital vascular malformations that alter normal cerebral perfusion may result in abnormal development or in infarcts or hemorrhages before maturation is complete and, at times, resemble genetically determined dysgeneses.

The embryology of the vascular development is complex and was reviewed and illustrated (Sarnat 2004b). The basilar artery initially is a pair of parallel vessels, the longitudinal neural arteries, at the base of the embryonic brain; it then undergoes a true fusion to form the basilar artery. It receives its blood from the internal carotid arteries, with rostrocaudal flow because the plexus that coalesces to form the vertebral arteries occurs at a later stage. The carotid blood is provided to the early fetal basilar artery through a series of transient communicating vessels, mainly the trigeminal, otic, and hypoglossal arteries on each side, and some small and less constant communicators such as the stapedia artery. Because of the pontine flexure, the internal carotid and early basilar arteries lie in parallel and in close proximity, making these transient communicating arteries anatomically feasible. With the straightening of the pontine flexure, the carotid and basilar arteries move farther apart. Occasionally, the transient fetal arteries persist rather than regress, particularly the most rostral or trigeminal artery, and in such cases the carotid circulation also provides most of the blood to half of the brainstem and half of the cerebellum. Persistent fetal cerebral vessels and other congenital vascular malformations of the brain are well described in an article by Pascual-Castroviejo and Pascual-Pascual (2002).

The anterior cerebral artery arises from the first branchial pouch (really, *pharyngeal* pouch, since humans do not have gills at any stage) associated with rhombomere 1, and the middle cerebral artery from the second branchial pouch and rhombomere 2; only later do they fuse with the internal carotid artery on each side. The full circle of Willis, including the anterior and posterior communicating arteries, are the final elements to form.

Most of the microcirculation of the cerebrum is from radial arteriole-like immature fetal vessels that span the cerebral mantle from the subventricular zone to the cortical plate, initially with few collaterals and communications between them, but these increase with advancing gestational age. Vessels in the subventricular zone or "germinal matrix" around the ventricles are mainly thin walled vascular channels, variable in diameter, that are fragile and easily rupture with reperfusion after an episode of systemic hypotension. In the brainstem, the microcirculation arises exclusively from the basilar artery, from a series of 25 to 30 pairs of vessels: the paramedian penetrating and circumferential arteries with short and long branches. The latter course around

the brainstem before penetrating the parenchyma to supply the lateral tegmentum. The cerebellum also receives its blood supply from the vertebrobasilar circulation through several vessels: superior, anterior inferior cerebellar, posterior inferior, and middle cerebellar arteries.

Watershed zones are territories between the circulation zones of two major arteries with overlap. In the cerebrum, the major watershed zones are between the anterior and middle cerebral and between the middle and posterior cerebral arteries. In the brainstem, the main watershed zone is in the middle of the tegmentum of the pons and medulla oblongata, and infarcts in this area are usually symmetrical and produce several syndromes that mimic genetic disorders and can cause Möbius syndrome (paralysis of lateral rectus and facial muscles and other cranial neuropathies), central respiratory insufficiency or apnea, dysphagia, ankylosis of the jaw and micrognathia (Sarnat 2004b).

## CONCLUSION

Neuroembryology is prerequisite to understanding cerebral dysgeneses because all malformations of the nervous system—focal or widespread, genetic or acquired in utero—are disturbances in one or more of the developmental processes. To explain the pathogenesis of malformations, one must invoke not only descriptive morphogenesis, or “classical” embryology, but also the molecular genetic regulation of programming and induction, the “new” neuroembryology. For pediatric neurologists, neuropsychiatrists, neurosurgeons, neuroradiologists, neuropathologists, and other medical specialists who treat persons with congenital defects of the brain and spinal cord, the foundation that modern neuroembryology provides becomes as practical and indispensable as a knowledge of clinical complications such as hydrocephalus, epilepsy, and cognitive disorders.

### **MAJOR THEORIES AND THEORISTS OF CHILD DEVELOPMENT**

The changing patterns of abilities and behavior we call “development” present intriguing challenges to clinicians. Children and adolescents are unique because they are changing, and at a greater rate than at any other time in life, which creates a special challenge to clinicians. In this section, we present a brief overview of the major theories of child development and provide principles to guide clinicians. For the various stages of development, we present the classical theory and also describe the clinical manifestations.

One of the forebears of child development, Arnold Gesell, described development as a spiral, with alternating periods of equilibrium and disequilibrium (Gesell and Amatruda 1964). Each transition in the child’s progress elicits and requires reciprocal changes in the parents, so that, ideally, parenting has its own developmental course that is coordinated with the child’s changing abilities and behaviors.

It is not surprising that such a complex phenomenon fostered several major schools of thought to explain the

transitions. In the broadest classifications, the theories can be divided into two frameworks: reactive and structural (Lewis and Volkmar 1990). *Reactive* theorists postulate that the child’s mind begins as a *tabula rasa* (i.e., blank slate) and that changes in behavior and development result almost exclusively from environmental events. These theorists believe that abnormal development should be regarded as involving *learned* behaviors and that only through relearning or environmental change can the “symptom” be removed and the behavior modified.

*Structural* theorists postulate a genetically determined capacity for the development of patterns, or systems, of behavior. The child is seen as interacting with and actively shaping his or her environment. The continuing behavior patterns or stages that emerge are sequential and different from one another; progress is orderly and straightforward, building on the stage before it. Theoretical schools with this perspective are quite diverse and include the psychoanalytic school (Freud) (see Dare 1985), the emotional school (Erikson), the cognitive school (Piaget) (see Hobson 1985), and the attachment school (Mahler). A summary of these theo-

**TABLE 2.1**  
**MAJOR STRUCTURAL THEORIES OF CHILD DEVELOPMENT**

Age	Psychoanalytic (Freud)	Emotional (Erikson)	Cognitive (Piaget)	Attachment (Mahler)
Newborn	Oral	Trust vs. mistrust	Sensorimotor: Stage I Reflexive	Normal autistic phase
1 month			Sensorimotor: Stage II Primary circular reactions	Normal symbiotic phase
4–5 months			Sensorimotor: Stage III Secondary circular reactions	Peak of symbiosis Beginning of separation and individuation
7 months				First subphase: Differentiation Second subphase: Early practicing phase
9 months			Sensorimotor: Stage IV Coordination of existing scheme	Practicing phase
1 year	Anal	Autonomy vs. shame/doubt	Sensorimotor: Stage V Tertiary circular reactions	
18 months			Sensorimotor: Stage VI Representational period Preoperational period	Third subphase: Rapprochement
2–3 years				
3–6 years	Oedipal	Initiative vs. guilt		
6–12 years	Latency	Industry vs. inferiority	Concrete operational thought	Object constancy (libidinal)
12–18 years	Genital	Identity vs. identity diffusion	Formal operational thought	Resolution of omnipotence

ries is presented in Table 2.1. Each of these theories provides a different structural lens through which to understand an individual child's development.

The *transactional model*, formulated by Sameroff and colleagues, attempted to reconcile these apparently contradictory views of child development. In this view, both behavioral and biological attributes must be considered in their reciprocal relationships to other characteristics of the child. In this theory, development is conceived of as a fluid, dynamic reciprocal process between biological attributes and environment that can reinforce, modify, or change specific psychological patterns at all age periods—that is, the child affects the environment, and the environment affects the child (Sameroff and Seifer 1983). The transactional model counsels looking at the mutually independent nature of the relationship between a child and his or her environment in order to understand development. The innate characteristics of an individual child (e.g., health, personality, temperament) affect the way a child responds to his or her environment. These patterns of reaction will in turn change certain aspects of the environment (e.g., parental caregiving style). Conversely, the environment has certain qualities (e.g., socioeconomic status, family structure) that have a profound effect on the child. Development must be understood as resulting from the complex interplay of the child and his or her environs. Each modifies and potentiates the other. Together, they weave a complex pattern of development that cannot be under-

stood by examining a single thread of nature or of nurture (Parker et al. 1988).

The process of development is complex and, in spite of much research, still not completely understood. It is helpful when examining human development to apply the preceding above theories as a clarifying, but not conclusive, lens through which to view human behavior and growth. In the following sections, we describe innate characteristics of children that contribute to individual behavioral differences and then explore the stages of human development using the structure of these theories as a framework.

## INDIVIDUAL DIFFERENCES THROUGHOUT DEVELOPMENT

### Overview of Temperamental Theory

In addition to understanding the theory and sequence of development, it is important to understand individual differences among children. In the early 1900s, it was thought that parents totally shape their children's personalities—in other words, children were born as “lumps of clay” for parents to mold through daily interactions over the course of childhood. Such a theory of personality development, however, does not explain why some children who were born into nurturing families had problems and some who were born into troubled families did well.

Children are intrinsically different from one another, and although parents may love all their children, they respond to each child differently because the children are different. Siblings experience both shared and nonshared aspects of their environment. Research from behavioral genetics suggests that nonshared environmental influences on each child tend to have a greater effect than shared ones. Consequently, parents can respond differently to a persistent, slow-to-warm child—for example, with more frustration or anger—than to a sibling who is more adaptable and less persistent. The folk wisdom is that the person who “invented” temperament was the first parent who had a second child! The dilemma of intrinsic differences between children has led child developmentalists to embrace the concept of innate “temperamental” characteristics that play a role in personality development.

*Temperament* is often defined as *how* the child behaves, in contrast to *why* the child does what he or she does (motivation) and *what* he or she does (abilities) (Chess and Thomas 1986). The nine characteristics of temperament that were initially described by researchers Stella Chess and Alexander Thomas (1986) in the New York Longitudinal Study are outlined in Table 2.2. This landmark study demonstrated that children are born with a unique combination of temperamental characteristics that describe an individual’s particular behavioral style. These characteristics are presumably derived from a combination of genetic, intrauterine, central nervous system, and postnatal environmental factors. Although not fixed, an individual’s temperamental style is likely to be consistent over time, especially when the interplay between the individual and the environment is relatively stable.

This is in contrast to *personality* which is commonly defined as what makes one person different from other

people, perhaps even unique. This aspect of personality is called *individual differences*. However, personality theorists are just as interested in the *commonalities* among people. The central point is that the major personality traits will vary “with the nature of the adaptive demands created by the social setting, as the profile of animal species varies with the local ecology” (“Normal Personality Development,” Kagan, J in *Textbook of Pediatric Neuropsychiatry*, First Edition p. 14).

### Specific Temperamental Characteristics

*Activity level* refers to the motor component of a child’s functioning. A child with high activity level is one for whom a parent needs four hands to change a diaper: two to hold the baby down and two to change the diaper. These children are running instead of walking at 1 year of age, and at age 5 years they can sit at the dinner table for only 5 minutes at a time. On the other hand, a child with low activity level moves very little while being dressed or during sleep and, when older, can stay seated through dinner.

*Rhythmicity* refers to the degree of predictability and rhythm in the timing of biological functions (e.g., sleep, hunger, elimination). A child with predictable rhythms sleeps, eats, and eliminates at roughly the same times each day. Although all newborn infants take a couple of days to adjust to extrauterine life, the child with unpredictable rhythms never seems to develop regular, predictable patterns.

*Approach-withdrawal* refers to the nature of a child’s initial response to new or altered stimuli (e.g., new foods, toys, or people). A child with a positive approach likes new foods and approaches strangers and new surroundings readily. A child with a negative approach-withdrawal

**TABLE 2.2**  
**TEMPERAMENTAL CHARACTERISTICS**

Characteristic	“Easy”	“Difficult”
Activity level	<i>Low:</i> Moves very little while being dressed or sleeping	<i>High:</i> Is constantly on the move; four hands needed to change a diaper
Rhythmicity	<i>Regular:</i> Eats, sleeps, and eliminates at predictable times	<i>Irregular:</i> Is unpredictable from day to day
Approach-withdrawal	<i>Positive approach:</i> Approaches strangers easily	<i>Negative approach:</i> Does not like new clothes or toys; initially rejects new environments
Adaptability	<i>Quick:</i> Easily learns to accept new situations	<i>Slow:</i> Has difficult time adjusting to new situations
Threshold of responsiveness	<i>High:</i> enjoys being touched and cuddled; is not easily aroused	<i>Low:</i> Is easily startled; rejects new textures
Intensity of reaction	<i>Mild:</i> Whines but does not cry when angry	<i>Intense:</i> Cries loudly and laughs hard
Quality of mood	<i>Positive:</i> Generally has a “sunny” disposition	<i>Negative:</i> Has serious disposition
Distractibility	<i>High:</i> Can be coaxed away from forbidden activities	<i>Low:</i> Is not easily drawn away from desired activity
Attention span and persistence	<i>Long:</i> Intently concentrates and continues activity despite obstacles	<i>Short:</i> Gives up easily; stays briefly on each activity

Source: Adapted from Chess and Thomas 1986.

rejects the first tastes of infant cereal, will not sleep in strange beds, and can be expected to hide behind mother on the first day of school.

*Adaptability* refers to the ease with which a child's response to new or altered situations can be modified in a desired direction, irrespective of his or her initial response. A highly adaptive child could have been somewhat tentative during the first bath but now enjoys bathing; could have initially rejected new foods but now accepts them well; could have been afraid of certain toy animals at first but now plays with them happily. On the other hand, a child with low adaptability has a difficult time adjusting to new situations, even after multiple exposures. These children have difficulty with transitions; for example, resisting daily dressing and facing the start of each school year or of summer camp with dread.

*Threshold of responsiveness* refers to the intensity of stimulation that is necessary to evoke a discernible response from a child. Parents of a child with a high threshold of responsiveness do not need to tiptoe around the house during nap times for fear that a sudden noise will awaken their sleeping baby. These children also enjoy being touched and handled and often enjoy roughhousing during play. On the other hand, a child with a low threshold of responsiveness is easily startled, is awakened from sleep by normal household sounds, finds certain articles of clothing unbearable against his or her skin, and refuses to eat foods with certain textures.

*Intensity of reaction* refers to the energy level or vigor of a child's response (either negative or positive) to stimuli. Intensely reacting children reject foods vigorously, scream when frustrated, and laugh loudly when amused. Children with low intensity of reaction whine but do not cry when angry, and give a brief smile but do not laugh when happy. Some parents of children with low response levels might consider their babies "boring" and have a difficult time establishing an emotional connection because the children offer little or no emotional feedback.

*Quality of mood* refers to the amount of pleased, joyful, and friendly behavior versus the amount of displeased, crying, and unfriendly behavior. A child with a positive mood is "quick with a smile" or has a "sunny disposition," whereas a child with a negative mood has a serious disposition or frequently acts sullen or cranky. This is not to say that children with negative demeanors never feel pleasure, but rather that they do not express their pleasure openly and with the behaviors typically associated with happiness.

*Distractibility* refers to the ease with which a child can be diverted from ongoing activity by extraneous peripheral stimuli. Highly distractible children stop crying when their parents sing to them and are alert to sounds and sights in their environment. These children also can be coaxed away from a forbidden activity by being led into something else. Parents who "distract" their children during temper tantrums will be successful with highly distractible children, but not with children who have low distractibility. Children

with low distractibility do not seem to hear when they are spoken to if they are involved in their favorite activities.

*Attention span* and *persistence* refer to the length of time a child will pursue a particular activity and the continued maintenance of the activity in the face of obstacles, respectively. Children with long attention spans and persistence will intently watch toy mobiles over the crib and will stay with tasks like puzzles or blocks for long periods of time. When these children start a temper tantrum, it is difficult to stop it. Children with short attention spans go from one activity to another but, if they have high persistence, will return to the original task. However, if they have low persistence, they have difficulty completing any task.

### "Goodness of Fit"

When one is looking at a particular child's behavior, it is possible to see the temperament characteristics of a child emerge and to understand how a child's behavior could affect different parents differently. These characteristics do not in and of themselves cause problems. Rather, it is the "fit" between the child's temperament and the demands and expectations of the parents and other caretakers that can determine whether a struggle will take place. The question is whether the parents and child complement or antagonize each other—in other words, is there a "good fit"?

A classic example of this concept is routinely experienced at dinnertime. There will inevitably be friction between a "10-minute parent" and a "5-minute child," because the parent has the expectation that the child should sit at the table for 10 minutes, but the child can sit there for only 5 minutes. Obviously, if the parent wants the child to stay, he or she will have to fight for the last 5 minutes. On the other hand, a "5-minute parent" with a "5-minute child" has expectations that fit with the child's temperamental capabilities.

If there is a good fit between parent and child, optimal development is likely. On the other hand, if there is a poor fit between parent and child (i.e., parental and caretaker expectations are not consistent with the child's temperament), the ensuing dissonance will result in stress and potential problem behavior. There is a tendency for healthy growth if the fit is good or for disturbed behavior if the fit is poor. Importantly, the notion of goodness of fit is situational. When parents see a consistent style of expression in "good" behavior as well as "bad," they can understand the pattern and see it as a unique feature of their child's temperament.

Children may have a good fit with some, but not all, caregivers or in some, but not all, settings. For example, there may be a good fit with a child in a relaxed home, and he or she is regarded as an "easy" child. Later, upon entering a day care or preschool program, the same child is labeled "difficult" because the expectations and practices in these structured environments can be very different from those in the more relaxed environment the child experiences in the

home. The opposite case can also be true. A child thought of as difficult by the parents can be more comfortable—and consequently better behaved—in a structured school environment. Understanding a child’s temperamental style will help parents—and, later, teachers—find the appropriate fit.

### Temperament in Clinical Practice

Understanding a child’s temperament can be a very liberating experience for parents, freeing them from a lot of unproductive parental guilt. For example, parents can be assured that the characteristics of their “colicky” baby are constitutional and not caused by parental inadequacy, or that their intensely reacting child is prone to tantrums unrelated to anything the parents have done. Once parents feel “off the hook,” they learn to appreciate the child’s unique style and to develop behaviors that complement him or her. A child’s basic temperament cannot be changed, but a parent’s expectations and behavioral response to the child can be adjusted to create a better fit.

### Emotional Regulation and Dysregulation

Another concept useful in understanding the “how” of children’s behavior is *emotional regulation*, a process that is intimately connected to temperament (Harris 1995). Emotional regulation is a developmentally acquired process, and various experiences of the child require the child to master this skill (coping), leading to adaptation. Various behaviors, such as out-of-control temper tantrums, social withdrawal, and excessive response to severe pain, can represent failures of emotional regulation, or *dysregulation*. During normal development, there are marked changes in the child’s abilities and behavior that allow the child to master new developmental tasks. The failure to *regulate* the emotional input can result in maladaptation or delay. There has been increasing interest in *regulatory disorders* (Diagnostic Classification 0-3, 1997). Regulatory disorders are characterized by the infant or young child’s difficulties in regulating behavior and physiological, sensory, attentional, motor, or affective processes, and in organizing a calm, alert, or affectively positive state. The diagnosis of regulatory disorder involves both a sensory, sensory-motor, or processing difficulty and a distinct behavioral pattern indicated by one or more behavioral symptoms.

### DEVELOPMENTAL STAGES

It is important to preface a discussion of normal developmental pathways with two caveats. First, the suggestion that development follows a series of discrete stages that proceed in an unvarying order is no longer accepted. The intrinsic variation of each individual is both recognized and respected. Second, at any of the stages following birth, nervous system disease, environmental changes, infections, and so forth can all perturb the normal development discussed. Thus, not only individual variability but also individual

vulnerability from other areas must be considered in assessing the developmental course of any individual child.

### Pregnancy

Behavioral development begins long before delivery of the child. Mothers are aware of the pattern a fetus follows: sleep/wake, with certain intermittent periods of increased activity. Ultrasound studies show coordinated movements such as thumb sucking and kicking by 16 weeks; evidence of such movements is that some children are born with blisters on their forearms from the strength of in utero sucking.

There are also developmental stages for parents that begin during pregnancy and continue for the remainder of the child’s life (Howard 1990) (Table 2.3). Possibly the largest adjustment, though, takes place when the parents first take the child home from the hospital and recognize the reality of a new life and the issues and responsibilities concomitant with this lifelong commitment. Clinicians can help parents by understanding and discussing this important adjustment.

### Early Infancy: “A Small Collection of . . . Reflexes”

#### Neurobehavior of the Newborn

During the first weeks of life, the physiological organization of infants is not entirely stable. For instance, periodic breathing (i.e., breathing stops and starts) occurs in healthy, full-term infants about 20% of the time during active sleep. Other autonomic functions, including temperature control, skin color, urination, defecation, yawning, gagging, hiccupping, and vomiting, are also variable during the first weeks of life. The normal physiological instability of the newborn is as varied as all aspects of normal development, such as tone. Some infants emit long, lusty squalls; others tend to voice their opinions a bit less noisily but more frequently. There is no average duration to individual crying spells, although there is a tendency toward very abrupt starts and stops. Newborns sleep from 14 to 16 hours per day, or approximately 60% to 70% of the time, and rarely sleep longer than 4.5 hours before waking. In full-term babies, “active” sleep (i.e., rapid eye movement [REM] sleep) occupies 45% to 50% of

**TABLE 2.3**  
**PARENTAL DEVELOPMENT**  
**DURING PREGNANCY**

Stage	Parental Concerns
First trimester: Incorporation	Ambivalence Anxieties about responsibilities
Second trimester: Differentiation	Recognition of fetus as separate Fantasies/dreams about child
Third trimester: Separation	Fears about delivery Concrete preparations

Source: Howard 1990.

**TABLE 2.4**  
**DEVELOPMENT OF THE NEWBORN (0–3 MONTHS)**

Age	Motor	Communication	Cognition
Birth	Lifts/turns head in prone position Exhibits complete head lag on pull-to-sit motion Hand fisted, flexes arms Is able to track moving object up to 180°	Has mature hearing—prefers human voice frequencies	Has mature vestibular senses Has mature touch, taste, smell—prefers sweet Color vision 20/800
1 month	Lifts head enough to get chin off surface in prone position	Returns parents' gaze	Prefers faces with talking movements
2 months	Lifts head up to 45° in prone position	Coos in response to voices Exhibits social smile	Becomes excited in anticipation of objects Coos in response to voices
3 months	Grasp reflex disappearing; may voluntarily hold/wave a toy Lifts head 90° Makes prereach movements with fingers/toes Is able to sit with support	Chuckles Exhibits vocal-social response	Recognizes taste/smell of mother's breasts Is alert to/consoled by rocking/changes of position

total sleep time, while indeterminate sleep (passing between stages) occupies 10% and “quiet” sleep occupies 35% to 45% of total sleep time.

*Colic* is often one of the first major developmental obstacles that parents and clinicians encounter. Most basically defined, colic is excessive crying seen in infants who are otherwise well. Usually agreed-on characteristics include the Wessel criteria: unexplained fussiness or crying, child is under age 3 months, lasts (cumulative) more than 3 hours per day, occurs more than 3 days per week, persists longer than 3 weeks. The crying is described as “intense” and lasts for several hours at a time, often on a daily basis, occurring in the late afternoon or evening. Colic starts as a cycle of increased crying and decreased sleep that leads ultimately to neurobehavioral disorganization involving increased tone and reflexes and poor state regulation. The problem affects between 9% and 26% of infants, making it one of the most frequent complaints of parents seeking the help of clinicians in the first year of a child's life (Jenkins et al. 1980). Thus, it is important that clinicians distinguish colic from two other etiologies of crying in this period: normal crying and secondary excessive crying resulting from physical illness.

Normal crying was first studied by Brazelton (1962), who found that in a sample of 80 middle-class infants, crying lasted about 2 hours per day at 2 weeks, increased to a peak of almost 3 hours per day by 6 weeks, and then gradually decreased to about 1 hour per day by 3 months. Thus, when presented with a baby who by history is crying excessively, it is important to recall that the amount of parental concern about crying is not necessarily directly proportional to the degree of crying, since parents can have different thresholds of concern. Likewise, the clinician must evaluate the child for any physical etiology of the crying, including (1) acute disorders, such as infection,

intestinal cramping with diarrhea, corneal abrasion, or incarcerated hernia; (2) allergy or lactose intolerance; and (3) external modifiers, such as open diaper pin, occult skin burn, or strangulated finger, toe, or penis.

### **Neurodevelopment in the Newborn**

Infancy is a time of rapid neurological growth and development. During the fetal period, the development of the brain, in terms of volume percentage, proceeds in a caudocranial direction (Tanner 1970). Therefore, at birth, the medulla, pons, and spinal cord are more advanced than the cerebellum. The more advanced development of the former structures is congruent with the newborn's developmental activity, for which complex coordination is not required. The cerebellum, which is least advanced at birth relative to other brain and CNS structures, grows rapidly beginning just before birth and extending through the first year of life. In response to experience, cortical synaptic connections increase during infancy, reaching a maximum of about 50% above the adult mean at age 12 to 24 months and remaining at that level until about age 16 years, at which time they begin to decrease (pruning) to adult levels (Huttenlocher 1979). Some of the motor and sensory milestones of the newborn period are noted in Table 2.4, and the primitive reflexes are listed in Table 2.5.

### **Examination of Newborn Behavior**

Until a generation ago, a newborn was thought to be little more than a warm lump of clay that loosely resembled a miniature human body. Jean Piaget, in *The Origins of Intelligence*, referred to the neonate as a “small collection of somewhat clumsy, unfinished, and isolated reflexes” (Piaget 1952/1985, p. 17). Research and observation of the newborn have shown that the newborn is much more than that. Newborn behavior is commonly classified according

**TABLE 2.5****REFLEXES**

Reflexes	Appears/Disappears
<b>Postural Reflexes</b>	
<i>Asymmetric tonic neck reflex:</i> When face is turned to one side, arm and leg on that side extend	1 month/4 months
<i>Symmetric tonic neck reflex:</i> When head extends, arms and tongue extend and legs flex; when head is flexed, arms and legs extend	
<b>Primitive Reflexes</b>	
<i>Moro:</i> When head suddenly drops back, arms and fingers first extend, then flex	Extension phase/Startle persists into adult life
<i>Galant:</i> When back is scratched beside the spine, lateral flexion occurs	Birth/6 months
<i>Grasping:</i> When pressure is placed on palm of hand and sole of foot, infant grasps	Birth/6 months
<i>Stepping:</i> When held vertically over a surface, infant touches feet to the surface in an alternating pattern	Birth/2 months
<i>Uncovering:</i> When eyes are covered with cloth, infant fusses and swipes at it	Birth/Becomes voluntary
<i>Leg scraping:</i> When one foot is restrained, infant scrapes that leg with free foot	Birth/Becomes voluntary
<b>Feeding Reflexes</b>	
<i>Rooting and sucking:</i> When the cheek is touched, infant turns head and searches for the nipple; when the nipple touches the lips, infant sucks	Birth/Become differentiated feeding patterns
<i>Cuddling:</i> When held, the infant cuddles up to the chest and grasps at the breast	Birth/Becomes voluntary

to six behavioral states or states of alertness (Nugent 1985) (Table 2.6). The infant's ability to maintain an alert state and to move smoothly from one state to another is an important sign of neurobehavioral integrity (Windmayer and Field, 1980).

#### The Neonatal Behavioral Assessment Scale (NBAS)

The NBAS was developed by Brazelton to examine newborn behavior in a research setting. A clinical tool, the CLINBAS, has been derived from the NBAS. To conduct the assessment, a graded series of procedures is carried out that involves slowly arousing a sleeping infant and then testing 20 reflexes and 26 behavioral responses over 30 to 40 minutes and rating them on a 9-point scale (Nugent 1985) (see Table 2.7 for specific reflexes and behavioral responses).

**TABLE 2.6****NEWBORN BEHAVIORAL STATES**

Deep sleep	Breathing/heart rate regular; eyes closed; no spontaneous movement; no rapid eye movement; startles may appear
Light sleep	More modulated motor activity; irregular heart/respiratory rates; rapid eye movements present (often called REM sleep)
Drowsy/Semialert	Eyes may be open or closed; activity levels variable
Alert	Bright look; minimal motor activity
Fussing	Eyes open; considerable motor activity
Active crying	Vocalizations and uncoordinated movement

**TABLE 2.7****SUMMARY OF REFLEXES AND BEHAVIORAL RESPONSES ASSESSED ON THE NEONATAL BEHAVIORAL ASSESSMENT SCALE (NBAS)**

Item	Task
1	Initial observation of state
2	Habituation to light, rattle, bell, tactile stimulation of the foot
3	Foot reflexes: plantar, Babinski, and ankle clonus
4	Uncovering, undressing, and placing in supine
5	Passive resistance of arms and legs
6	Rooting and sucking
7	Glabella reflex
8	Hand grasp
9	Pull to sit
10	Placing
11	Primary walking
12	Prone position and crawling
13	Galant reflex and tone assessment
14	Spin and nystagmus
15	Defensive movements
16	Asymmetric tonic neck reflex
17	Moro reflex
18	Cuddliness
19	Irritability, crying, and consolability
20	Orientation to animate and inanimate visual stimuli
21	Orientation to animate and inanimate auditory stimuli
22	Signs of stress: Startles
23	Signs of stress: Tremors
24	Signs of stress: Color change
25	Signs of stability: Hand to mouth
26	Signs of stability: Smiles

The NBAS assesses four general categories of infant behavior: habituation, regulation of states of consciousness, motor control, and reflexes. *Habituation* is the capacity of the newborn to cope with environmental stimuli and is assessed by evaluating the decrement of behavioral response to repetitive visual, auditory, or tactile stimuli in the sleeping infant. Infants usually respond to stimuli, for example, with startles that diminish with ongoing presentation of the stimuli. Infants who have difficulty habituating cannot shut out their environments and become aroused or inconsolable with repeated stimulation. This can lead to frustration and anxiety for parents.

*Regulation of states of consciousness* reflects an infant's ability to maintain an alert, responsive state and to move smoothly from one state to another. Infants with a small range of state, for example, go from sleeping to crying and back to sleep, with little ability to maintain an alert responsive state. Problems with state regulation are also seen with lethargic infants or irritable infants (e.g., those who were exposed to opiates in utero). State control not only reflects neurobehavioral integrity but is a key contributor to parent-infant interactions and parental feelings of competency. An alert, responsive state provides parents with an enhanced opportunity to interact visually and feel connected with their infant. Lethargic infants or those with small ranges of state are difficult to reach, and this leads to some parents becoming disappointed or frustrated. Irritable infants provoke feelings of anger or helplessness because of parents' inability to console them. Some investigators believe that "reading" and understanding the infant's regulation of state is the first developmental task of parenting.

*Motor control* refers to the smoothness of infants' movements, reflecting the balance between extensor and flexor tone, and the frequency and extent of startles and jitteriness. Smooth movements and minimal startles and jitteriness typically are indicative of a *coordinated* infant, whereas the other extreme raises concerns in the parents about the infant's neurological integrity.

Assessment of *reflexes* provides the neurological context in which to interpret the behavioral findings. Reflexes have most clinical significance in the assessment of neurological integrity when they are absent, asymmetrical, or excessive. The goal of the NBAS and the CLINBAS is to help parents identify specific infant behaviors that enable them to "read" their infants' behavioral cues and therefore respond more contingently.

### **Bonding and Attachment: The Beginning Stages**

The terms *bonding* and *attachment* describe important processes in early infancy by which a unique relationship is established between infant and caregiver (Klaus and Kennel 1982). These two processes can be distinguished by the direction of the parent-child relationship: *bonding* generally refers to the parent's relationship to the infant, whereas *attachment* generally refers to the infant's relationship to the parent. Sensitivity to the importance of early infant

relationships generated the preceding research that provided information on the potential detrimental effects that can occur when newborns are separated from their mothers, which was common hospital policy until 25 years ago. Infants with early and extended contact with their mothers were more readily accepted and consoled at 4 months by their mothers. At age 12 months, they showed a significant increase in positive, compared with negative, behaviors in the home (Siegal et al. 1980). Among infants of mothers who were allowed 12 additional hours of contact in the first 2 days of life, there was a significantly lower incidence of child abuse or neglect in the 17 months that the children were followed (O'Connor et al. 1980). However, there has been no scientific research to support a *critical* period of bonding; that is, no evidence that if bonding does not happen in a specified period of time, such as the newborn period, it will not happen.

### **Later Infancy: "Attachment as a Goal"**

#### **Neurodevelopment in Infancy**

By 3 months of age, the infant has begun to establish control over physiological processes and states of alertness. Although not mobile, the 3-month-old infant is rapidly developing prerequisites for independent locomotion. Gross motor development in this stage is characterized by increasing control of flexor muscles, especially in the lower back and legs. At the same time, the infant displays increasingly fine control of fingers and hands and inhibition of generalized movements of the opposite extremity, which, along with disappearance of the primitive reflexes, enable him or her to engage in more overtly purposeful movements.

#### **Attachment**

The attachment of the infant to primary caregivers begins in the first months of life and continues over time, as noted in the prior discussion. The infant's actual appearance and behavior are major determinants of the attachment process. For example, with an alert infant who reacts readily to parents' faces and responds promptly to consoling maneuvers, parents' positive feelings and sense of competence are enhanced. Conversely, with a drowsy, relatively hypotonic infant who provides less satisfying feedback, parents may feel disappointed when they attempt to gain emotional satisfaction from him or her.

Attachment theory grew out of ethology, developmental psychology, and psychoanalysis to provide a model by which the attachment process could be explained. At the core of attachment theory is the concept of "internal working models," which describe how the infant's sense of self and other unfolds through interactions with a primary caregiver. The motivation for attachment itself, as explained by Bowlby (1958) and Ainsworth (Ainsworth and Bell 1970), is the process of learning: the more the infant seems interested in things, the more he or she wants

to see. Since human beings are the most interesting phenomena in his or her environment, the infant becomes most interested in learning more about them. Primary attachment is also based on the baby's biological need to be close to the mother as a means of protection from internal needs (e.g., hunger, cold, pain, and negative feelings) and from dangers in the environment.

Infants respond to their primary attachment figures in a certain pattern. At 3 to 4 months of age, infants smile more quickly at and are consoled more readily by their primary attachment figures than by others. At age 9 months, these infants will cry when their attachment figures leave them, but not when others leave them. At age 12 to 18 months, these infants will use their attachment figures as a secure base to explore new surroundings. They will explore but will return to their attachment figure periodically, for example, frequently burying their head into a parent's lap, a process that can be understood in terms of a "refueling" metaphor.

A commonly used research paradigm to describe attachment relationships was designed by Mary Ainsworth in the 1970s (Ainsworth and Bell 1970). A mother and infant (younger than 24 months of age) are together in a strange environment with age-appropriate toys for the child to explore. A stranger then enters the room, and the infant's response is noted and scored on a scale of behavioral descriptions. The mother then exits from the room, leaving the child with the stranger. The infant's response is then coded. The mother returns, and the child's response to the reunion is observed and scored. The stranger leaves the room, followed by the mother, and the child is left alone. The stranger then returns, followed by the mother. Children are classified on the basis of their response to the strange situation as exhibiting one of the following attachment patterns (Ainsworth and Bell 1970)

- Pattern A: "Anxious/avoidant" attachment (gave the impression of independence and snubbed mother on return; are affect sharing)
- Pattern B: "Secure" attachment (cried on separation, but greeted mother with pleasure on return, seeking to restore proximity and contact after the stress of being away from her)
- Pattern C: "Anxious/resistant" attachment (were ambivalent; anxious initially and at reunion)
- Pattern D: "Disorganized" attachment (had variable, ambiguous response to departure and reunion)

Disorders of primary attachment can have serious implications for a child's future development. Avoidant or anxiously attached children, for example, are often far less able to engage in fantasy play than are securely attached children, and their play often is characterized by irresolvable conflict. Some researchers feel that security of attachment can be an important factor in predicting healthy functioning as far into the future as the teenage years (Karen 1990). Although the quality of attachment can influence the course of development, it should not be considered as a

**TABLE 2.8**  
**PHASES IN THE DEVELOPMENT OF ATTACHMENT**

Age	Phase
0–3 months	Undiscriminating social responsiveness
3–8 months	Discriminating social responsiveness
7 months–35 months	Active initiative in seeking proximity and contact

fixed attribute in the child's evolving personality, no more than temperament is. Changing life circumstances can alter the quality of attachment, leading to improvement or deterioration, depending on how these changes affect the primary caretakers' availability to the child. The major phases of attachment are summarized in Table 2.8. The general development of the infant is summarized in Table 2.9.

### The Toddler Years: Emotional and Adaptive Development to the Forefront

#### *Neurodevelopment in the Toddler Years*

Once a child is up on his or her feet and walking, the experiential possibilities (as well as the demands of parenthood!) enter a new and more challenging dimension. Securely attached toddlers usually cope with the developmental tasks of these years with greater ease and competence than do anxiously attached children. For example, they are more cooperative with their mothers and more persistent and enthusiastic in trying to master a developmental task. Securely attached 4-year-old children are often more comfortable with their peers. As 5-year-olds, they are able to problem solve and look at challenges from others' perspectives. At 6 years of age, they are more open-minded and accepting and face fewer behavioral challenges. In this way, a secure early attachment provides a solid foundation by which the child can interact with and learn from the outside world.

The life of a toddler is constantly changing. One new developmental task rapidly builds on the next, and over a course of weeks, children can learn vast amounts of new knowledge. For example, a child at 9 months can be crawling, at 10 1/2 months walking, and by 13 months climbing up stairs "marking time." In terms of fine motor development, toddlers become increasingly capable of refined actions both in their play with other children and when alone, as well as in activities of self-care. Therefore, the toddler is able to string beads easily in play, as well as to become toilet trained and brush his or her teeth. Gross motor development involves balance and coordination skills. The parenting issues that arise with the child's development are primarily those of limit setting, safety, and the parent's physical exhaustion.

**TABLE 2.9**  
**DEVELOPMENT OF THE INFANT (3–12 MONTHS)**

Age	Gross Motor	Fine Motor	Communication	Cognition
3 months	Rolls over Lifts head 45° in prone position	Makes prereach/pointing motions	Initiates cooing conversation with adults	Interacts differently with different people
4 months	Head midline when pulled to sit Can get chest wall well up from surface in prone position Lifts head 90° in prone position	Bats at objects; may engage in bilateral “hand play”	Laughs and squeals	Associates experiences
5 months	When prone, “swims” with arms/legs	Reaches more with hand closer to object, although both arms activate	Makes raspberries	
6 months	Sits alone When standing supported, will bounce	Obtains objects by raking with both hands equally	Imitates sounds Babbles in one-consonant syllables	Is attached to adults who take care of him or her Looks for falling object at place where it came from
9 months	Crawls Pulls to stand May cruise along furniture	Transfers object from one hand to the other Uses radialized raking motion for reaching small objects	Uses “mama,” “dada” specifically	Uncovers object hidden from view
12 months	Most can walk	Uses fine pincer grasp with index finger/thumb	May know one or two words and responds appropriately to several more Understands simple command combined with gesture	Suits actions to object qualities (i.e., explores other ways besides mouthing)

Successful parents are sensitive to their child’s changing needs. They are able to be securely bonded to the toddler and yet sensitive to autonomy strivings, wants, and needs while at the same time providing clear and firm guidelines. Parents can encourage this partnership in several ways: by using a tone of voice that conveys conviction; by appealing to the toddler’s sense of fairness; by explaining that they, the parents, are the ones in charge of deciding what to do; and by having a sense of humor.

### **Emotional Development of the Toddler**

One of the major emotional milestones of the toddler years is gaining independence, which results largely from attaining mastery motivation. *Mastery motivation* is a psychological force that stimulates a child to attempt independently, in a focused and persistent manner, to solve a problem or to master a skill or task that is at least moderately challenging for him or her (Morgan et al. 1990). Specifically, these mastery skills are obtained in children ages 15 to 36 months and apply to all domains of behavior. There are five domains in which mastery motivation plays out in the emotional life of a toddler: gross motor skills, combinatorial skills, means-end skills, social skills, and symbolic skills. It is this quest for the unknown that drives the toddler to reach the next developmental milestone.

Toddlers fear that their activities can result in the loss of parental love. Thus, a primary motivator for much of the behavior of a toddler is an increase in the love and attention they receive from their primary caretakers. Unfortunately, toddlers lack the cognitive insight to recognize which behaviors result in positive attention and which result in negative attention. Thus, the majority of discipline techniques that are advocated for use with children of this age emphasize the child’s innate quest for attention and love. These techniques emphasize the importance of the amount and quality of positive contact between parent and child (called “time-in”). Increasing the amount of parental attention the child receives and teaching parents strategies that encourage positive interactions (i.e., active listening, physical nurturing) are basic tenets of the success of these discipline techniques (Christopherson 1992).

*Separation anxiety* is another fear experienced by toddlers. It is often distinguished from *stranger anxiety*, which occurs at age 6 to 9 months when the infant has developed a concrete schema of the primary caregiver’s face and notes that a stranger’s face is now a discrepant one. Separation anxiety and protest, which also begin at approximately 9 months of age and wane at about age 18 months, have two major components. The first occurs when a child is placed in a strange environment without the primary caretaker

and realizes that the primary caretaker is gone. The second involves the child's realization that he or she is powerless in the face of the separation—that he or she cannot “get to mother.”

The child's and parent's responses to everyday experiences of physical separation, such as bedtime, child care, and parent's vacations or hospitalization, can vary widely. In assessing the developmental progress of the child's internal process of separation, the clinician should anticipate that the child and parent will show mixed feelings about separations. Appropriate management of a physical separation depends on its duration and context as well as on the developmental readiness of both parents and child. If parents are ambivalent about the separation and communicate their feelings to their children, there is greater difficulty in negotiating separation. Parents can help children master separation by introducing the new caretakers over time and having small doses of separation after the initial contact with the new person without *prolonged* separation. By the end of the third year, most children are able to accept the absence of the primary caregiver and to be sufficiently comforted by a secondary figure (e.g., child care provider, friend, other family member). Parents need to prepare themselves and the child and to build a mutual confidence that the experience will be rewarding and the reunion joyous. The process of internal separation does not end in infancy for either parent or child, but it must be negotiated repeatedly throughout the life cycle.

Anger and frustration are prominent emotions in most toddlers, and thus it is not surprising that somewhere between ages 24 and 36 months, most children will have their first (but not their last) temper tantrum. This occurs most frequently at home because of the combination of normal autonomy strivings (children want to do everything themselves) and normal developmental limitations involving gross and fine motor functioning that result in frustrating experiences. Children who are temperamentally intense respond with a high activity level and high persistence and have the longest, loudest tantrums, including throwing themselves on the floor. As language development progresses, most children will begin to verbalize their frustrations instead of acting them out motorically. Though most tantrums diminish by 3 or 4 years of age, parents often need guidance both in understanding the cause of a tantrum and in dealing with the behaviors exhibited.

Gender differences are evident as early as age 12 months. The toddler has already internalized his or her gender, based on how he or she interacts and compares himself or herself with father and mother. The 3-year-old child can reliably state his or her sex and is entering a period of intense gender role practicing. Though there are inherent difficulties in studying the concept of gender identification, research has shown that boys and girls are treated similarly by their parents in the first 3 to 4 years

of life. For example, in areas such as warmth, nurturing, acceptance, restrictiveness, allowing dependency, and allowing aggression, very young boys and girls do not seem to be treated differently by their parents (Maccoby and Jacklin 1980). Boys do seem to receive more physical punishment. This may be a direct result of differential levels of aggression in boys and girls that lead to differing behavior of parents.

### **Cognition in the Toddler**

Children are also exploring in this period the concept of cause and effect. At the end of the sensorimotor period described by Piaget, at 2 years of age, the child has decided that everything happens for a reason and will try to figure out what that reason might be. For Piaget, during the preoperational stage, there are two substages that make the exploration of causality possible: the stage of *symbolic activity and make-believe play* and the stage of *decentration* (discussed later in this chapter). As a result of symbolic activity in play, the child becomes able to reason symbolically rather than motorically as he or she had in infancy. Thus, the child, who as a toddler considered a hairbrush as serving only one purpose, will transform the brush into a phone and a bat and a broom, all within seconds!

The child's reasoning, though, is still limited in two key ways. The first is that the child's judgments are dominated by *his or her perceptions* of events, objects, and experiences. The young child cannot take the perspective of another. This leads to the second limitation, which is that the child can attend only to one perceptual dimension or attribute at a time, to the exclusion of all others. The child's reasoning at this stage is often described as *transductive*, by which is meant events are related not because of any inherent cause-and-effect relationship, but simply on the basis of spatial or temporal contiguity or juxtaposition (Inhelder and Piaget 1958).

### **Language Development in the Toddler: A Key to the World!**

The elaboration of language is one of the most striking developments of the toddler years. Actual language begins when the brain has matured to two thirds of its full extent. (The brain has reached about four fifths of its adult weight by age 3 years [Marshall 1968].) The child progresses in this brief period from speaking 1 to 2 words at 1 year of age to having a vocabulary of as many as 500 words, including first and last names and his or her own sex, by age 2 years, with the largest explosion of new words between ages 18 and 24 months. By age 3 years, the child is speaking sentences that average 3 to 4 words in length. Between the ages of 2 and 4 years, the child has acquired most of the fundamental rules of grammar. The “why” question becomes incessant as the child attempts both to learn the answer to the question and to control the situation with his or her new-found autonomy. This growth occurs equally in expressive and receptive language. By 3 years

**TABLE 2.10**  
**DEVELOPMENT IN THE TODDLER YEARS (12–36 MONTHS)**

Age	Gross Motor	Fine Motor	Communication	Cognition
12 months	Walks with “tip toddling”	Uses a cup Cooperates briefly in dressing	Uses one to two words Understands gestural commands	Practices independence Begins having temper tantrums Plays peek-a-boo, imitative games
15 months	Runs Pivots Walks backward	Stacks two blocks Does free scribbling Uses spoon	Uses four to six words, simple jargon Understands commands without gestures	Experiences separation anxiety Is self-consoling
18 months	Walks up stairs with rail Throws ball	Makes stroke on paper Can take off most clothes	Uses 10+ words Uses two-word combinations Points to one body part	Is capable of representational play and imitates household tasks
24 months	Jumps with two feet Stands briefly on one foot Kicks ball Walks downstairs two feet/stair “marking time”	Stacks eight blocks Puts on pieces of clothing	Uses 300 words Uses noun-verb sentences 25% of speech intelligible	Tries to figure out how things work Does pretend play
30 months	Jumps forward Stands on one foot for 1 second Pedals tricycle	Pulls on pants	Uses “I”	Can imagine what another child might think/feel
36 months	Alternates feet on stairs Jumps off bottom step	Stacks 10 blocks Copies a circle Copies three-block bridge	Uses 900 words Uses three- to four-word sentences 75% of speech intelligible	Role plays Prefers “gender appropriate” toys Participates in true cooperative play

of age, a child can follow two- or three-step commands and can formulate answers to “what if” questions. The developmental tasks of toddlerhood are summarized in Table 2.10.

## THE PRESCHOOL YEARS: “PRACTICING INDEPENDENCE”

### Neurodevelopment in the Preschool Years

It is in the span from ages 3 to 6 years that children are transformed from still-dependent toddlers to academically ready 6-year-old children. Motor planning continues to develop, so that complex tasks like “bear walking” can be copied, but posturing and poor balance during such activities are still common. Fine motor planning as well becomes more complex, and children are able to copy and complete a circle by age 3 years, a cross by age 4 years, a box by age 5 years, and a triangle by age 6 years. Language, which grew at logarithmic rates in the previous stage in terms of both reception and expression, begins to be more refined and complex.

Children begin to understand the *semantics* (“meaning”) of language as well as the *pragmatics* (“mechanics”). The preschooler still uses language primarily for qualitative description; quantitative language is still to come.

### Cognitive Development in the Preschool Years

In terms of cognitive development, the preschooler is increasingly able to understand the subtleties of categories and has firmly entered the *preoperational stage* (i.e., before logical mental operations) described by Piaget. In the second half of the preoperational stage, as Piaget described, there is an *intuitive stage*, from 4 to 7 years of age. In this stage, there is an increased accommodation to reality, with progressive “decentering” from the child’s own interests, perception, and point of view. Decentering takes place primarily through socialization, which occurs on entry to school. The child discovers that what one thinks is not necessarily the same as what one’s peers think, and so the child learns to take into consideration the points of view of others.

Children’s conception of illness causation follows a similar developmental progression, changing from primitive, circular, and egocentric reasoning to more abstract and

logical views (Perrin and Gerrity 1981). For example, it is only when a child has mastered concrete operational thought that he or she could be expected to link isolated concrete symptoms to other bodily events and thus understand the relationship between, for example, a cough, runny nose, and fever. This understanding contrasts with that of a child at the preschool level, who can easily think that a broken arm is a result of misbehavior.

### **Play: Window to a Child's World**

Play is an essential occupation of children and becomes an important way for children to test their reasoning as well as to learn and master feelings. The preschooler's play is quite spontaneous, with the child using a wide range of feelings and fantasy themes. Play involves the coordination of the various regulatory systems of the child: neurophysiological-biochemical, cognitive-experiential, and motor-behavioral (Harris 1995). Superheroes often take center stage in this period. Role playing is highly characteristic, with a rich use of dolls, props, and costumes. Much of play at this stage is an attempt to copy adults' behavior and roles, sometimes out of anger, envy, or fear (Lowe 1975). Occasionally, children's play can be an attempt at mastering self-reassurance in stressful situations, such as when the child imitates big and powerful roles such as a parent, doctor, or police officer. In this regard, play can be extremely useful in preparation for a hospitalization or another stressful event such as parental remarriage (Perrin and Gerrity 1981).

### **Emotional Development of the Preschooler**

In the classic psychoanalytic model, the years from 3 to 6 encompass the *oedipal period*, when the child wants the opposite-sex parent all to himself or herself and even thinks of eliminating the same-sex parent. The resolution of these oedipal feelings appears to require some degree of identification with the parent of the same sex and internalization of the good and bad aspects of both parents into the consolidation of the child's individual superego.

Although not a distinctly preschool aspect of development, but one whose roots lie in this period, *moral judgment* is a concept that many theorists have begun to explore in the preschool years. One theorist of moral development, Lawrence Kohlberg, has built on the cognitive stages of Piaget. Kohlberg suggests three major levels of development of moral judgment: *premorality*, *morality of conventional role conformity*, and *morality of self-accepted moral principles* (Kohlberg 1967). Further work in defining these levels identified two types of reasoning in general, each of which is used to a lesser or greater degree as the child develops. Type A emphasizes *literal* interpretation of the rules, and type B, a more consolidated form, refers to the *larger intent and interpretation of the normative standards* (Colby and Kohlberg 1987). Kohlberg's theory of moral development is summarized in Table 2.11. General preschool development is summarized in Table 2.12.

**TABLE 2.11**  
**KOHLBERG'S STAGES OF MORAL REASONING**

Stage 1	Punishment and obedience orientation (i.e., obedience to parent's superior force)
Stage 2	Naive instrumental relativistic hedonism (i.e., agreement to obey only in return for reward)
Stage 3	Conventional morality: good-boy morality of maintaining good relations/approval of others (i.e., conformity to rules in order to please and gain approval)
Stage 4	Social order: authority maintaining morality (i.e., adherence to the rules for the sake of maintaining social order)
Stage 5	Morality of social contract of individual rights (i.e., reliance on legalistic "social contract")
Stage 6	Morality of individual principles of conscience (i.e., voluntary compliance based on ethical principles)

## **Middle Childhood: "Crossing the Threshold"**

### **Neurodevelopment in Middle Childhood**

Middle childhood represents a period of consolidation, when the pieces of earlier development seem to fit together and function in a smooth, integrated fashion. Gross motor development of children is fairly complete by age 6 years, but the degree of stamina and coordination varies. Children, however, continue to refine their fine motor and perceptual skills. Proficiency in fine motor tasks varies across a wide spectrum, and the child's particular talents and weaknesses become most evident in this stage. This aspect is particularly critical when children enter school and begin having difficulties. Coordinated motor skills that become evident between ages 5 and 12 years include heel-toe walking, performance of rapid, alternating movements, simultaneous sensory stimulation, and performance of crossed commands (e.g., "Put your right hand on your left knee"). Failure to perform one or more of these tasks at certain ages can be associated with the child's difficulty in performing school-related tasks such as reading or writing (McInerney 1995).

### **Cognitive Development in Middle Childhood**

Children's cognitive functioning becomes increasingly complex in middle childhood, and more mature ways of using moral judgment are possible. A child moves from the "law-abiding" morality of the first grader to the more sophisticated perception that rules are necessary to maintain social order. For example, the first grader who needed to focus on the head of the child in front of him to stay in line now becomes the fifth grader who understands that in a fire drill, orderly exit is key to survival. In this period, there is an increased capacity for more complex thought in other cognitive processes in addition to morality.

**TABLE 2.12**  
**DEVELOPMENT IN THE PRESCHOOL YEARS**

Age	Gross Motor	Fine Motor	Communication	Cognition
3 years	Rides tricycle	Draws circle Draws person with two facial features	Uses prepositions/pronouns Often stutters	Dresses with supervision
4 years	Steers well Hops	Draws square Constructs five-block train Puts clothes on correctly	Understands size concepts Makes novel grammatical errors Enjoys rhyme and wordplay Follows three commands	Understands the rules of social interaction but may not always observe them
5 years	Skips	Draws triangle Copies five-block gate Spreads with knife		Can compare different objects but still only one feature at a time
6 years	Rides bicycle Walks sideways	Draws Union Jack Copies 10-block steps Ties bow	Understands passive voice Understands double negatives Understands the subjunctive	Understands that dreams are not “real”

Piaget termed this stage the *concrete operations period*. This period, which begins at age 6 to 7 years, has two outstanding characteristics: acquisition of (1) the ability for “reversible operations” (i.e., the child can reason that  $6 + 4 = 10$  but also that  $10 - 6 = 4$ ) and (2) the ability to perceive two or more variables at the same time (i.e., the child can understand “conservation of volume”). An example of the logic involved in the latter is the classic experiment of the two beakers: A child is first asked to make sure that the amount of water in two identical beakers is the same. Water from one of the beakers is then transferred into a tall, thin cylinder, and the child is asked, “Is the amount of water the same?” A child who is in the pre-operational stage will say no and then, if asked to explain, the child will say that the taller beaker has more because it is higher. A child in the concrete operations period, having mastered the concept of conservation, will say that the amount of water is the same. Gradually, the thought processes of a child in this stage become increasingly organized into a complex network through which he or she can confront and systematically respond to the surrounding world.

### **School Entry and the “World Outside”**

At 6 years of age, children officially leave the “family circle” and formally enter the world of peers and school. This world becomes the arena for their development and is best summarized by a character from the television show *The Wonder Years* who stated, “Who you are in sixth grade is who the other sixth graders say you are.”

It is likewise important to emphasize the pivotal role of sixth grade in a child’s development. Most students in sixth grade are 11 years old, physically and emotionally on the brink of puberty. A wide range of body types is evident. The combination of hormonal changes and the tumultuous nature of entering junior high school makes the sixth

grade a safety net for the transition between the worlds of childhood and adolescence. Friendships switch rapidly, and these switches of loyalty are experiments in social skills. Children often have an increased body awareness in this stage and thus may present with a steady litany of somatic complaints, especially following stressful experiences. Sexual development begins in this stage, with children exploring how their bodies function. Fears are particularly common in this stage, as a whole new outside world opens up to the child. This is particularly true in school systems where sixth grade marks the passage into junior high school. These range from concrete fears of monsters and ghosts in the earlier years to fears of robbers and child abductors in the later years. Correlated with the child’s widening experience of the outside world is the large role played by peer pressure. At the same time, the demands of school and academics loom increasingly larger in a child’s world.

### **Learning and School Failure**

All children want to be successful in the academic arena, although their motivation and anxiety level are profoundly influenced by their family expectations. Key elements to success in academics are self-expression and self-esteem, characteristics that are vital to developmental success in middle childhood. In learning, an individual adapts present behavior to the results of previous interactions with the environment. Adequate perception, memory, attention, and motivation are all necessary for learning. Higher cognition is composed of a range of complex “thinking skills.” Included in this category of neurodevelopmental function are concept acquisition, problem-solving skill, critical thinking, brainstorming (including creativity), metacognition, and rule recognition and application (Levine 1992).

Children with problems in any of these areas may present with difficulties in learning. Perhaps the single most common problem found in school-age children who come

to mental health attention or to pediatric clinics is some form of school learning difficulty, often a reading disability (Rutter 1974). Estimates of the number of children receiving some degree of specialized educational assistance range from 10% to 15% of the school-age population (McInerney 1995). School failure has numerous etiologies, including the following:

- Mental retardation
- Learning disability
- Attention-deficit/hyperactivity disorder
- Emotional disturbance
- Chronic illness

The precise definition of *learning disability* is likewise difficult to agree on. Most clinicians agree that a discrepancy of 2 or more years between actual achievement and the child's developmental age constitutes a learning disability, but even this standard is not universally accepted. Others prefer to use a span of greater than 15 points between the verbal and performance portions of a standardized test. Regardless of the criteria used, a learning disability presents significant challenges to a child's sense of success and self-esteem. It is critical to the success of any intervention that the appropriate etiology be sought for school failure. The medical workup for school failure must include a search for the cause of the learning problem(s), including internal factors such as heredity, developmental variations, medical problems (e.g., hypo- or hyperthyroidism, depression, hearing or visual impairment), chromosomal disorders, and prenatal and perinatal insults to the developing CNS, as well as prematurity. External factors include language dysfunction, sociocultural deprivation, prenatal and postnatal toxins, and CNS infections and trauma.

Evaluation of the child must include a thorough physical examination and history. The history must include past and present school performance, as well as pertinent medical history, including any current or past medications. Formal tests that should be part of the evaluation include cognitive testing (e.g., overall IQ score), tests of perception and visual-motor skills (e.g., Bender Visual Motor Gestalt [Bender 1938]), achievement tests (e.g., Wide Range Achievement Test—Revised [Jastak and Wilkinson 1981]), and tests of adaptive behavior (e.g., Vineland Adaptive Behavior Scales [Sparrow et al. 1984]).

### **Social Development in Middle Childhood**

A common phenomenon in middle childhood is *labeling*. Years ago, childhood labels, such as “bully” or “clown,” were dismissed as funny and harmless, with their use considered a rite of passage not unlike fraternity hazing. Unfortunately, though, research has shown that labels can become self-fulfilling prophecies. Labeling in its purest form is a natural and necessary human behavior similar to verbal categorization. However, a label impedes a child's development when it closes off other possibilities, and it has the potential to become a self-fulfilling prophecy.

Labeling often intensifies when children begin school; labels such as “bookworm,” “class clown,” “little princess,” “nerd,” and “mental” often peg children into slots from which it is difficult to escape. Misleading labels can draw attention away from real problems, which can then go undiagnosed, such as with the child called “shy” who is actually hearing impaired. Parents, teachers, and other involved adults need to help children recognize that the world is full of possibilities and that being “different” is not wrong. The major developmental tasks of middle childhood are summarized in Table 2.13.

## **Adolescence: “Growing Into Maturity”**

### **Stages in Adolescence**

Adolescence, which is felt by many to be the healthiest and yet most challenging phase of development, is often classified into three stages of development: early (12 to 14 years), middle (15 to 17 years), and late (18 years and older). Unlike the earlier phases of development, to which one could easily assign milestones across the four developmental lines (motor, communication, cognition, and social/emotional), adolescence is a period of integration and enhancement of earlier skills. The major domain of growth involves social and psychological development and behavior. Common issues across all stages of adolescence include identity formation, autonomy, achievement, and intimacy. A common definition of the end point of adolescence is the achievement of an adult work role, though in current societies where advanced training can postpone this several years, this definition might be irrelevant.

### **Physical Development and Neurodevelopment in Adolescence**

The onset of adolescence, which more or less coincides with the onset of puberty, is influenced by the physical changes associated with puberty. Puberty starts in girls at about 10 years of age and in boys at about age 12 years (Marshall and Tanner 1969). There has been a downward trend over the past 150 years in the average age at menarche of about 2.3 months per decade, with the most recent average at 12.7 years (Sizonenko 1987) and when stratified by race, 12.16 for African-American girls and 12.88 for White girls (Herman-Giddens et al. 1997). Hence, cognitive or emotional age can be at variance with chronological age during adolescence.

The early adolescent faces new, preemptive challenges when adjusting to the following: (1) the physical changes of puberty, (2) entry into a new social system (namely, high school), and (3) sudden entry into a new role status (i.e., as “teenager”), with all the social challenges that imposes (Hamburg 1974). Obviously, the challenge of each of these areas is formidable in its own right. Additional stress occurs from the superimposition of these challenges at a time when the child's physical being is also rapidly changing (Carnegie Quarterly 1986).

**TABLE 2.13**  
**DEVELOPMENT IN MIDDLE CHILDHOOD**

Age	Gross Motor	Fine Motor	Communication	Cognition
6 years	Able to broad jump smoothly Hops on one foot	Writes, eats neatly Copies square touching a circle Ties shoe Reverses some letters	Verbalizes emotions Can follow three serial commands Uses dependent clauses	<i>Preoperational thinking:</i> Is not yet able to engage in true mental operations, has difficulty keeping more than one aspect of a problem in mind at a time
7 years	Is able to run at least 4 yards Begins to learn complex motor tasks	Draws three interlocking circles Knows right/left	Understands passive voice Articulates clearly	<i>Concrete operational thinking:</i> Begins to consider multiple features simultaneously; has internalized mental actions that fit into logical system
8 years	Is more adept at specific sport skills (e.g., batting, kicking)	Draws vertical diamond Cuts with knife		Reasons with increasing exactness or quantitiveness
9 years	Is able to throw a ball overhand at least 6 feet	Draws circle made of eight dots	Masters irregular verbs	Is increasingly able to place things in sequence
10 years	Has more strength Has good eye-hand coordination	Draws cube		
11–12 years	Gender differences in sport skills/interactions apparent Has much-increased strength, endurance, and coordination			<i>Formal operational thinking:</i> Is able to consider theoretical possibilities

### Cognitive Development in Adolescence

Cognitive development during adolescence is characterized by a widening scope of intellectual activity, increased awareness, and development of a capacity for insight. During adolescence, there is a transition from concrete to abstract thought, the latter defined by Piaget as “formal operations.” In the *formal operational period*, the adolescent is able to grasp highly abstract concepts (e.g., infinity) and to reason logically from hypotheses (e.g., generate all possible hypotheses that may apply during a biological experiment) (Inhelder and Piaget 1958). Even with these changes, the egocentrism of middle childhood remains, but in the early adolescent it takes on a new form: the early adolescent is convinced that other people are as obsessed as he or she is with his or her own behavior and appearance. By 15 to 16 years of age, many adolescents have undergone enough reality testing to be able to perceive situations both logically and realistically. It is at this age that the adolescent risk taker starts to be able to weigh choices and visualize consequences more readily. It is after this stage has been accomplished that primary prevention programs that rely on cognitive insight into consequences can be successful.

### Socialization in Adolescence

In all cultures, adolescence is a phase of development marked by rites of passage, with the major developmental goal being *socialized* behavior in order to support the continuation of the culture. The process of individuation and separation from family, which plays such a prominent role in the development of an adolescent in Western society, is not universal. In cultures where adolescents are needed to do adult work to support the family, the period of initiation is short, and the identification as adult is based on familial tradition and responsibility. In contrast, in societies where adolescence can be protracted because of prolonged dependence on parents for support—for example, to finance the completion of advanced education—the attaining of adult responsibility can be more philosophical than realistic.

The role of peer relationships in the life of an adolescent cannot be overemphasized. What began in middle childhood as a new arena to test skills becomes an all-encompassing and ruling domain of “peer definition” of self. For early adolescents, the peer group generally consists of members of the same sex. Boys usually belong to a group of friends from childhood, and girls have two or three best

friends. These unisexual groups provide a safe haven for early adolescents to test out ideas. In middle adolescence, close peer group relationships are expanded to include heterosexual friendships; this marks the beginning of dating. In late adolescence, individual relationships assume increasing importance, in many cases overriding the peer group. It is often through both the group and individual relationships that adolescents cement and define their gender identity.

### **Emotional Development of the Adolescent**

One cannot ignore the impact of psychological issues—in particular, the role of fluctuating moods and that of risk taking as developmental markers—on the adolescent's development.

Adolescence is a period of development characterized by fluctuating moods and periods of intermittent euphoria and dysphoria. This cycle is a normal part of emotional development in adolescence but can be trying for the individual and the family. Recently several health issues have taken on increased significance in adolescents, specifically their weight. The percentage of overweight adolescents age 12 to 19 years has increased from 5% in 1970 to 14% in 1999. (Centers for Disease Control and Prevention 1999).

The view that risk taking is an integral aspect of adolescent life is supported by statistics. More than half (57%) of adolescents have tried cigarettes by the 12th grade, and 27% of current 12th graders are smokers (Grunbaum et al. 2002). Alcohol is the most commonly used psychoactive substance during adolescence. In 2002, 20% of 8th graders, 35% of 10th graders and 49% of 12th graders admitted to drinking an alcoholic beverage in the 30 days prior to the survey (Johnston et al. 2003). Marijuana is the most commonly used illicit substance; in 2001, 23% of high school students reported using marijuana in the past 30 days (Grunbaum et al. 2002). Sexual activity and identity is a major issue in adolescence. In 2001, 46% of high school students reported that they had been sexually active (Grunbaum et al. 2002). Of the 33% of currently sexually active teenagers in 2001, 58% reported that their partner had used a condom in their last sexual encounter. On a positive note, teenage pregnancy decreased 27% between 1990 and 1999 for girls 15 to 19 years of age (Child Trends 2002).

Risk taking, in essence, defines adolescence and varies throughout the early, middle, and late stages. Much as in the progressive cognitive development of the toddler, early adolescents take risks to test the relation of themselves to their families and peers. Like younger children, they move out from a secure base but require frequent check-ins to reaffirm their place in society. Middle adolescents, who cognitively are now capable of abstract reasoning, are able, often for the first time, to visualize the consequences of their risks, and for that reason preventive education may be successful at this age. Because all teenagers spend most of their time in one of three spheres—school, family, or friends—much information can be gained by evaluating

**TABLE 2.14**  
**TASKS OF PSYCHOLOGICAL AND SOCIAL DEVELOPMENT IN ADOLESCENCE**

Value system	From self-centered testing of parental values to idealism and identification of individual values, often with rigid concepts of right and wrong
Conceptualization	From concrete thinking to abstract thought
Career plans	From vague and unrealistic goals to specific goals and steps for implementation
Relationships	From unisexual to heterosexual peer group, with individual relationships predominating at conclusion of adolescence
Sexual drives	From curiosity and experimentation to the beginning of adult intimacy and caring
Body image	From adjusting to the physical changes, through "trying on" different self-images, to, eventually, integration of satisfying body image with personality
Independence	From ambivalence about independence to, eventually, integration

Source: Abstracted from Felice 1992.

the adolescent's functioning in each of these areas. It is important to remember that risk taking, at its essence, is often a positive and sustaining characteristic of adolescent development. The tasks of social and psychological development in adolescence are summarized in Table 2.14.

# Assessment of Children and Adolescents

---

3

*Paul D. Larsen, MD*

Neurology has traditionally claimed the domain of diseases that have a structural or anatomical correlate and can be defined in neuropathological terms. The time-honored clinical pathological correlation has been the gold standard with the utility and validity of the neurological examination and diagnostic tests being measured against the neuropathological examination. Psychiatry grew from medical science's inability to account for mental illnesses that lacked a demonstrable pathological correlate and as a result the mind-brain dichotomy evolved with the mind becoming the providence of psychiatry. The psychiatrist's diagnostic tools became the patient's history and the mental status examination with a combination of symptom complexes used to define disease states. With the tools of functional neuroimaging and genetic-molecular neurobiology, the potential for narrowing the brain-mind divide is ever increasing (Price et al. 2000). The common ground of neuropsychiatry is the reemerging of the two disciplines to explain behavior in terms of cortical and subcortical function.

The clinical neuropsychiatric assessment is a blend of the diagnostic strengths of traditional neurology with those of psychiatry. This chapter focuses on assessing children as opposed to adults, comparing and contrasting the adult versus the child examination when appropriate. The emphasis is on how the examination is used for anatomical localization.

The history plus the examination become the diagnostic foundation for determining etiology and the basis for extending the diagnostic process with the tools of appropriate formal neuropsychiatric and neurodiagnostic tests.

## **ADULT VERSUS CHILD, DIFFERENCES AND COMMON GROUND**

---

To begin with, it is helpful to compare and contrast the differences between the child and the adult brain. One of the immediate and obvious differences is that of growth and development. The term infant's brain weighs about 400 grams, while the adult brain weighs about 1400 grams. The increase in the size of the neurons, the elaboration and proliferation of dendritic and axonal processes and connections, along with myelination accounts for most of this growth. These changes are reflected in the increased metabolic activity and the more widespread activation of the cortex for attention and language tasks in children (Casey 1997; Gaillard 2000). Myelination is reflected by the acquisition of motor and cognitive milestones with the last axonal pathways being myelinated in adolescence and young adulthood.

Understanding these developmental aspects of the brain is important in assessing the child clinically. It is essential to tailor the neuropsychiatric examination to the age and developmental level of the child. It is also essential to interpret the findings in the context of developmental expectations for that age of child. The examination of the newborn is different than the examination of a 3-month-old or 12-month-old infant. If the 12-month-old has the motor and behavior responses of a 3-month-old, then there is significant neurodevelopmental disease. Because of the developmental aspects of brain function, the level of maturity of the brain also affects the expression of disease. An infarction of the left middle cerebral artery in the adult will produce a right hemiparesis. The same infarct in a neonate will present with right-sided focal seizures without any signs of hemiparesis because the motor control of the newborn is predominantly brainstem in nature and lacks cortical modulation. The motor expression of the infarct will not be manifested until at least 4 to 5 months of age. The nature of the infarct has not changed; rather the maturation of the brain has now reached a level where that deficit becomes apparent.

The spectrum of diseases that are seen in children are different than in adults. C. Miller Fisher stated the house officer and student learns neurology “stroke by stroke” (Adams et al. 1997). The incidence of cerebrovascular disease in adults is between 100 to 300/100,000 per year (Chung 2003) compared to 2.7/100,000 per year in children (Broderrick et al. 1993). So stroke, although important, is not the mainstay of pediatric neurology practice. Focal lesions, degenerative disease, and the effect of lifestyle and aging are predominant in the adult spectrum of neurological disease while diffuse disease processes, congenital, infectious, and metabolic diseases are predominant in children. Seizure disorders, on the other hand, are a common neurological problem for both adults and children.

Although there are differences between adult and child neuropsychiatry, there is fundamental common ground. The temporal profile of the basic pathological disease processes is the same. The first diagnostic task for both is regional or anatomical localization. The second task is using the temporal profile to identify the disease process. For the child, a third task must be added and that is to take into account neurodevelopment and its affect on the expression of brain function or dysfunction. An emerging fourth task that is impacting both adult and child neurology is the molecular-genetic understanding of disease. The challenge at this level will be to correlate molecular/genetic defects with phenotypic disease realizing that one genotype does not always equal one phenotype.

## THE DIAGNOSTIC PROCESS

---

The first step in approaching the diagnosis in a patient with suspected neuropsychiatric disease is regional or anatomical localization of the lesion. Where in the nervous system is the

lesion? Is the lesion focal or diffuse? Both the history and the examination are essential in this process. The second step is to recognize or identify signs or symptoms and laboratory or imaging findings that are specific, demand explanation, and quickly focus attention on a specific diagnosis (Weiner, 1986). For example, in a patient with tremor, ataxia, dystonia, and psychosis, the finding of a Kayser-Fleischer ring leads to the correct diagnosis of Wilson’s disease. Similarly, identification of a cherry red spot on funduscopic exam narrows the diagnostic considerations to just a few diseases.

## HISTORY

---

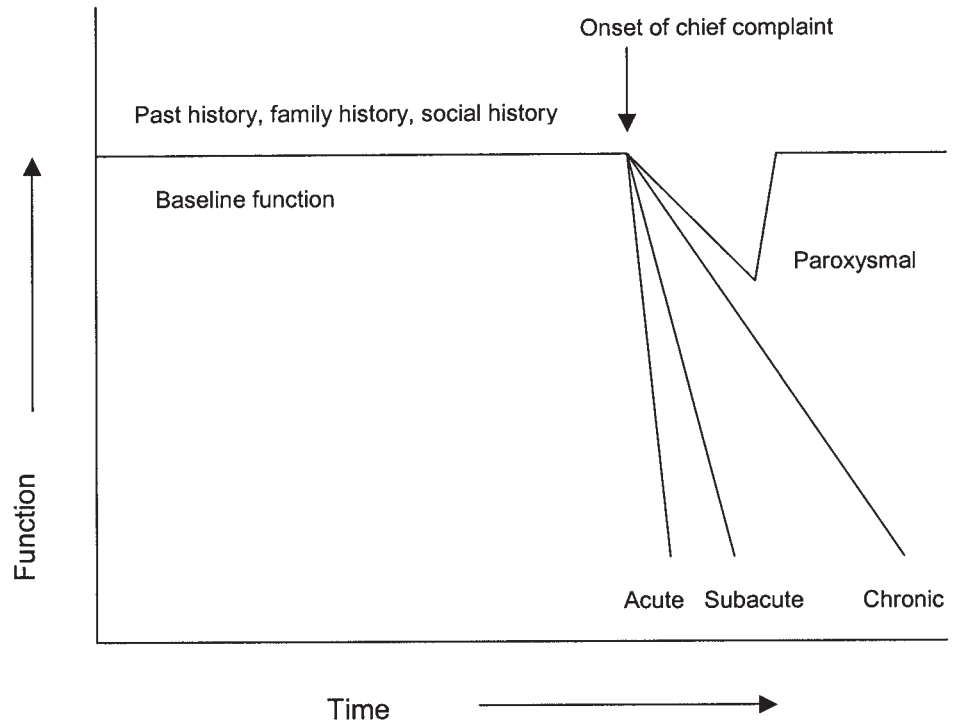

The patient comes to the physician because of a problem—something is wrong and is causing distress, discomfort, or dysfunction. The physician’s task is to take the complaint of the patient and work backward to the cause of the problem. To do this, the physician listens to the patient’s story, constructs a timeline or temporal profile of the problem, and selects those elements of the story that are essential clues or parts of the puzzle of “What’s wrong with me?” The problem or complaint does not occur as an island unto itself but must be considered in the context or the landscape of the patient’s past medical history, social history, and family history. Only when the essential elements of the present illness are considered in the context of the patient’s overall history can a complete and accurate picture be pieced together, which allows the physician to identify a probable cause (a diagnosis) or generate a list of possible causes (a differential diagnosis). By the time the history portion of the patient encounter is completed, the physician should be well on the way to understanding the patient’s problem and formulating a hypothesis, which the physical examination and appropriate diagnostic tests will confirm or negate. The nature of neuropsychiatric problems necessitates a complete and accurate history as a foundation for a diagnosis.

## TEMPORAL PROFILE AND NEUROPSYCHIATRIC DISEASE

---

Constructing a temporal profile of the patient’s complaint is essential in arriving at a correct diagnosis. Basic pathologies have certain temporal profiles, and the temporal profile is often the key to the diagnosis. Multiple different pathological processes can cause weakness of the right side of the body from an upper motor lesion. If the temporal profile of the deficit is acute it is most likely a vascular event or stroke, if subacute it could be an infectious or immune process, or if chronic then a neoplastic process. The temporal profile can be conceptualized as a graph (Fig. 3.1). Function can be plotted over time. The patient’s baseline function is defined by the patient’s past medical history, family and social history, and review of systems. The point of departure from the baseline function is the onset of the chief complaint. The

**Figure 3.1** Temporal profile of diseases affecting the brain.

signs and symptoms of the chief complaint usually have one of four temporal profiles: acute (seconds, minutes, hours), subacute (hours, days), chronic (days, months), or paroxysmal (episodes of symptoms/signs with return to baseline function). Most diseases of the nervous system are due to one of ten types of pathology. Each one of these pathologies has a usual or typical temporal profile (Benarroch, 1999) (Table 3.1). These pathologies can also be considered in light of their location, whether they affect the nervous system focally or diffusely and whether or not they have a progressive or nonprogressive course (Table 3.2).

### CHIEF COMPLAINT AND PRESENT ILLNESS

At the beginning of a patient encounter, the first question that should be asked is “In your own words, what is it that

brings you to see me today?” The reply is recorded as the chief complaint. Listen carefully to the story, interrupting only if clarification is needed. Because the patient is a child, it is tempting to skip over the child and obtain the history from the parent. Most of the history will be from the parent, but it is important to circle back to the child

**TABLE 3.1**  
**TYPICAL TEMPORAL PROFILE OF PATHOLOGIES AFFECTING THE BRAIN**

Acute	Subacute	Chronic	Paroxysmal
Hypoxic	Inflammatory/ Infectious	Congenital	Seizure
Vascular	Immune	Degenerative	Vascular/ Syncope
Trauma	Toxic/Metabolic	Neoplastic	Pain/ Headache

**TABLE 3.2**  
**LOCALIZATION AND COURSE OF BASIC BRAIN PATHOLOGIES**

#### Acute

Vascular-focal or diffuse  
Hypoxic-diffuse  
Trauma-focal or diffuse, progressive

#### Subacute

Inflammatory/Infectious-focal or diffuse, progressive  
Immune-focal or diffuse, progressive  
Toxic/Metabolic-diffuse, progressive

#### Chronic

Congenital-focal or diffuse  
Degenerative-diffuse, progressive  
Neoplastic-focal, progressive

#### Paroxysmal

Seizure-focal or diffuse  
Vascular/Syncope-diffuse  
Pain/Headache-focal or diffuse

and if the child is able, have him or her describe what has happened and what he or she is experiencing. The physician then asks directed questions to fully characterize the chief complaint and present illness. Because the temporal profile is so important for a diagnosis, the physician must be able to reconstruct from the history an accurate and detailed timeline of the symptoms. The physician should seek other characteristics of the symptoms, such as impact on activities of daily living, aggravating and alleviating factors, progression and relationship of symptoms, associated complaints, previous diagnostic studies, and treatments and their effects. Because neuropsychological problems are typically chronic in nature, one important question to ask the parents is “Is there anything that your child used to do that he cannot do now?” This question is helpful in determining if the disease process is static, such as in cerebral palsy, or progressive, such as in one of the neurodegenerative diseases.

## PAST MEDICAL HISTORY

For a child, the past medical history starts with a review of the mother’s pregnancy, labor, and delivery. It is important to ask if there was any exposure to alcohol, smoking, and drugs during the pregnancy. Complications of the pregnancy and information about fetal movement and results of fetal ultrasound or any diagnostic tests should be noted. Specific questions should be asked about the labor, delivery, and nursery course of the baby. It is not uncommon for parents to attribute the baby’s neurodevelopmental problems to a difficult delivery. If the patient did not have any neurological symptoms or signs during the nursery course, but fed well and went home with the mother at the usual time, then the parents can be reassured that the child’s problems were not a result of perinatal events (Volpe 2001).

A developmental history should be obtained next. The physician should have a checklist of developmental milestones that either the parent goes through and indicates attainment of milestones or that the physician verbally obtains from the parent. Typically, developmental milestones can be divided into personal-social, language, fine motor, and gross motor skills. Standardized references and tests such as the Denver II or Infant-Toddler Checklist, have been developed and can be used or adapted for screening purposes. The failure of the child to obtain developmental milestones as well as the pattern of developmental delay are important diagnostic clues.

Included in the medical history should be any hospitalizations, surgeries, significant illnesses, trauma (especially head injuries), medications, and allergies. Most of this information can be obtained by having the parent fill out a new patient history form, which the physician reviews with the parent during the visit for any needed clarifications.

**TABLE 3.3**  
**FAMILY HISTORY QUESTIONNAIRE**

Mother, Father, and Siblings: age, health problems
Is there anyone in the family with the following conditions and what is their relationship with the patient?
Seizures
Mental retardation
Cerebral palsy
Learning problems
Headaches
Fainting
Deafness
Blindness
Muscle disease
Stroke
Ataxia
Tics
Birthmarks (neurocutaneous syndromes)
Degenerative neurological diseases
Depression
Schizophrenia
Attention deficit disorder
Anxiety disorder
Substance abuse and alcoholism
Anyone with the same or similar problem as the patient

## FAMILY HISTORY

Because genetic disease has such an important impact on a child’s health and can be key to making a diagnosis, this part of the history should be explored in detail. It is important to understand the health and medical problems of the parents and the siblings. The family history is frequently unknown or, due to circumstances such as adoption, can be limited; these limitations should be noted. Constructing a family tree or pedigree chart with ages, medical conditions, and deaths is essential when genetic disease is a possibility for the patient. A review of possible neurological and psychiatric illnesses in the family is particularly important to emphasize. A questionnaire that the parent fills out prior to the clinic visit can facilitate this and be used to further explore diseases that occur in the family (Table 3.3).

## SOCIAL HISTORY

The patient’s social history should include an understanding of the patient’s family constellation and home setting as well as the preschool and school function. This history is the physician’s opportunity to gain insight into the child’s behavior and adaptation in the important realms of the child’s life. Although the parents are the primary source for this information, day care, preschool, school, or special education provider assessments and evaluations are important to obtain and review. The patient’s grade level and academic performance should be noted. The results of any formal

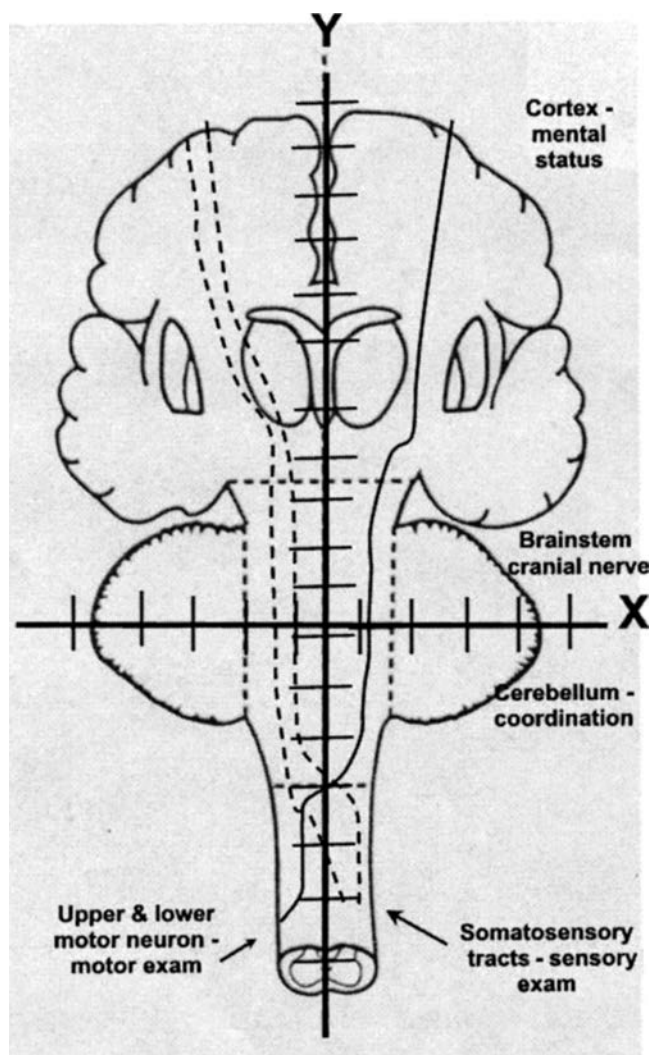

psychological or psychometric testing should be reviewed. This is the time to review if there are any comorbid psychological problems such as conduct, anxiety, attention, affect, psychotic, or compulsive disorders. Any unusual environmental exposures should be noted and identified.

## REVIEW OF SYSTEMS

The review of systems provides the physician with one last chance to make sure that he or she has not missed important elements of the history. It can be done quickly, but should include all major organ systems with the neurological and psychiatric systems review being expanded. It is surprising how often important pieces of information are forgotten or ignored by the family, and this last review will sometimes jog their memory. A checklist can facilitate a rapid but complete review.

## NEUROLOGICAL EXAMINATION

As stated previously, the first step in neuropsychiatric problem solving is anatomical or regional diagnosis. The neurological examination is the physician's window to the brain. If the examination is approached in a systematic and logical fashion that is organized in terms of anatomical levels and systems, the physician can establish where in the nervous system the problem is. In a sense, the physician can think of the neuraxis in terms of an "x, y graph" (Larsen 2001) (Fig. 3.2). The vertical location of the lesion on the graph can be determined by examining the cortex (mental status examination and neuropsychological examinations), brainstem (cranial nerve examination), cerebellum (coordination examination), and spinal cord and peripheral nerve (motor and sensory examinations). Because the motor and sensory examinations test the function of crossed descending and ascending tracts that connect the cortex to or from the periphery, these parts of the neurological examination are very helpful, in combination with the other elements of the examination, to determine not only the level of the lesion or disease but also the horizontal (right, left, or midline) location. Cranial nerve and cerebellar findings are also important in determining right versus left location in the neuraxis. Because of cerebral hemisphere dominance and cortical functional location, parts of the mental status examination also help in determining anatomical localization at the cerebral hemisphere level. For example, if the patient has a right hemiparesis plus an expressive aphasia, then the lesion would be localized to the cerebral hemispheres because of the combination of a language deficit plus the motor deficit. If a patient presents with a right hemiparesis plus diplopia from a left third cranial nerve palsy, the only place that the lesion can be located in the neuraxis is at the level of the midbrain, on the left side where the corticospinal tract and the third cranial nerve are in close proximity.

**Figure 3.2** Neuraxis and the neurological examination in terms of an "x, y graph."

For children, regional or anatomical localization is the basis of neurological assessment; however, it is not sufficient. The examination and the interpretation of the examination must be couched in the context of neurodevelopmental milestones. As mentioned previously, the assessment of the acquisition of motor and cognitive milestones is an essential part of the neurological examination. Delay in obtaining developmental milestones and abnormal patterns of development are important indicators of underlying neurological disease.

## NEUROLOGICAL EXAMINATION IN CHILDREN

Because the infant and child are unable to fully cooperate for the standard neurological examination, the examination must be tailored to their developmental level and

temperament (Larsen 2003). The first part of the examination requires the physician to *stop, look, and listen*. More can be learned about the child's neurological status by initial hands-off careful observation than by forcing the child to conform to the physician's set pattern of performing the neurological examination. By watching a baby's spontaneous activity, a great deal can be determined about mental status, cranial nerve function, coordination, and motor status.

The second part of the examination is the hands-on part, which extends and further clarifies the physician's initial observations. For this part of the examination, make it into a game that engages the child's curiosity and imagination. The examination is less threatening and the child is much more cooperative when toys are used and the examination tools are turned into inviting play objects. For example, use a finger puppet for coordination testing and turn the reflex hammer into an imaginary horse when testing deep tendon reflexes.

The third and last part of the examination includes all those things that are the most threatening and unsettling for the child such as undressing the child for a complete body examination, looking at the fundus with an ophthalmoscope, using the otoscope, testing the gag reflex, or measuring the head circumference.

## ELEMENTS OF THE MENTAL STATUS EXAMINATION

The purpose of the mental status examination is to examine the function of the cerebral cortex. Because the behavior that is produced by the cortex is dependent on the developmental level of the child, the mental status examination must be directed by age-appropriate expectations. For the newborn, the mental status examination consists mainly of observations of the baby's alertness, sleep-wake changes, temperament, and ability to adapt and react to environmental stimuli (Brazelton 1973). The exam is heavily weighted in reflex behavior. By age 2 to 3 months, a social smile develops and the baby is more socially interactive. At age 6 months, the baby laughs, coos, jabbbers, is socially engaging, and is inquisitive. By 12 months of age, the infant has developed stranger anxiety, indicates wants, plays simple games, and has a few meaningful words. As the child becomes verbal, more detailed testing can explore other domains of cortical function. With the preschool and school-aged child, the elements of the traditional psychiatric and neurological mental status examination can be used. Observation of the child's behavior is the main tool of the exam. The mental status examination includes observation of the child's appearance, mood, affect, thought processes, and content. In addition to these areas of behavior, the mental status examination should explore the cognitive domains of attention, executive function, language, memory, and visuospatial function (Guy 2003). These cognitive

domains allow functional examination of various regions of the cerebral cortex. Attention and executive function are predominantly frontal lobe functions. Language can be divided into receptive areas in the posterior temporal-inferior parietal lobes and expressive areas in the inferior frontal lobe. The cognitive domain of memory depends on an intact hippocampal-limbic system of the temporal lobes. The parietal lobes are important for visuospatial function. This is an oversimplification of the anatomical location of these cognitive domains, but it provides a working system to organize the clinical approach to the patient and anatomical localization in the cerebral cortex.

Assessment of cortical function is facilitated by the use of standardized tests, which for the infant include the Cattrell Infant Intelligence Test and the Bayley Scales of Infant Development (Table 3.4). For the child 2 to 8 years of age, the McCarthy Scales of Children's Abilities (McCarthy 1972) allows for the assessment of language, memory, and visuospatial skills. Other tests that are helpful in assessing the young child's cognitive function at this age are the Stanford-Binet Intelligence Scale and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI) (Table 3.4). For the child 3 to 12 years of age, the NEPSY allows for testing in the domains of attention-executive function, language, sensorimotor, visuospatial, and memory (Neepser 1998).

These tests require additional evaluation beyond the initial office visit. Table 3.5 provides an outline of the mental status examination of the verbal child, which can be done as part of the initial office visit. It is not a substitute for formal assessment, but it should help the clinician recognize those cognitive domains that will need more extensive assessment.

## Frontal Lobe Function

The frontal lobes are important for executive function, judgment, and volition. Dysfunction of the frontal lobes can be seen in many neuropsychiatric conditions including attention deficit disorder, neurotrauma, neoplastic, and neurodegenerative diseases. Functional neuroimaging studies have demonstrated that frontal lobe functions can be tested by specific clinical tests (Sarazin 1998). Conceptualization tests correlate with dorsolateral frontal lobe activity, word generation with medial-frontal, and inhibitory control with orbital-frontal areas. The Frontal Assessment Battery (FAB) is a bedside screening test developed to assess frontal lobe dysfunction (Dubois 2000). Although this battery has not been standardized for children, it has value as a set of six clinical tests that can be done in 10 minutes and can be performed on older children and adolescents (Table 3.6). Similarities are used to test conceptualization. Mental flexibility and verbal fluency is tested by asking the patient to list in one minute as many words possible that begin with a certain letter. Patients with frontal lobe dysfunction have difficulty with temporal organization and sequencing of motor tasks. Testing this aspect of frontal lobe function can be

done using the Luria technique of having the patient imitate and then demonstrate the fist-palm-edge of hand sequence tests. Proper frontal lobe function allows the child to direct attention and ignore extraneous or competing sensory or environmental stimuli. The Stroop test can be used to determine whether the patient can maintain attention and not be distracted by conflicting sensory cues. The patient is asked to name the color of a printed word rather than saying

the color that the word names. In the Frontal Assessment Battery, the same frontal lobe function is tested by asking the patient to do a motor task that is different than what the examiner is doing (Table 3.6). The examiner asks the patient to tap twice when the examiner taps once and to tap once when the examiner taps twice. The patient with frontal lobe dysfunction will be echopractic and will repeat the demonstrated pattern rather than following the directions. Patients

**TABLE 3.5**  
**MENTAL STATUS EXAMINATION**

**Attention/Executive Function**

Similarities

Set generation (name all the words you can think of that begin with the letter s)

Fist-palm-edge motor sequence

Go-No Go test

Working memory: digit span, spell words backward

**Language**

Naming objects—pen, watch, button, ring, etc

Meaning of these words: money, flower, summer, book, and so on

Repeat “no ifs, ands or buts”

Following commands

Show a picture and make up a story

Read an age-appropriate paragraph, observe for accuracy and fluency

Ask questions about the paragraph content, check comprehension

Write a sentence (dictated and spontaneous), check for spelling and grammar

**Memory**

List of three words—recall in 5 minutes

Question recent and remote events

**Visuospatial**

Copy a design (simple to complex depending on age)

Draw a person (count body parts, see and draw a man reference)

Draw a clock—draw certain time if age appropriate

Name fingers

Tell right-left and mirror right-left (age appropriate)

with orbital-frontal lobe dysfunction have difficulty controlling impulsiveness and inhibiting inappropriate responses. The Go–No Go test assesses this aspect of frontal lobe function. The patient is asked to tap when the examiner taps once and not to tap when the examiner taps twice. The Go–No Go test has been studied in children and it has been demonstrated that the same underlying prefrontal circuitry is activated in children as in adults (Casey 1997). The last subtest of the Frontal Assessment Battery tests environmental autonomy. Patients with prefrontal lobe dysfunction cannot inhibit their motor response to environmental cues. Testing for environmental autonomy is done by instructing the patient not to grasp the examiner’s hand and then placing a hand in the patients outstretched hand. Normally the patient should be able to inhibit the impulse to grab the examiner’s hand.

Another area of assessment for frontal lobe function is testing working memory, which evaluates the child’s ability to maintain and focus attention. Digit span, spelling words backward, and naming the months of the year backward are good screening tests for working memory.

**Language Function**

In the classical construct of language there are two nodes: the receptive node in the posterior superior gyrus of the dominant hemisphere (Wernicke’s area) and the expressive node in the inferior frontal gyrus (Broca’s area). The nodes are connected by the arcuate fasciculus. Language is certainly more complex than this simple paradigm, but this model allows the clinician to organize an approach to the child. Children with language disorders can have difficulty with phonology, morphology, syntax, semantics, and pragmatics (Crosley 1999).

The child initially develops recognition of spoken words (phonology and morphology) and attaches meaning to words (semantics). This is a function of Wernicke’s area and the adjacent association cortex in the superior temporal-inferior parietal area. Children with developmental receptive dysphasias are often uncomfortable in verbal settings and have difficulty with hearing words correctly and understanding their meaning. They are most comfortable in nonverbal settings and prefer visual and tactile interaction. Assessment of receptive language must take into account age-appropriate expectations. The 12- to 18-month-old should know the meaning of “no,” “come here,” and be able to point to body parts. By 24 months the child should obey simple commands and be able to point to many named objects. By 3 to 4 years the child should be able to name objects by their actions and understand prepositions. Important speech and language milestones are outlined in Table 3.7. Comprehension and inner vocabulary can be tested for age-appropriate levels by using a screening test such as the Weinberg Symbol Language and Communication Battery (SLCB) (Table 3.8, item 1) (Weinberg 1998, 2001).

Expressive language skills are slower to develop than receptive language skills. In a child who has language delay, expressive language is typically more affected than receptive language. It is not uncommon to have children comprehend more than they express. An infant first develops babbling, then nonspecific “da-da” or “ma-ma.” At age 10 to 12 months the infant will develop one to two specific words. A vocabulary growth spurt occurs at age 18 to 24 months, and two-word sentences are used by 2 years of age (Rescorla 1997). By age 3 to 4 years the child uses three-word to four-word sentences and past and future verb tenses (Table 3.7).

Assessment of expressive language begins with listening to the child’s spontaneous speech. The child can be encouraged to talk by showing colorful action pictures and asking the child questions about the picture. More formal assessment of expressive language can be accomplished by asking the child to repeat words and name colors, shapes, numbers, and letters. The hallmark of expressive dysphasia is nonfluency, grammatical errors, and articulation problems. The older child should be able to use correct grammar including pronouns, possessives, prepositions, and

**TABLE 3.6**  
**FRONTAL ASSESSMENT BATTERY (FAB)**

1. Similarities (conceptualization)
 

"In what way are they alike?"

A banana and an orange (in the event of total failure: "they are not alike" or partial failure: "both have peel," help the patient by saying, "both a banana and an orange are . . ." but credit 0 for the item; do not help the patient for the following items).

A table and a chair

A tulip, a rose, and a daisy

Score (only category responses [fruits, furniture, flowers] are considered correct)

Three correct:	3
Two correct:	2
One correct:	1
None correct:	0
2. Lexical fluency (mental flexibility)
 

"Say as many words as you can, beginning with the letter S, any words except surnames or proper nouns."

If the patient gives no response during the first 5 seconds, say, "for instance, snake." If the patient pauses 10 seconds, stimulate him by saying, "any word beginning with the letter S. The time allowed is 60 seconds."

Score (word repetitions or variations [shoe, shoemaker], surnames, or proper nouns are not counted as correct responses)

More than nine words:	3
Six to nine words:	2
Three to five words:	1
Less than three words:	0
3. Motor series (programming)
 

"Look carefully at what I'm doing."

The examiner, seated in front of the patient performs alone three times with his left hand the series of Luria "fist-edge-palm." "Now, with your right hand do the same series, first with me, then alone." The examiner performs the series three times with the patient, then says to him or her, "Now, do it on your own."

Score

Patient performs six correct consecutive series alone:	3
Patient performs at least three correct consecutive series alone:	2
Patient fails alone, but performs three correct consecutive series with the examiner:	1
Patient cannot perform three correct consecutive series even with the examiner:	0
4. Conflicting instructions (sensitivity to interference)
 

"Tap twice when I tap once."

To be sure that the patient has understood the instruction, a series of three trials is run: 1-1-1. "Tap once when I tap twice." To be sure that the patient has understood the instruction, a series of three trials is run: 2-2-2. The examiner performs the following series: 1-1-2-1-2-2-2-1-1-2.

Score

No error:	3
One or two errors:	2
More than two errors:	1
Patient taps like the examiner at least four consecutive times:	0
5. Go–No Go (inhibitory control)
 

"Tap once when I tap once."

To be sure that the patient has understood the instruction, a series of three trials is run: 1-1-1. "Do not tap when I tap twice." To be sure that the patient has understood the instruction, a series of three trials is run: 2-2-2. The examiner performs the following series: 1-1-2-1-2-2-2-1-1-2.

Score

No error:	3
One or two errors:	2
More than two errors:	1
Patient taps like the examiner at least four consecutive times:	0
6. Prehension behavior (environmental autonomy)
 

"Do not take my hands."

The examiner is seated in front of the patient. Place the patient's hands palm up on his or her knees. Without saying anything or looking at the patient, the examiner brings his or her hands close to the patient's hands and touches the palms of both the patient's hands, to see if he or she will spontaneously take them. If the patient takes the hands, the examiner will try again after asking him or her, "Now, do not take my hands."

Score

Patient does not take the examiner's hands:	3
Patient hesitates and asks what he or she has to do:	2
Patient takes the hands without hesitation:	1
Patient takes the examiner's hand even after he or she has been told not to do so:	0

**TABLE 3.7**  
**IMPORTANT SPEECH AND LANGUAGE MILESTONES**

Receptive Language	Age	Expressive Language
Turns to sound of bell	6 months	Cries, laughs, babbles
Waves bye-bye	9 months	Imitates sounds and makes dental sounds during play (e.g., "da-da")
Knows meaning of "no" and "don't touch"	12 months	Uses 1–2 words (e.g., "da-da" "mama" "bye")
Responds to "come here"	15 months	Uses jargon (speech-like babbling during play)
Points to nose, eyes, hair	18 months	Uses 8–10 words (one third are nouns); puts two words together (e.g., "more cookie"), repeats requests
Points to a few named objects	24 months	Asks one- to two-word questions (e.g., "Where kitty?")
Obeys simple commands		
Repeats two numbers	30 months	Uses "I" "you" "me"
Can identify by name "What barks?" and "What blows?"		Names objects
Responds to prepositions "on" and "under"	3 years	Uses three-word simple sentences
Responds to prepositions "in," "out," "behind," "in front of"	4 years	Masters consonants <i>b, p, m</i>
		Speaks in three- to four-word sentences
		Uses future and past tenses
		Masters consonants <i>d, t, g, k</i>
Can repeat a seven-word sentence	6.5 years	Masters <i>th</i> sound
		Uses six- to seven-word sentences
		Says numbers up to 30s

Source: Reprinted from Olson WH, Brumback RA, Gascon GG, et al. *Handbook of Symptoms-Oriented Neurology*. 2nd Ed. St. Louis, MO: Mosby-Year Book, p. 347, 1994, Copyright 1994, Mosby-Year Book. Used with permission.

correct sentence structure (syntax). Children with expressive dysphasia will have trouble repeating words or sentences. For example, a child who has an expressive dysphasia would have trouble repeating the phrase, "no ifs, ands, or buts." This is also seen in conductive dysphasia. The child with conductive dysphasia from a lesion of the arcuate fasciculus has adequate comprehension (i.e., Wernicke's area is intact) and spontaneous speech (i.e., Broca's area is spared), but the child cannot repeat what is said.

Another important aspect of language that should be assessed in the older child is written language, including both reading comprehension and written expression. Comprehension of written language is assessed by having the child read age-appropriate material and checking for both accuracy and fluency. The young child with dyslexia will have problems with phonology and decoding the word, but comprehension will be intact. Another hallmark of dyslexia is that reading fluency is always impaired so that the child's reading is slow and laborious. Dyslexics also have difficulty with spelling. Early identifiable risk factors for dyslexia include delay in speaking, difficulties in pronunciation, insensitivity to rhyme, and inability to learn the names and sounds of the letters (Shaywitz 2003). Screening tests for reading readiness, phonemic recall, and spelling ability, which are associated with reading ability as well as tests for reading accuracy and comprehension, are outlined in the Weinberg SLCB, subtests 2 to 4 (Table 3.8). Another informal way of assessing the child's reading ability is to have a collection of children's books in the office from the first

grade to high school level. The child can then be tested for age-appropriate reading accuracy, fluency, and comprehension. Formal reading assessment tools include the Woodcock-Johnson III, the Woodcock Reading Mastery Test, and the Gray Oral Reading Tests.

Prosody is the affective and emotional quality of language. Much of the meaning of language is embodied in the way or manner that something is said (pragmatics). Intonation, inflexion, rate, volume, and emphasis of speech, as well as facial expression and body gesturing, are all a part of the meaning of language. An example of this would be the changing of a statement into a question by adding an inflexion at the end or the use of sarcasm to mean just the opposite of what is said. A simple declarative statement such as "I'm going to school now" can convey a state of being sad, happy, or angry about going to school. The prosody of language is a function of the nondominant cerebral hemisphere with the same anatomical nodal organization of reception and expression as semantic language in the dominant hemisphere. The anatomical location for the receptive node of prosody is the posterior part of the nondominant superior temporal gyrus analogous to Wernicke's area in the opposite hemisphere. Likewise, expressive prosody is located in the posterior region of the nondominant inferior frontal gyrus analogous to Broca's area. The receptive and expressive prosody nodes are connected by a fasciculus. The disorders of prosody (aprosody or dysprosody) are clinically categorized in the same way as left hemisphere aphasias (receptive, expressive, and conductive).

**TABLE 3.8**  
**SELECTED TESTS FROM WEINBERG SYMBOL LANGUAGE AND COMMUNICATION BATTERY (SLCB)**

### 1. Reading Readiness

This section of the test asks the child age 3 to 6 years to name the classic symbols: colors, shapes, numbers, and letters. A child unable to name the symbols should be presented with a multiple-choice format using three choices. If the child is unable to select the proper choice, then assume that the symbol has not been stored.

- Color naming.** "What color is this?" Show the child red, blue, green, yellow, and brown. Children ages 3 to 4.5 years should be able to name colors.
- Geometric shapes.** "What shape is this?" Show the child a square, triangle, diamond, cross, and star. Children ages 3.5 to 6 years should be able to name geometric shapes.
- Number discrimination.** "What number is this?" Show the child a 1, 3, 6, 7, and 9. If the child is unable to name the number, offer three possible responses for the child to choose from. Children ages 4 to 5 years should be able to name numbers.
- Number naming.** "What number is this?" Show the child a 1, 3, 6, 7, 9, 25, and 50. Children ages 5 to 6 years should be able to name numbers.
- Letter discrimination.** "What letter is this?" Show the child the uppercase A, B, C, D, and E. If the child is unable to name the letter, offer three possible responses for the child to choose from. Children ages 4 to 5 should be able to discriminate letters.
- Letter naming.** "What letters are these?" Show the child lowercase a, b, c, d, h, j, k, m, n, p, u, w, x, y, and z. Children ages 5 to 6 years should be able to name letters.

### 2. Reading Comprehension

(Spelling words A: Backward words spelling test). This test relates directly to reading comprehension.

- "Spell the word **dog**." "Spell **dog** backward." "What does that new word spell?" Children ages 6 to 7 years should correctly spell and label the backward word (**god**) and should understand first-grade reading material.
  - "Spell the word **was**." "Spell **was** backward." "What does that new word spell?" Children ages 7 to 8 years should correctly spell and label the backward word (**saw**) and should understand second-grade reading material.
  - "Spell the word **tip**, like the **tip** of my finger." "Spell **tip** backward." "What does that new word spell?" Children ages 7.5 to 8.5 years should correctly spell and label the backward word (**pit**) and should understand third-grade reading material.
  - "Spell the word **not**. Like, 'I will **not** go.'" "Spell **not** backward." "What does that new word spell?" Children ages 9 to 10 years should correctly spell and label the backward word (**ton**) and should understand fourth-grade reading material.
  - "Spell the word **live**." "Spell **live** backward." "What does that new word spell?" Children ages 9.5 to 10.5 years should correctly spell and label the backward word (**evil**) and should understand fifth-grade reading material.
- "Spell the word **dial**. Like, '**dial** a telephone number.'" "Spell **dial** backward." "What does that new word spell?" Children ages 9.5 to 11 years should correctly spell and label the backward word (**laid**) and should understand fifth-grade to sixth-grade reading material. A child able to do **live/evil** and **dial/laid** is literate.

### 3. Phonemic Recall and Sequencing of Graphemes

(Spelling words B). "Now, these are more difficult words. Some may be fifth-grade words, but do the best you can. Spell them as well as you can." Children who are able to spell the fifth-grade words are considered to be literate for spelling.

- |                              |                       |                                       |
|------------------------------|-----------------------|---------------------------------------|
| a. <b>First-grade words</b>  | (ages 6–7 years):     | it, cat, look, stop, spot             |
| b. <b>Second-grade words</b> | (ages 7–7.5 years):   | hit, hot, hat, hut                    |
|                              | (ages 7.5–8 years):   | work, talk, girl, went                |
| c. <b>Third-grade words</b>  | (ages 8–9.5 years):   | should, could, phone, house           |
| d. <b>Fourth-grade words</b> | (ages 9–10.5 years):  | monkey, elephant, receive, friend     |
| e. <b>Fifth-grade words</b>  | (ages 10–11.5 years): | purchase, ethics, delicate, delicious |

### 4. Word Storage

(Inner vocabulary) Ask the child to define one or more age-appropriate words. If the child is unable to do so, offer three verbal choices. If the child is unable to choose the correct definition, offer three pictorial choices. If the child is still unable to do this task, then offer one or more words appropriate for a younger age group. If the child is unable to offer a definition, then offer three verbal choices. If the child is unable to choose the correct definition, offer three pictorial choices.

- Ages 6 to 8 years:** baby, name, green, second
- Ages 8 to 10 years:** visit, spring, money, thought
- Ages 10 to 12 years:** grasp, moist, stride, browse, coward
- Ages 12 to 14 years:** freight, obsolete, drought, absorb, occupation
- Ages 14 to 16 years:** fortuitous, vaguely, judicious, vocation, absurd
- Ages greater than 16 years:** serendipity, foment, impecunious, litigious

(continued)

**TABLE 3.8**  
(continued)

**5. Gilmore Oral Reading Test—Form C: Accuracy (Gilmore and Gilmore 1968).**

"I want you to read for me. Some of the words may be difficult. That's okay; just do the best you can. I am going to ask you some questions after you have read the stories." Start by having the child reading aloud at a grade level below the child's estimated ability. When possible, find the grade level at which the child makes no errors (base) and at which he or she makes four or fewer errors (ceiling). Stop after the fifth error at a grade level. Record the number of errors made for each test grade level. Types of errors are substitutions, omissions, blanks, mispronunciations, and skipping around on the page.

**6. Gilmore Oral Reading Test—Form C: Comprehension (Gilmore and Gilmore 1968).**

Using the child's ceiling paragraph, read the questions to the child. For each question that the child cannot answer, present a multiple choice using three choices, with one being correct.

Source: Modified from Coffey CE, Brumback RA. *Textbook of Pediatric Neuropsychiatry*. Washington, D.C., London: American Psychiatric Press, Inc. 1998. Used with permission.

Prosody develops early in infancy and is fully established for communication by the late toddler and early preschool years (Weinberg, 1998, 2001). A child who has problems with receptive or expressive prosody is significantly impaired in social and contextual interactions. Such a child can understand the meaning of words and say them correctly, but without normal prosody the child is bewildered and frustrated with social language.

The examiner can learn the most about the child's prosody by watching spontaneous verbal and gestural interactions. The examiner should note if the child understands the emotional and contextual aspects of language and if the gestures and language prosody are appropriate for the occasion. Formal screening can be divided into tests for gestural prosody and verbal prosody (Weinberg 1998, 2001). For gestural prosody, use cards or the examiner's own face and ask the child to identify the expression of happy, sad, or angry (Fig. 3.3). Then ask the child to demonstrate facial expressions of these same emotions. Verbal prosody is tested by having the child listen to the examiner say a sentence in a happy, sad, or angry fashion and then asking the child to identify the correct emotion. The child can then demonstrate the ability to express these same emotions in a sentence. While testing verbal prosody, the examiner and child should not be able to see each other's facial expression.

## Memory

Memory can be subdivided into episodic and semantic memory (Tulving 1972). Episodic memory is the ability to recall personal experiences including time, place, persons, and objects. Semantic memory is knowledge of facts without a personal reference such as general knowledge of world events or rules of arithmetic. Both types of memory depend on an intact hippocampus for consolidation.

Insight into the child's memory function is obtained throughout the mental status examination as well as the history part of the evaluation by observing responses to

questions asked during the course of the office visit. A specific screening test for recent memory is to give the child a list of three things to remember, and then later in the examination ask the child to recall the list. If the child can't recall all of the objects, then progressive prompting should be used to see how much help the child needs to be able to recall the objects. Another way of testing recent memory is to give the child a list of words to be memorized and then later in the examination have the child pick out the memorized words from a longer list of words. The same testing can be done for nonverbal recent memory by showing the child several pictures to remember and then later in the examination having the child identify the memorized pictures from a larger assortment of pictures. Episodic memory can be tested by asking the child to recall recent personal events or activities as well as important personal historical events. Semantic memory can be tested by asking the child to recall presidents of the United States, events of history, or other age-appropriate world knowledge.

## Parietal Lobe Function and Visuospatial Processing

The parietal lobes are important for somatosensory perception and visuospatial organization. The nondominant parietal lobe is particularly important for visuospatial tasks. Testing for parietal lobe function can be subdivided into tests for cortical discriminatory somatosensory function, sensory neglect, visuospatial tasks of constructional praxis, and a constellation of tests used to examine the function of the dominant inferior parietal area for evidence of the developmental Gerstmann syndrome.

Cortical discriminatory somatosensory function is tested in several ways. Having the child identify numbers that are written on the palm of the hand with eyes closed tests for graphesthesia. Having the child name objects that are placed in the hand with the child's eyes closed tests stereognosis. Tactile direction movement is a sensitive test

**Figure 3.3** Faces for testing gestural prosody.

of cortical discriminatory function (Casey 2000). First, explain and demonstrate to the child that the examiner is going to ask the child to report which direction the skin is stroked with a pointed object, either up or down, to the right or left. A young child can point to the direction of movement rather than say the direction. The examiner then applies a stimulus of at least 2 to 3 cms length on the right and left sides of the body with the child's eyes closed.

Children with a parietal lobe lesion neglect space on the side opposite of the lesion, especially with a nondominant

parietal lesion. This is sensory neglect. Subtle neglect can be detected by testing double simultaneous stimulation. The child is tested by touching homologous parts of the body on one side, the other side, or both sides at once with the child's eyes closed and asking the child to identify right, left, or both. If the child neglects one side on double simultaneous stimulation (extinction or simultanagnosia), this indicates dysfunction of the contralateral posterior parietal lobe. This test can also be done with visual stimuli.

Constructional praxis is tested by asking a child to draw a person, a clock, or geometric figures. By 5 years of age, a child should be able to draw a person, and by age 7 to 8 years, the child should be able to draw a clock. Difficulty with these visuospatial tasks can be seen in nondominant inferior parietal lobe dysfunction.

The dominant inferior parietal lobe is important for symbol sequencing such as in counting, number processing, letter writing, and spatial orientation such as in right-left orientation. By age 6 to 8 years, the child should be able to identify right and left on herself or himself, and by age 8 to 9 years, the child should be able to identify right and left on others and the environment. Children with dominant inferior parietal lobe dysfunction will have elements of the developmental Gerstmann syndrome, such as right-left confusion, finger agnosia, dyscalculia, and dysgraphia. It is interesting that finger naming (finger agnosia) is a predictor of arithmetic abilities in children (Fayol 1998).

## CRANIAL NERVE EXAMINATION

The cranial nerve (CN) examination allows the physician to "view" the neuraxis from the level of the olfactory and optic tracts to the caudal extent of the medulla. The 12 cranial nerves can be divided into four anatomical levels: CN 1 and 2-telencephalon, CN 3 and 4-midbrain, CN 5 through 8-pons, and CN 9 through 12-medulla. Cranial nerve findings when combined with long tract findings (corticospinal and somatosensory) are important for localizing lesions in the brainstem.

The cranial nerve examination in children must be adapted to the age and cooperation of the child (Larsen 2003). Most of the exam can be completed by specifically observing the function of each of the cranial nerves during the patient's spontaneous behavior and play. Cranial nerves 3, 4, and 6 are tested as the child tracks and follows a colorful toy. Observing smiling, crying, and spontaneous facial expression and blinking indicate CN 7 function. The child turning to soft noises or clicks of a toy is an initial screening for hearing (certainly more detailed audiometric screening of hearing must be done if there is any question of language delay or hearing loss). Listening to the child's vocalizations, then watching chewing and swallowing, reflects CN 5, 9, and 10 function. For the older child, repeating "lahpakhah," tests CN 12, 7, and 10.

**TABLE 3.9**  
**CRANIAL NERVE EXAMINATION ADAPTED FOR CHILDREN**

Cranial Nerve (CN)	Sensory/Motor	Standard Test	Adaption for Infants and Children
CN 1	Sensory	Identify nonnoxious odor	Use small container of lemon, orange, vanilla. Ask if child can smell something with eyes closed.
CN 2	Sensory	Snellen or Rosenbaum chart	Does infant regard small objects. Is the object held too close to the eyes? Use E or animal pictures Snellen chart.
		Visual fields	Child focuses on object in front of him while another object is introduced from the side into his field of vision.
		Funduscopy exam	Check for symmetric red reflexes. Have child focus on colorful object as fundus is examined.
CN 3, 4, and 6	Motor	Six cardinal positions of gaze	For neonate, rotate head in horizontal and vertical planes and observe conjugate eye rotation in opposite direction. For infant and child, use face, finger puppet, doll, or colorful object for the child to track and follow.
CN 5	Motor	Jaw movement	Watch baby suck, older infant chew and open mouth.
CN 5	Sensory	Corneal and facial sensation	Blink and grimace to corneal reflex. Nasal tickle also tests ophthalmologic division of CN5. Observe reaction to tickle of regions of the face.
CN 7	Motor	Muscles of facial expression	Infant: Watch cry, smile, grimace. Child: Blow kisses, blow on tissue, response to tickle, say "pah-pah-pah."
CN 8	Sensory	Soft click, softly spoken words, each ear	Infant: Turns to voice, click or novel sounds. Test both right and left ear.
CN 9 and 10	Motor/Sensory	Say "ah," gag	Infant: Watch suck and swallow, sound of cry and vocalizations, gag reflex—save until end of the exam. Child: Watch swallow, say "kah-kah-kah," listen for hypernasalized sound to vocalizations, gag reflex.
CN 11	Motor	Turn head against resistance, shrug shoulders	Infant: Turn head and watch for sternocleidomastoid muscle action to resist the turning. Child: Touch chin on shoulder, shrug shoulders.
CN 12	Motor	Side to side and in-out tongue movements	Lick lips, wiggle tongue side to side, try to touch tongue to nose, say "lah-lah-lah."

Observations of spontaneous cranial nerve function should be combined with examination maneuvers directed to assess specific cranial nerve function. Table 3.9 lists the cranial nerves and suggestions for examination adaptations for children.

## COORDINATION

The principle area of the brain that is examined by the coordination examination is the cerebellum. The cerebellum is important for motor learning and timing of motor activity. Recent research indicates that it is a sensory coordinator, integrating and processing sensory input that is essential for feedback and feed-forward control of motor movements (Bower 2003). It fine-tunes the force of agonist and antagonist muscle activity simultaneously and sequentially across multiple joints to produce smooth flowing,

goal-directed movements. Its integration and timing function also extend beyond the motor control realm to include a role in cognition. At the present time, the cerebellum is examined in terms of motor coordination. To test the cerebellum, the motor and somatosensory systems have to be sufficiently developed and intact because the cerebellum has a primarily supportive function for these systems. For the newborn, the coordination examination is not even a part of the neurological examination. At age 3 to 6 months, the infant has developed the ability to start to reach for objects and grasp objects. At this point most of the tasks that are tested in the infant are gross motor skills. In the 6 to 12 months age range, the fine motor skills start to emerge and as the repertoire increases, the need for cerebellar input also increases. As the baby develops a fine pincer grasp at 10 to 12 months of age and is manipulating small objects, fine motor testing takes on the familiar characteristics of coordination testing. As an infant develops the ability to sit,

**TABLE 3.10**  
**COORDINATION EXAMINATION ADAPTED FOR CHILDREN**

Appendicular coordination
Pick up small object such as a Cheerio or raisin. Observe for pincer grasp development.
Take small object and place in a small container.
Reach for and grasp the end of a measuring tape.
Touch nose or eyes of a finger puppet.
Stack blocks (15-month-old: tower of 2, 18-month old: 4–6 blocks, 30-month old: 6–8 blocks, 3-year old: 3 block bridge).
Drawing/copying geometric shapes (age appropriate): line, circle, triangle, square
Midline or gait coordination
Sitting: able to stabilize trunk
Standing: stable station, broad based as toddler, narrower as older child
Stoop and recover: 12–14 month old
Toddlers gait: 10–18 months
Stand on one foot: 3-year-old
Hop on one foot: 4-year-old
Tandem walk: 6-year-old

stand, and then walk, the immaturity of the cerebellar system is demonstrated in the unsteadiness of the toddler's gait and motor movements. With time and maturation, the gait and movements become more coordinated. The station narrows and the gait becomes more steady. At 3 to 4 years of age, the child is able to balance on one foot. At age 6 years, the child can narrow the station to the point of being able to tandem walk.

Cerebellar dysfunction results in the decomposition of movements and the undershooting and overshooting of goal-directed movements (dysmetria). Decomposition of movements and dysmetria are the main elements of ataxia. Ataxias can be divided into gait ataxia and appendicular ataxias (ataxia of an extremity). Gait ataxia is usually caused by disease of the midline cerebellar structures (vestibulocerebellum and spinocerebellum), whereas appendicular ataxia is caused by the ipsilateral cerebellar hemisphere (cerebrocerebellum). Suggestions for adapting the coordination examination to children are given in Table 3.10.

## SOMATOSENSORY EXAMINATION

The somatosensory examination is the most subjective portion of the neurological examination and perhaps the hardest to perform in children. A child who is verbal, can follow instructions, and can report sensation accurately is tested in the same manner as an adult. A younger child can only be tested for the presence or absence of sensation. The child should be able to localize where he or she is touched. Also, children should have an affective response to noxious or painful stimuli such as pinprick. Obviously, once a painful stimulus is used, the child's cooperation will diminish and

the potential to continue the examination will be limited. For children, the sensory examination is most important when there is a possible spinal cord, nerve root, or peripheral nerve lesion. When a child is old enough to follow directions and stand with eyes closed, testing needs to be performed to determine the ability to maintain balance. A positive Romberg sign is present when the child can maintain balance with their eyes open but loses balance when eyes are closed. If the child loses balance only with eyes closed, that is a proprioceptive problem and an important indicator of dorsal column-medial lemniscus system disease. If the child has poor balance with eyes open or closed, that is a cerebellar problem and not a sensory problem.

## MOTOR EXAMINATION

The motor examination includes observing muscle bulk and palpating of the muscles when appropriate; assessing tone, strength, deep tendon reflexes; and noting any pathological reflexes. For infants and children, attainment of motor milestones and the assessment of primitive and postural reflexes should be added to these standard elements of the motor examination.

Inspection of the child's muscle bulk is the beginning of the motor examination. Any atrophy or asymmetry should be noted. Atrophy is pronounced in neuromuscular disease, while it is less noticeable in diseases of the upper motor neuron. The distribution of the atrophy is also important. A lesion of the brachial plexus, such as an Erb's palsy, will have a characteristic distribution of atrophy and weakness, while a disease like spinal muscular atrophy will give diffuse weakness. When weakness is present, the muscle should be palpated for tenderness, consistency, or contractures.

Muscle tone is the resistance of the muscle to stretch. Two types of tone are assessed clinically: postural and phasic (Fenichel 2001). Postural tone is the bias or tension maintained by the muscle to resist gravity. The examiner can assess it by applying a sustained low amplitude stretch of the muscle with passive range of motion. Phasic tone is assessed by applying a high amplitude quick stretch of the muscle with a resulting brief phasic contraction of the muscle. Testing deep tendon reflexes (DTRs) refers to the clinical method of assessing phasic tone.

Tone assessment is important in determining the intact function of the upper motor neuron (connections from the motor cortex to the anterior horn cell) as well as the lower motor neuron unit (anterior horn cell, nerve, and muscle). Diseases of the upper motor neuron typically cause increased postural and phasic tone (spasticity and hyperreflexia), whereas diseases of the lower motor unit cause decreased postural and phasic tone (hypotonia and hyporeflexia). In infants and young children, an upper motor neuron lesion can cause cerebral or central hypotonia. Postural tone is diminished, but phasic tone is preserved or even increased. Cerebral hypotonia is seen with congenital

**TABLE 3.11**  
**TONE, REFLEXES, AND STRENGTH IN CENTRAL VERSUS PERIPHERAL NERVOUS SYSTEM DISEASE**

	Postural Tone	Phasic Tone	Pathological Reflexes	Weakness
Spasticity: UMN	Increased	Increased	Present	Variable
Cerebral hypotonia: UMN	Decreased	Increased or normal	Present	Variable
Peripheral hypotonia: LMN	Decreased	Decreased	Absent	Invariable

brain malformations, chromosome disorders, metabolic diseases, and as a type of cerebral palsy. When hypotonia is cerebral in origin, additional neurological findings are usually present, such as pathological reflexes, persistent primitive reflexes, cognitive impairment, and other signs of central nervous system dysfunction. Table 3.11 summarizes the tone changes and other findings in central versus peripheral nervous disease.

Strength testing can be a challenge in children who cannot follow directions or who are uncooperative. In the child who can follow directions, strength testing is the same as in the adult examination. For the infant, strength can be tested by putting the baby through maneuvers that require muscle strength to oppose gravity (Table 3.12). For the hypotonic infant, it is important to determine if the child can increase tone and demonstrate strength when irritated and crying. The infant with cerebral hypotonia will be able to reinforce tone and strength when angry or upset, but the infant with peripheral hypotonia will not. This is an important diagnostic clue in determining the cause of hypotonia (Table 3.11). For the older, uncooperative child, strength testing

can be observed when getting out of a chair, getting up off the ground, walking, running, squatting, and rising. The examiner can have the child do a push up or use the wheelbarrow maneuver to assess shoulder girdle strength.

For the infant, an important part of the motor examination is the testing for primitive reflexes and postural reflexes. Neurodevelopmentally, primitive reflexes, such as the Moro, Galant, root, suck, and grasp (Table 3.13), should be present in the newborn and their absence is pathologic. The primitive reflexes normally diminish over the next 4 to 6 months. The postural reflexes, such as the positive support reflex, Landau, lateral propping, and parachute (Table 3.13), emerge at 3 to 8 months of age. Postural reflexes are essential for postural stability and without them the child will be unable to sit independently or walk. Persistence of primitive reflexes and the lack of development of the postural reflexes are the hallmark of an upper motor neuron abnormality in the infant.

Other reflexes to test for in the motor examination are pathological reflexes. An upgoing great toe on noxious plantar stimulation is normal during the first year of life be-

**TABLE 3.12**  
**ASSESSING STRENGTH IN AN INFANT**

### Head Control

The newborn should be able to lift the head to upright position at least for a few seconds while sitting. By 3 months, there may be some wobbling of the head but most of the time the head is held upright with good control.

### Traction

While pulling the newborn to sitting from the supine position, the head will lag behind the trunk but not in full extension. By 3 months, there may be slight head lag. By 6 months, the head leads the trunk when the baby is pulled to the sitting position. The baby then sits with a straight back and good head control.

### Ventral Suspension

With the newborn suspended in the prone position, the head should stay in the same plane as the back and the extremities would be a semiflexed position. By 3 months, the baby's back should be straight, the head extended and looking forward.

### Vertical Suspension

The examiner should be able to hold the baby in the vertical position without the baby slipping through his hands because of shoulder girdle weakness. By 3 months, the baby should be able to support some weight on his or her feet.

### Prone Position

The newborn should be able to turn the head side to side and the extremities should be in flexion. By 3 months, the baby should lift the head 45 to 90 degrees off the mat, support weight on the forearms. By 6 months, the chest should be off the mat and weight is on the hands.

**TABLE 3.13**  
**PRIMITIVE AND POSTURAL REFLEXES**

**Primitive Reflexes**

**Moro:** With sudden downward movement of a supine baby, the arms will fully extend and abduct and then return to midline.

**Root, suck:** When the cheek is gently stroked toward the lips, the baby should open his or her mouth and turn toward the stimulus. Suck should be strong with a coordinated stripping action of the tongue.

**Galant (trunk incurvation):** With the baby in ventral suspension, stroking the skin on one side of the lower back will cause the trunk and hips to swing toward the side of the stimulus.

**Grasp:** The baby should have a strong grasp with the fingers or toes when pressure is applied to the palm of the hand or ball of the foot.

**Postural Reflexes**

**Positive support:** When held in the vertical position with feet touching a surface, the infant will extend the legs and attempt to support his or her weight.

**Landau:** With the infant held in ventral suspension, the head and legs will extend.

**Lateral propping:** In the sitting position, the infant will extend the appropriate arm and hand to prevent falling.

**Parachute:** When the infant is turned upside down and suspended in the air, the arms extend forward and the hands spread out in order to catch him or her. This is the last of the postural reflexes to appear.

cause of the incomplete myelination of the corticospinal tracts during this time. After 1 year of age, extension of the great toe (or Babinski sign) is abnormal and is a sign of corticospinal tract disease. When a child is old enough to cooperate, he or she should be tested for pronator drift. The patient extends the arms in front with the palms up and eyes closed. The examiner watches for any pronation and downward drift of either arm. Any pronator drift indicates corticospinal tract disease. This sign is a sensitive indicator of corticospinal tract disease and has the same clinical significance as a Babinski sign.

Attainment of motor milestones is an important part of the motor examination (Larsen 2003). The development of motor control proceeds in a head to toe fashion and reflects the progressive myelination of the corticospinal tracts. The baby first develops head then trunk control (able to sit) and finally develops motor control of the lower extremities to be able to walk. Delay in obtaining motor milestones can indicate the presence of neurological disease. The infant less than 1 year of age does not have a hand preference and uses both hands equally well. Early handedness is an indication of a motor deficit of the nonpreferred hand. Significant motor milestones are listed in Table 3.14, along with the age at which they typically are obtained.

For many of the children that are assessed for neuropsychiatric problems, the findings on the standard motor examination will be normal yet they are often noted to be awkward or clumsy. These children will frequently have subtle neurological findings such as mirror movements, associated or overflow movements, and impaired fluency and accuracy of repetitive movements (Denckla 1985). In assessing subtle neurological findings, it is important to remember the neurodevelopmental aspect of when these findings should disappear (Table 3.15). These subtle motor neurological findings do not have the same anatomical localization power as the classic motor examination findings. Nevertheless, they have value in

indicating that the motor control in these children is not totally normal and these findings can be associated with such conditions as attention deficit disorder and learning disorders. Other unusual movements that should be searched for include tics, repetitive self-stimulation movements such as hand flapping, twirling, rocking, choreiform movements, and pseudo-choreiform movements (pseudo-choreiform movements are seen in hyperactive children and can be difficult to distinguish from true chorea).

**GAIT**

Assessing the child's gait is an essential part of the neurological examination. As infants develop, they will start to support weight on their legs at 3 to 4 months, get in and out of the sitting position at 7 to 9 months, cruise at 10 to 12 months, and walk by 12 to 16 months. As infants start to walk, the station is wide based and the arms are held up in front in the high guard position as if they are ready to catch themselves. Gradually, over the next few months, the position of the arms is lowered to the midguard, then low-

**TABLE 3.14**  
**MOTOR MILESTONES**

Milestone	Age Accomplished
Rollover	2–4 months
Sitting without support	5–7 months
Crawling	6–8 months
Getting to sitting	8–9 months
Creeping	8–10 months
Cruising	9–11 months
Walking	12–16 months
Running	14–18 months
Hop on one foot	3–4 years

**TABLE 3.15**  
**SUBTLE NEUROLOGICAL SIGNS**

Sign or Finding	Age
Can't hop on one leg 5 times	4 years
Can't hop on one leg 25 times	6 years
Can't balance on one leg for 10 seconds	5 years
Can't balance on one leg for 30 seconds	8 years
Persistence of feet-to-hands overflow (hands mirror position of feet) on toe walking	6 years
Persistence of feet-to-hands overflow on heel walking	7 years
Persistence of mirror movements of any simple repetitive movement (such as hand or foot patting)	7 years
Persistence of feet-to-hands overflow with walking on sides of feet	9 years
Persistence of mirror movements with complex movement of repetitive hand patting front to back	10 years
Persistence of mirror movements with the thumb opposing each finger sequentially	13 years

Source: Modified from Denckla MB. Revised Neurological Examination for Subtle Signs (1985). *Psychopharmacology Bull* 21:773–800, 1985. Used with permission.

guard position. By 18 months, the arms are held down by the side and the normal associated swing of the arms is present with walking. For the older child, maneuvers to stress the gait can be used such as toe, heel, hop, and tandem walking. Although there are multiple types of abnormal gaits, most children with neuropathological gaits will fit in one of seven basic types (Table 3.16). Each of these pathological gaits can be recognized by the distribution and pattern of the gait abnormality (Larsen 2001).

### GENERAL PHYSICAL EXAMINATION: IMPORTANT ASPECTS

Growth parameters are important in assessing the child with neuropsychiatric problems. Height, weight, and head circumference should be measured and plotted on standardized growth curves. Obtaining previous measurements is helpful so that growth trends can be analyzed. Excessive somatic growth is seen in the overgrowth syndromes, such as Sotos, Weaver, or Beckwith–Wiedemann Syndromes (Jones 1997). Short stature is associated with numerous syndromes and chromosomal abnormalities. Head circumference is an essential part of the neurological evaluation of the infant and child. The measurement is obtained by measuring the head around the greatest circumference, which is from the frontal prominence around the most prominent part of the occiput. The most accurate measurements are obtained with a plastic or steel tape rather than a paper tape because the paper tape can stretch. A head that is less than the 2<sup>nd</sup> percentile is microcephalic and correlates with a brain that is abnormally small (microcephaly). A head circumference greater than the 98<sup>th</sup> percentile is macrocephaly or macrocrania and can be caused by abnormal collections of blood (subdural hematomas), obstructed CSF pathways (hydrocephalus), or a larger than normal brain (megalencephaly). Head shape is determined by growth of the cranial bones, which occurs

perpendicular to the cranial sutures. A misshapen head can be caused by craniosynostosis (premature closure of the sutures) or by a positional deformity. The most common type of misshapen head is a positional deformity with flattening of the occiput (usually the right side) with a compensatory prominence of the ipsilateral forehead (plagiocephaly). This deformation is caused by the baby being placed on the back to sleep and the head being turned to one side as the preferred position. The abnormal head shape of craniosynostosis is determined by which suture is prematurely closed and the compensatory growth that occurs in sutures that remain open. Synostosis of the sagittal suture causes scaphocephaly (the most common form of craniosynostosis) and is usually an isolated finding, while synostosis of the coronal suture causes brachycephaly and is often associated with an underlying syndrome, such as Apert, Crouzon, Pfeiffer, or Saethre–Chotzen syndromes (Jones, 1997). Synostosis of the metopic suture results in trigonocephaly, which can be an isolated finding or can be associated with brain malformations and cognitive and behavior abnormalities.

A child should be carefully examined for any dysmorphic features that may have an associated brain malformation. This is especially true of the face. There is the adage that *the face predicts the defective brain* (DeMyer 2004). This is especially true for defects in the parts of the face that are embryologically derived from the frontonasal process. The frontonasal process produces the forehead, upper eyelids, nose, and the medial third of the upper lip. Dysmorphic findings in these facial structures should prompt evaluation of an associated brain malformation. Not only should the face be carefully analyzed for dysmorphic features, but there should be inspection of the rest of the body including the hands and feet for anomalies. A constellation of dysmorphic features can be the key for making a syndrome diagnosis with brain involvement (Jones 1997).

The eye examination of a child with neuropsychiatric problems should not be neglected. Observation of pupillary

**TABLE 3.16**  
**PATHOLOGICAL GAITS**

**Hemiplegic**

The patient has unilateral weakness and spasticity with the upper extremity held in flexion and the lower extremity in extension. The foot is in extension so the leg is “too long,” therefore the patient will have to circumduct or swing the leg around to step forward. This type of gait is seen with a UMN lesion.

**Neuropathic**

This type of gait is most often seen in peripheral nerve disease where the distal lower extremity is most affected. Because the foot dorsiflexors are weak, the patient uses a high stepping gait in an attempt to avoid dragging the toe on the ground.

**Parkinsonian**

This type of gait is seen with rigidity and hypokinesia from basal ganglia disease. The patient’s posture is stooped forward. Gait initiation is slow, and steps are small and shuffling. Turning is en bloc like a statue.

**Ataxic**

The patient’s gait is wide based with truncal instability and irregular lurching steps, which results in lateral veering and if severe, falling. This type of gait is seen in midline cerebellar disease. It can also be seen with severe loss of proprioception (sensory ataxia).

**Diplegic**

The patient has spasticity in the lower extremities greater than the upper extremities. The hips and knees are flexed and adducted with the ankles extended and internally rotated. When the patient walks, both lower extremities are circumducted and the upper extremities are held in a middle or low guard position. This type of gait is usually seen with bilateral periventricular lesions. The legs are more affected than the arms because the corticospinal tract axons that are going to the legs are closest to the ventricles.

**Myopathic**

With muscular diseases, the proximal pelvic girdle muscles are usually the weakest. Because of this, such patients will not be able to stabilize the pelvis as they lift their leg to step forward, so the pelvis will tilt toward the non-weight-bearing leg, which results in a waddle type of gait.

**Choreiform**

This is a hyperkinetic gait seen with certain types of basal ganglia disorders. There is intrusion of irregular, jerky, involuntary movements in both the upper and lower extremities.

reactivity, ocular alignment, conjugate eye movements, and visual acuity is a part of the cranial nerve examination. Added to these observations should be a funduscopic examination. The appearance of the optic nerve, optic disc margin, vessels, and retinal background should be noted.

Because the skin and the brain share a common embryological origin, cutaneous lesions can lead to the diagnosis of one of the neurocutaneous disorders. As a part of the neurological evaluation there must be a careful head-to-toe skin search. The most common lesions that have neurological significance include the hypopigmented lesions and facial angiofibromas of tuberous sclerosis, café au lait spots and axillary freckling of neurofibromatosis I, and the forehead and upper eyelid port-wine nevus of Sturge-Weber syndrome.

In the context of a child who is developmentally delayed or who has lost neurodevelopmental milestones, it is important to exam the abdomen for visceromegaly. Enlargement of the liver and the spleen occurs in the storage diseases such as Gaucher, Tay-Sachs, or Hurler syndrome. The spine should be inspected for scoliosis and the lumbar-sacral region should be inspected for cutaneous lesions, masses, unusual hair patterns, and cutaneous dimples and tracts. These clinical findings can be an indication of an underlying defect of the lower spinal cord and nerve roots.

**PATTERNS OF ABNORMAL NEURODEVELOPMENT**

There are certain basic patterns of abnormal neurodevelopment that the clinician should be familiar with and readily recognize in children who present with neuropsychiatric problems (Table 3.17). A delay in language acquisition should first be evaluated with a formal hearing evaluation. In the infant this can be done using evoked otoacoustic emissions or with auditory brainstem evoked responses, but in the child who can cooperate, it should be done with audiometric testing. The pattern of failure to develop meaningful language associated with impaired social interaction and stereotypical behavior is seen with infantile autism. In a child who loses receptive language abilities after a period of normal language development, the diagnosis of acquired epileptiform aphasia should be considered. Most of these children will have a history of having seizures, and the electroencephalogram (EEG) is important in confirming the diagnosis (Tuchman 1997).

A delay in the acquisition of motor milestones can be seen in multiple disorders of the nervous system, but there are patterns of motor abnormalities that help make a diagnosis. The motor abnormalities of cerebral palsy are static,

**TABLE 3.17**  
**PATTERNS OF ABNORMAL NEURODEVELOPMENT**

Abnormality	Condition
Isolated language delay	Neurosensory hearing loss
Language deficits plus behavior abnormalities	Autism
Loss of language plus seizures	Acquired epileptic aphasia
Static motor deficits with persistent primitive reflexes, lack of postural reflexes and may have other associated neurological deficits	Cerebral palsy (types include quadriplegia, diplegia, hemiplegia, hypotonic, choreoathetoid, and cerebellar)
Loss of motor milestones	Neurodegenerative
Hypotonic infant without associated CNS deficits	Neuromuscular disease
Motor delay with symmetric delay in language and social skills, may have mild hypotonia	Mental retardation

nonprogressive, and usually fit the pattern of an upper motor neuron lesion or, less frequently, a lesion of the basal ganglia or cerebellum (Table 3.17). There can be associated findings such as epilepsy, mental retardation, or neurobehavioral problems depending on the severity of the prenatal event that caused the brain injury. One of the hallmarks of cerebral palsy is the persistence of the primitive reflexes and the failure to develop the postural reflexes. In making the diagnosis of cerebral palsy it is important to establish that the motor deficits are static and nonprogressive. If there is loss of developmental milestones, then the pattern is not that of cerebral palsy but of a neurodegenerative disease or a progressive lesion of the brain. The pattern of hypotonia with preserved cognitive function can be seen in neuromuscular diseases. Global developmental delay that is symmetric in all areas of development and without pathological motor findings except for perhaps mild hypotonia is often the pattern of mental retardation.

### EXTENSION OF THE EXAMINATION: DIAGNOSTIC TESTING

The choice of the appropriate diagnostic tests is based on the differential diagnosis that is generated by the history and physical examination of the patient. As a general rule, diagnostic testing has its highest yield in a child who has severe mental retardation, focal neurological deficits, or findings on physical examination that suggest a specific disease entity. The main diagnostic tests that are considered include imaging the brain for structural abnormalities (magnetic resonance imaging, cranial tomography, head ultrasound in the neonate), tests for brain and nerve function (electroencephalography, evoked potentials, electromyography and nerve conduction studies, positron-emission tomography, single-photon emission computed tomography, and functional magnetic resonance imaging), cytogenetic studies (particularly in the setting of the dysmorphic child), and

metabolic studies (inborn errors of metabolism). Other diagnostic tests to be considered are tests of neurodevelopment, intelligence, language, behavior, and other specific cortical skills and functions. These neuropsychological tests are discussed in the following chapter.

### NEUROIMAGING

For the neonate, head ultrasound can be done at the crib-side in the newborn intensive care unit and is valuable in assessing midline structures and ventricular anatomy. The periventricular brain parenchyma can be visualized, but ultrasound is inadequate for assessing cortical and posterior fossa anatomy.

Head cranial tomography (CT) is most valuable in the acute emergency setting when the patient is being assessed for increased intracranial pressure, mass effect, and hemorrhage. CT is also the modality of choice when assessing bone and looking for intracranial calcifications as seen in congenital infections.

Head magnetic resonance imaging (MRI) has become the imaging modality of choice in most diagnostic settings where imaging the brain is important. The images are obtained in three different planes and with different acquisition parameters that help identify pathology. Cortical anatomy and the ability to identify brain malformations are much greater with MRI than with CT. For evaluation of posterior fossa abnormalities, malformations, tumors, and imaging for seizures and headaches, MRI has replaced CT.

### FUNCTIONAL STUDIES

The traditional mainstay study for assessing neuronal function has been electroencephalography (EEG). The EEG is a summation of dendritic synaptic potentials recorded from various locations on the scalp and therefore reflects

underlying brain cortical activity. It has some localization power, but because the electrodes are recording at a distance from the surface of the brain and the waveforms are a summation of neuronal activity, the precision of localization is approximate. EEG is most helpful in the diagnosis, classification, and management of seizure disorders. It is not, however, a substitute for a detailed and accurate history since most paroxysmal events, such as seizures, are diagnosed by history and not by laboratory studies. The EEG can also be helpful in assessing altered states of consciousness and encephalopathic states. Some EEG findings are specific for certain diseases, but most EEG findings are nonspecific as far as etiology. A routine EEG has limited value in assessing psychiatric illness. It may help in the assessment of the child who has possible seizures, intermittent explosive disorder, or organic disorders (Johnson 1996). When a paroxysmal event is frequent but it is difficult to determine whether or not the event is seizure, then video EEG monitoring can be helpful.

Evoked potentials, both visual and auditory, have value when assessing the central pathways of these special senses in the appropriate clinical setting. Visual evoked potentials are useful in inflammatory and demyelinating diseases affecting the optic nerve, tract, and radiations. Auditory evoked potentials can identify and localize lesions in the auditory pathways from the auditory nerve to the level of the inferior colliculus. In the infant who is too young for audiometric testing, auditory evoked potentials is an indirect way of assessing hearing by assessing the brainstem auditory pathways.

Electromyography (EMG) and nerve conduction studies are used to assess the peripheral nervous system. In neuropsychiatry, these tests are mainly used in the setting of diseases that can affect the brain and nerve or muscle. The dystrophies and mitochondrial diseases that affect the brain and muscle can have neuropsychiatric manifestations. Nerve conduction studies are useful in establishing the presence of myelination abnormalities in diseases such as the leukodystrophies and axonal abnormalities in diseases such as Friedreich's Ataxia.

Positron-emission tomography (PET) scanning with the tracer 2-deoxy-2-[<sup>18</sup>F]fluoro-D-glucose combines the structural definition of computed tomography with the measurement of glucose utilization which indicates metabolic activity. PET scanning has been used to study the maturation of cerebral function and is clinically useful in epilepsy surgery, neurooncology, and as a research tool. At this point in time, its application in neuropsychiatry is limited except as a research tool. Single-photon emission computed tomography (SPECT) scans use changes in regional blood flow as an indirect measure of localized cerebral function.

Functional magnetic resonance imaging (fMRI) combines the anatomical definition of MRI with changes in regional blood flow. This change in blood flow serves as an indicator of neuronal activation by specific tasks that activate that particular region(s) of the brain. fMRI has become the major research tool for localization of cerebral function

in behavioral and cognitive neuroscience in both adults and children. It has opened the door to understanding normal and abnormal function in the brain in vivo. Its role in clinical practice has yet to be established, but its promise is exciting to consider. Magnetic resonance spectroscopy (MRS) is used to measure the level of biochemical substances in the brain, such as creatine and N-acetyl-aspartate. It is being used in the setting of hypoxic brain injury, traumatic brain injury, and metabolic diseases especially where levels of lactate may be elevated in the brain (Wycliffe 1999).

## CYTOGENETIC STUDIES

More genes are expressed in the brain than in any other organ of the body. Genetic syndromes and chromosomal defects are often associated with neurological dysfunction. Cytogenetic studies that are useful in child neuropsychiatry include high-resolution chromosome studies, DNA studies for trinucleotide repeat diseases such as fragile X, myotonic dystrophy, and spinocerebellar atrophies, fluorescence in situ hybridization (FISH) of subtelomeric deletions, for syndromes such as Prader-Willi, Angelman, and Williams, and testing for mutation in the X-linked gene causing Rett syndrome (methyl-CpG-binding protein 2- MECP2). Even in the child who has global developmental delay without dysmorphic features, cytogenetic studies can have a diagnostic yield (see Table 3.18).

**TABLE 3.18**  
**DIAGNOSTIC YIELD OF TESTS IN CHILDREN WITH GLOBAL DEVELOPMENTAL DELAYS**

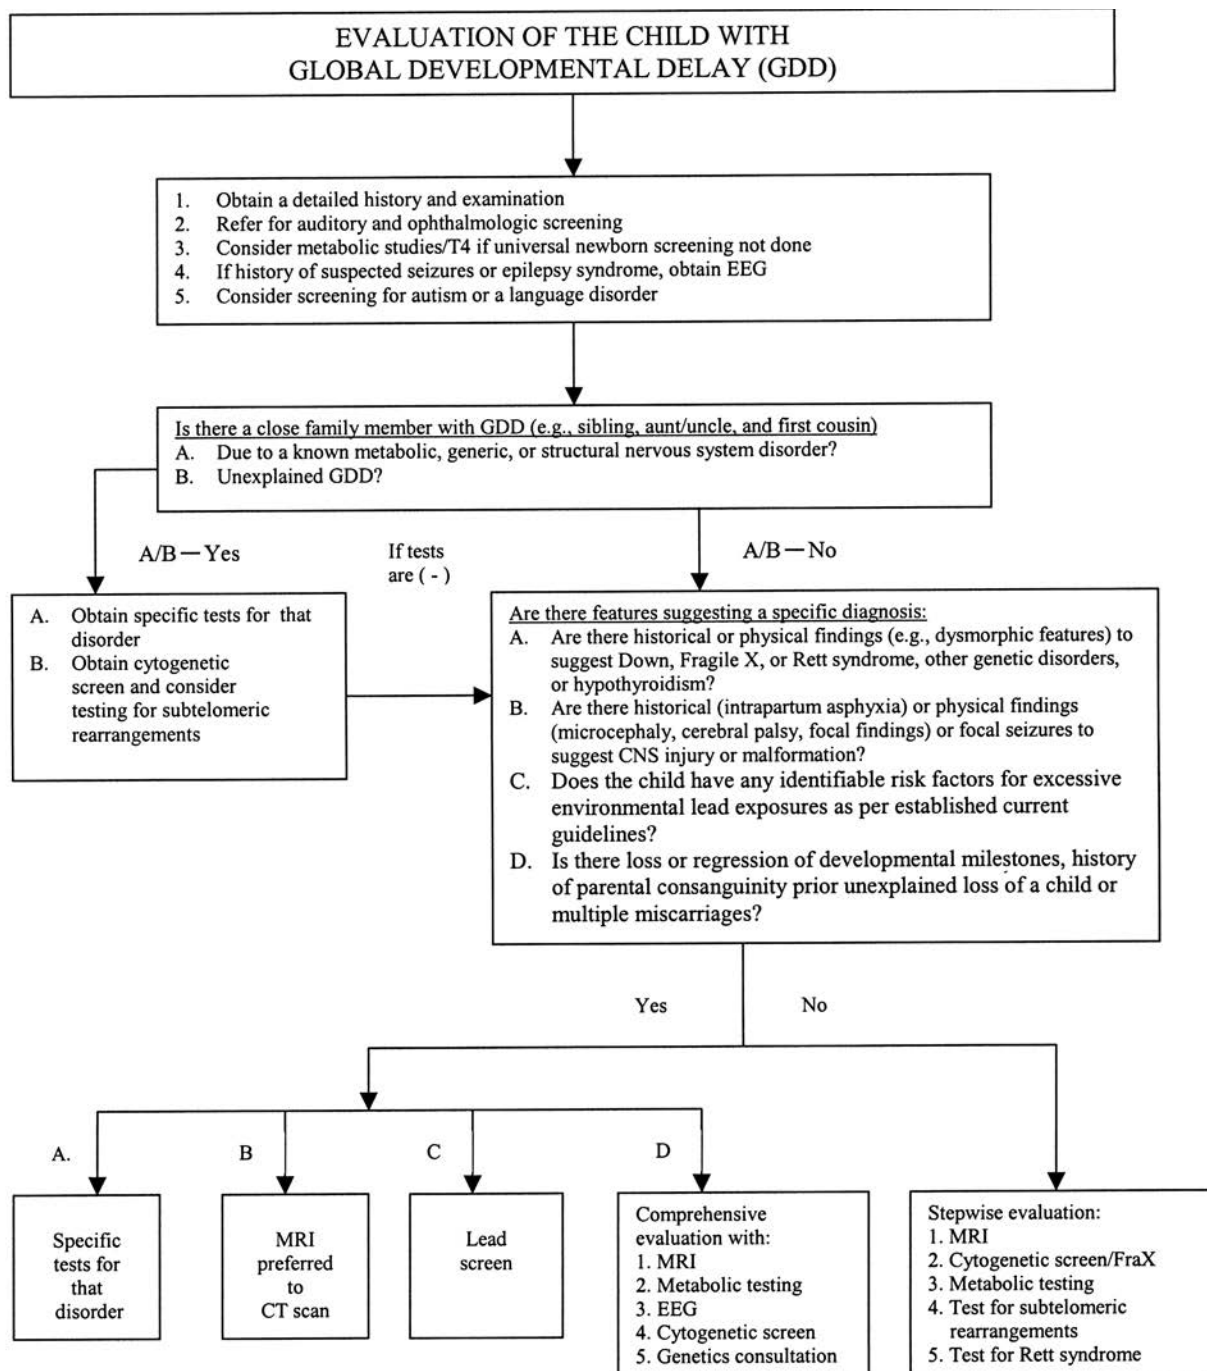

Test	Diagnostic yield, %
<b>Neuroimaging</b>	
MRI scan, nonenhanced	55.3
CT scan	39.0
<b>Genetic studies</b>	
Routine cytogenetic studies	3.7
Subtelomeric deletion	6.6
Fragile X screen	2.6
MECP2	Unknown
<b>Metabolic testing<sup>a</sup></b>	≈1
Thyroid screen (serum TSH, T4)	Near 0 if UNS; ≈4 if no UNS
<b>Serum lead level</b>	<b>Unknown</b>
EEG (routine)	≈1

<sup>a</sup>Metabolic testing usually consists of urine organic acids, serum amino acids, serum lactate, ammonia level, and a capillary blood gas.

TSH = thyroid stimulating hormone; T4 = thyroxine; UNS = universal newborn screening

## METABOLIC STUDIES

Multiple identifiable inborn errors of metabolism affect the developing brain. These diseases should be considered when there is a loss of developmental milestones. These studies also have their place (although the yield is low; see Table 3.18) in the child without an explanation for his or her developmental delay when neuroimaging and cyto-

netic screening have been nondiagnostic. Because the phenotypes of the metabolic diseases are so variable, multiple metabolic pathways are usually screened simultaneously unless the clinical presentation and findings are specific enough to suggest a certain disease (Table 3.19).

One of the most common evaluations that face the clinician in neurology is the child with global developmental delay. A practice parameter has been developed for the

**TABLE 3.19**  
**METABOLIC SCREENING**

Serum amino acids: amino acidopathies
Urine organic acids: organic acidurias
Serum lactate and pyruvate: deficits in intermediary metabolism and respiratory chain
Serum ammonia: urea cycle defects
Thyroid function studies: hypothyroidism
Plasma acylcarnitine profile: fatty acid oxidation defects
Plasma very long chain fatty acids: peroxisomal defects
Leukocyte lysosomal enzyme profile: lysosomal storage diseases

evaluation of the child with global developmental delay (Shevell et al. 2003). Figure 3.4 is an algorithm that provides a useful guide in this situation and reflects the thought pattern that is generally used in evaluating most children with neurodevelopmental disease. Table 3.18 provides perspective as to the frequency these tests provide a diagnosis in the child with global developmental delay.

## CONCLUSION

This chapter provides the clinician with an overview of the clinical neuropsychiatric assessment of children. The essential elements of that evaluation are an understanding of the temporal profile of the child's disease as well as regional or anatomical localization. A complete accurate history and the neurological examination are the clinician's window to the brain, and they have not been replaced by laboratory or diagnostic tests. For neuropsychiatric problems, an expanded mental status evaluation is particularly important. The elements of the mental status examination allow for examination of the cerebral cortex and the behaviors that are associated with cortical function. The bedside neuropsychiatric examination is not a substitute for formal neuropsychological testing, but rather it should establish the formulation of the physician's diagnostic concerns, which will then direct and provide focus for the more detailed evaluation of neuropsychological testing as well as selection of the appropriate neuroimaging, neurophysiologic, and diagnostic laboratory studies. The neuropsychiatric evaluation of the child must include an understanding of neurodevelopment and how neurodevelopment influences the examination process, expectations, and diagnostic interpretation.

# Neuropsychological and Psychoeducational Testing

4

**Renée Lajiness-O'Neill, PhD**    **Isabelle Beaulieu, PhD**

Pediatric neuropsychology has seen significant advances over the past several decades, surfacing as one of the areas of unrivaled growth in psychology and psychiatry. Pediatric neuropsychology emerged concurrent with adult neuropsychology when the primary populations serviced were children with traumatic injuries and learning disorders from various etiologies. Historically, children were examined as if they were merely downward extensions of adults (Reitan and Herring 1985). Advances in the cognitive neurosciences, particularly developmental neuropsychiatry, as well as in technologies that have improved mortality have assisted in widening the breadth of populations serviced by pediatric neuropsychology as is evident with the autistic spectrum disorders (Happé and Frith 1996; Ozonoff et al. 2004), genetic and metabolic syndromes (Diamond et al. 1997; Lajiness-O'Neill and Beaulieu 2002; Phillips et al. 2004), and low birth weight (Taylor et al. 2004). An increasing awareness of the utility of a child's cognitive and behavioral phenotype to aid in diagnosis as well as the use of his or her strengths and weaknesses to guide intervention efforts has become apparent (Volkmar et al. 2004). The first comprehensive compendium strictly devoted to the measures and methods used in the neuropsychological assessment of children including the compilation of normative data has been published (Baron 2004), an analog to the well-known compendium by Lezak (1995).

More recently, a substantially greater reliance on developmental theory has impacted test construction and the approach to the assessment of children (Gottlieb 2001;

Rourke et al. 2002a). Nonetheless, the general approach remains consistent with what is seen in adult assessment with three core components necessary. The assessment begins with an examination of the *clinical presentation* or *presenting problem*. This information is often obtained from multiple informants such as the referral source, a parent or legal guardian, and in some cases from the child depending on his or her age. Presenting complaints from the child are sometimes limited by his or her developmental level of functioning, conceptual capacity and self-awareness, and limitations stemming directly from the difficulties for which the child was referred for evaluation (e.g., mutism, brain damage). Consistency and contradictions in the nature and severity of presenting problems described by various informants must be considered. Also, the pervasiveness of the problems—that is, their persistence across setting—should be closely assessed. This information will be useful with regard to understanding the role that certain environmental contingencies may play in supporting or alleviating problem behaviors. Determination of the timeline during which problems have been present is important in helping to identify etiological factors (e.g., developmentally based, acute reaction to stressors, acute or graded onset).

For children, the presenting complaints are typically related to development, learning, or behavior from a known or suspected etiology. Unlike adult referral questions that are often interested in examining a more specific complaint such as memory, as is seen in dementia, referrals for children are often prompted by academic or learning

difficulties given that school is a child's occupation, and this is the functional area most often impacted. Unfortunately, the reasons for "learning difficulties" are extremely varied and can result from developmental (e.g., developmental delay), medical (e.g., epilepsy), or acquired (e.g., head injury) etiologies. As such, it is important to recognize that a suspected "learning disorder" is always justification for the neuropsychological examination of a child. Obviously, children with medical illnesses known to negatively impact the central nervous system also benefit substantially from a comprehensive neuropsychological assessment. Behavioral or social concerns are frequently encountered referral questions, and neuropsychological testing can help to illuminate markers that will aid in diagnosis. For example, impaired sustained attention and executive deficits (e.g., poor impulse control, decreased working memory, etc.) are typically encountered in children with attention-deficit/hyperactivity disorder (Roth and Saykin 2004). Likewise, nonverbal learning disability is often noted in children with Asperger syndrome (Stein et al. 2004), although the ability to discriminate Asperger syndrome from high-functioning autism (HFA) continues to be an area of much debate (Ghaziuddin and Mountain-Kimchi 2004).

The second component consists of a comprehensive review of the relevant *history*. This involves obtaining information about the child's developmental history including prenatal, intrapartum, and postnatal events, developmental milestones, medical and psychiatric history including relevant family history, academic history, and longstanding functioning in social, emotional, and adaptive domains. The majority of this information will have to be obtained from a parent or guardian and through a review of the medical and school records. It is also important to interview children and adolescents regarding social and emotional issues as their developmental level of function allows. After sufficient appraisal of the presenting problems and the relevant historical data, the pediatric neuropsychologist develops hypotheses about the possible etiology, pattern of strengths and weaknesses, and the possible severity of neuropsychological deficits that are reasonable to expect.

Research within pediatric neuropsychology and the neurosciences as it relates to brain-behavior relationships aids the clinician in the development of his or her hypotheses regarding a child's expected areas of impairment. Traditional areas of practice and research such as traumatic brain injury have provided a strong foundation for the field, with more recent clinical practice and research in traumatic brain injury focusing on factors affecting outcome, such as age at injury and the presence of family support (Ewing-Cobbs et al. 2003; Wade et al. 2003). While lesion "localization" was an objective in pediatric neuropsychology during its inception in traditional areas of practice, current practice does not constrain itself by attempting to suggest a focal region of disruption as there is a clear appreciation that the central nervous system is a complex array of vast neural networks and systems that work in concert to

execute all aspects of complex cognition and behavior (Booth et al. 2004; Sporns et al. 2004). Pediatric neuropsychology has become increasingly interested in attempting to understand the cognitive and behavioral phenotypes of the multitude of developmental neuropsychiatric disorders to aid in diagnosis and guide treatment efforts as well as to increase our understanding of the neurobiological basis of these disorders. Predictable cognitive and behavioral phenotypes are also evident in acquired disorders such as those from teratogen exposure, whether from a drug of abuse (e.g., alcohol) (Connor et al. 2000) or environmental toxin (e.g., lead) (Canfield et al. 2004).

The final component is the *neuropsychological examination* itself. This involves the utilization of a variety of technical procedures. Selection of procedures depends, in part, on the nature of the referral question. It also depends on the child's age and on his or her physical and mental capacities. The specific tests used in a neuropsychological examination will vary according to the neurophysiologist's own preferences. Despite these variations, the comprehensive neuropsychological examination will attempt to measure, at least in a molar fashion, all domains of neuropsychological functions believed to be of importance for supporting the child's abilities to successfully interact in his or her environment. Making decisions as to which tests are most appropriate under what circumstances requires substantial sophistication and training. Such training includes an understanding of the psychometric characteristics of the procedures themselves and of their validity and reliability in the context in which they are being considered. A number of excellent books and reviews of psychological and neuropsychological tests are used in the context of neuropsychology available (Baron 2004; Lezak 1995; Spreen and Strauss 1998). A detailed listing of those measures more commonly used is reviewed in this chapter.

The development of pediatric measures has appropriately evolved from being atheoretical in its approach to being significantly more grounded in developmental and neuroscience theory (Korkman 1999). Early batteries such as the Halstead-Reitan Test Battery for Children (Reitan and Wolfson 1985) and the Luria-Nebraska Test Battery for Children (Golden 1987) further advised a fixed battery approach. That is, all subtests of a well-defined battery were administered in a generally fixed manner. As pediatric neuropsychology began to embrace a more diverse referral base that included preschool-aged children and those with complex neurodevelopmental and medical conditions, more flexibility has been necessary to garner the appropriate data.

As stated, comprehensive neuropsychological evaluation requires sufficient coverage of the full domain of neuropsychological functions believed to be important for supporting developmentally "normal" behavior. Although neuropsychological domains are not entirely or even mostly independent constructs, they do have some level of functional independence from each other, and neuropsychological

tests are commonly labeled based on the primary domain that the test putatively measures (e.g., memory, speech and language, executive, etc.). Although clinicians can vary substantially in the specific tests included in their neuropsychological test batteries (e.g., Wechsler Intelligence Scale for Children-IV versus Stanford-Binet Intelligence Scale, 5th Edition), there is substantial agreement about which neuropsychological constructs or domains of functioning should be measured to obtain a comprehensive assessment. Domains to be considered include intellectual, academic achievement, speech and language, visuospatial and perceptual-motor, memory and learning, and attention and executive functioning. In addition, assessment of basic sensory and motor functions is typically included because of their established importance for diagnosing and lateralizing brain dysfunction as well as their importance for understanding the potential contribution of impaired performance on "cognitive tasks" that have a sensorimotor component as well. In general, for pediatric neuropsychological assessment, a broad-based comprehensive examination is necessary to provide the clinician with multiple data points from which to make inferences. The data will provide the clinician with a profile or pattern of strengths and weaknesses from which to generate diagnoses as well as compensatory, remedial, therapeutic, and rehabilitation recommendations. Other tests, called "sign tests," should be included. These are tasks on which poor performance is generally seen as pathognomonic for a specific neuropsychological syndrome (e.g., presence of clearly aphasic speech). Multiple tests that assess abilities believed to be normally distributed (i.e., distributed along bell curve) in the general population (e.g., IQ, memory) should be administered. These tests lend themselves most readily to interpretation based on the child's level of performance relative to normative expectation. Behavioral, social, and emotional adjustment are also evaluated in the comprehensive neuropsychological examination.

Often, in addition to assessment of children's performance across multiple domains (e.g., reading skill), further, "process"-oriented assessment is performed in an attempt to better understand the qualitative aspects of performance of the child and its relationship to specific and overall functioning (Kaplan 1990). Testing of limits is also often conducted as well to discern a child's maximum capability. For example, after a child's reading abilities have been identified as poor, it may be useful to eliminate time demands to discern if processing speed has negatively impacted performance.

## **NORMAL AND ABNORMAL DEVELOPMENTAL ISSUES**

The nature and extent of the neuropsychological examination are, in large part, determined by the developmental level of the child. Many pediatric neuropsychologists develop expertise in the assessment of school-aged children

from approximately 5 years of age to adulthood. However, clinicians interested in the mental retardation syndromes, pervasive developmental disorders, and developmental delay must develop expertise that extends to as young as 2 years of age. Extensive knowledge of normal childhood development is a unique aspect of the pediatric neuropsychologists' repertoire of skills. Likewise, a strong appreciation of the extremely wide range of normal variability is critical. The issue of reliability is an often-encountered problem in testing young children. Nonetheless, this is typically addressed through the examination of core abilities with multiple measures as well as with serial testing so that patterns of strengths and weaknesses can be monitored closely. Since the mid-1990s, a number of measures and batteries used to assess neurocognitive and developmental levels of functioning in children and toddlers with developmental neuropsychiatric disorders have been developed, such as the Differential Ability Scale (DAS), NEPSY, and Mullen Scales of Early Learning (Elliott 1990; Korkman et al. 1997; Mullen 1995). This has been fueled by an increasing awareness that distinct cognitive and behavioral profiles exist even in children with mental retardation syndromes, and this is often with islets of abilities that can aid in the eventual diagnosis and treatment planning. Moreover, these distinct profiles are likely to lead to subsequent markers for disorders and the identification of potential etiological variables.

In general, the etiology of neuropathology in infants and children is substantially different from that in adults. For example, children are far more likely to be referred for evaluation because of difficulties stemming from congenital or developmental rather than acquired conditions. More specifically, as noted, learning and attentional problems are often encountered referral questions. If a child is referred for an acquired condition, the primary etiology and contributing factors are often different than that noted in the adult population. For example, intracranial neoplasms identified in children are much more often found to be subtentorial compared with tumors found in adults (Spren et al. 1995). The primary risk for strokes in children occurs during the prenatal period (Schoenberg et al. 1978), and the neurocognitive outcome is typically more variable given multiple developmental factors (Sreenan et al. 2000; Stiles et al. 2003). Children with traumatic brain injuries are most likely to occur from falls, whereas in adults traumatic brain injuries most commonly occur in the context of motor vehicle accidents (Annegers et al. 1980). In adults, neurological injury affects the cognitive-behavioral substrate (the brain) after the individual has acquired and mastered skills. In children, however, brain damage often has a cascading effect on later developing cognitive and neurobehavioral functions, with a particular impact on prefrontal and executive functions (Eslinger and Biddle 2000).

Although prediction from infants' and young children's test performance to later ability level is possible at the extremes of the ability distribution, there has been generally

poor success with predicting later skill levels from test scores obtained in infancy among those infants who were not unusually delayed or gifted (Aylward et al. 1987; Bornstein and Sigman 1987; Gibbs 1990). Nonetheless, distinguishing a global developmental delay (GDD) from a specific delay in development (e.g., mixed receptive and expressive language disorder) can be an important question answered by neuropsychological testing, which will subsequently guide immediate therapeutic efforts. The distinction between GDD and mental retardation is often a perplexing one for clinicians examining children of toddler age, and it frequently surfaces as a comorbid issue in children within the autistic spectrum. As stated in the Practice Parameters set forth by the American Academy of Neurology (Shevell et al. 2003), the diagnosis of GDD typically is reserved for younger children (i.e., younger than 5 years) who exhibit age-specific deficits in learning and adaptation (i.e., two standard deviations or more below the mean on an age-appropriate norm referenced test), for which the etiology is heterogenous and the degree of improvement following intervention is yet to be determined. In general, a diagnosis of mental retardation should rarely be made prior to age 5 when the assessment of intellectual abilities is much less valid and reliable.

An equally difficult distinction to make is between children with pervasive developmental disorder not otherwise specified and those with significant developmental language disorders. Neuropsychological testing can often illuminate many of the distinguishing features with standardized tools such as the Autism Diagnostic Interview-Revised (ADI-R: Lord et al. 1994) or the Autism Diagnostic Observation Schedule (ADOS: WPS Edition; Lord et al. 1999) in conjunction with traditional neuropsychological measures. In concert, these tools can improve diagnostic specificity as well as provide the clinician with a pattern of cognitive and behavioral strengths and weaknesses from which to generate remedial interventions.

Issues typically assessed in school-aged children are related to academic or learning, and behavioral difficulties, although the etiologies are vast. As noted, the etiology may be congenital, ideopathic, or acquired (e.g., epilepsy or traumatic brain injury), and the neuropsychological assessment will help to define cognitive deficits that may negatively impact academic functioning. For example, delayed processing speed in a child with a brain injury may suggest the need to extend or eliminate time demands to maximize the child's performance. With the advances made in modern medicine in improving infant mortality, school-aged children with histories of low birth weight are becoming an increasingly prevalent diagnostic group assessed by pediatric neuropsychology (Doyle and Casalaz; Victorian Infant Collaborative Study Group 2001; Taylor et al. 2004). Children with low birth weight (LBW) often encounter long-term neurocognitive and behavioral difficulties secondary to the known medical complications that are linearly related to the degree of LBW, such as

intraventricular hemorrhage, hydrocephalus, cerebral palsy, and retinopathy of prematurity.

## NEUROPSYCHOLOGY IN THE PEDIATRIC NEUROPSYCHIATRIC SETTING

Neuropsychological evaluation has a substantial role to play in pediatric neuropsychiatry. Research in child psychopathology has demonstrated that many of the disorders of childhood that were previously only presumed to result, in large part, from dysfunctional brain systems have been found, in fact, to be related to aberrant patterns of connectivity within the central nervous system (e.g., learning disorders [Bigler et al. 1998; Hiemenz and Hynd 2000], attention-deficit/hyperactivity disorder [ADHD] [Hale et al. 2000]). Several of the DSM-IV childhood behavior disorders (e.g., conduct disorder, oppositional defiant disorder, ADHD) are associated with a high prevalence of comorbid learning problems, and for this reason the use of neuropsychological assessment in these patient groups is commonly indicated. Likewise, children with Tourette's frequently encounter comorbid attentional, learning, and emotional difficulties, and neuropsychological testing can be useful in distinguishing an attentional disorder from anxiety.

The role of pediatric neuropsychology in the assessment of children with suspected or known genetic disorders that present with comorbid psychiatric illness is also becoming increasingly prevalent. Genomic disorders such as velocardiofacial syndrome (VCFS)(22q11.2 deletion syndrome), William syndrome, Prader-Willi syndrome, and Angelman syndrome present with characteristic physical, cognitive, and behavioral features (Lajiness-O'Neill et al. 2005; Nichols et al. 2004). For example, the rate of schizophrenia, bipolar disorder, and possibly obsessive compulsive disorder has been reported to be as high as 30% in individuals with 22q11.2 deletion syndrome, significantly higher than the general population (Eliez et al. 2001). As discussed by Finegan (1998), behavioral phenotypes will play a critical role in (1) delineating syndromes, (2) illuminating intrasyndrome variability, (3) spawning theory development, and (4) understanding brain-behavior relationships and the genetic bases of behavior.

Children with teratogen exposure often present to the pediatric neuropsychologist due to significant behavioral and learning difficulties. For example, children who have chronic and significant lead exposure experience a predictable pattern of difficulties that includes substantial dysregulation and features of attention-deficit/hyperactivity disorder, aggression, and learning disorders (Ris 2003; Trask and Kosofsky 2000). Without a thorough assessment, these children are often missed or misdiagnosed, with an emphasis placed on the manifest behavior (oppositional defiant disorder, conduct disorder) and without a clear understanding of the precipitant.

## NEUROPSYCHOLOGY IN THE PEDIATRIC MEDICAL REHABILITATION SETTING

---

Historically, both neuropsychiatry and neuropsychology have been involved in the assessment and treatment of children with medical disorders that have a direct impact on central nervous system functioning such as hydrocephalus, brain injury, tumors, and epilepsy (Yeates et al. 1999). A sizable empirical knowledge base has developed demonstrating that medical disorders secondarily affecting the central nervous system (e.g., craniofacial) or primarily affecting nonbrain organ systems can, under certain conditions, have neuropsychological sequelae as well. Examples include research relating cardiac, renal, pulmonary, and immune disorders to neuropsychological deficits (Fennell 1999; Pulsifer and Aylward 1999). Of course, behavioral adjustment to certain medical procedures and conditions can be difficult even in the absence of neuropsychological sequelae. Loss of cognitive functioning, however, can make emotional and behavioral adjustment even more difficult.

Neuropsychologists, because of their background in both clinical psychology and neuropsychology, have special skills to offer pediatric medical patients and their families. The neuropsychologist can assist in behavioral management, family treatment, and consultation to the child's other treatment providers. Children with behavioral difficulties stemming from neurological disorders may present with poor compliance behaviors, emotional lability, or general adjustment difficulties. Illness, recovery from injury, and certain treatments are difficult for cognitively intact children to manage. This set of circumstances becomes even more overwhelming for the child who may be experiencing confusion or frustration because cognitive (including perceptual, language, and conceptual) processes have become impaired. The neuropsychologist can be particularly useful in both assisting the child with behavioral adjustment and in making recommendations to physicians, parents, and teachers about intervention strategies.

## NEUROPSYCHOLOGY IN THE SCHOOL SETTING

---

Outpatient pediatric practices include referral of a large number of children whose difficulties are recognized primarily within the classroom setting. Difficulties prompting referrals include behavioral, emotional, and academic problems. Diagnosis and treatment planning can be substantially aided by comprehensive neuropsychological assessment. A complex issue that frequently surfaces in the academic setting is that of the distinction between attention-deficit/hyperactivity disorder (ADHD) and learning disability. Children are often perceived or diagnosed as having (ADHD) when learning disability is the primary source of their inattention and distractibility. Nonetheless, it is also important to recognize that many individuals with

ADHD also have comorbid learning disorders, with rates as high as 10% to 25% reported (American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders-IV, 1994). Likewise, primary language disorders can significantly interfere with the acquisition of reading while sensorimotor deficits may negatively impact graphomotor and written language abilities. Provision of data on the child's cognitive strengths and weaknesses can allow more realistic, positive, and useful strategies to be developed for use in the classroom.

Emotional and interpersonal adjustment difficulties are commonly seen in combination with cognitive deficits. The neuropsychological assessment can help to distinguish a primary anxiety or mood disorder from an attentional or learning disorder. Neuropsychological evaluation may help the treatment provider and family members understand why a child is having a difficult time interpersonally. Clinicians and researchers have begun to identify additional forms of learning disorders such as nonverbal learning disability (NLD) (Rourke 1995) that may serve as a marker for other developmental (e.g., Asperger syndrome) and psychiatric conditions for which interpersonal difficulties is a crucial feature. Children with NLD display a predictable pattern of cognitive strengths and weaknesses that are purported to underlie their social deficits. More specifically, children with NLD exhibit deficits in sensorimotor, visuospatial, perceptual motor functioning, nonverbal memory, and novel problem solving with a concomitant weakness in mathematics. The constellation of deficits is purported to contribute to the child's inability to accurately interpret the subtle nuances in social exchanges, which interferes with appropriate reciprocity in relationships and subsequently cascades into significant interpersonal deficits.

## EXAMINATION OF BRAIN-BEHAVIOR RELATIONSHIPS

---

### Domains of Neuropsychological Functioning

#### *General Intelligence/Developmental Assessments*

Intelligence, most commonly represented by IQ tests, is an area of broad coverage that should be included in the neuropsychological examination of children. Intelligence measures are widely used across disciplines, specialties, and settings. They provide an assessment of cognitive abilities and intellectual potential that can be used to compare a child's relative standing with that of his or her same age peers and corresponding demographic factors. They have been found most useful in predicting academic success. However, they also offer clinicians important information on a child's pattern of cognitive strengths and weaknesses. For example, certain tests will provide information on verbal compared to visual-spatial intellectual skills, attention and working memory abilities, and processing speed, as well as information processing styles. However, certain limitations exist

that must be taken into consideration when choosing to administer an intelligence test. For example, IQ subtest scores are thought to provide limited information as to domain-specific abilities, to be relatively insensitive to brain dysfunction including mild cognitive impairment (Peavy et al. 2001), and to have limited value and reliability in identifying students with learning disabilities based on the IQ-academic achievement discrepancy model (Stuebing et al. 2002; Vellutino et al. 2000).

Since the late twentieth century, several tests have been designed to assess intellectual potential in children (Table 4.1). The well-known Wechsler series of intelligence tests typically assess verbal and nonverbal intellectual abilities, processing speed, and working memory performances. These tests are designed to measure intellectual potential in toddlers (i.e., WPPSI-III), children and adolescents (i.e., WISC-IV), and adults (i.e., WAIS-III). An abbreviated version also exists that can be used in children and adults (i.e., WASI). Other widely used measures of intellectual potential

include, but are not limited to, tests that assess both verbal and visual-spatial intellectual abilities in the context of fluid versus crystallized forms of intelligence (e.g., SB-5), tests that co-norm results of cognitive ability and academic achievement (e.g., DAS and WJ-III-Tests of Cognitive Abilities), tests of nonverbal intelligence where language influences are reduced to a minimum (e.g., TONI-3 and Leiter-R), and tests assessing intelligence through sequential versus simultaneous mental processing styles (e.g., K-ABC-II). The choice of which test to select depends on the individual's age, cultural aspects (e.g., familiarity with the English language), reason for referral, presence of specific or global delays in development, report of functional impairments (e.g., impaired hearing or vision), and nature and severity of psychopathology.

In light of recent advances in the early detection of neurodevelopmental disorder, pediatric neuropsychologists are more than ever asked to provide developmental assessment of toddlers and preschoolers. These assessments are often requested when an underlying neurodevelopmental

**TABLE 4.1**  
**SELECTED TESTS OF INTELLIGENCE AND ACADEMIC ACHIEVEMENT**

Test	Age/Grade Range
<b>Intelligence</b>	
Cattell Infant Intelligence Scale	3–30 months
Detroit Test of Learning Aptitude–4 (DTLA-4)	6–17 years
Differential Ability Scale (DAS)	2½–17 years
Kaufman Assessment Battery for Children–II (K-ABC-II)	3–18 years
Leiter International Performance Scale, Revised (Leiter–R)	2–20 years
Miller Assessment for Preschoolers	2½–5 years
Slosson Intelligence Test, Revised 3 (SIT R3) for Children and Adults	4–65 years
Stanford-Binet Intelligence Scale, 5th Ed. (SB-5)	2–85 years
Test of Nonverbal Intelligence, 3rd Ed. (TONI-3)	6–89 years
Wechsler Adult Intelligence Scale, 3rd Ed. (WAIS-III)	6–89 years
Wechsler Intelligence Scale for Children–IV (WISC-IV)	6–16 years
Wechsler Preschool and Primary Scale of Intelligence, 3rd Ed. (WPPSI-III)	2½–7½ years
Woodcock Johnson III (WJ-III) Tests of Cognitive Abilities	2–90+ years
<b>Academic Achievement</b>	
Kaufman Test of Educational Achievement–II (K-TEA-II)	4½–25 years
Peabody Individual Achievement Test, Revised (PIAT-R)	5–18 years
Wechsler Individual Achievement Test, 2nd Ed. (WIAT-II)	4–85 years
Wide Range Achievement Test, 3rd Ed. (WRAT-3)	5–75 years
Woodcock Johnson Tests of Achievement, 3rd Ed. (WJ-III)	2–90 years
<b>Specific Academic Areas</b>	
Boder Test of Reading-Spelling Patterns	6–24 years
Gray Oral Reading Test, 4th Ed. (GORT-4)	6–18 years
Nelson-Denny Reading Test	Grades 9–16
Test of Early Mathematics Ability, 3rd Ed. (TEMA-3)	3–8 years
Test of Early Reading Ability, 3rd Ed. (TERA-3)	3½–8½ years
Test of Early Written Language, 2nd Ed. (TEWL-2)	3–10 years
Test of Mathematical Abilities, 2nd Ed. (TOMA-2)	8–18 years
Test of Reading Comprehension, 3rd Ed. (TORC-3)	7–17 years
Test of Written Expression (TOWE)	6½–14 years
Test of Written Language, 3rd Ed. (TOWL-3)	7½–17 years

**TABLE 4.2**  
**SELECTED TESTS OF DEVELOPMENTAL AND ADAPTIVE FUNCTIONING**

Test	Age Range
Adaptive Behavior Assessment System, 2nd Ed. (ABAS 2nd Ed.)	0–89 years
Adaptive Behavior Inventory	6–18 years
Adaptive Behavior Scale–School, 2nd Ed. (ABS-S:2)	3–21 years
Batelle Developmental Inventory, 2nd Ed. (BDI-2)	0–8 years
Bayley Scales of Infant Development, 3rd Ed. (BSID-3)	0–3½ years
Child Development Inventory (CDI)	0–6 years
Denver Developmental Screening Test-II (DDST-II)	0–6 years
Developmental Profile II (DP-II)	0–7 years
Mullen Scales of Early Learning	0–68 months
Scales of Independent Behavior-Revised (SIB-R)	Infancy to 80+ years
Vineland Adaptive Behavior Scales	Birth to 18 years

Dashes in age ranges indicate “through.”

disorder is suspected early on, when delays are noted in specific areas (e.g., motor, language, or socialization development), to determine a child’s need for early intervention and treatment, and to determine a child’s readiness for school. A number of tests were constructed based on developmental models and use developmentally appropriate tasks (Tables 4.2 and 4.3). For example, the BSID–3 is a measure of early motor and cognitive development that can be used with infants and toddlers and is adjustable to account for prematurity. This test yields index scores that can be translated into age equivalents to determine a child’s developmental level of functioning. Other tests such as the Mullen Scales of Early Development and NEPSY provide information on a range of abilities such as motor development, expressive and receptive language skills, visuospatial skills, memory, and executive functions. During the toddler and early childhood years, tests such as the Bracken Basic Concept Scale-Revised (Bracken 1998) measures basic concept acquisition and receptive language skills to determine a child’s readiness for school by assessing preliteracy skills. However, caution is suggested in interpreting the results generated from these measures as they are not designed to

be used as predictors of eventual long-term cognitive deficits. Instead, an impaired performance on these measures would lead to recommendations that would include the need for follow-up neuropsychological evaluations of those identified as developmentally delayed or at-risk, as well as recommendations toward appropriate medical, psychological and academic interventions.

### Academic Achievement

Children who are perceived as struggling academically should be referred for a comprehensive psychoeducational or neuropsychological evaluation. Deficits in acquiring general academic skills (reading, spelling, mathematics) in the first few years of elementary school set the child up for having difficulties in the later grades, when these skills must be efficiently used to acquire new knowledge and to keep up with the classroom curriculum. In addition to information that is typically obtained through a psychoeducational evaluation usually provided by a school psychologist, neuropsychological assessments are helpful in ruling out other factors that might be contributing to a child’s academic difficulties beyond learning disabilities, such as problems with executive functioning abilities and behavioral regulation, language processing difficulties, sensorimotor problems, and emotional factors. In light of federal guidelines, the model used to determine a child’s eligibility for educational services is that of a discrepancy between intellectual abilities and academic achievement. Over the years, many concerns have been raised about the use of the IQ-achievement discrepancy model as the basis for identifying and providing services to children with learning disabilities. Efforts have been made to pass a bill for which response to intervention would be used to identify students with learning disabilities.

### Reading

Many students with a reading disorder or dyslexia have difficulty with one or more aspects of the reading process

**TABLE 4.3**

**82 Section I: Neuropsychiatric Assessment of the Child and Adolescent**

that cannot be accounted for by intellectual limitations, functional impairments, or inadequate schooling. Some students have difficulty decoding words; others have problems acquiring a sight vocabulary or accessing words rapidly; still others have difficulty comprehending (Catts et al 2002). Dyslexia may also be categorized depending on a child's primary deficits: problems with phonetic processing (dysphonetic dyslexia), problems with orthographic retrieval (dyseidetic dyslexia), or a combination of both (dysphonetic/dyseidetic dyslexia) (Boder and Jarrico 1982). Nonetheless, it is important to recognize that attempts at subtyping are purely descriptive as no valid subtypes have been delineated. As Pennington (2002) noted, reading disorders are a form of language disorder, and two primary processes have been found to be critical for efficient reading: phonological decoding and rapid naming. As such, reading diagnostic tests are typically designed to assess phonological processing such as word attack skills and rapid automatized naming as well as sight word reading, reading rate, fluency, and reading comprehension (Table 4.1).

Problems with reading are often observed when a child is asked to read single words orally. Although tests for oral reading of sight words are widely used to determine word recognition and decoding skills, they are not sufficient for planning intervention. They typically yield information about expected age and grade-level performance, but they provide limited information as to the etiology of these difficulties, such as problems with phonological processing, rapid access to sight words, and so on. To assist in evaluating phonological processing abilities, clinicians will administer tasks that examine many aspects of phonological processing, such as a child's ability to transform sounds into graphemes, apply phonic rules to decode nonwords, substitute syllables in words, detect initial or final sounds of words, categorize sounds, or segment words by syllable and phoneme. Several studies have found that students with dyslexia and related reading disabilities struggle with phonological processing (Habib 2000; McCandliss and Noble 2003; Temple 2002).

As noted, rapid access of words from one's lexicon or naming is considered to be a critical skill for efficient reading. Tests that assess this skill may require the subject to rapidly name letters, numbers, or objects with specific characteristics, under time constraints. Therefore, the subject must first process the information visually, followed by forming a semantic representation, accessing a corresponding phonological word and recognizing the sequence of articulated phonemes (Denckla and Rudel 1976). Another aspect of reading that is often identified as problematic is a child's reading comprehension skills. Tests that assess literal and inferential reading comprehension typically require that a student read brief or lengthy passages or stories, silently or out loud, and then answer questions. Certain children, such as those within the autistic spectrum, are often noted to exhibit another form of reading disorder called hyperlexia syndrome, in which superior ability for reading is noted with poor reading comprehension (Grigorenko et al. 2002).

**Writing**

Several aspects of writing should be examined when a disorder of written expression or dysgraphia is suspected (Sandler et al. 1992). Therefore, the use of tests that diagnose deficits in legibility, fluency, spelling, written grammar, and thought expression are frequently used (Table 4.1). In a significant portion of children, the written language disturbance is associated with reading difficulties, developmental language disorders, or developmental motor coordination disorders. Visuomotor integration or copying ability as well as fine motor problems should first be ruled out as contributing factors (see Sensorimotor Functions), as these difficulties can interfere with a student's ability to convey ideas in writing. Spelling skills are typically assessed through dictation. However, in children with severe graphomotor problems, tests for which the student identifies the correct word can be administered (e.g., Peabody Individual Achievement Test—Revised). Third, written grammar should be assessed to determine if writing problems are secondary to the student's oral language or unique to the written domain. Certain measures also test for proofing, punctuation, and spelling (e.g., WJ-III). Finally, the ability to express ideas through a written modality should be assessed to evaluate organization, cohesion, and sense of audience, as well as other skills discussed earlier. Often, problems related to spelling, vocabulary, and grammar interfere with written discourse. However, some students have particular difficulty generating and organizing their ideas. Some have difficulty adjusting their language to meet the needs of the reader. Tests assessing this dimension of written language usually require the child to write a story about a picture or write sentences to complete short paragraphs. Results are analyzed for vocabulary, cohesion, organization, level of abstraction, and thematic maturity, as well as for contextual spelling and grammar. When working with younger children, tests such as the TEWL-2 focus on a child's ability to copy, spell words, write sentences from dictation, and write simple messages, notes, and other types of discourse expected of the developing writer.

**Mathematics**

Certain students have a specific learning disability that affects primarily the acquisition of arithmetic skills (Shalev and Gross-Tsur 2001). This type of learning disability is referred to as a mathematics disorder or dyscalculia. Although dyscalculia typically refers to children who exhibit significant difficulty with computations or difficulty with problem-solving abilities, other students with visual-spatial difficulties can display problems understanding quantitative and measurement concepts or aligning numbers properly to perform calculations. Tests measuring aspects such as calculations, mathematical fluency through rote memorization of basic calculations, and the ability to apply mathematical concepts through story problems are helpful in determining the presence of this type of learning disability (Table 4.1). How-

ever, the presence of comorbid learning disabilities should be examined as those with reading disorders may have adequate understanding of concepts and computation abilities but struggle with understanding story problems.

### Sensorimotor Functions

Sensorimotor functions have traditionally been considered markers of normal development and provide the clinician with information regarding lateralized dysfunction (Thelen 1995). Prior to generating an interpretation based on observations and test results of more complex integrative skills, primary sensory processes must be intact. Therefore, determining a child's visual and auditory acuity through documentation of recent screens, as well as observations during testing, is crucial. Moreover, the assessment of complex sensory integrative functions (e.g., visual, auditory, and tactile) are assessed by examining sensory suppressions (extinction) in response to bilateral sensory stimulation. Neurological soft signs are a useful component of a neuropsychological assessment. They can provide insight into the presence and severity of neurological compromise, provide information as to areas of cerebral dysfunction, and document developmental as opposed to acquired brain dysfunction. For example, rapid alternating and fine finger movements as well as evidence of dysmetria are examined. Handedness is generally established by the time a child is starting elementary school and provides information as to lateralization of cognitive functions. Dominance may be determined by using tests and inventories of hand, eye, and foot preference in a number of activities or by observing hand preference in tasks such as writing. Bilateral fine motor speed, dexterity, and strength are typically assessed through tasks in which the child is asked to manipulate small objects, accomplish simple finger movements in a rapid fashion, and grip an apparatus. Deficits in tactile and kinesthetic information processing may also be measured. Deficits in these areas may lead to difficulty in tasks that rely heavily on motor control such as graphomotor activities, manual coordination, and eye-hand coordination (Levine 1987; Luria 1973). A number of children who are described as clumsy or uncoordinated and who are otherwise neurologically intact may be apraxic or dyspraxic. In other words, they struggle with movement representation and performance of sequential movements to accomplish an action (Luria 1973). Asking a child to pantomime acts such as brushing his or her hair, hammering a nail, and waving good-bye may assess this condition. An informal screen of other aspects of motor functioning such as oculomotor and oral motor functions is also frequently conducted to discern their relative contribution to a child's difficulties.

### Visuospatial, Visuoconstructional, and Visuoperceptual Functions

Deficits in this cognitive domain can lead to academic difficulties and reluctance of a student to engage in tasks that rely heavily on perceptual and spatial abilities, such as

mathematics, drawing, and handwriting. In more severe cases, it can affect a child's ability to process social cues and nonverbal communication and lead to emotional distress and stress in social settings (Dimitrovsky et al. 1998; Ross et al. 2000; Rourke et al. 2002b; Wooden et al. 2001). Many tests exist that measure different aspects of visual-spatial abilities from basic perceptual processes to basic drawing abilities, visuospatial orientation, figure-ground discrimination, visuospatial reasoning, and so on (Table 4.4). Children may be asked to draw a picture as a way of initiating testing while assessing perceptual-motor skills, emotional status, and developmental maturity. One of the most widely used measures of developmental visuomotor ability is the Beery-Buktenica Developmental Test of Visual-Motor Integration (Beery et al. 2004), which involves the reproduction of increasingly complex shapes. For school-aged children, the Rey Complex Figure Test is another popular visuomotor test that provides information on a child's ability to plan and execute a complex design. To assess visuoconstructional praxis and provide information about other aspects of visual-spatial and executive functioning abilities, clock drawing may be used in children (Cohen et al. 2000). In children with suspected fine motor deficits, motor-free tests that measure visuospatial abilities are useful.

### Speech and Language

Speech refers to the mechanics of oral communication while language refers to the ability to communicate information. Children who display early language impairments are at greater risk of developing academic difficulties (Rapin 1998). Difficulties in communication, either in receptive or expressive language functions, may be developmental or acquired. A number of screening measures ex-

ist that assess several aspects of expressive and receptive language skills such as articulation, phonological processing, naming, verbal fluency, repetition, reading, spelling (oral and written), written expression, and comprehension of instructions (Table 4.5). Difficulties with phonological processing, naming, reading, spelling, and writing skills were previously discussed (see Academic Achievement). Other aspects of language that are frequently assessed are receptive and expressive language skills.

### Receptive Language

To ascertain whether a child has a disturbance in auditory receptive language, he or she may be required to demonstrate an understanding of spoken words, but with demands on verbal responding reduced. For example, the child may be given a set of pictures and asked to identify the one that corresponds with words spoken by the examiner (e.g., “Point to rectangle”). Certain tests that are considered to be a measure of the child’s vocabulary can also be used as a screening measure for verbal intelligence. Some children understand single words but have difficulty understanding more complex language. Certain tests are designed to assess receptive language components such as comprehension of oral language, figurative language, and other types of discourse. Listening skills may also be assessed by asking a child to follow commands when grammatical and syntactical complexity is increased. Children who struggle with behavior regulation, with holding on to verbal information, or with sequencing oral instructions may display poorer performances on these tasks. Memory is essential for comprehension, and some children have

difficulty retaining what they have heard because of deficits in auditory memory. Therefore, they may struggle in school not because they are unable to complete assignments, but because they cannot remember a series of oral directions. Failure to understand spoken language may result in problems with social communication and academic difficulties.

### Expressive Language

Children who have a history of delays or difficulty with expressive language skills tend to struggle academically in areas such as reading as well as oral and written expression (Lewis et al. 2000; Rescorla 2002). Expressive language deficits may also interfere with impairments in arithmetic skills (Manor et al. 2001). Measures used to assess basic expressive language skills focus on a child’s ability to name objects and pictures. More complex expressive language skills involve other aspects of language, such as word definition and the ability to formulate and express ideas and thoughts orally. These skills are assessed by asking children to explain how to make or do something, to tell a story, or to give directions. Finally, pragmatics, or social language use, is evaluated. Pragmatics, which is in some respects the most important aspect of language, involves the ability to use language for various functions, to meet the needs of listeners in various contexts, and to use nonverbal communication appropriately. Disturbances in any of the previously discussed areas of language can interfere with pragmatics. These individuals may have adequate phonology, vocabulary, and syntax but do not use language appropriately for communication. They may not use good listening behaviors; for example, they may not look at the speaker, or they

may not wait for the speaker to finish a sentence. Others cannot maintain a conversation or focus on a topic. Generally, pragmatic problems can be observed throughout the evaluation during informal conversations and by noting eye contact, turn taking, requests for clarification, and the ability to convey ideas clearly.

### Attention and Concentration

Neuropsychologists are often recruited to determine whether a child has attentional problems or attention deficit/hyperactivity disorder (ADHD), as a neuropsychological evaluation can assist in ruling out whether attentional problems may be secondary to other factors, such as learning disabilities or emotional disturbances. Disrupted attentional processes can be responsible for performance deficits on other tests that examine cognitive abilities such as memory, problem solving, visual-spatial processing, and so forth. The comprehensive neuropsychological battery will include tests, some computer-based, that assist in isolating deficits in attentional processes from deficiencies in other cognitive domains (Table 4.6). Depending on the type and severity of attentional problems, different treatment approaches may be recommended in both home and school settings.

Attention and concentration are thought to be composed of several different components that may be assessed through tests. For example, selective/focused attention refers to an individual's level of vigilance in monitoring information in the presence of distracting stimuli. Tests that measure this type of attentional skills assess an individual's ability to stay focused despite the presence of distractors. For example, a child could be asked to scan a page with different stimuli and cross out target stimuli. Divided attention refers to an individual's ability to attend to more than one task at a time. This type of attention refers to one's ability to multitask and appears to have the most effect on daily experiences. Tests that would measure this attentional skill

would, for example, require the child to perform two types of tasks at the same time, such as remembering three letters for a brief period of time while counting backward out loud. Sustained attention refers to one's ability to maintain vigilance and performance over time, in the context of a continuous or repetitive activity. The two latter types of attention are particularly affected in children with ADHD, as they tend to struggle on tests for which sustained attention over an extended period of time is required. Finally, alternating attention is used in describing an individual's ability to mentally shift his or her attention from one task to another. Tests that measure this type of attention will typically examine a child's tendency to perseverate in their response pattern despite instructions or redirection during testing. Children with an autistic spectrum disorder tend to struggle with this aspect of attention (Baron 2004).

Tests that examine brief auditory attentional capacity or a child's ability to hold on to as much information as possible are referred to as span tests. For example, on such tests a child may be instructed to repeat a series of letters, numbers, or words in a specific order, or repeat a sequence of hand movements. In adults, an average span has traditionally been of 7  $\pm$  2 bits of information (Miller 1956). Children will increase their ability to hold on to information with cerebral maturation and reach adult level performance around age 9 (Rudel and Denckla 1974). Children who struggle with these tasks are often described as forgetful and as struggling with following multistep instructions.

### Memory and Learning

Problems with memory are often cited as reasons for referrals for a neuropsychological evaluation in almost all age groups. Many children and adolescents struggle with remembering instructions and with learning information, hindering their academic success. Although memory deficits or amnesic disorders exist in children, they are quite rare and are most often secondary to cerebral insult such as epilepsy, anoxia, brain tumors, or head injuries (Vargha-Khadem et al. 2003; Williams and Sharp 1999). Memory or learning problems most often reflect difficulties with other cognitive functions such as attentional processes, executive functioning, and language or visuospatial processing. Most child memory batteries or tests will use downward extensions of tasks used in adult memory batteries and assess a child's ability to encode and consolidate information, as well as retrieve or recognize the information after a short and long delay (Table 4.7). Memory tasks have been developed for children as young as 3. They typically involve tasks that assess verbal and nonverbal memory processes, or both simultaneously. Verbal memory can be examined by asking a child to repeat stories, sentences, lists of words, or words that have been paired with other words, and so on. Nonverbal memory tasks may involve remembering faces, locations, and designs or pictures, for example. The child's performance across separate memory

tests will provide the clinician with a reliable pattern of strengths and weaknesses (e.g., visual versus verbal learning) that assist in the elaboration of educational strategies.

### Executive Functions

Executive functions refer to a wide variety of complex cognitive processes and behaviors. For example, complex problem solving and reasoning, working memory, mental flexibility, inhibition, initiation, planning, and organization all fall under the umbrella of executive functions (Denckla 1989; Welsh et al. 1991). Executive dysfunction is a core aspect of the difficulties encountered by many children, and these deficits may be developmental in nature (i.e., ADHD, autism, Tourette’s syndrome) or acquired (e.g., traumatic brain injury). Executive dysfunction may manifest as problems with attention, impulse control, perseveration, apathy, or emotional dysregulation (Gioia et al. 2002). Students with learning disabilities tend to display executive functioning difficulties such as problems with initiation, inhibition, and set shifting (Hooper et al. 2002). Tests have been developed to assess executive functioning in children starting at a very young age (Table 4.8). When executive functions are of concern, it is also important to obtain information about the student’s behavior in natural contexts, since highly structured test situations do not always reveal the problems. Observations by parents, teachers, and the student themselves are helpful in noting whether assistance and accommodations are needed.

### Personality and Psychosocial Functioning

The evaluation of psychological, social, and behavioral factors is an important part of the neuropsychological evaluation (Table 4.9). It provides information about a child’s emotional and behavioral level of functioning across settings, as well as information about his or her coping abilities when faced with difficulties. Although formal projective personality measures can be administered (ex. CAT, Rorschach Test), the assessment of a child’s emotional and

**TABLE 4.8**  
**SELECTED MEASURES OF EXECUTIVE FUNCTIONS**

Test	Age Range

Wisconsin Card Sorting Test	6½ years–adulthood

Dashes in age ranges indicate “through.”

psychological level of functioning relies heavily on information obtained from parents and teachers. Attention and concentration difficulties, problems with impulse control, mood disturbances, social difficulties, and other behavioral or emotional problems may be assessed through a variety of subjective paper-and-pencil questionnaires completed by the parent, teacher, and the child. This information is useful for interpreting performance on cognitive tests, as deficits may be accounted for by developmental psychopathology (for example, ADHD) or exacerbated by the onset of emotional distress (such as depression).

## INTERPRETATION OF THE EXAMINATION

### Validity of Test Scores

Interpretation within the neuropsychological assessment is not performed in a vacuum. There are multiple potential explanations for a child’s poor performance on any test. The first point to consider in determining the validity of obtained test scores is the child’s level of cooperation and effort. Test scores, unlike radiographs or other medical procedures, require the child’s cooperation before they can be considered a true reflection of that child’s capabilities. When a child does not cooperate with the test procedures, the confidence with which statements can be made about the child’s abilities across various domains of neuropsychological functioning is lessened. The conclusion that a child may not be performing up to his or her true ability level is based in part on an experienced clinician’s and technician’s observation of level of effort allocated toward the test procedures. More recently, formal measures have been developed that are used exclusively to determine whether an adolescent has provided their best effort or if less than optimal effort has been

**TABLE 4.9**  
**SELECTED MEASURES OF PSYCHOSOCIAL AND PERSONALITY FUNCTIONING**

Test	Age/Grade Range
Achenbach System of Empirically Based Assessment (ASEBA Child Behavior Checklist)	6–18 years
Behavior Rating Profile, 2nd Ed. (BRP-2)	6–18 years
Brown Attention-Deficit Disorder Scales	12 years–adulthood
Children’s Apperception Test (CAT)	3–10 years
Children’s Depression Inventory (CDI)	6–17 years
Conners’ Rating Scales-Revised (CRS-R)	3–17 years
Devereux Scales of Mental Disorders	5–18 years
Minnesota Multiphasic Personality Inventory—Adolescents (MMPI-A)	14–17 years
Multidimensional Self-Concept Scale	Grades 5–12
Personality Inventory for Children, 2nd Ed. (PIC-2)	5–19 years
Revised Children’s Manifest Anxiety Scale (RCMAS)	6–19 years
Reynold’s Adolescent Depression Scale, 2nd Ed. (RADS-2)	11–20 years
Rorschach Inkblot Test	8 years–adulthood

Dashes in age/grade ranges indicate “through.”

extended during memory testing (Green et al. 1996). This type of testing has been found to be particularly useful in forensic examination. Validity is also examined in the profiles completed by a child’s parent to discern if a parent is endorsing symptoms in a child to a degree that are in excess of what would likely be expected in most children and may suggest a plea for help.

## BRAIN-BEHAVIOR RELATIONSHIPS

### Methods of Inference

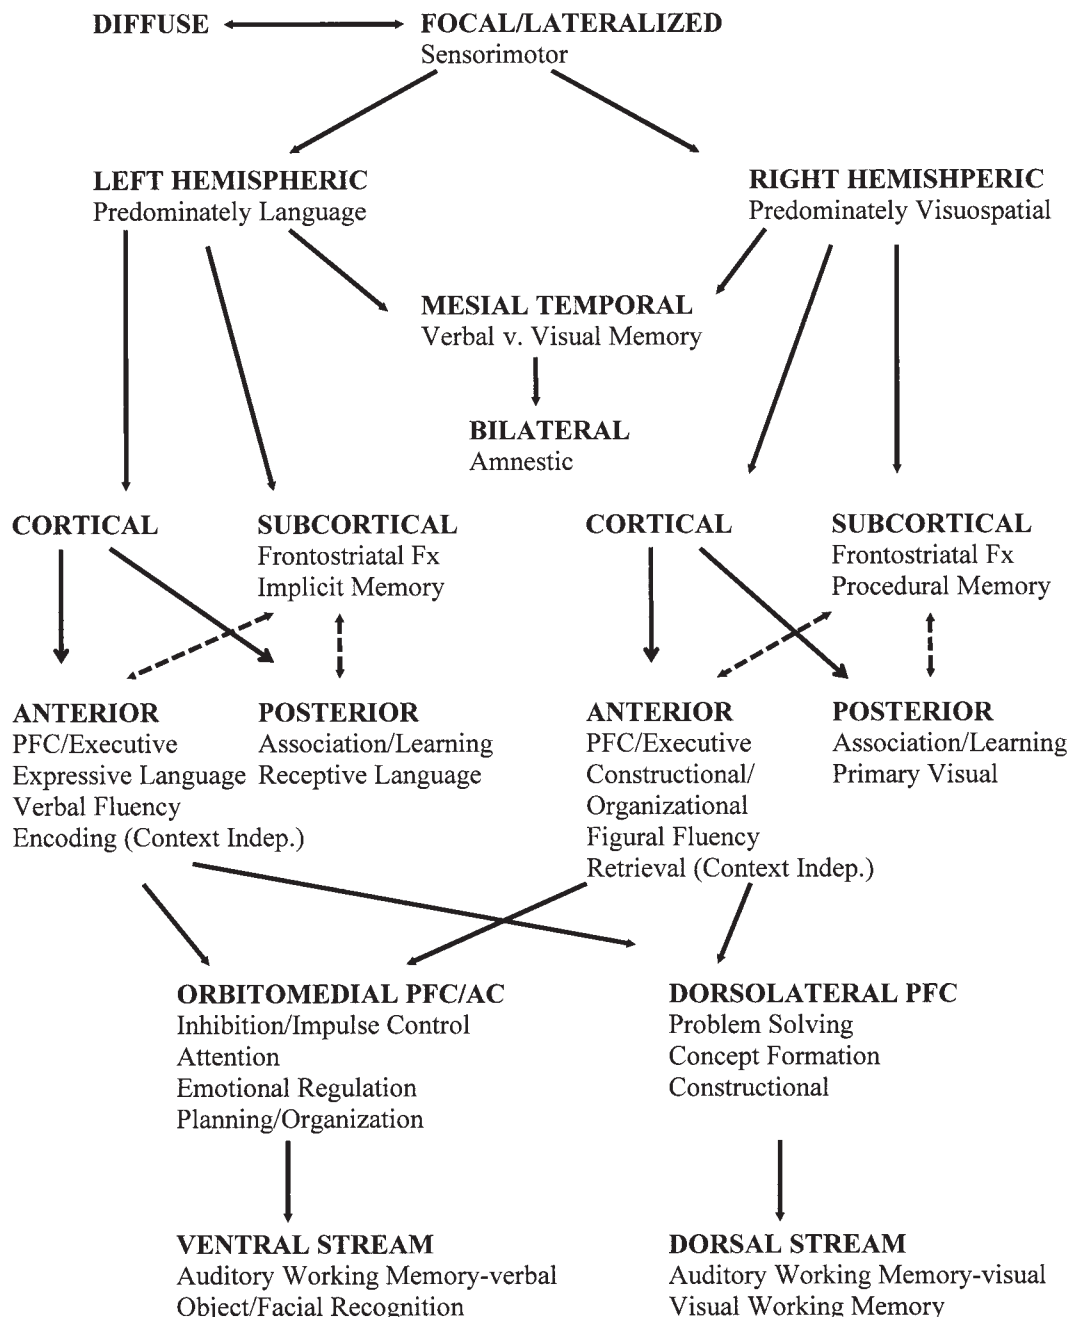

If the test data are judged to be a valid and reliable measure of the child’s abilities, then multiple methods of inference are used to interpret the neuropsychological data. Historically, the major methods of inference have been level of performance, pattern of performance, pathognomonic signs, right-left patterns, and test-retest performance patterns. As brain-behavior relationships have become more fully illuminated other axes including cortical-subcortical, anterior-posterior, orbitomedial and dorsolateral, and dorsal-ventral stream patterns of performance have become important aspects of the method of inference. Figure 4.1 provides a partial example of a method of inference that a neuropsychologist would employ in the interpretation of the test data. The conclusions drawn from the aforementioned inferential method will be subsequently integrated with information obtained regarding the presenting concerns and historical data in formulating the case with regard to potential diagnoses, brain-behavior relationships, and strengths and weaknesses. The future of pediatric neuropsychological assessment is, however, entering an era in which the etiological yield is likely to be the most fruitful

when conducted in conjunction with neuroimaging and there is a more substantial appreciation of the variance in performance and outcome based on environmental contingencies (see Table 4.10).

### Level of Performance

Drawing conclusions about functions based on a child’s norm-referenced performance level on a test is a common method of inference used by both psychologists (e.g., IQ score) and nonpsychologists (e.g., values of laboratory tests). For example, standardized IQ tests typically provide scores ranging from around 50 to approximately 150. Individuals who take an IQ test can be compared with the population with regard to their standing in the distribution. Someone with an IQ of 110 is in the upper 25th percentile of the general population, whereas someone with an IQ of 85 is at the lower 15th percentile. Neither of these IQ scores implies normality or abnormality, but they do position an individual with regard to his or her competitive level in a number of respects. Knowing that a person is consistently above or below average and the degree of difference from the average of the population are significant elements in proper educational and occupational placement.

The risk of considering level of performance in isolation from other data is that performance level does not provide adequate information about whether or not the obtained scores are normal or abnormal for any given child. An individual with lifelong cognitive abilities in the superior range who now has average intelligence is certainly not normal. In addition to the individual’s having lost mental skills to the level of average, it may be the case that those losses have occurred in areas sufficiently specific to preclude behavior consistent with that typifying

**Figure 4.1** An example of a method of inference employed in neuropsychology. Cognitive constructs listed are intended to be merely examples of abilities known or suspected to be representative of the specific brain region or system. Note: Brain regions: PFC, prefrontal cortex; AC, anterior cingulate.

the broad range of individuals with lifelong average cognitive abilities. The frustrations experienced by such a child who has lost intellectual abilities are difficult to appreciate and are simply not elucidated by obtaining an IQ score of 95 to 105. Thus, an “average” IQ considered alone can be quite misleading by suggesting that all is well, when, in fact, dramatic changes may have occurred.

Similarly, even subtle changes in motor functioning (from superior to average), though not likely to be appar-

ent in a variety of clinical evaluations, may make a substantial difference in a child’s athletic prowess, thereby affecting the child’s self-concept and perceptions by his or her peers. Certainly, brief neuropsychological screenings run a substantial risk of missing these kinds of difficulties.

Level of performance encourages the utilization of tests with adequate normative data, and this method of inference is appropriate to a broad range of neuropsychological tests. Test reports that fail to provide information on level

of performance are hardly ever fully informative; test reports that rely exclusively on the child's position relative to a normative sample leave out significant amounts of information that may be pertinent to the child's day-to-day performance.

### **Pattern of Performance**

Pattern analysis has the advantage of encouraging utilization of a wide range of psychological tests covering broad domains of functioning. Identifying and interpreting "unusual" patterns of performance within and across tests re-

quires knowledge about the base rates for specific patterns and the relationship of specific patterns to neurological or developmental syndromes.

The most common pattern referred to is the split between scores on verbal versus performance subtests of the Wechsler intelligence scales, since such splits have been associated with various types of neurological impairment. However, verbal-performance differences on the Wechsler scales do not necessarily reflect neurological impairment in children, much less necessarily indicate lateralized brain damage to the left or right hemisphere (Boll and Barth 1981; Chadwick and Rutter 1983). Despite this, many clinical reports continue to allude to left and right brain differences in children based on these data without neurological criteria to support such conclusions. Drawing inferences based on the amount of variability in performance among the Wechsler subscales, a process often referred to as “scatter analysis,” is also invoked as a way of deriving information from these scales. Unfortunately, no scientifically valid data of a criterion-based nature have been produced to suggest that specific relationships among subtests have a particular reference either to presence or absence or to location of brain damage. Nonetheless, the degree of spread or IQ discrepancy in a profile will be critical in the interpretation in some forms of developmental and learning disorders. For example, Figure 4.2 reveals data of a child with an NLD who was subsequently diagnosed with Asperger syndrome. In this case, superior verbal intellectual abilities relative to low average visuospatial intellectual skills have resulted in the regression to an average overall IQ, and an exclusive reliance on any IQ in isolation will not help one to appreciate the degree to which the child is struggling. Moreover, his generally low average visuospatial IQ does not fully illuminate his rather profound constructional and organizational

deficit (Fig. 4.3). Qualitative interpretation of the vocabulary responses (Fig. 4.2) further reveals a classic feature of language in Asperger syndrome: the tendency to be pedantic. It is important to note that NLD is an academic distinction that may or may not be evident in Asperger syndrome, though it is frequently observed.

A more valid and reliable form of analysis occurs when one examines and compares the pattern of performance across a variety of different types of tests covering a broad range of neuropsychological domains. In other words, a child who displays a relative strength on tests of language but a substantial weakness in motor functioning provides information with regard to the child’s areas of needed emphasis and required intervention, independent of whether or not these relative strengths and weaknesses relate in a specific way to underlying brain damage, normally occurring individual differences, or poorly understood (in terms of brain substrate) neuropsychological syndromes (e.g., hyperlexia).

Children whose pattern of performance across multiple tests is substantially different from the normative pattern (e.g., substantial differences between performance on IQ tests and performance on achievement tests) may have learning difficulties requiring further assessment. At times, the pattern is puzzling for families and school personnel. For example, many children with autism with hyperlexia and hypergraphia as depicted in Figure 4.4 are frequently believed to be “bright” given their often early and rather exquisitely developed sight reading abilities until more complex reading demands are required. Pattern analysis is helpful for raising questions, answering questions, identifying areas of strength toward which learning strategies can be targeted, and identifying areas of deficit for which remediation may be attempted. Relative strengths and weaknesses can also help explain a child’s preferences for a variety of tasks and activities that might otherwise be attributed to personality variables. Recognizing that

Male, Age 10	
COGNITIVE/ACADEMIC PROFILE: NONVERBAL LEARNING DISABILITY (Mean = 100; S.D. = 15)	
CLINICAL DIAGNOSIS: ASPERGER SYNDROME	
Verbal IQ = 127 Performance IQ = 85 Full Scale IQ = 104	Reading SS = 105 Spelling SS = 81 Arithmetic SS = 62
Vocabulary Sample:	
<i>Umbrella:</i> An object used to keep—to displace rain over a taut surface—or to keep a section of an area dry.	
<i>Bicycle:</i> A two wheeled transportation unit powered by the legs.	

**Figure 4.2** Selected cognitive data from a 10-year-old boy with nonverbal learning disability and Asperger syndrome. Note his verbal greater than performance intellectual pattern and preserved sight reading, but significantly impaired mathematics performance. Spelling is below average partially due to orthographic errors. Further note examples of his rather pedantic vocabulary.

**Figure 4.3** Top figure: Rey complex figure stimulus. Bottom figure: The copy of the Rey complex figure by the 10-year-old boy with nonverbal learning disability and Asperger syndrome. Note his severe visuoconstructional skills combined with his superior verbal intellectual skills. Further note the lack of sensitivity of performance IQ, which is low average, to reveal the profound nature of his visuoconstructional impairment.

personality and ability interact in determining preferences helps lead to a more holistic understanding of the child's behavior and, it is hoped, to a more informed base from which to plan intervention strategies.

#### **Right-Left Patterns/Anterior-Posterior/ Orbitomedial-Dorsolateral/ Subcortical-Cortical/Dorsal-Ventral**

A comparison of the efficiency of sensory and motor functions on the two sides of the body (right-left patterns) provides important data that contribute to neuropsychological interpretation. Systematically obtained and consistently identified deficits on one side of the body are

likely to have a neurological origin (central or peripheral) and are unlikely to be influenced by environmental, motivational, academic background, or emotional factors as scores on "level of performance" tests can be. Lateralized sensory-motor deficits (e.g., right-sided manual weakness, speed, and coordination), when related to cortical lesion, will commonly co-occur with deficits in cognitive processes (e.g., language deficits in this example). As noted, it is now possible to consider additional axes of potential disruption, such as cortical-subcortical, anterior-posterior, orbitomedial and dorsolateral, and dorsal-ventral stream patterns, in the formulation of the assessment (Fig. 4.1). Research has suggested that some developmental disorders likely, in fact, represent disruptions in specific neural networks (e.g., William syndrome, dorsal stream) (Atkinson et al., 2003).

#### **Test-Retest Performance Patterns**

Test-retest analysis is particularly useful in assessing children. The child's performance on a battery of tests at an initial time is compared with his or her performance on retesting at a second time, usually 12 months or more after the initial testing. A child may perform poorly on one or another test because a real deficit is present, a temporary developmental lag is occurring, or certain nonneurological events (e.g., poor motivation) are at work. By retesting the child after a period of time, observations are made with regard to the stability of certain performance strengths and weaknesses.

Another important reason for use of test-retest comparisons is that in the developing child at risk given a history of early injury (e.g., prenatal/intrapartum stroke or traumatic brain injury in early childhood), initial testing may not reveal pronounced deficits. However, as the child develops there is frequently a cascading effect on more complex cognitive, particularly executive functions, as life demands increase.

## **CONCLUSION**

Neuropsychological testing represents only one of the three components of the neuropsychological evaluation. The neuropsychological test results are considered in the context of a comprehensive understanding of the presenting complaints and the child's life history to include developmental history, medical history, and longstanding functioning across behavioral, social, emotional, and cognitive domains. Selection of tests to include in the neuropsychological examination of the child will vary among neuropsychologists. However, substantial agreement exists indicating that the comprehensive child neuropsychological test battery will include tests and procedures that cover the following domains:

- Intellectual or developmental level of functioning
- Academic achievement
- Sensorimotor functions
- Visuospatial and perceptual-motor functions

Male, Age 11	
COGNITIVE/ACADEMIC PROFILE: HYPERLEXIA AND HYPERGRAPHIA (Mean = 100; S.D. = 15)	
CLINICAL DIAGNOSIS: AUTISTIC DISORDER	
<i>Intellectual</i>	<i>Academic</i>
Verbal IQ = 53 Performance IQ = 57 Full Scale IQ = 65	Sight Reading SS = 100 Spelling SS = 116 Arithmetic SS = 108
<i>Speech and Language</i>	Oral Reading (Mean = 10; S.D. = 3) Rate SS = 8 Accuracy SS = 11 Comprehension SS = 4 Oral Reading Quotient = 82
PPVT-III SS (Receptive Vocabulary) = 59 EOWPVT SS (Expressive Vocabulary) = 64	

**Figure 4.4** Selected cognitive data from an 11-year-old boy with autism who displays mental retardation with hyperlexia and hypergraphia. Note his preserved sight reading and spelling despite mental impairment and significantly impaired expressive and receptive vocabulary. Further note his significantly impaired reading comprehension despite preserved sight reading, reading rate, and accuracy.

- Speech and language functions
- Memory and learning
- Attention and executive functions
- Behavioral and emotional adjustment

Neuropsychological interpretation involves drawing conclusions based on the use of multiple levels of inference considered in the context of the child's pertinent developmental and medical history as well as what is known about the natural history of certain pathological conditions.

In the hands of a skilled child neuropsychologist, a neuropsychological evaluation (conducted in 2 to 5 hours) can be a useful diagnostic and treatment-relevant assessment tool that is also cost-effective. The information obtained from a comprehensive neuropsychological evaluation is unique, and in many cases pivotal to the diagnosis, and detailed enough to be useful in the development of psychological, medical, and educational interventions.

# Anatomic Imaging of the Developing

# Human Brain

5

**Jay N. Giedd, MD**

Many neuropsychiatric disorders of childhood may reflect subtle deviations in the normal development of the brain. Adult psychiatric illnesses, such as schizophrenia, are also increasingly being viewed from a neurodevelopmental perspective (Bloom 1993; Weinberger 1995).

Understanding of the relationship between abnormal brain development and developmental neuropsychiatric disorders has been challenged by nature's efforts to protect this most vital organ. Wrapped in a tough leathery membrane, immersed in fluid, and completely encased by bone, the brain's protective system has long served to thwart environmental insults, but it has also posed considerable obstacles for those studying the brain. Fortunately, advances in neuroimaging technology now provide an unprecedented opportunity to examine in vivo brain structure and function.

To meaningfully assess pathologic deviations it is imperative to first characterize the normal pathways of brain development. Postmortem data are of limited availability since the mortality rate is low for this age group and autopsies are infrequently performed. For example, only 13 of 483 "normal" brains in the Yakovlev Brain Collection in Washington, D.C., are from subjects aged 3 to 18 years. The use of ionizing radiation for in vivo imaging techniques, such as conventional radiography, computerized tomography (CT), or positron emission tomography, render them unsuitable for the study of normal pediatric populations.

Magnetic resonance imaging (MRI) provides many advantages for in vivo imaging studies. In addition to absence of ionizing radiation, MRI offers the capability to acquire

images in any plane of view; provides excellent spatial resolution and the ability to discriminate gray matter, white matter, and cerebrospinal fluid; has the flexibility to assess a variety of tissue characteristics (as opposed to relying solely on patency to radiographs); and can be used to visualize structures (temporal lobes, frontal lobes, posterior fossa) often obscured by interference from bone on CT scans. The lack of ionizing radiation with MRI also allows sequential exams, which is very desirable for developmental studies. These factors make MRI the imaging modality of choice for most pediatric neuroimaging studies.

In this chapter, which focuses on normal brain development from ages 4 to 18 years, we discuss methodologic issues relevant to pediatric neuroimaging, review previous imaging studies of normal development with emphasis on the National Institute of Mental Health (NIMH) Pediatric Brain MRI project, and conclude with a discussion of developmental changes in brain anatomy as they relate to the study of pediatric neuropsychiatry.

## **METHODOLOGICAL CONSIDERATIONS**

### **Subject Selection**

#### ***Clinically Referred Versus Community Recruited Subjects***

The common practice of deriving normative measures from children referred for clinical reasons whose scans were subsequently read as "normal" is problematic on at least

two counts. First, children referred for clinical scans are overrepresented in clinical groups, such as attention-deficit/hyperactivity disorder (ADHD). Second, a small but perhaps meaningful number of healthy children may have scans read as abnormal and excluding these subjects confounds comparisons to clinical groups. Recruitment of healthy subjects directly from the community provides a more appropriate sample to assess normal development.

### **Psychiatric History**

Abnormalities of brain structure have been observed in a number of pediatric neuropsychiatric illnesses, including autism (Brambilla et al. 2003), ADHD (Giedd et al. 2001), childhood-onset schizophrenia (Giedd et al. 1999; Gogtay et al. 2004; Keller et al. 2003; Sporn et al. 2003), dyslexia (Duara et al. 1991; Eckert and Leonard 2000; Eckert et al. 2003; Hynd and Semrud-Clikeman 1989; Hynd et al. 1990; Larsen et al. 1990; Rae et al. 2002; Rumsey et al. 1986), eating disorders (Laessle et al. 1989), obsessive compulsive disorder (Giedd et al. 1996), Sydenham's chorea (Giedd et al. 1995), and Tourette's syndrome (Peterson et al. 1993, 1994, 2000). It is evident that a normative sample must be carefully screened to rule out these conditions. Likewise, affective disorders (Coffey et al. 1993) and substance abuse (Cascella et al. 1991; Lishman 1990) have been associated with structural anomalies in adults and should be considered as potential confounds in pediatric samples as well.

### **Intelligence**

Studies have found small but statistically significant relationships between brain size and intelligence (Andreasen et al. 1993; Reiss et al. 1996; Willerman et al. 1991). Although in the most robust of these findings IQ accounts for only 17% of the variance (Andreasen et al. 1993), this parameter should be considered in any group comparison. Education and socioeconomic status have been reported to influence brain size as well, although the interdependence with factors such as nutrition, prenatal care, and IQ is not clear.

### **Handedness**

Beginning with Geschwind, several investigators have noted a relationship between handedness and structural or symmetry measures of the brain (Geschwind 1978; Kertesz et al. 1992; Witelson 1989). Handedness should not be viewed as strictly left or right, but as a continuum (Coffey et al. 1992) and quantified as such. Patient and control groups must be matched for handedness since symmetry differences are often key features in discriminating groups such as ADHD (Giedd et al. 2001), dyslexia (Hynd 1990, et al. Larsen et al. 1990), or Tourette's disorder (Peterson et al. 1993, 1994, 2000).

### **Body Size**

The relationship between brain size and body size in humans is surprisingly poor (Harvey and Krebs 1990). In contrast to the relative stability of brain weight after childhood,

body weight varies widely among individuals and can vary substantially within individuals from time to time. Height is also a poor indicator of brain size as can be implied by contrasting the notable increases in height from ages 4 to 18 years with the lack of corresponding increase in brain size. This general trend for the young to have disproportionately large head-to-height ratios compared to adults, termed neonatogony, is widely observed throughout the mammalian species.

## **Image Acquisition**

### **General Considerations**

MRI can provide excellent resolution between gray matter, white matter, and cerebrospinal fluid (CSF). This capacity is critical for quantitative anatomical studies since such contrasts define the boundaries of most brain structures. Generally, resolution can be purchased with the currency of time; that is, improvements in image quality must be weighed against patient discomfort from prolonged time in the scanner. Most children can tolerate scan times between 45 minutes and 1 hour.

The discomforts associated with getting an MRI scan are potential feelings of claustrophobia from being placed in the tunnel-like barrel of the scanner, the loud noise generated by rapid heating and cooling of gradient coils, and the need to remain relatively still during the approximately 10-minute intervals of image acquisition.

Although sedation is not an ethical option in acquiring scans of healthy children, several nonpharmacological steps may be taken to minimize these discomforts in a pediatric population. Allowing the child to become familiar and comfortable with the staff conducting the scan, scanning in the evening to promote the natural falling asleep, allowing the child to bring in a favorite blanket or stuffed animal, and assuring the children that they may stop the procedure at any time can all increase the chances of acquiring adequate scans and make the experience more enjoyable for the child.

Slice thickness is an important parameter in MRI scans. Greater slice thickness results in larger partial voluming effects and in less spatial resolution, especially critical for small but clinically pertinent subcortical structures.

The use of multichannel versus single-channel scanning protocols is another factor to consider in image acquisition. Multichannel scanning protocols provide nearly simultaneously acquired spatially registered image sets that highlight different tissue characteristics. The most common multichannel scanning protocol is one that combines a sequence best for identifying tissue pathology and white matter lesions (T2-weighted) with one that provides optimal discrimination between brain tissue and CSF (proton density weighted). The advantage of multichannel acquisition is that by combining information from the image sets, automated computer programs can maximally discriminate gray matter, white matter, and CSF (Rajapakse et al. 1996).

The disadvantage to multichannel images is that they characteristically have greater slice thickness (5 mm or greater). The most common single-channel sequences yield T1-weighted images, which are well suited for providing anatomical detail.

### Functional MRI

Functional MRI takes advantage of the fact that oxygenated hemoglobin has different magnetic properties than deoxygenated hemoglobin. This difference provides a natural contrast agent that can be detected by a properly configured MR scanner. As neuronal activity increases metabolic demands trigger an increase of blood flow to that area. By comparing blood flow while the subject performs an experimental task with blood flow during a passive control condition, images of brain activity can be generated. Both spatial (1 mm) and temporal (5 to 7 seconds, limited by blood flow characteristics) resolution far surpass the capabilities of Positron Emission Tomography (PET). The potential to study dynamic activity of the brain in real time without the use of ionizing radiation offers great promise for pediatric studies (Casey 1995, 1996).

## Image Analysis

### General Considerations

Validation of MR image analysis techniques is hindered by lack of an absolute gold standard. Postmortem data, even if more abundant, are less than ideal on several counts. When removed from the intracranial cavity and the cerebrospinal fluid in which it is immersed, the brain collapses on its own weight, distorting *in vivo* morphology. Fixation and drying processes affect different brain structures to different degrees with gray matter and white matter shrinking at separate rates. Also, age itself is a confound, since younger brains have higher water content and are differentially affected by fixation processes.

Studies using models that mimic the shape and tissue characteristics of the human brain can be useful, but valid models are difficult to construct. The standard for validation of automated measures for the quantification of many structures remains a comparison to results obtained from manual tracing by expert human raters.

MR image data are in the form of pixels (picture elements) or their three-dimensional counterpart voxels (volume elements). Each of these elements may have only one intensity value. At the time of image acquisition, these values may range from 1 to 65,536 ( $2^{16}$ ). However, to reduce the memory requirements for computation, most image analysis systems restrict this intensity value range to 256 ( $2^8$ ). A general goal of structural image analysis is to classify each voxel in the image data set according to tissue characteristic (e.g., gray matter, white matter, CSF, vasculature), as well as to assign it to the structure or region in which it belongs.

### Sample Size/Longitudinal Study Design

The enormous normal variability in size of brain structures calls for large samples and longitudinal study designs to characterize the heterochronous developmental changes of the pediatric population. Fortunately, the feasibility of longitudinal studies is supported by the relative stability of morphologic measures from scans acquired at 2- to 4-week intervals (Giedd et al. 1995). This stability indicates that quantitative differences in longitudinal scans are reflections of genuine changes in brain structure and not from variability related to the scan acquisition itself.

## DETERMINATES OF BRAIN SIZE

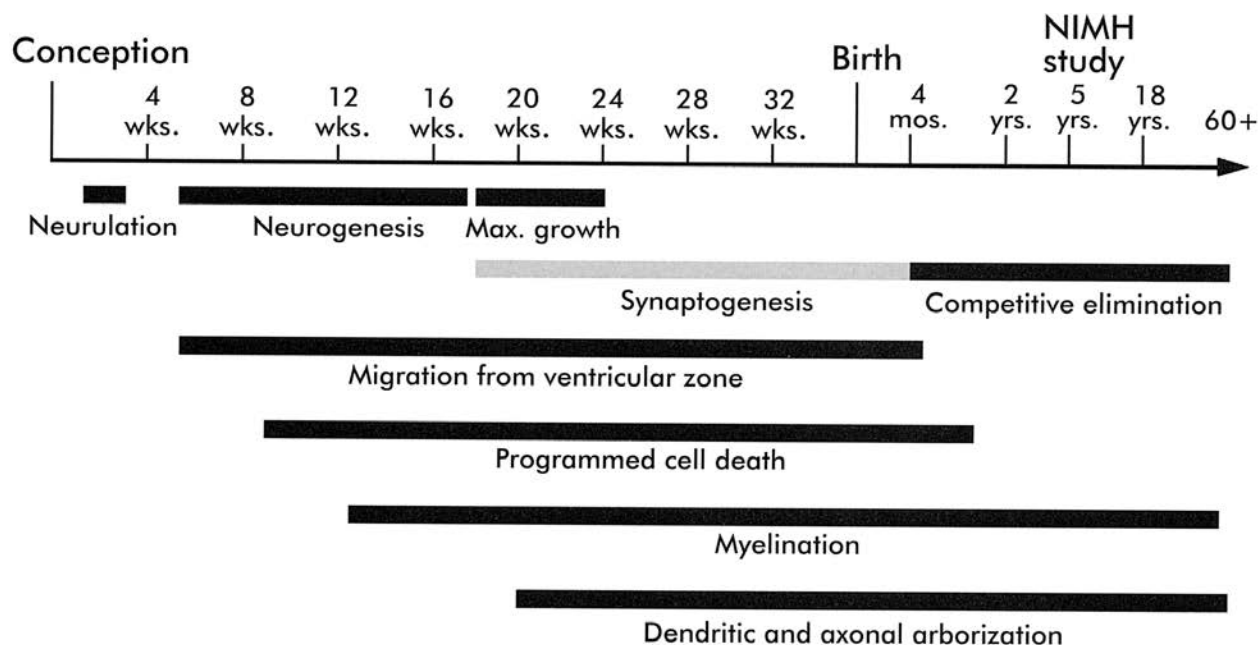

Human brain development, like central nervous system development in all vertebrates, takes place by an overproduction and then selective elimination of cells. The size of a given brain structure is determined by the size, number, and packing density of its constituent cells. The majority of dynamic brain development takes place *in utero*; however, changes in brain structure and function continue throughout the life span (see Fig. 5.1).

Brain cells are of two general types: neurons and glial cells. Although neuronal number peaks during gestation (Rabinowicz 1986), neuronal size changes with age (Blinkov and Glezer 1968) as axonal thickness, dendritic number, and number of synaptic connections undergo cyclic changes throughout development (Thatcher 1992). Environmental factors influence which synaptic connections and neurons thrive and remain viable. For instance, in children with cataracts who do not receive treatment prior to age 1, irreversible cortical blindness occurs (Lewis et al. 1986).

Synaptic pruning of neurons is an important aspect in the functional development of the brain but may have little impact on overall structure size. Estimates from research on the primary visual cortex of the macaque monkey indicate that a total loss of all boutons would result in only a 1% to 2% decrease in volume (Bourgeois and Rakic 1993). However, synaptic pruning may have an effect on the thickness of the parent axon or dendritic branches.

The other main class of CNS cells is made up of the glial cells, which unlike neurons continue to actively proliferate and die postnatally. Glial cells outnumber neurons by ratios ranging from 1.7 to 10 (Brizzee et al. 1964). Myelination by a subclass of glial cells, oligodendrocytes, is an important determinant of increases in structure size during childhood and adolescence. Ultimate structure size is determined by this dynamic interplay between glial cells and decreasing numbers but increases in size of neurons.

Another parameter to consider in structure size is packing density, which is influenced by degree of vascularity, extracellular volume, and hydration. Genetics, hormones, growth factors, nutrients in the developing nervous system, diet, infections, toxins, trauma, stress, or degree of enriched

**Figure 5.1** Time course of critical events in the determination of human brain morphometry.

environment (Diamond et al. 1964; Jacobson 1991) all have a role in determining structure size and the complexity of these factors and their interactions should be considered in any interpretation of the clinical significance of gross structural volume.

## SUMMARY OF PREVIOUS STUDIES

More than 1,000 studies have been reported regarding brain MRI in fetuses or infants. However, only a handful of brain MRI studies have assessed healthy children from the ages of 4 to 18 years. In one study (Jernigan et al. 1991) of 23 males and 16 females, ages 8 to 35 years, both cortical and subcortical gray matter decreased with age, and cerebrospinal fluid (CSF) volumes increased with age. Another study of 88 clinically referred subjects, ages 3 months to 30 years, also found age-related decreases in gray matter, as well as increases in cortical white matter, but no changes in CSF volume (Pfefferbaum et al. 1994).

Postmortem studies or PET studies of this age group are equally rare. A postmortem study including subjects aged 3, 5, 11, and 13 years indicated developmental changes in synaptic density, neuronal density, and dendritic arborization occurring at least up until adolescence (Huttenlocher 1990). PET studies also indicate dynamic changes throughout development with cerebral metabolic rates rising rapidly during the first years of life, maintaining higher-than-adult levels throughout childhood, and declining to adult levels during adolescence (Chugani et al. 1987).

## NATIONAL INSTITUTE OF MENTAL HEALTH PEDIATRIC NEUROIMAGING PROJECT

The child psychiatry branch of the NIMH is conducting an ongoing brain imaging project to assess the hypothesis that many of the most severe neuropsychiatric disorders of childhood-onset are associated with deviations from normal brain development, the anatomical substrates of which may be detectable by MRI. The study includes twin and nontwin healthy controls and subjects from a variety of diagnostic groups. Longitudinal scans are acquired at approximately 2-year intervals.

The healthy control subjects are recruited from the community and undergo screening including physical and neurological exams, clinical interviews and family history assessment, and an extensive neuropsychologic battery. Approximately one in six initial contacts are accepted for the study. For this chapter, only nontwin healthy subjects are used and only one subject from each family. The resulting sample is 329 scans from 95 boys and 66 girls (longitudinal scans acquired at approximately 2-year intervals) across ages 4 to 20 years.

Once the images are acquired, they are analyzed by a variety of automated and manual tracing techniques through collaboration with several imaging centers throughout the world. Further details of the testing and screening of this sample and the methods of image analysis are published elsewhere (Chung et al. 2001; Giedd et al. 1999; Zijdenbos et al. 1994).

## Brain Maturation Changes During Childhood and Adolescence

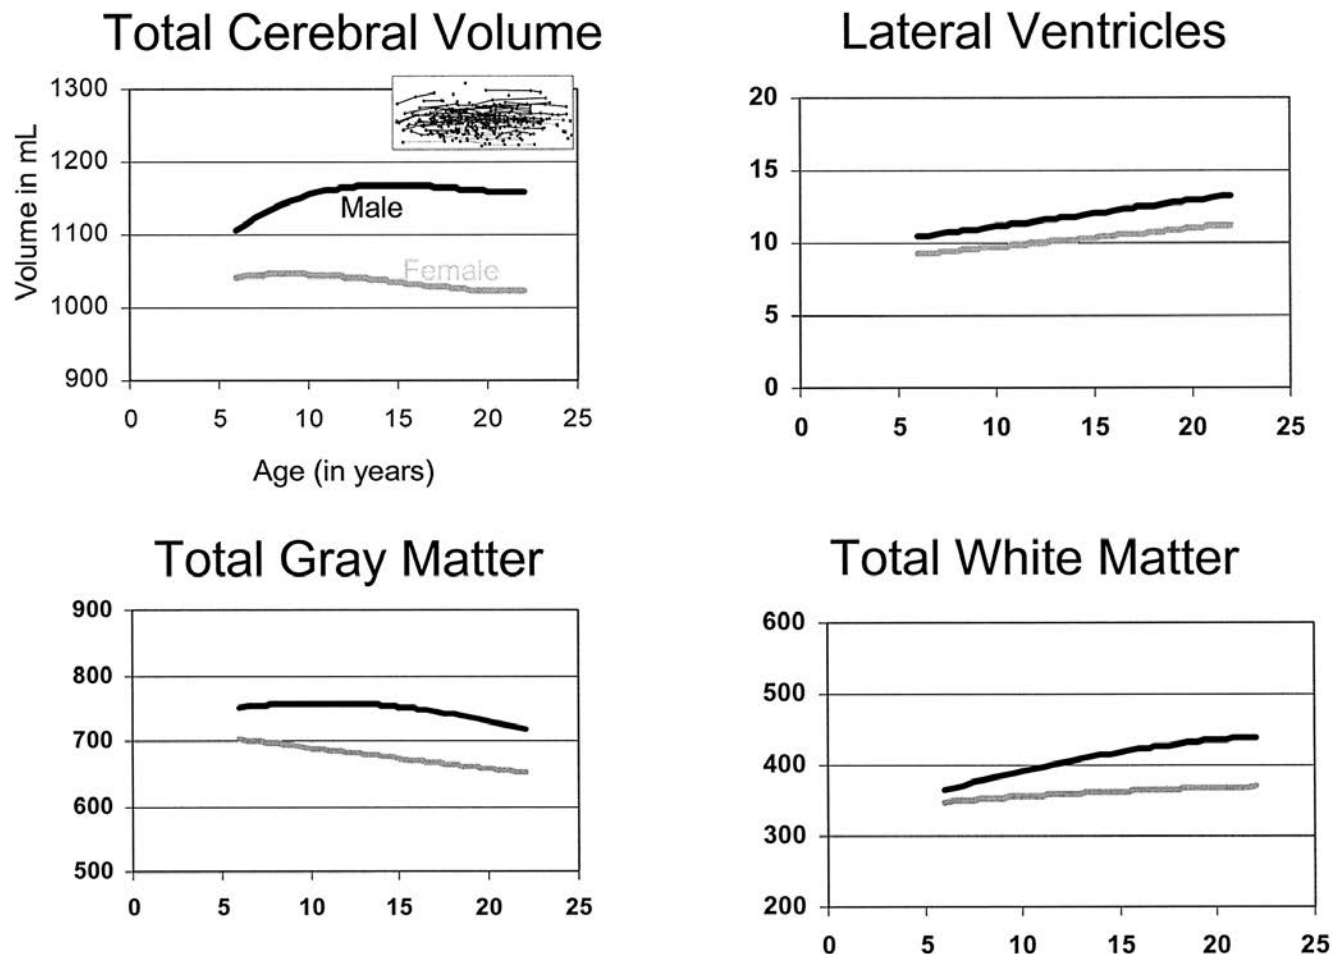

### Total Cerebral Volume

In the longitudinal NIMH sample, the total cerebral volume of children and adolescents remained relatively stable across ages 4 to 20 years (Fig. 5.2). This is consistent with our previous cross-sectional studies (Giedd et al. 1996) and postmortem studies indicating the brain is approximately 95% of its adult size by age 5 years (Dekaban 1977; Dekaban and Sadowsky 1978). However, the finding is counter-intuitive to anyone who has tried putting an adult's hat on a 5-year-old and watched it fall down over the child's eyes. Indeed, head circumference does increase from age 4 to 18 years (approximately, 2.0 inches in boys and 1.9 inches in girls) (Nellhaus 1968), but this is accounted for by an increase in skull thickness (Shapiro and Janzen 1960) and less so by an increase in ventricular volume. Although total cerebral volume remains relatively constant, various sub-components of the brain do undergo significant age-related changes (see Fig. 5.2).

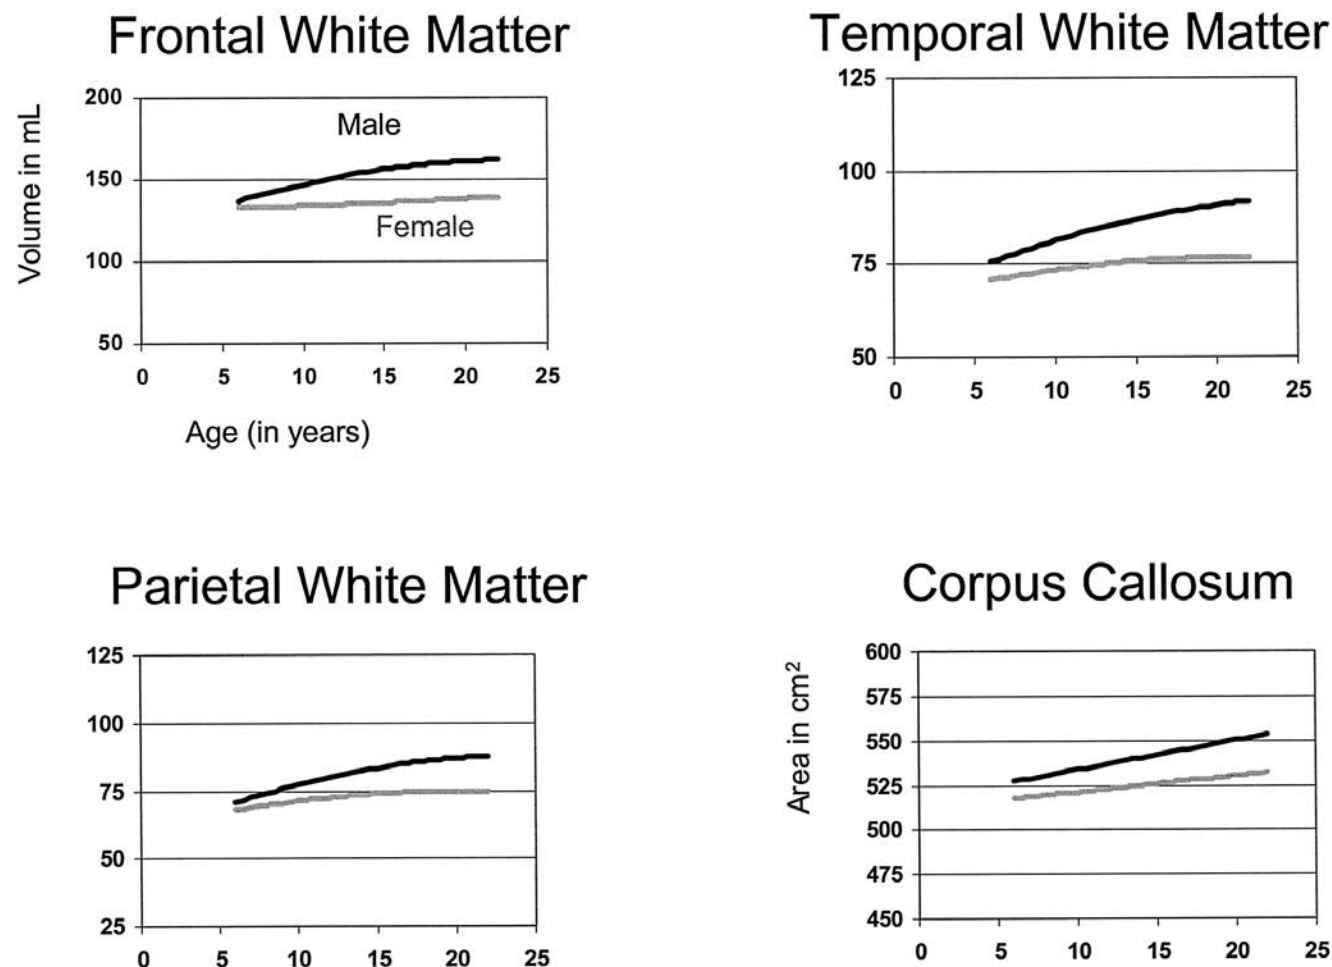

Male brains were approximately 12% larger on average than those of females. This difference was statistically significant, even when controlling for height and weight. Of course, gross size of structures may not reflect sexually dimorphic differences in neuronal connectivity or receptor density. Given the myriad of parameters influencing brain size, size alone should not be interpreted as imparting any sort of functional advantage or disadvantage.

### Ventricles

In the NIMH sample, lateral ventricular volume increased robustly with age (see Fig. 5.2), a fact not widely appreciated for children and adolescents. This pattern is noteworthy in light of the fact that increased ventricular volumes, or ventricular-to-brain ratios, are associated in a nonspecific fashion with a broad range of neuropsychiatric conditions. That this phenomenon is a normally occurring event in healthy adolescents adds to the complexity of interpreting changes in ventricular volume in patient populations.

**Figure 5.2** Changes in volume of the total cerebral, lateral ventricles, total gray matter, and total white matter derived from 329 scans of 95 boys and 66 girls (longitudinal scans acquired at approximately 2-year intervals) across ages 4 to 20 years.

**Figure 5.3** White matter volume changes in the frontal lobes, temporal lobes, parietal lobes, and the midsagittal cross-sectional area of the corpus callosum from 329 scans of 95 boys and 66 girls (longitudinal scans acquired at approximately 2-year intervals) across ages 4 to 20 years.

## White Matter

### Regional Volumes of White Matter

On MRI scans, white matter indicates myelinated axons. Throughout childhood and adolescence the amount of white matter in the brain generally increases (see Fig. 5.2). The white matter increases are roughly linear and the slope of increase is approximately the same in the frontal, temporal, and parietal lobes (Fig. 5.3).

### Corpus Callosum

The corpus callosum is the most prominent white matter structure consisting of approximately 200 million myelinated fibers, most of which connect homologous areas of the left and right cortex. The midsagittal cross-sectional area of the corpus callosum is easily visualized on MRI scans, which along with its clinical interest has made it a frequent target of investigations. The organization of the corpus callosum is roughly topographic with anterior segments containing fibers from the anterior cortical regions, middle

segments containing fibers from the middle cortical regions, and so on. Several studies have indicated that development of the corpus callosum continues to progress throughout adolescence (Allen et al. 1991; Cowell et al. 1992; Pujol et al. 1993; Rauch and Jenkins 1994), and anomalous corpus callosal morphology has been reported in several disorders manifesting in childhood (Bigelow et al. 1983; Giedd et al. 1994; Hynd et al. 1990, 1991; Njiokiktjien 1991; Peterson et al. 1994; Parashos et al. 1995; Rosenthal and Bigelow 1972). Effects of sex have been widely debated with some authors finding gender-related differences (Clarke et al. 1989; Cowell et al. 1992; de Lacoste 1986; Holloway and de Lacoste 1986), while many have not (Bell and Variend 1985; Byne et al. 1988; Oppenheim et al. 1987; Weis et al. 1988, 1989; Witelson 1985a, 1985b). In the NIMH sample, total midsagittal corpus callosum area increased robustly from ages 4 to 18 years, but there were no significant gender effects (see Fig. 5.3).

The functions of the corpus callosum can generally be thought of as integrating the activities of the left and right

cerebral hemispheres and include unifying sensory fields (Berlucchi 1981; Shanks et al. 1975), facilitating memory storage and retrieval (Zaidel and Sperry 1974), allocating attention and arousal (Levy 1985), and enhancing language and auditory functions (Cook 1986). The relationship between improved capacities for these functions during childhood and adolescence and the noted morphologic changes is intriguing. Creativity and intelligence have been linked to efficiency of interhemispheric integration (Bogen and Bogan 1969), and interhemispheric integration becomes more critical as task difficulty increases (Hellige et al. 1979; Levy and Trevarthen 1981).

## Gray Matter

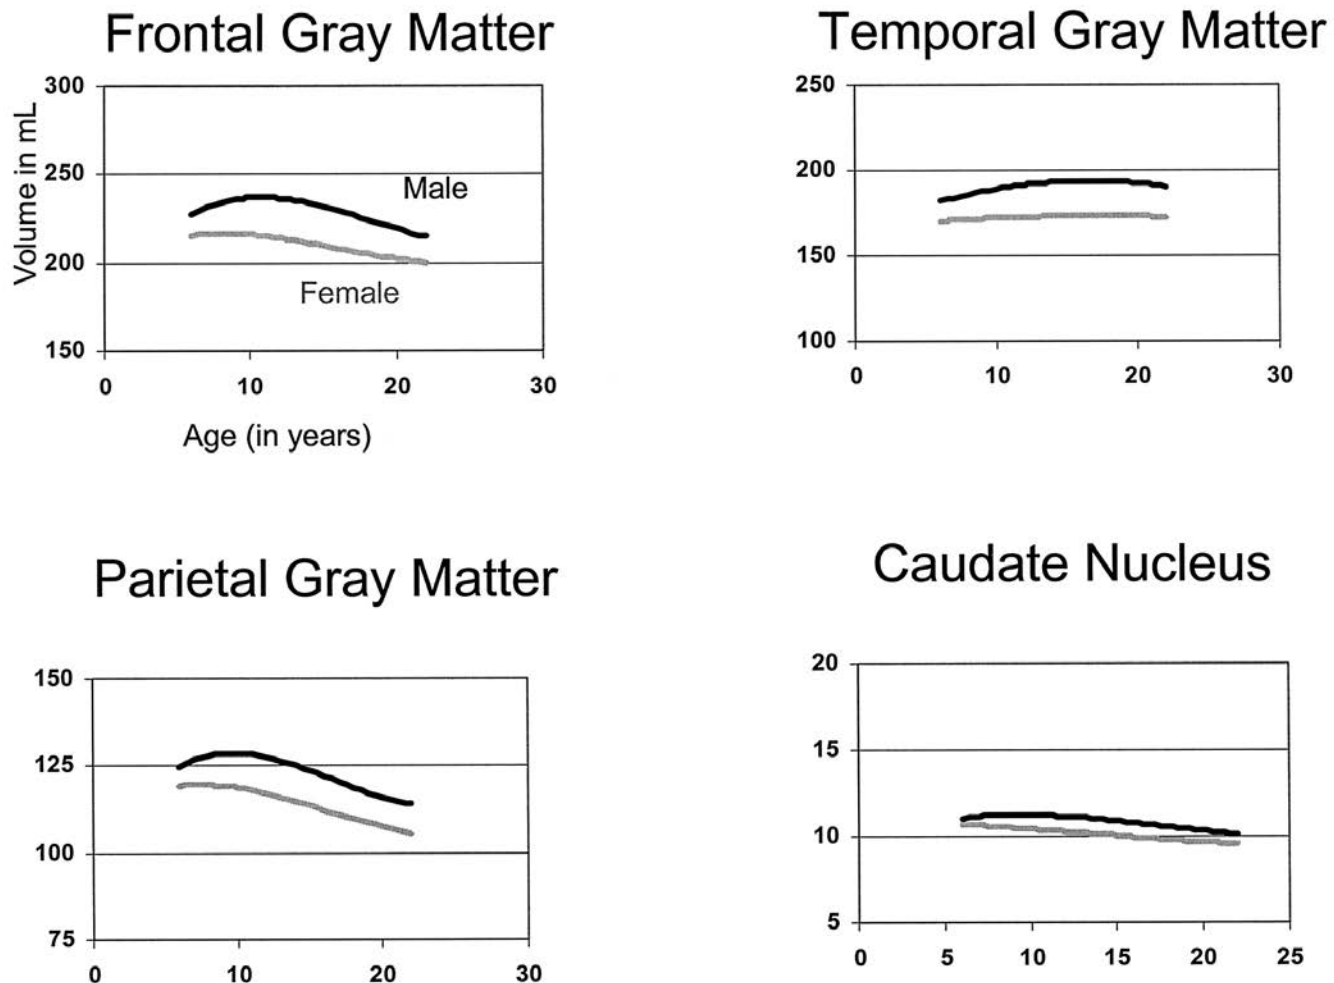

### Cortical Gray Matter

Unlike white matter increases, which tend to be mostly linear, cortical gray matter volume tends to follow an “inverted U” developmental course with different peak volumes in different lobes (Fig. 5.4). For example, frontal

lobe gray matter reaches its maximal thickness at 11 years in girls and 12.1 years in boys. Temporal lobe cortical gray matter peaks at 16.7 years in girls and 16.2 years in boys. Parietal lobe cortical gray matter peaks at 10.2 years in girls and 11.8 years in boys (Giedd et al. 1999).

The thickening and thinning of gray matter is thought to reflect changes in the size and complexity of neurons, not a change in the actual number. The increasing size may reflect a process called arborization as the cells grows extra branches, twigs, and roots, growing bushier and making a greater number of connections to other cells. The decreasing amount of gray matter may reflect the process of pruning where certain connections are eliminated.

The forces guiding these processes of arborization and pruning are not well understood. Genetics, nutrition, toxins, bacteria, viruses, hormones, and many other factors have been shown to have an effect. One hypothesis for the pruning phase is the “use it or lose it” principle in which those connections that are used well survive and flourish, whereas those connections that are not used will wither and die. If

**Figure 5.4** Gray matter volume changes in the frontal lobes, temporal lobes, parietal lobes, and caudate nucleus from 329 scans of 95 boys and 66 girls (longitudinal scans acquired at approximately 2-year intervals) across ages 4 to 20 years.

this hypothesis is correct, the activities of the child or teen may have a powerful influence on the ultimate physical structure of the brain.

To examine cortical gray matter development with greater regional specificity we examined the change in gray matter density on a voxel-by-voxel basis in a group of 13 subjects who had each been scanned four times at approximately 2-year intervals (Gogtay et al. 2004). An animation of these changes is available at [www.loni.ucla.edu/~thompson/DEVEL/dynamic.html](http://www.loni.ucla.edu/~thompson/DEVEL/dynamic.html).

As gray matter volume reaches its maximum at about the time of puberty, a reduction in cortical gray matter volume is interpreted as maturation, in the sense that is becoming closer to the adult state. Cortical gray matter loss occurs earliest in the primary sensorimotor areas and latest in the dorsolateral prefrontal cortex (DLPFC) and superior temporal gyrus. The general pattern is for those regions subserving primary functions, such as motor and sensory systems, to mature earliest and the higher order association areas, which integrate those primary functions to mature later. For instance, in the temporal lobes the latest part to mature is the superior temporal gyrus/sulcus, which serves as a heteromodal association site integrating memory, audiovisual input, and object recognition functions (along with prefrontal and inferior parietal cortices) (Calvert 2001; Martin and Chao 2001; Mesulam 1998).

### Subcortical Gray Matter

#### Basal Ganglia

The basal ganglia consist of the caudate, putamen, globus pallidus, subthalamic nucleus, and substantia nigra. Of these only the first three are readily quantifiable by MRI. In addition to their central role in control of movement and muscle tone, basal ganglia structures are also involved in circuits mediating higher cognitive functions, attention, and affective states.

Caudate volumes decreased significantly from ages 4 to 20 years (see Fig. 5.4). Caudate nucleus volume differences have been reported for several pediatric neuropsychiatric disorders such as ADHD (Castellanos et al. 1996; Giedd et al. 1994; Hynd et al. 1993), early onset schizophrenia (Chakos et al. 1994; Frazier et al. 1996; Keshavan et al. 1994), Sydenham's chorea (Giedd et al. 1995), and Tourette's syndrome (Peterson 1993, 2000; Singer et al. 1993).

#### Amygdala and Hippocampus

The temporal lobes, amygdala, and hippocampus are integral players in the arenas of emotion, language, and memory (Nolte 1993). Human capacity for these functions changes markedly between the ages of 4 and 18 years (Diener et al. 1985; Jerslid 1963; Wechsler 1974), although the relationship between the development of these capacities and morphological changes in the structures subserving these functions is poorly understood.

The amygdala and hippocampus have not been quantified for the longitudinal sample. In a previous report from

a cross-sectional sample subset of the NIMH sample, amygdala volume increased significantly only in males and hippocampal volume increased significantly with age only in females (Giedd et al. 1996). This pattern of gender-specific maturational volumetric changes is consistent with nonhuman primate studies indicating that the amygdala contains high numbers of androgen receptors (Clark et al. 1988) and a smaller number of estrogen receptors (Sholl and Kim 1989), while the hippocampus contains higher amounts of estrogen receptors (Morse et al. 1986).

Influence of estrogen on the hippocampus is further supported by both rodent and human studies. Gonadectomized female rats have lower density of dendritic spines and decreased fiber outgrowth in the hippocampus, which can be alleviated with hormone replacement (Gould et al. 1990; Morse et al. 1986). In humans, women with gonadal hypoplasia have smaller hippocampi (Murphy et al. 1993). A MRI study of 20 young adults also showed proportionately larger hippocampal volumes in females (Filipek et al. 1994).

Further support for these findings is provided by a postmortem study of hippocampal volume in 164 psychiatrically normal individuals, ages newborn to 76 years, which revealed ongoing myelination in the subicular and pre-subicular regions of the hippocampus throughout adolescence and into adulthood (Benes et al. 1994). A sexually dimorphic effect was also noted in this postmortem study, with females showing a greater degree of myelin staining from 6 to 29 years, but with no significant differences thereafter.

## RELATIONSHIP BETWEEN BRAIN STRUCTURE AND BEHAVIOR

Because even the simplest of tasks eventually involves the majority of brain systems, it is not surprising that straightforward relationships between volumes of a single structure and performance on a particular cognitive task are not usually found. The diversity of afferent and efferent connections to the many distinct nuclei of most structures as well as the intricacy of their various neurochemical systems further complicates functional correlates of gross volume size.

Despite this complexity, relationships between memory function and hippocampal size have been noted. For instance, food-storing species of birds have larger hippocampi than related nonfood-storing species (Krebs et al. 1989; Sherry et al. 1989). This relationship has been found in mammals as well, particularly for voles. Male voles of the polygamous species travel far and wide in search of mates. They perform better than their female counterparts on laboratory measures of spatial ability and have significantly larger hippocampi (Sherry et al. 1992). Conversely, in the monogamous vole species, which do not show male-female differences in spatial ability, no sexual dimorphism of hippocampal size is seen (Jacobs et al. 1990). In humans also, correlations between memory for stories and left

hippocampal volume have been noted (Goldberg et al. 1994; Lencz et al. 1992).

A sizable literature has addressed cognitive ability/brain structure relationships in patients with dementia. However, literature regarding healthy subjects has been sparse, and results have been conflicting (Coffey 1994).

## CONCLUSION

Although total cerebral volume approaches adult sizes at a young age (5 to 8 years), developmental changes in various subcomponents of the brain across childhood and adolescence are striking. Indeed, examination of maturational changes in several regions throughout the brain indicates a dynamic balance achieved between growth and regression throughout childhood and adolescence. In particular, changes are noted in basal ganglia structures, the lateral ventricles, the amygdala, and the hippocampus. It is of note that structures undergoing the most robust developmental changes are by and large the same structures implicated in neuropsychiatric disorders of childhood onset (Castellanos et al. 1994; Frazier et al. 1996; Hynd et al. 1990, 1991, 1993; Semrud-Clikeman et al. 1994; Singer et al. 1993).

# Functional Imaging of the Developing Human Brain

6

*Harry T. Chugani, MD   Csaba Juhász, MD PhD*

Functional neuroimaging modalities include primarily positron emission tomography (PET) and single photon emission computed tomography (SPECT). Through PET and SPECT applications, a variety of physiological and biochemical processes in the brain can now be imaged quantitatively and noninvasively. Functional magnetic resonance imaging (fMRI) techniques and applications have become widely used in adults because of their ready availability, although clinical applications in children remain limited. After briefly reviewing some clinically relevant fMRI applications, this chapter discusses the impact of PET and SPECT technologies and findings on pediatric neuropsychiatric disorders and indicates some potential future applications in this rapidly evolving field.

## **FUNCTIONAL MAGNETIC RESONANCE IMAGING**

Functional MRI (fMRI) is a noninvasive technique that is able to map activity of neural networks that underlie various (normal and abnormal) cerebral functions. fMRI is clinically feasible because it can be performed by using a regular 1.5 T clinical MRI scanner. The most commonly used technique is the blood oxygen level-dependent (BOLD) echo planar imaging, which is based on a delayed (few seconds after stimulus onset) change in oxy/deoxy-hemoglobin ratio following regional brain activation. Application of fMRI in children is particularly advantageous since it does not involve

radiation exposure. However, there are important physiologic and anatomic differences between pediatric and adult fMRI studies, affecting the acquisition, analysis, and interpretation of pediatric fMRI data (Gaillard et al. 2001). The main disadvantage of this technique is its sensitivity to motion artifacts. Since most activation tests require patient cooperation, only older, more cooperative children can be studied with fMRI. Sedation of children is not typically used because it interferes with most activation paradigms. For young children or children with cognitive impairment, it is often difficult or impossible to achieve sufficient cooperation to perform a task while limiting motion. Conditioning and personal interactions can improve compliance, and motion reduction techniques can diminish artifacts due to head motion. Application of fMRI is most successful in children of 7 to 8 years of age or older, and normal children at these ages appear to have similar activation maps as adults (Gaillard et al. 2001, 2003).

Functional MRI is increasingly being used to determine language dominance noninvasively, but currently there is no universally accepted clinical indication for fMRI in children (International League Against Epilepsy Commission Report 2000). Language activation fMRI studies can be useful to localize eloquent cortical areas before resective brain (e.g., epilepsy) surgery, and they also provide novel data on development of language dominance in the human brain. Initial studies on children older than 8 years of age demonstrated that normal patterns of verbal fluency are established by this age, but the general extent

of speech-related activation is larger than that in normal adults (Gaillard et al. 2000). Also, while hemispheric language dominance is largely established by 7 to 8 years of age (Lee et al. 1999), the degree of lateralization increases as children approach adulthood (Holland et al. 2001). In addition to language functions, other cognitive functions investigated by fMRI in children have included working memory, spatial memory, reading visual recognition, as well as motor and sensory tasks (reviewed by Gaillard et al. 2001). fMRI was reported to be comparable in accuracy to the carotid Amobarbital (Amytal) test for cerebral lateralization of language functions (Yetkin et al. 1998) and can provide clinically useful localizing information for sensory and motor function. In patients with intractable epilepsy, fMRI alone or combined with other techniques such as transcranial magnetic stimulation can demonstrate reorganization of motor function preoperatively (Macdonell et al. 1999), thus predicting motor outcome following resection. More recently, combination of fMRI and diffusion tensor imaging (DTI)-based tractography has been explored to analyze motor connectivity in vivo (Guye et al. 2003). Another potential clinical application of fMRI can be to localize actively spiking epileptic foci. This, however, is feasible only in patients with frequent seizures or in those in status epilepticus. In patients with motor seizures or impaired cooperation during seizures, movement artifacts preclude meaningful data acquisition, while fMRI signals arising from an area close to air cavities can be poor (Lazeyras et al. 2000). Localization of interictal epileptiform activity using EEG-triggered fMRI is more feasible (Krakow et al. 1999), although resective epilepsy surgery generally cannot purely rely on functional data derived from interictal epileptiform activity.

In summary, fMRI holds the promise of being a safe, powerful clinical tool for noninvasive mapping of various brain functions in older children with intractable epilepsy.

## PET AND SPECT METHODOLOGY

The development of PET technology has allowed the imaging and quantification of local chemical functions in various body organs to be carried out noninvasively in humans (Phelps et al. 1975; Ter-Pogossian et al. 1975; Ter-Pogossian 1995). This technique utilizes detectors that are capable of detecting the paired photons (each with energy of 511 KeV) that travel in opposite directions (coincidence detection) and are released as a result of positron-electron annihilations. Quantification of the biochemical or physiological process being imaged can be achieved with tracer kinetic mathematical models that describe the in vivo behavior of the PET probe, which is labeled with a positron-emitting isotope. In general, the isotopes used in PET have short half-lives (Table 6.1) and are produced onsite with a cyclotron. Use of PET tracers in children has allowed the measurement of local cerebral metabolic rates for glucose

**TABLE 6.1**  
**POSITRON-EMITTING ISOTOPES**

Isotopes	Half-Life (min)	Energy (MeV) <sup>a</sup>
<sup>18</sup> F	109.7	0.6–1
<sup>11</sup> C	20.4	0.96
<sup>13</sup> N	9.9	1.19
<sup>15</sup> O	2.1	1.72
<sup>82</sup> Rb	1.2	3.36

<sup>a</sup>Maximal energy.

utilization, cerebral blood flow, oxygen utilization, protein synthesis, and neurotransmitter function.

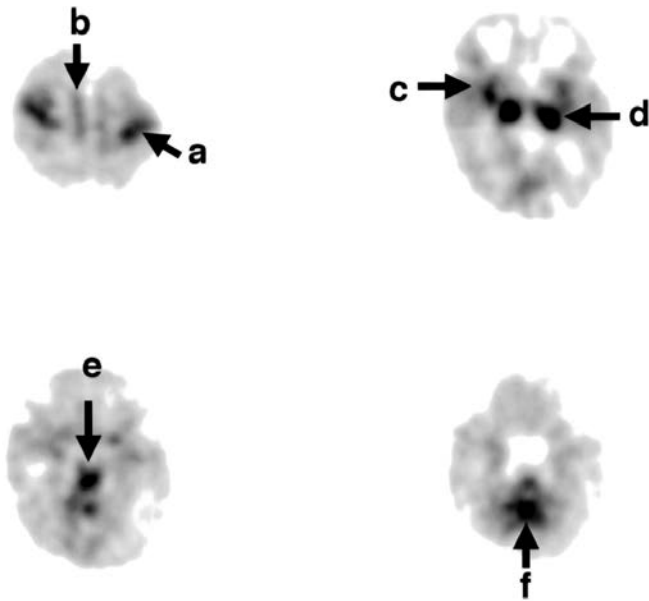

SPECT is also a noninvasive functional imaging technique, but it uses simpler and less expensive equipment than does PET. SPECT provides tomographic imaging through the use of either a single rapidly rotating gamma camera or multiple gamma cameras to detect and reconstruct gamma-ray emissions (Ell et al. 1987). Because of the longer half-life of SPECT isotopes compared with the isotopes used in PET, and the readily available equipment, SPECT is suited for even the smallest hospitals and clinics. The isotopes can be obtained commercially and can be stored onsite. However, the spatial resolution of SPECT images is about half of that achieved with PET, a distinction that is particularly relevant in pediatric studies. Furthermore, SPECT techniques are semiquantitative at best, compared with PET, which is fully quantitative.

In brain studies, SPECT has been used primarily to provide an index of cerebral blood flow. Radioactive probes developed for this purpose have included xenon, iodamines, technetium-99m hexamethyl propylene amine oxime (99mTc-HMPAO), and technetium-99m-ethyl cysteinate dimer (ECD). Scanning of the brain can be initiated at leisure after the brain uptake phase because the trapped agent remains relatively stable for at least 1 hour, and the isotopes used in SPECT have rather long half-lives (e.g., <sup>123</sup>I has a half-life of 13 hours). These properties are particularly favorable for studies in children (Iivanainen et al. 1990).

## NORMAL BRAIN DEVELOPMENT

Developmental studies using PET with the tracer 2-deoxy-2[<sup>18</sup>F]fluoro-d-glucose (FDG) have shown that the pattern of brain glucose utilization in the human infant evolves during the first year of life from a simple neonatal pattern to one that qualitatively resembles an adult pattern. Beyond the first year, the brain continues to manifest metabolic maturational changes that persist well into the second decade of life (Chugani and Phelps 1986, Chugani et al. 1987b).

**Figure 6.1** PET images from a human newborn showing the pattern of brain glucose metabolism. Although there is relatively low glucose metabolism in most of the cerebral and cerebellar cortex, a number of brain regions appear to be metabolically active including (a) sensorimotor cortex, (b) cingulate cortex, (c) striatum, (d) thalamus, (e) brainstem, and (f) cerebellar vermis. The auditory cortex is also relatively active in newborns.

## ONTOGENY OF BRAIN GLUCOSE UTILIZATION

The pattern of glucose utilization in the newborn brain is markedly different from that in the adult brain. In the newborn, glucose metabolic activity is most prominent in primary sensory and motor cortex, thalamus, brainstem, and cerebellar vermis (Chugani 1994; Chugani and Phelps 1986; Chugani et al. 1987b; Kinnala et al. 1996). More recent studies with high-resolution PET scanners have suggested that the cingulate cortex, amygdala, hippocampus,

striatum, and auditory cortex may also show relatively prominent activity in the newborn period (Fig. 6.1) (Chugani 1999). The limited number of brain regions displaying metabolic activity could be related to the relatively limited behavioral repertoire of newborns (Table 6.2). For example, reaching movements in newborns are relatively poor and imprecise (von Hofsten 1982) because of inadequate visual-motor integration. Intrinsic brainstem reflex behaviors, such as the Moro, root, and grasp responses, are present transiently in newborns and are gradually suppressed with further brain maturation (Andre-Thomas and Saint-Anne Dargassies 1960).

Between ages 2 and 4 months, glucose utilization increases in several cortical regions, including parietal, temporal, and primary visual cortex, as well as in the basal ganglia and cerebellar hemispheres (Chugani 1994; Chugani and Phelps 1986; Chugani et al. 1987b; Kinnala et al. 1996). The frontal cortex, however, remains relatively dormant in terms of glucose consumption (Fig. 6.2). Coinciding with these changes in glucose metabolism is the emergence of a number of behaviors, such as improved visual-spatial and visual-sensorimotor integration (Bronson 1974) and the disappearance or reorganization of neonatal brainstem reflex behaviors (Table 6.2) (Andre-Thomas and Saint-Anne Dargassies 1960; Parmelee and Sigman 1983). The cortical maturation is evident also on the electroencephalogram (EEG), which undergoes dramatic changes during this period as a result of increasing cortical influence (Kellaway 1979).

The frontal cortex is the last cortical region to undergo a maturational rise in glucose consumption. Even within the frontal lobe, there is a rank order of metabolic maturation, with the lateral and inferior portions of the frontal cortex becoming active between ages 6 and 8 months (Fig. 6.3), and the dorsal and medial frontal regions showing increased glucose utilization between ages 8 and 12 months (Fig. 6.4). These maturational changes in frontal lobe coincide with the appearance of more cognitively related

**TABLE 6.2**

### RELATIONSHIP BETWEEN LOCAL CEREBRAL GLUCOSE METABOLISM AND BEHAVIORAL LANDMARKS IN THE FIRST YEAR OF LIFE

Age	Glucose Metabolic Pattern	Behavior
≤ 1 month	Active sensorimotor cortical and subcortical regions, midbrain, brainstem, paleocerebellum	Predominantly, subcortical and primitive sensorimotor level of function; intrinsic brainstem reflexes
2–4 months	Increasing glucose metabolic activity in basal ganglia, cerebral cortex (except frontal and association regions), and cerebellar hemispheres	Suppression of intrinsic subcortical reflexes; visual-sensorimotor integration <i>Electroencephalogram</i> : disappearance of neonatal patterns (trace alternans, frontal sharp transients, frontal rhythmic delta); appearance of sleep spindles and precursor of alpha rhythm
8–12 months	Increasing glucose metabolic activity in frontal and association cortices	Cognitive or hypothesis-forming development; stranger anxiety; more meaningful interaction with surroundings

**Figure 6.2** PET images from a 3-month-old infant showing maturational increases of glucose metabolism in (a) parietal cortex, (b) temporal cortex, (c) occipital cortex, (d) striatum, and (e) cerebellar cortex. Note the persistently low metabolic activity in frontal cortex.

behaviors, such as stranger anxiety (Kagan 1972), and improved performance on the delayed response task (Table 6.2) (Goldman-Rakic 1984; Fuster 1997). Neuroanatomic studies have shown that toward the end of the first postnatal year, dendritic fields expand (Schade and van Groenigen 1961) and capillary density increases (Diemer 1968) in the frontal cortex. A pattern of glucose utilization not unlike that seen in adults is present by

approximately 1 year of age (Chugani 1994; Chugani and Phelps 1986; Chugani et al. 1987b), although a few brain structures (e.g., in the thalamus) undergo further maturation as late as beyond 6 years of age (Van Bogaert et al. 1998).

### Glucose Metabolic Rates

Measurement of absolute rates of glucose utilization during development indicates that the brain is far from mature at 1 year of age. The cerebral cortex undergoes a dynamic course of metabolic maturation that persists until ages 16 to 18 years (Chugani 1994; H. T. Chugani 1999; Chugani and Phelps 1986; Chugani et al. 1987b). Initially, there is a rise in the rates of glucose utilization from birth to about age 4 years, at which time the amount of glucose used in the child's cerebral cortex is more than twice that used in the adult's cerebral cortex (Fig. 6.5). From ages 4 to 10 years, these high rates of glucose consumption are maintained, and only after age 10 years is there a gradual decline of glucose metabolic rates, with rates reaching adult values by age 16 to 18 years. Similar changes, but of lesser magnitude, are observed in basal ganglia and thalamus, whereas the brainstem and cerebellum do not show significant changes of glucose metabolic rates over the course of postnatal development.

### Significance of Brain Glucose Metabolic Changes

The important maturational changes just described could be determined only following the development of PET technology. Similar studies using SPECT have confirmed some of the observations described with PET (Chiron et al. 1992; Rubinstein et al. 1989; Tokumaru et al. 1999), but the poor spatial resolution of SPECT precludes its being useful in the study of maturation in small brain regions such as the amygdala and hippocampus.

Functional brain imaging has shown that in the first year of life, the ontogeny of glucose metabolism follows a phylogenetic order, with functional maturation of older anatomic structures preceding that of newer areas. In addition, the ranking of structures in terms of the degree to which maturational increases in glucose metabolic rates exceed adult values follows a phylogenetic order; with the greatest changes observed in cerebral cortex, followed by basal ganglia and thalamus, and, lastly, cerebellum and brainstem. Although a general relationship between the maturational sequence of regional glucose metabolism and the behavioral maturation of the infant has been shown, further studies are required to explore this anatomic-behavioral relationship that forms the basis for the development of complex neuroanatomic networks that mediate human behavior.

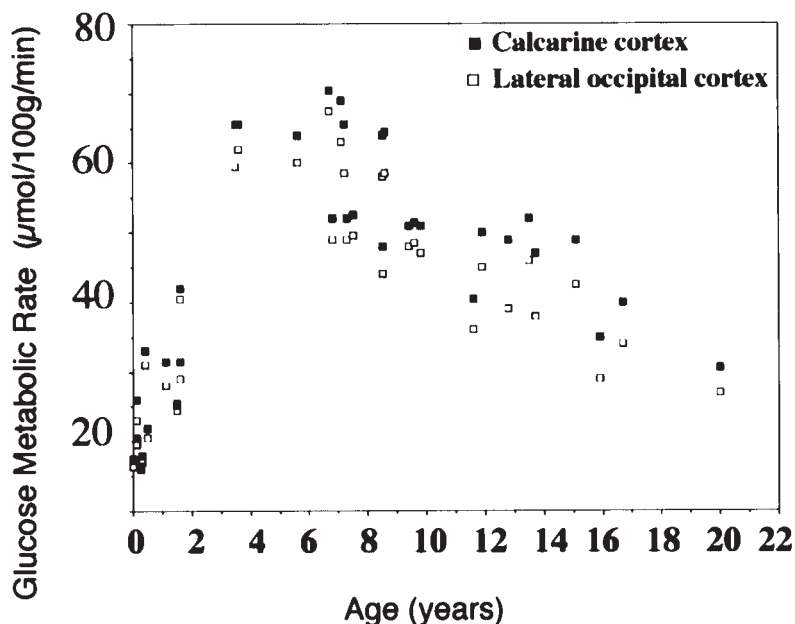

**Figure 6.3** PET images from an 8-month-old infant showing the pattern of brain glucose metabolism. Note that glucose metabolic maturation in lateral frontal cortex (*a*) precedes that in dorsal mesial frontal cortex (*b*).

The dynamic profile of glucose metabolic rates in cerebral cortex as a function of age (Fig. 6.5) matches that of synaptic proliferation and dendritic pruning in the postnatal period. We believe that the ascending portion of the implied curve in Figure 6.5, representing a period of rapid increase in glucose metabolic rates, corresponds to the period of rapid

overproduction of synapses and nerve terminals that is known to occur in the human brain. The “plateau” period, during which glucose metabolic rates exceed adult values, corresponds to the period of increased cerebral energy demand that is a result of transient exuberant connectivity. Finally, the descending portion of the curve, representing the

**Figure 6.4** PET images from a 10-month-old infant showing the pattern of brain glucose metabolism. An adult pattern of glucose metabolism is almost present, except for in the most rostral portion of the mesial prefrontal cortex (*arrow*).

**Figure 6.5** Absolute values of local cerebral glucose metabolic rates (LCMRglc) in cortical (lateral occipital and calcarine) brain regions plotted as a function of age in individual healthy infants and children.

developmental decline in the rates of glucose utilization, corresponds to the period of selective elimination, or “pruning,” of excessive connectivity and marks the time when developmental plasticity markedly diminishes in humans. This interpretation is supported by our studies in the cat (Chugani et al. 1991) and the rhesus monkey (Jacobs et al. 1995). Furthermore, there is an abundance of data to suggest that in humans, developmental brain plasticity begins to decline at about the time of puberty (Awaya 1978; Curtiss 1981; Lenneberg 1967; Newport and Supalla 1990; Schwartz et al. 1987; Vaegan and Taylor 1979).

## EPILEPSY

Both PET and SPECT are used clinically to define epileptogenic brain regions in children with medically refractory epilepsy who are being evaluated for possible surgical treatment. These functional neuroimaging tools are particularly useful in epileptic patients who show no evidence of structural abnormalities on MRI and in whom, therefore, EEG localization is the sole guide for the localization of epileptic foci. With these patients, *interictal* PET with FDG and other tracers is a powerful tool for determining functional disturbances in the cortex associated with epilepsy. When PET is not available, *ictal* SPECT can provide localization of seizure onset. In patients with a single epileptic focus and seizures that are frequent and last at least a minute or so, ictal SPECT may be sufficient. However, when multiple foci, large epileptogenic regions, or brief and infrequent seizures are present, ictal SPECT is of limited value. In addition, interictal SPECT is not nearly as sensitive as PET in delineating epileptogenic zones. Ictal PET, on the other hand, is not practical with these patients, since PET isotopes have a short half-life (e.g.,

108 minutes for  $^{18}\text{F}$  and 20 minutes for  $^{11}\text{C}$ ). The routine use of functional neuroimaging in presurgical evaluation has reduced the necessity for chronic invasive EEG monitoring in many children undergoing epilepsy surgery (reviewed by Zupanc 1997).

## Partial Epilepsy

In patients with refractory temporal lobe epilepsy, interictal FDG-PET scans reveal decreased glucose utilization of the affected temporal lobe in about 85% of cases. These areas of hypometabolism correspond anatomically to pathological and depth-electrode EEG localization of epileptogenicity (Henry et al. 1993). It is important to monitor the EEG during the PET tracer uptake period, since an active focal epileptiform discharge present on the EEG can be associated with local *hypermetabolism*, even on the interictal PET scan. In such instances, the relative hypometabolism on the contralateral (normal) side could be mistakenly interpreted as an interictal epileptic focus; an interpretation that would lead to false lateralization of the focus (Chugani et al. 1993a). Advances in analysis techniques of MRI have eliminated the need for functional imaging or invasive EEG monitoring in the majority of patients with temporal lobe epilepsy. FDG-PET rarely provides additional clinical information when hippocampal atrophy is present on the MRI (Gaillard et al. 1995) and is increasingly reserved for those cases in which the MRI fails to provide the necessary localization.

In seizures of extra-temporal lobe origin, particularly frontal lobe epilepsy, FDG-PET was initially less sensitive in detecting focal areas of abnormal metabolism than in temporal lobe epilepsy. Recently developed high-resolution PET scanners, however, are able to show hypometabolic

**Figure 6.6** PET scan from a 14-year-old girl with uncontrolled seizures and no evidence of focal abnormalities on MRI. Decreased glucose metabolism is clearly seen in the right front cortex (arrows), also extending posteriorly with milder hypometabolism in the parietal region. Intracranial EEG showed right frontal seizure onset.

cortical regions in the majority of children with intractable frontal lobe epilepsy (da Silva et al. 1997a) (Fig. 6.6). A different strategy has been to use PET with various tracers other than FDG. For example, PET studies of the central benzodiazepine receptor with the antagonist  $^{11}\text{C}$ -labeled flumazenil (FMZ) have shown that adult patients with partial epilepsy have significantly reduced binding in the epileptic focus (Savic et al. 1988). Subsequent studies with detailed intracranial EEG comparisons showed that FMZ-PET was more sensitive than FDG-PET in delineating cortex with seizure onset and frequent interictal spiking in children with intractable epilepsy of extratemporal origin (Muzik et al. 2000).

Frontal lobe seizures that begin in the neonatal period or in early infancy typically are associated with an underlying structural lesion detected by MRI. However, when the MRI is normal, PET with FDG almost always shows the area of seizure onset, with the result that early surgical treatment is possible. The area of metabolic abnormality correlates with the extent of microdysgenesis (Chugani et al. 1988), but the extent of decreased FMZ binding appears to be more accurate to delineate the epileptogenic zone to be resected to achieve seizure-free surgical outcome (Juhász et al. 2001a).

*Interictal* SPECT studies are generally less sensitive than ictal SPECT studies in localizing the epileptic focus in children, but have some clinical utility. The typical interictal SPECT scan is either normal or shows one or more areas of decreased perfusion. For example, in one  $^{99\text{m}}\text{Tc}$ -HMPAO-SPECT study of 14 children with frequent seizures (Heiskala et al. 1993), the typical finding in 11 patients with partial secondary generalized seizures was a single hypoperfused area involving the cerebral cortex. The 3 children with Lennox-Gastaut syndrome had multiple areas of hypoperfusion and a worse clinical outcome. In this study, SPECT was more sensitive than EEG, CT, or MRI in detecting abnormalities. Similar sensitivity of interictal SPECT was found in another study of 14 children with intractable temporal lobe epilepsy (Cross et al. 1997).

However, most studies using SPECT interictally have found a sensitivity of no more than 50% (Harvey et al. 1993).

*Ictal* SPECT is more sensitive than interictal studies in detecting the epileptic focus in both temporal lobe and extra-temporal lobe epilepsy. A well-circumscribed area of increased perfusion is the most common finding (Fig. 6.7), and in patients whose ictal EEGs are nonlocalizing, the SPECT localization is particularly useful in surgical planning (Marks et al. 1992). Harvey and coworkers (1993) found that ictal, but not interictal, studies were informative in 14 of 15 children with temporal lobe epilepsy, with ictal SPECT findings corresponding well with ictal EEG, MRI,

**Figure 6.7** Ictal SPECT focus in a 2.5-year-old girl with seizures of left frontal origin. The red area represents the region with highest blood flow increase. Coregistration with high-resolution MRI demonstrated that the focus (arrow) was just in front of the precentral gyrus (CS = central sulcus). Seizure onset on intracranial EEG monitoring colocalized with the SPECT focus. (For color detail, see color insert.)

**Figure 6.8** PET scan of an infant with medically refractory infantile spasms and with normal MRI. The focus of decreased glucose utilization in the left temporal lobe (arrows) corresponded to the interictal and ictal epileptiform activity on the EEG.

and pathology. Even in patients with focal cortical dysplasias seen on the MRI but a nonlocalizing EEG, ictal  $^{99m}\text{Tc}$ -HMPAO-SPECT can prove to be invaluable in providing the necessary localizing data to proceed to surgical resection (Kuzniecky et al. 1993). Sensitivity and spatial accuracy of ictal SPECT findings can be enhanced by using subtraction ictal SPECT coregistered to MRI (SISCOM) (Vera et al. 1999); that is, the interictal SPECT images are subtracted from the ictal images and the results displayed on coregistered MR images. In 40 children with epilepsy, SISCOM showed localized hyperperfusion in agreement with the seizure onset zone in 95% of the cases. Importantly, previously not appreciated MRI abnormalities (such as areas of subtle cortical dysplasia) can be identified in some cases (Chiron et al. 1999b). One study compared the value of ictal SPECT to localize the ictal onset as defined by intracranial EEG in children with epilepsy and found that the area with highest ictal perfusion increase colocalized with the onset area in 12 of 15 children, while it was consistent with early propagation in the remaining 3 (Kaminska et al. 2003). False localization was due to rapid seizure propagation or subclinical seizure onset. In addition, the majority (70%) of children with favorable outcome of resective epilepsy surgery had their SPECT focus colocalized with the resected area.

Some investigators claim that *postictal* SPECT is more sensitive than interictal SPECT in identifying the epileptogenic cortex. Rowe and coworkers (1989) found increased uptake mainly in the anteromesial temporal region in 83% of

patients during the first several minutes after the seizure. The mesial temporal hyperperfusion was often accompanied by hypoperfusion in the lateral temporal cortex and other areas of the ipsilateral cortex corresponding to both degree and extent of postictal slow-wave activity on the EEG. This postictal hypoperfusion can last up to 20 minutes. The unilateral seizure focus was localized correctly in 31 of 45 patients as a result of postictal SPECT (Rowe et al. 1991). Studies have demonstrated that postictal SPECT localization of epileptic foci can also be improved by subtraction of interictal studies, and then coregistering with MRI (O'Brien et al. 1999).

### Infantile Spasms

Infantile spasms are seizures that typically have their onset at between 3 and 8 months of age and are characterized by brief jerks of the neck, trunk, or extremities resulting in flexion, extension, or a combination of the two. Depending on whether an underlying condition has been identified or not, the spasms are classified as *symptomatic* or *cryptogenic*. A third group, the *idiopathic* group, is distinctly rare and is characterized by rapid response to treatment, benign course, and favorable outcome (Dulac and Plouin 1994).

Glucose metabolism PET studies in children with intractable cryptogenic infantile spasms have shown unifocal (Fig. 6.8) and, more commonly, multifocal (Fig. 6.9) cortical areas of hypometabolism interictally. Less commonly, increased focal glucose utilization can be seen if the study is performed ictally or in the presence of an actively

**Figure 6.9** PET images from an infant with medically refractory infantile spasms showing multifocal cortical hypometabolism (arrows). Although MRI showed normal results, PET showed foci of decreased glucose utilization in the left frontal and in the right parietal cortex as well as in the right temporal region.

discharging focus on the EEG. The EEG localization of focal ictal or interictal abnormalities corresponds well to the PET focus in most cases (Chugani et al. 1990, 1993b). However, when hypsarrhythmia is present on the EEG, focal electrographic abnormalities either preceding or following the presence of hypsarrhythmia correlate best with the location of PET cortical abnormalities. When available, therefore, EEGs performed before the onset of spasms must be reexamined in conjunction with the PET study.

The discovery of these focal cortical metabolic abnormalities on PET has allowed some infants with refractory spasms to be treated with cortical resection. Thus, when a single region of abnormal glucose metabolism is present, and there is good correlation between the region localized with PET and the focus identified on the EEG, surgical removal of the epileptogenic region results not only in seizure control but also in complete or partial reversal of the associated developmental delay. Neuropathological examination of the resected tissue typically reveals cortical dysplasia (Chugani et al. 1990, 1993b; Vinters et al. 1992).

Unfortunately, about 65% of infants with cryptogenic infantile spasms show more than one area of cortical hypometabolism on the PET scan (Chugani and Conti 1996) and are therefore not ideal candidates for cortical resection (Fig. 6.9). Within this group is a subgroup of infants with bilateral temporal hypometabolism and a typical clinical phenotype, comprising about 10% of all infants with cryptogenic infantile spasms. The clinical features include severe developmental delay (particularly in the language domain) and autism (Chugani et al. 1996).

The high sensitivity of PET in detecting focal cortical abnormalities allows most infants diagnosed with cryptogenic infantile spasms to have their spasms reclassified into the “symptomatic” category. In a study of 140 infants with infantile spasms, 97 had infantile spasms that were initially classified as cryptogenic before the application of PET in evaluation of etiology (Chugani and Conti 1996). With PET, unifocal cortical metabolic abnormalities were uncovered in 30 and multifocal abnormalities in 62 of these infants. Whereas these findings were confirmed to represent cortical dysplasia in many of the infants with unifocal abnormalities, because the infants underwent cortical resection (Chugani et al. 1990, 1993b), pathological studies were not available for the infants with multifocal abnormalities. It is likely that these lesions represent cortical dysplasia or ischemic insults. Importantly, only 5 of the 97 infants in this study continued to be classified as having cryptogenic infantile spasms after the benefit of a PET study. It is now recommended that all infants with intractable cryptogenic infantile spasms undergo an evaluation with PET. In some cases, PET reveals bilateral symmetric or generalized cortical (with or without associated cerebellar) hypometabolism (Fig. 6.10). This pattern suggests an underlying genetic/metabolic condition, rather than cortical dysplasia, and strongly discourages pursuing of presurgical evaluation but may prompt more detailed metabolic and genetic studies.

**Figure 6.10** Generalized cortical hypometabolism in a 6-month-old child with infantile spasms. Note the prominent basal ganglia and cerebellar vermis (arrow) as a result of diffuse cortical cerebral and cerebellar hypometabolism. In such cases, a genetic or metabolic condition can be suspected and presurgical evaluation is typically not pursued.

Another important finding with PET in patients with infantile spasms is evidence of complex cortical-subcortical interactions believed to be important in the secondary generalization of focal cortical discharges to result in the infantile spasms. PET studies have shown that, regardless of the type or extent of cortical abnormality, prominent glucose metabolism in lenticular nuclei and brainstem is a common feature in infantile spasms (Chugani et al. 1992). It is postulated that the infantile spasms result primarily from focal or diffuse cortical abnormalities interacting with brainstem and lenticular nuclei and that this type of generalization accounts for the bilateral motor involvement and relative symmetry of the majority of infantile spasms even in the presence of a discrete focal lesion (Chugani et al. 1992; reviewed in Juhasz et al. 2001b).

Investigators using SPECT technology have also found focal areas of cortical hypoperfusion in patients with infantile spasms (Dulac et al. 1987). Furthermore, one study found that the mean cerebral blood flow decreased just after corticosteroid treatment (Chiron et al. 1993). Correlation of focal hypoperfusion with behavior of the infants showed that parietal-occipital SPECT foci are often associated with visual inattention at the time when the infants present with infantile spasms and with long-term cognitive compromise (Jambaque et al. 1993). Both visual inattention and cognitive delay have been reversed with successful focal cortical resection. In a study of 40 children with West syndrome, localized cortical perfusion abnormalities were seen in 24 patients (60%), supporting that focal cortical lesions play an important role in the development of West syndrome (Haginoya et al. 2000). However, the existence of cortical dysfunction as defined by SPECT did not seem to predict seizure prognosis or developmental outcome in that study.

### Other Epilepsy Syndromes

Both PET and SPECT have been used in the study of various other epilepsy syndromes occurring in infants and children. *Lennox-Gastaut syndrome* in children has diverse etiologies

but manifests three common features: a slow spike-wave pattern (1 to 2.5 Hz) on the EEG, some degree of intellectual impairment, and the presence of multiple seizure types, including tonic seizures (Blume et al. 1973). Studies with FDG-PET have provided a new classification of Lennox-Gastaut syndrome based on metabolic anatomy. Four metabolic subtypes have been identified: (1) unilateral focal, (2) unilateral diffuse, (3) bilateral diffuse hypometabolism, and (4) normal patterns (Chugani et al. 1987a; Iinuma et al. 1987; Theodore et al. 1987). These glucose metabolic patterns can be useful in determining the type of surgical intervention indicated for those patients with uncontrolled seizures. Surprisingly, there were no differences in glucose metabolic rates between PET studies performed during continuous slow spike-wave activity and studies in which there was minimal epileptiform activity on the EEG (Chugani et al. 1987a).

*Sturge-Weber syndrome* is a sporadic neurocutaneous syndrome characterized by facial capillary nevus (port-wine stain) in the distribution of one or more divisions of the fifth cranial nerve and ipsilateral leptomeningeal angiomas. Neurological consequences include intracerebral calcification, epilepsy, hemiparesis, hemianopia, and glaucoma (reviewed in Sujansky and Conradi 1995). In children with Sturge-Weber syndrome, FDG-PET typically reveals hypometabolism ipsilateral to the facial nevus and thus allows the degree and extent of hemispheric involvement to be determined (Chugani and Dietrich 1992; Chugani et al. 1989). In addition, the rate of hemispheric deterioration can be determined by quantifying the degree of hypometabolism in sequential PET studies. PET has been useful both in guiding the extent of focal cortical resection (i.e., correlating better with intraoperative electrocorticography than CT or MRI) and in assessing candidacy for early hemispherectomy in patients with Sturge-Weber syndrome. Paradoxically, children with mild but extensive glucose hypometabolism (confined to one hemisphere) often have worse cognitive outcome than children with early and

severe unilateral hypometabolism (Lee et al. 2001); this finding suggests that early and rapid demise of the affected hemisphere could be beneficial in allowing unaffected areas to take over lost functions. In contrast, when the affected areas show slow deterioration, seizures tend to persist and plasticity is not optimal; such patients should be good candidates for resective surgery in our efforts to prevent cognitive decline. Interestingly, an unusual pattern of ipsilateral hypermetabolism (Fig. 6.11) can be seen instead of hypometabolism in young infants with Sturge-Weber syndrome studied in the interictal state (Chugani et al. 1989). The cause of this transient increased glucose utilization is yet to be clarified. SPECT studies demonstrated presence of regional hyperperfusion even before the occurrence of clinical seizures (Pinton et al. 1997). After 1 year of age, the pattern of hypoperfusion is typically seen on SPECT; and this corresponds topographically to the CT scan abnormality in Sturge-Weber syndrome (Chiron et al. 1989).

*Hemimegalencephaly* is a brain malformation characterized by congenital hypertrophy of one cerebral hemisphere with ipsilateral ventriculomegaly. The larger hemisphere is the more abnormal one and is highly epileptogenic, often requiring hemispherectomy for alleviation of the seizures (Vigevano et al. 1989). PET scanning of glucose metabolism in infants and children with hemimegalencephaly reveals the expected, severe interictal hypometabolism of the affected hemisphere and, more important, allows the functional integrity of the better hemisphere to be evaluated. In a study of eight children with hemimegalencephaly, seven of whom underwent hemispherectomy, a general correlation was found between the degree of metabolic involvement of the less-affected hemisphere and overall prognosis (Rintahaka et al. 1993). Another study, using SPECT in two children with hemimegalencephaly, showed a similar pattern of decreased perfusion in the malformed hemisphere (Konkol et al. 1990), despite the patients having very different EEG findings.

**Figure 6.11** Interictal glucose metabolism PET scan from a 2-month-old infant with seizures and Sturge-Weber syndrome. The left facial port-wine stain, left-sided epileptogenicity on the EEG, right hemiparesis, and subsequent development of left cerebral calcifications were all consistent with an abnormal left cerebral hemisphere. However, note the increased interictal glucose metabolism (arrows) in left frontal, parietal and superior temporal cortex, which is in contrast to the right hemisphere, in which there is a normal pattern of glucose metabolism for age (cf. Figure 6.1).

*Tuberous sclerosis complex* (TSC) is a neurocutaneous disorder, characterized by tumor growths that involve multiple organs, including brain, retina, kidney, heart, and skin. It is inherited as an autosomal dominant trait with a high degree of penetrance and a high spontaneous mutation rate. Approximately 70 to 90% of patients with TSC have seizures, which are attributed to the presence of brain cortical malformations, which typically are evident as areas of cortical hypometabolism on interictal FDG-PET. These hypometabolic areas often extend beyond the structural lesions visible on MRI. However, FDG-PET is not able to identify which of the multiple tubers are epileptogenic and, therefore, is not useful to guide surgical resection in TSC patients with medically intractable seizures. A relatively new PET tracer,  $\alpha$ -[ $^{11}\text{C}$ ]methyl-L-tryptophan (AMT) has proven to be helpful in this respect. AMT, which has been developed as a tracer for serotonin synthesis with PET (Diksic et al. 1990), is an analogue of tryptophan, the precursor for serotonin biosynthesis. The properties of AMT make it a suitable tracer substance for the PET measurement of serotonin biosynthesis in vivo in humans (Chugani et al. 1998b; Muzik et al. 1997) (see Autism on page 121). Alternatively, increased AMT uptake can occur due to activation of the alternative kynurenine pathway, producing important neurotoxic and convulsant metabolites, such as quinolinic acid (reviewed by Stone 2001).

AMT PET can identify a single tuber or a small subset of epileptogenic tubers with increased uptake in approximately two thirds of the cases, while nonepileptogenic tubers show decreased AMT uptake (Asano et al. 2000; Chugani et al. 1998a; Fedi et al. 2003) (Fig. 6.12). Thus, AMT PET is a powerful imaging tool to guide intracranial electrode placement for resective epilepsy surgery in children with TSC. More recent studies have also shown AMT PET to be a promising imaging method to localize epileptic foci in children with extratemporal epilepsy not associated with TSC. In such cases, AMT PET can identify epileptogenic cortex as an area of increased uptake even if FDG-PET and MRI show ambiguous results, and appears to be most sensitive in epilepsies associated with malformations of cortical development (Juhasz et al. 2003). Increased cortical AMT uptake can also identify nonresected epileptic cortex after failed resective epilepsy surgery (Juhasz et al. 2004) (Fig. 6.13).

## DISORDERS OF COGNITIVE DEVELOPMENT

Structural neuroimaging with CT and MRI has been of limited value in the evaluation of children with cognitive disorders. For example, anatomic abnormalities are rarely evident with CT or MRI in children with learning disabilities (such as developmental dyslexia). Yet, most learning disabilities are believed to be neurobiologically based (Filipek 1995; Pennington 1995; Weinberg et al. 1995). Furthermore, the

**Figure 6.12**  $\alpha$ -[ $^{11}\text{C}$ ]Methyl-L-tryptophan (AMT) PET identifies an epileptogenic tuber by showing increased uptake in a child with tuberous sclerosis and intractable epilepsy. Out of the three tubers (1. right frontal; 2. left frontal; 3. left parietal) shown on this plane, only the right frontal one showed increased AMT uptake, while the other two had decreased uptake. Ictal EEG confirmed that the right frontal region was epileptogenic.

various types of learning disorder probably have their abnormal function in different brain regions and circuits, and functional neuroimaging could be suitable in detecting these neuroanatomic substrates. With this strategy in mind, Zametkin and colleagues (1990) evaluated adults with

**Figure 6.13**  $\alpha$ -[ $^{11}\text{C}$ ]Methyl-L-tryptophan (AMT) PET can identify nonresected epileptic regions following a failed cortical resection in some patients. This 8-year-old boy had undergone a left superior frontal, parietal, and temporal resection but continued to have seizures. AMT PET showed an area of increased uptake in the left inferior frontal cortex (arrow), which was corroborated as a residual seizure focus by ictal intracranial EEG.

childhood-onset hyperactivity using FDG-PET and found about 8% reduction of global cerebral glucose metabolic rates in the patients compared with control subjects, with the largest degree of reduction in premotor and superior prefrontal cortical regions bilaterally. These studies suggested that functional neuroimaging with PET and SPECT could be powerful tools for the evaluation of various disorders of cognitive development, including the learning disabilities.

When performed in the resting state, PET and SPECT studies indicate brain regions of abnormal function. In contrast, when obtained during the performance of a specific task by the subject, a PET scan of  $^{15}\text{O}$ -labeled water will show patterns of cerebral blood flow that indicate the circuits activated by the task and whether they are functioning abnormally (Posner and Raichle 1994). The advantage of PET activation studies, compared with SPECT activation studies, is that the half-life of  $^{15}\text{O}$  is about 2 minutes, allowing multiple tasks to be performed within a session. In contrast, SPECT allows only a single activation paradigm to be studied. Task activation of neuronal circuits can also be achieved with echoplanar MRI technique (functional MRI, discussed earlier). Since absolute cooperation of the subject is required in activation studies, these methods are generally not suitable in young children.

### Developmental Dyslexia

Both resting FDG-PET studies and PET/SPECT activation studies have been performed in patients with developmental dyslexia. Resting FDG-PET studies in dyslexic subjects have revealed several patterns of abnormal glucose metabolism, including bilateral hypometabolism of temporal and parietal cortex (Fig. 6.14), bilateral temporal hypometabolism, and unilateral left temporal hypometabolism (Chugani, un-

published data). These findings are in agreement with neuropsychological data indicating heterogeneity in patients with developmental dyslexia. Activation studies with SPECT in adults who were dyslexic as children have demonstrated deficient Wernicke's area activation and excessive temporoparietal activation during a spelling task, findings that suggest a trait anomaly of the left hemisphere (Flowers et al. 1991). Subsequent PET studies using  $^{15}\text{O}$ -labeled water in dyslexic adults showed a failure to activate the left temporoparietal cortex during a rhyme detection task, and reduced activation/unusual deactivation in mid- and posterior temporal cortex bilaterally and in inferior parietal cortex, predominantly on the left side, during both pronunciation and decision making (Rumsey et al. 1992, 1997). More recent PET studies have also revealed abnormal cerebellar activation (Nicolson et al. 1999) and functional disconnection of the left angular gyrus from other parts of the reading network in adults with persistent developmental dyslexia (Horwitz et al. 1998). Subsequent fMRI studies support the notion that impaired activation of key regions for language perception and auditory attention in dyslexic subjects could account for persistent deficits in phonological awareness and reading tasks (Ruff et al. 2003).

### Developmental Dysphasia

Two groups of children with developmental language disabilities (expressive dysphasia and expressive-receptive dysphasia) and a group of children with attention-deficit/hyperactivity disorder (ADHD) were evaluated with SPECT in the resting condition, during the performance of a simple auditory task, and during performance of an auditory phonemic discrimination task. Unlike the expressive and ADHD groups, the expressive-receptive group showed

**Figure 6.14** PET images from an adolescent boy with developmental dyslexia showing cerebral glucose metabolism. Note the bilateral parietal cortex hypometabolism (arrows). The MR images did not show any abnormalities.

an absence of left-hemispheric activation during the phonemic discrimination task. In addition, neither of the two language disability groups showed the left inferior parietal activation seen in the children with ADHD (Tzourio et al. 1994). A subsequent study added to these findings by demonstrating a lack of increase of rCBF in the left hemisphere (in Broca's area) but increased rCBF in the right hemisphere (in the region homologous to Broca's area) during a dichotic listening task given to boys with expressive dysphasia (Chiron et al. 1999a). The resting physiological asymmetry was reversed in favor of the right hemisphere in all areas except Broca's area. These findings illustrate how functional imaging can demonstrate abnormal lateralization and localization of language functions in the brain.

### Learning Disability in Turner's Syndrome

Turner's syndrome is one of the most common of the human chromosomal aneuploidies, with an incidence of about 1 in 2,500 live female births. Both the severity and the type of cognitive impairment are highly variable among individuals with Turner's syndrome and cannot easily be accounted for by genotypic differences associated with chromosomal karyotype. The cognitive impairments often involve visuospatial and mathematical difficulties. Structural neuroimaging with MRI and CT scanning, and even neuropathological studies, have failed to identify any consistent abnormality to account for the cognitive difficulties in Turner's syndrome. On the other hand, PET investigations have shown a consistent pattern of bilateral occipital and parietal hypometabolism in adults with Turner's syndrome (Clark et al. 1990). A study of children with Turner's syndrome showed similar results, with the additional findings of temporal lobe hypometabolism in some subjects and a general correlation between the neuropsychological profile and the metabolic pattern (Elliott et al. 1996). This has been confirmed by subsequent quantitative PET studies of cerebral glucose metabolism, which have also revealed, in addition to focal hypometabolism in associative cortical areas, a generalized cerebral hypermetabolism in patients with Turner's syndrome, probably reflecting abnormal neuronal packing (Murphy et al. 1997). These studies suggest that the X chromosome is likely to be involved in development of cortical association areas in the brain.

### Autism

Functional neuroimaging has been used in attempts to identify the neuroanatomic substrates involved in autism. In one study, elevated glucose metabolic rates were found in multiple brain regions of 10 autistic adults, but there was considerable overlap with control subjects, and no common regional abnormality could be identified in the autistic subjects (Rumsey et al. 1985). Further analysis of these data using correlation coefficients, a method that allows the strength of functional association between brain regions to

be measured, revealed abnormal correlations between frontal and parietal regions and between the neostriatum and thalamus (Horwitz et al. 1988). In a study involving 18 autistic children, neither the rates nor the regional distribution of brain glucose metabolism was different from that in control subjects (De Volder et al. 1987). Similarly, Siegel et al. (1992) compared autistic adults and normal controls mixed for gender and found no difference in global cerebral glucose metabolism. In another study involving autistic children, some of whom had seizures and other coexisting conditions, MRI revealed evidence of neuronal migration anomalies in 3 of 13 children, and PET showed evidence of abnormalities in 5; however, no common or uniform abnormality could be demonstrated (Schifter et al. 1994). In contrast, Haznedar et al. (1997) performed MRI and glucose PET scans on high-functioning autistic patients and reported that the right anterior cingulate was significantly smaller in relative volume and was metabolically less active in the autistic patients compared to the normal subjects. The data from SPECT studies on autism have also been hard to interpret. One study found global hypoperfusion as well as hypoperfusion in the right lateral temporal lobe and right, left, and midfrontal lobes in four autistic adults compared with control subjects (George et al. 1992). Another study found no regional perfusion abnormalities in 21 autistic children evaluated with SPECT (Zilbovicius et al. 1992). In a subsequent longitudinal study, the same group studied five autistic children (three males, two females) at the age of 3 to 4 years and again 3 years later, in comparison to two age-matched groups of nonautistic children (five children ages 3 to 4 years and seven children aged 6 to 12 years) with normal development (Zilbovicius et al. 1995). The investigators reported frontal hypoperfusion in the autistic children at ages 3 to 4 years, but not at the ages of 6 to 7 years, suggesting a delayed frontal maturation in childhood autism. Another SPECT study showed hypoperfusion in the temporoparietal region in six autistic patients between 9 and 21 years of age, but further clinical information on these subjects was not provided (Mountz et al. 1995).

Studies investigating alterations in neurotransmitters, hormones, and their metabolites in the blood, cerebrospinal fluid (CSF), and urine of autistic patients have provided some evidence for the potential involvement of several neurotransmitters in autism (for review, see Anderson 1994). Furthermore, given that there is evidence for dysfunction in widely distributed brain regions in autism, the monoamine neurotransmitters are interesting candidates to be examined due to their widespread modulatory role in the brain. To this purpose, functional imaging has been used to examine in autism the role of two monoamine transmitters, dopamine (Ernst et al. 1997) and serotonin (Chugani et al. 1997, 1999).

Ernst et al. (1997) studied 14 medication-free autistic children with [<sup>18</sup>F]-labeled fluorodopa (F-DOPA) using PET. F-DOPA is a precursor of dopamine, which is taken up, metabolized, and stored by dopaminergic terminals.

These authors reported a 39% reduction of the dopaminergic activity in the anterior medial prefrontal cortex in the autistic group, but no significant differences in any of the other regions measured. It was therefore suggested that decreased dopaminergic function in prefrontal cortex could contribute to the cognitive impairment seen in autism.

Although there is evidence for the potential involvement of several other neurotransmitters in autism, the most consistent findings involve serotonin. Pharmacological treatments that decrease serotonergic neurotransmission, such as tryptophan depletion, have been reported to result in an exacerbation of symptoms in autistic subjects (McDougle et al. 1996b). Conversely, administration of serotonin reuptake inhibitors appears to result in improvement of compulsive symptoms, repetitive movements, and social difficulties in autistic adults (Cook et al. 1992; Gordon et al. 1993; McDougle et al. 1996a).

Chugani et al. (1997) used AMT PET scanning (see also the earlier section on tuberous sclerosis) to study healthy, seizure-free children with autism (seven males and one female, ages 4 to 11 years) and their healthy nonautistic siblings (four males and one female, ages 8 to 14 years). Gross asymmetries of AMT standard uptake value (SUV) in frontal cortex, thalamus, and cerebellum were visualized in seven autistic boys (Fig. 6.15), but not in the one autistic girl studied or in four of the five siblings. Decreased AMT accumulation was seen in the left frontal cortex and thalamus in five of seven autistic boys. This was accompanied by an elevated AMT accumulation in the right cerebellum, in the region of the cerebellar dentate nucleus. In the remaining two autistic boys, AMT accumulation was decreased in the *right* frontal cortex and thalamus and elevated in the left dentate nucleus. The overall difference in asymmetry scores between the autistic boys and their siblings was found to be statistically significant, and regional asymmetry scores in the frontal cortex and thalamus were also found to differ significantly. The specificity of these abnormalities to serotonin synthesis was apparent when comparing the AMT scans to the FDG-PET and MRI scans, both of which were normal. Chugani et al. (1999) also measured whole brain serotonin synthesis capacity in autistic and nonautistic children at different ages using AMT and PET. Global brain values for serotonin synthesis capacity were obtained for 30 healthy, seizure-free autistic children (24 males and 6 females, ages 2 to 15 years),

eight of their healthy nonautistic siblings (six males and two females, ages 2 to 14 years), and 16 epileptic children without autism (nine males and seven females, ages 3 months to 13 years). For nonautistic children, serotonin synthesis capacity was greater than 200% of adult values until the age of about 5 years and then declined toward adult values. Serotonin synthesis capacity values declined at an earlier age in girls than in boys. In autistic children, serotonin synthesis capacity increased between the ages of 2 years and 15 years to values 1.5 times of the adult normal values and showed no gender difference. The data indicated a period of high brain serotonin synthesis capacity during childhood, and that this developmental process is disrupted in autistic children.

### Landau-Kleffner Syndrome (Acquired Epileptic Aphasia)

Landau-Kleffner syndrome, or acquired epileptic aphasia, is characterized by progressive language loss after the acquisition of normal language function. The associated epilepsy is usually relatively mild (Landau and Kleffner 1957). During slow-wave sleep, continuous spike-and-wave discharges can be seen in some patients, but the presence of this electroencephalographic pattern is not required to make the diagnosis. Typically, the CT and MRI scans in Landau-Kleffner syndrome are normal. An FDG-PET study performed during sleep in three children with Landau-Kleffner syndrome showed metabolic disturbances consisting of hypermetabolism or hypometabolism in the temporal lobes and were right-sided, left-sided, or bilateral (Maquet et al. 1990). In children with Landau-Kleffner syndrome and continuous spike-and-wave discharges during sleep, PET scans have shown bilaterally increased temporal lobe glucose metabolism in the sleep state compared with the awake state, suggesting that the temporal lobes could be involved in the generation of continuous spike-and-wave discharges during slow-wave sleep (Rintahaka et al. 1995). The role of temporal lobe dysfunction in the pathophysiology of this condition has been also supported by a subsequent FDG-PET study of 17 children with Landau-Kleffner syndrome, demonstrating bilateral temporal lobe hypometabolism in 15 of them, although several other cortical regions also displayed hypometabolism in a subset of the patients (da Silva et al. 1997b).

**Figure 6.15** Focal abnormalities of tryptophan metabolism in an autistic boy, demonstrated by  $\alpha$ -[ $^{11}\text{C}$ ]methyl-L-tryptophan (AMT) PET. The figure shows a typical pattern of decreased AMT uptake in the left frontal cortex and thalamus, and an increased uptake in the cerebellum, in the region of the dentate nucleus (arrows).

**Figure 6.16** FDG-PET scan of a 6.5-year-old child who was adopted from an Eastern European orphanage. Note the severe hypometabolism in the region of hippocampus and amygdala bilaterally (arrows). An objective group analysis using SPM revealed further hypometabolic areas in the orbital frontal and infralimbic prefrontal cortex, the lateral temporal cortex, and the brainstem (Chugani et al. 2001).

### Children With Early Severe Socioemotional Deprivation

Previous studies conducted in orphans adopted from Eastern European orphanages have found a variety of physical, cognitive, and social disturbances in such children (Ames 1997; Rutter 1998). The behavioral abnormalities reported in these children are similar to those seen in early socially deprived nonhuman primates (Suomi 1997). The impact of early social deprivation on human brain function has been studied recently using functional neuroimaging. In one study, FDG-PET scans in 10 postinstitutionalized Romanian orphans (ages 7.1 to 11.3 years) revealed decreases of brain glucose metabolism in mostly limbic structures, including the medial temporal region (amygdala and head of hippocampus), orbital frontal and infralimbic prefrontal cortex, the lateral temporal cortex, and the brainstem (Chugani et al. 2001) (Fig. 6.16). These brain regions form networks that have been shown to be activated by stress and damaged with prolonged stress (Lopez et al. 1999). Findings from these imaging studies suggest that the chronic stress endured by children from severe socioemotional deprivation during infancy can result in altered development of limbic structures and that altered functional connections in these circuits could represent the mechanism underlying persistent behavioral disturbances. Although preliminary, such functional neuroimaging studies provide an unprecedented opportunity to further understand the biological basis of early social deprivation and could prove useful to monitor therapeutic attempts in the future.

### PERINATAL HYPOXIC-ISCHEMIC BRAIN INJURY

The earliest PET studies performed in the pediatric population involved newborns with perinatal asphyxia. These studies provided a new perspective on the mechanisms of neonatal brain injury and established the feasibility of PET studies on sick neonates.

In preterm infants with intraventricular hemorrhage, FDG-PET studies found that the area of metabolic abnormality (hypometabolism) extended beyond the regions that had been noted to be anatomically abnormal with CT (Doyle et al. 1983). Subsequently, measurements of local cerebral blood flow with PET in preterm infants with intraventricular and intracerebral hemorrhage demonstrated that in addition to a paucity of cerebral blood flow in the area of hemorrhagic involvement, there was markedly reduced blood flow throughout the affected cerebral hemisphere (Volpe et al. 1983). It therefore appeared that in these premature infants, intracerebral hemorrhage was but one manifestation of a large ischemic infarct. In *full-term* asphyxiated neonates, PET showed that the most consistent abnormality of cerebral blood flow was a relative hypoperfusion to the parasagittal regions of the brain (Volpe et al. 1985). In a further study, the same investigators found that cerebral blood flow rates of less than 10 ml/100 g/minute in newborns are compatible with normal neurological development (Altman et al. 1988). A subsequent study of children suspected of having hypoxic-ischemic brain injury found that children who were developing normally had the expected maturational increases of brain glucose uptake, whereas children who were developing abnormally tended to show persistently low glucose metabolism (Suhonen-Polvi et al. 1993). Similar observations have been made with SPECT, which showed hypoperfusion of all parts of the brain except the basal ganglia, brainstem, and sensorimotor cortex in neurologically affected infants (Konishi et al. 1994). A correlational study of PET findings with neurological outcome in term infants with hypoxic-ischemic encephalopathy found that total cerebral glucose metabolism rates measured during the first 3 weeks after birth was predictive of neurological sequelae, which were still present at 2 years of age (Thorngren-Jerneck et al. 2001).

### Spastic Diplegia

Spastic diplegia is the typical motor manifestation in children with static encephalopathy associated with premature birth. The expected neuropathology, referred to

**Figure 6.17** PET images from a 4-year-old child with spastic diplegic cerebral palsy associated with premature birth who was evaluated for delayed language skills. MRI revealed irregular contour to the walls of the lateral ventricles and high signal intensity in the periventricular white matter but no abnormalities in the cortex. PET revealed moderate hypometabolism in the left parietal and temporal cortex (large arrows). In addition, there may be mild thalamic hypometabolism bilaterally (small arrows).

as *periventricular leukomalacia*, in these children is readily identified on MRI scanning and represents ischemic lesions in the watershed region peculiar to the premature infant (Volpe 1995). These lesions are limited to white matter tracts dorsal and lateral to the lateral ventricles, seen most frequently near the foramen of Monro and the occipital horn. Cognitive difficulties are common in children with spastic diplegia, with an incidence of up to 20 to 40% in some follow-up studies of low-birth-weight infants (Blennow et al. 1986; Lefebvre et al. 1988). These cognitive problems are poorly predicted by MRI studies (e.g., Feldman et al. 1990). Functional neuroimaging studies in children with spastic diplegia associated with premature birth have demonstrated focal areas of SPECT hypoperfusion (Denays et al. 1989) or PET hypometabolism (Kerrigan et al. 1991) in the parietal-occipital cortex adjacent to ultrasound or CT/MRI lesions representing periventricular leukomalacia. These findings suggest that the hypoperfusion and hypometabolism are the result of disrupted white matter tracts to and from the cortex (Fig. 6.17). Focal cortical volume loss was subsequently demonstrated in these children using MRI volumetry (Inder et al. 1999), thus confirming the functional neuroimaging studies. The clinical significance (and possible predictive value) of these focal cortical functional lesions with respect to the cognitive difficulties so frequently encountered in these children is currently being examined.

### Choreoathetoid/Dystonic Form of Cerebral Palsy

In the full-term infant who has suffered from perinatal asphyxia, a static encephalopathy associated with chorea, athetosis, or dystonia can be seen. The neuropathological correlate of this disorder is usually gliosis and dysmyelina-

tion of the thalamus and basal ganglia, particularly the striatum (Volpe 1995). FDG-PET studies in a number of such children have shown either absent or markedly depressed glucose metabolism in the thalamus and lenticular nuclei, with relative sparing of the caudate nucleus (Kerrigan et al. 1991). The cerebral cortex is also relatively spared (Fig. 6.18), a finding that is consistent with the clinical observation that most of these children have relative preservation of cognitive function compared with their severe motor impairment. FDG-PET can be used in this group of children to evaluate their cognitive potential as a guide to early intervention.

## CEREBROVASCULAR DISEASE

Functional neuroimaging is often helpful in the study of pediatric cerebrovascular disease, providing an assessment of the extent of functional involvement, which generally involves an area exceeding in size the anatomically affected area. In a series of 15 infants and children presenting with cerebrovascular disorders, SPECT showed focal hypoperfusion in all patients, with three patients also being shown to have adjacent hyperemia. Interestingly, two of the patients showed no abnormalities on repeated CT scans (Shahar et al. 1990). In patients with sickle cell disease, PET studies have shown increased regional cerebral blood flow and blood volume, but no differences in oxygen extraction or consumption, compared with control subjects (Herold et al. 1986). A subsequent FDG-PET study of 49 children with sickle cell disease showed abnormalities in glucose metabolism that were much more extensive and often bilateral when MRI abnormalities were lacking or subtle (Powars et al. 1999). PET was particularly sensitive in detecting focal abnormalities in children with no overt

**Figure 6.18** PET images showing glucose utilization and MR images from a 10-year-old girl with choreoathetoid cerebral palsy associated with abruptio placentae and birth asphyxia at term. The MR images show increased T2 signal intensity in the periventricular white matter, thalamus, and lenticular nuclei. The PET images show bilateral hypometabolism in the thalamus and lenticular nuclei (*arrow*); the cerebral cortex is relatively normal except for hypometabolism in the right parietotemporal region (*arrowheads*).

neurological symptoms. Thus, PET can be a sensitive and objective clinical tool to monitor response to therapeutic interventions in children with sickle cell anemia.

## MOVEMENT DISORDERS

Most of the functional neuroimaging studies performed in this category have been on adults with disorders such as parkinsonism, Huntington's disease, and dystonia. For these

and other dyskinesias in adults, PET studies using  $^{18}\text{F}$ -labeled 6-fluorodopa to measure presynaptic dopaminergic function have been particularly useful (see, e.g., Turjanski et al. 1993). But use of PET with FDG or other PET ligands—for example, [ $^{11}\text{C}$ ]raclopride, which labels the dopamine  $\text{D}_2$  receptors (Brooks et al. 1992), and [ $^{11}\text{C}$ ]l-deprenyl, which labels monoamine oxidase B (Fowler et al. 1993)—has also provided useful information. Only a few studies have been performed in children, and these also have yielded interesting findings.

**Figure 6.19** PET images from a 16-year-old girl with Huntington's disease showing glucose metabolism. Note the absence of metabolic activity in the caudate and lenticular nuclei. The thalami appear normal (arrows).

### Huntington's Disease in Children

Abnormal basal ganglia metabolism is seen in children with juvenile Huntington's disease, in whom the caudate and lenticular nuclei show markedly decreased glucose utilization (Fig. 6.19) (De Volder et al. 1988a). This finding is interesting because it is similar to what is found in adult Huntington's disease (Kuhl et al. 1982), yet the clinical presentations are quite different between the two forms. The juvenile form is characterized by intellectual decline, rigidity, seizures, and behavioral difficulties, whereas the adult form has as major manifestations chorea and dementia. Another study, however, found that the metabolic pattern in a child with juvenile Huntington's disease consisted of hypometabolism in the posterior nuclei of the thalamus (Matthews et al. 1989), a pattern that has not been seen in the adult form of the disease.

### Tourette's Syndrome

In the few children with Tourette's syndrome who have been studied with FDG-PET, no consistent abnormalities have been found. However, a perfusion SPECT study reported subcortical asymmetries in Tourette's syndrome patients due to reduced right basal ganglia perfusion (Klieger 1997). Several studies evaluated various aspects of dopaminergic transmission, since it is believed that disturbances in the dopaminergic system contribute to the pathophysiology of Tourette's syndrome. Such studies reported elevated striatal dopamine transporter levels (Krause et al. 2002) and also abnormal presynaptic DOPA decarboxylase activity (Ernst et al. 1999). Another study also demonstrated increased dopamine release in the striatum of Tourette's syndrome patients (Singer et al. 2002). Preliminary imaging data using AMT PET (discussed previously) appear to support the role of abnormal serotonergic neurotransmission in the pathophysiology of Tourette's syndrome and some of

its comorbid conditions, such as ADHD and obsessive-compulsive disorder (Ho et al. 2003).

## NEURODEGENERATIVE DISORDERS

Some neurodegenerative disorders of childhood are characterized by relatively specific findings on CT or MRI scanning. For example, in Hallervorden-Spatz disease, a disorder of abnormal iron metabolism in brain, the MRI shows hypointense areas in the basal ganglia and substantia nigra (see Rouault 2001 for review). However, structural neuroimaging in many childhood neurodegenerative disorders reveals nonspecific abnormalities such as progressive cerebral atrophy and is of limited value in these cases. In such disorders, imaging of glucose metabolism or a variety of biochemical processes with PET or SPECT can provide more specific findings and yield important insight into the pathophysiology of these disorders.

### Mitochondrial Encephalopathies

The combined use of PET and magnetic resonance spectroscopy (MRS) can be useful in the evaluation of children with disorders involving mitochondrial function. In one such study, FDG-PET in children with defects of oxidative phosphorylation and lactic acidosis showed a massive increase in glycolysis, believed to be a result of compensatory efforts to meet energy requirements of the brain. Elevated lactate in the brain was confirmed with MRS. An increase in glycolysis was not seen in children with normal respiratory chain activity and lactic acidosis due to stress and exercise (Duncan et al. 1995). An earlier study on subjects with mitochondrial diseases evaluated both oxygen and glucose utilization with PET and found that patients with brain disease in addition to muscle disease had a lower ratio of oxygen-to-glucose consumption in the brain, a finding

**Figure 6.20** PET images from two children with Spielmeyer-Vogt disease showing cerebral glucose metabolism. **(A)** Early in the course, there is hypometabolism in the occipital cortex (*thick arrows*); as the disease progresses, hypometabolism is seen in other posterior cortical regions and may be asymmetric, as shown in the images from this child, with occipital, right parietal, and posterior temporal cortex hypometabolism (*thin arrows*). **(B)** Diffuse and severe cortical hypometabolism is seen in the late stages of the disease. Note the relative preservation of glucose metabolism in the basal ganglia, thalamus, brainstem, and mesial temporal structures.

which suggests that there is aerobic glycolysis to lactate and possibly other intermediate metabolites (Frackowiak et al. 1988). Elevated brain lactate level is indeed an important diagnostic finding in mitochondrial diseases and, since it can indicate functional involvement irrespective of structural MRI abnormalities, MRS can be a useful complementary tool to monitor disease progression or treatment efficacy (Castillo et al. 1995; Pavlakis et al. 1998). SPECT has also been used to evaluate children with mitochondrial disorders. SPECT is less useful than PET in this context but does show focal areas of decreased perfusion believed to be related to stroke events (Fujii et al. 1995).

### Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses are a group of autosomal recessive diseases that are characterized, in general, by seizures, developmental regression, and progressive visual impairment. The juvenile form (CLN-3) is also known as Spielmeyer-Vogt (or Batten) disease. FDG-PET studies in children with Spielmeyer-Vogt disease evaluated early in the course of the disease have revealed decreased glucose

metabolism in the calcarine cortex (Philippart et al. 1994) (Fig. 6.20). In contrast, late infantile neuronal ceroid lipofuscinosis (CLN-2; Jansky-Bielschowsky disease, with curvilinear inclusions) is characterized by rapid degeneration with generalized cortical and subcortical hypometabolism (Philippart et al. 1997). As the juvenile form of the disease progresses, a rostral spread of glucose hypometabolism to other cortical areas is observed. We have not seen this pattern of abnormality in any other childhood or adult neurodegenerative processes, and, therefore, PET may be of diagnostic value in Spielmeyer-Vogt disease. In addition, the rate of disease progression can be monitored with PET.

### RETT SYNDROME

The few studies that have been performed with PET in children with Rett syndrome have shown conflicting results. One study found reduced rates of oxygen metabolism and oxygen extraction fraction, particularly in frontal cortex (Yoshikawa et al. 1991), but another study found slightly increased glucose metabolism in frontal cortex and

hypometabolism in occipital cortex (Naidu et al. 1988). In addition, PET with [<sup>18</sup>F]-6-fluorodopa and [<sup>11</sup>C]-raclopride have been used to study dopaminergic function in young patients with Rett syndrome (Dunn et al. 2002). MRI scans of these patients showed significant volume reductions of the basal ganglia (caudate heads and thalami), which was corroborated by reduced fluorodopa uptake in the caudate and putamen. In contrast, dopamine D<sub>2</sub> receptor binding was increased significantly by almost 10% in both of these structures, suggesting a mild presynaptic deficit of nigrostriatal activity in Rett syndrome.

### Canavan's Disease

Canavan's disease is an autosomal recessive hereditary leukodystrophy due to deficiency of the enzyme aspartoacylase, which is the primary enzyme involved in the catabolic metabolism of N-acetylaspartate (NAA). Structural imaging studies typically show severe nonspecific white matter abnormalities compatible with demyelination. Proton MRS studies can be useful to support the presumed diagnosis of Canavan's disease by showing increased levels of NAA as compared to choline and creatine in the affected brain regions (Wittsack et al. 1996).

### Subacute Sclerosing Panencephalitis

In a single child with the rapidly progressive form of subacute sclerosing panencephalitis (SSPE), the absolute rates of glucose metabolism were markedly decreased in cortical gray matter structures but normal in caudate and lenticular nuclei. In contrast, cerebral glucose metabolic rates were normal in another child who appeared to have slow progression of the disease (Yanai et al. 1987). There is one study suggesting that abnormal patterns of cerebral glucose metabolism can return to normal in patients with SSPE following treatment with human interferon beta. A case was reported in which the patient prior to such treatment was shown to have symmetric hypometabolism in the thalamus, cerebellum, and cortex (except primary motor region) and hypermetabolism in the lenticular nuclei. After treatment, which was associated with some clinical improvement, glucose metabolic rates returned to normal in the cerebral cortex. However, the bilateral focal necrosis present in the putamen as shown on CT and MRI scans indicated disease progression. Persistent hypermetabolism was evident in the caudate and in the spared superoposterior portion of the putamen (Huber et al. 1989). The findings from this study are somewhat difficult to interpret, but further studies have not been performed.

### Alternating Hemiplegia of Childhood

Between attacks, FDG-PET studies in patients with alternating hemiplegia have shown normal findings (Mikati and Fischman 1995). However, an 11-year-old boy with

alternating hemiplegia studied with C<sup>15</sup>O<sub>2</sub> and PET during an acute episode of right hemiplegia was found to have slightly increased perfusion in the insula, putamen, and claustrum in the left hemisphere (Tada et al. 1989). Although this finding has been interpreted as suggesting a vascular etiology, this is not necessarily the explanation, because cerebral blood flow is tightly coupled to cerebral metabolism, and, therefore, intrinsic neuronal perturbations could also result in blood flow alterations. A more recent PET study of cerebral tryptophan metabolism in children with alternating hemiplegia performed during or shortly after an attack showed increased serotonin synthesis capacity in the frontoparietal cortex, lateral and medial temporal structures, striatum, and thalamus when compared to controls, and subjects with alternating hemiplegia studied interictally. In addition, larger estimated lifetime attack numbers were associated with delay in communication and daily living skills. These studies suggest that attacks in alternating hemiplegia are associated with increased regional serotonergic activity, and that frequent attacks can have an effect on neurodevelopment, thus supporting the notion that alternating hemiplegia of childhood can be a progressive disorder (Pfund et al. 2002).

### Other Childhood Neurodegenerative Disorders

Glutaricaciduria type I (Ozand and Gascon 1991a, 1991b) is an autosomal recessive disorder in the oxidative pathway of lysine, hydroxylysine, and tryptophan that is caused by a defect of the enzyme glutaryl-CoA dehydrogenase. The clinical presentation of individuals with this disorder is heterogeneous, with intermittent metabolic acidosis or extrapyramidal signs. FDG-PET shows a dramatic pattern of absent metabolic activity in the striatum bilaterally and diffuse cortical hypometabolism (Fig. 6.21). These findings suggest that although the brain is diffusely affected in this metabolic disorder, the striatum is particularly vulnerable to damage (Awaad et al. 1996).

In another inborn error of metabolism, adenylosuccinase deficiency, in which there is a deficiency in the synthesis of purine nucleotides, psychomotor retardation with autism is a prominent clinical feature (Jaeken and Van den Berghe 1984). PET scanning in this disorder has shown a consistent pattern of markedly diminished glucose metabolism in all gray matter structures except the cerebellum. The hypometabolism was most pronounced in the frontal lobes (De Volder et al. 1988b). The typical pattern of glucose metabolism on FDG-PET in patients with Wilson's disease is hypometabolism of the lenticular nuclei (Hawkins et al. 1987). When patients with Wilson's disease have been studied with PET and [<sup>11</sup>C]raclopride, reduced uptake is seen in the striatum; after treatment with d-penicillamine, [<sup>11</sup>C]raclopride uptake shows improvement, and this suggests that the defect in striatal neurons is reversible (Schwarz et al. 1994). Wilson's disease is an

**Figure 6.21** PET images from a 3-year-old boy with glutaric aciduria type I. Note the virtual absence of glucose metabolism in the basal ganglia and the open opercula (arrows) with severe frontotemporal atrophy.

example of a disorder in which the effectiveness of therapy can be monitored with PET, which provides unique information not otherwise obtainable.

## CONCLUSION

This chapter has shown how functional neuroimaging with PET, SPECT, proton MRS, and fMRI modalities continue to emerge as important tools in the diagnosis, monitoring, and eventual treatment of a variety of neuropsychiatric disorders in infants and children. In some cases, such as infantile spasms, functional imaging has led directly to new treatment options previously not considered. In other instances, properly selected functional imaging methods can provide specific diagnostic markers (such as increased NAA on proton MRS in Canavan's disease). In most cases, anatomic and functional neuroimaging provide complementary data and should be carefully used together for optimum management. Studies over the past few years have provided several examples of how application of new PET and SPECT tracers have gained clinical importance (e.g., those for imaging benzodiazepine and dopamine receptors, or serotonergic neurotransmission). With both SPECT and PET, the synthesis of even newer tracers designed to evaluate various biochemical processes in the brain is proceeding at a rapid pace. These tracers are being applied to pediatric neuropsychiatric disorders to yield a wealth of new and specific information related to pathophysiology and therapeutic guidance. Imaging specific biochemical functions can also lead to identification of various patterns of abnormal brain function. This subclassification allows more accurate genotyping in future genetic studies aimed to clarify the genetic background of pediatric neuropsychiatric disorders.

The electroencephalogram (EEG) and event-related potentials (ERPs) are two brain imaging methodologies that provide functional information about the developing brain. Both EEG and ERPs represent electrical activity recorded from the scalp, with the assumption that the origin of these electrical signals is in the brain itself. Although once thought to be the product of action potentials, there now is general agreement among researchers that the scalp signal is the summation of postsynaptic potentials (Nelson & Monk, 2001). The EEG signal is spontaneous but context-related, with the signal generated during quiet rest being different from that generated during mental activity. The ERP signal is event specific, with onset aligned to a temporarily locked event. This means that both the EEG and ERP signals have temporal resolution on the order of milliseconds. Thus, postsynaptic changes immediately are reflected in the EEG and ERP, making these methodologies outstanding for tracking rapid shifts in brain functioning. Furthermore, these brain electrical signals are robust and the techniques by which they are obtained are somewhat easy, noninvasive, and relatively inexpensive. These characteristics make the EEG and ERP methods some of the more favorable ones for studying brain development in infants and children and for relating brain development to changes in behavior (Casey & de Hann, 2002; de Haan & Thomas, 2002; Taylor & Baldeweg, 2002).

In this chapter we highlight the value of EEG/ERP for the study of typical and atypical brain/behavior relations in

infancy and childhood. We begin with an overview of the basic methodology associated with EEG and ERP techniques. Next, we describe research studies that have used the EEG in examining individual differences in social and emotional behaviors. The focus of this section is on studies examining behavioral inhibition or extreme shyness. In the final section, we describe studies that have been conducted using ERPs to measure the neural correlates of cognitive and social behavior in typically developing and atypical populations. Our review in this section focuses on studies of face processing, one method that has proven especially useful in studies of development.

## **ELECTROENCEPHALOGRAPH (EEG) AND EVENT-RELATED POTENTIALS (ERP) METHODOLOGY**

---

The EEG and ERP signals represent the electrical potential between two scalp electrodes. In reality, however, researchers utilize multiple electrodes in EEG/ERP studies. For ease and speed in application with pediatric populations, electrodes are available in configurations that contain multiple electrodes. Typically, one of two methods is used for electrode application. A Lycra stretch cap that can be custom made to different head sizes and number of electrodes is available for use with infants and children as well as adults (Fig. 7.1). After the EEG cap is placed on the head, recommended procedures regarding EEG data collection

**Figure 7.1** Infant wearing EEG/ERP electrodes.

with infants and young children should be followed (EEG: Pivik et al., 1993; ERP: Picton et al., 2000). Specifically, a small amount of abrasive gel is placed into each electrode-recording site and the scalp gently rubbed. This prepares the scalp by gently removing any dry skin that may interfere with EEG recordings. Following this, conductive gel is placed in each site.

A second method of electrode application is the geodesic net system (Electrical Geodesics, Inc.; Tucker, 1993). This system provides a large number of electrodes that are distributed evenly across the scalp. This system of electrode placement has the advantage of being very easy to apply even to young infants. In addition, the geodesic system uses high-impedance amplifiers that do not require scalp abrasion to improve the connection between electrode and scalp. The use of these amplifiers is somewhat controversial, although studies are beginning to emerge that show similar findings between this system and the Lycra cap system (Johnson et al., 2001).

A standard set of electrode placements referred to as the International 10–20 system has been used by most researchers (Jasper, 1958). For a number of reasons, the validity of this electrode application has been challenged over the years. Of greatest relevance for this summary are problems with application of the 10–20 system to infants and young children. The Jasper system relies for placement of electrodes on a ratio of distances between anterior and posterior sites. It is unclear whether this same ratio exists across development or whether different regions of the brain mature at different rates, leading to differences in the relation between anterior and posterior growth. However, several researchers have examined this problem, primarily through autopsy (Blume, Buza, & Okazaki, 1974) and radiograph (Hellstrom, Karlsson, &

Mussbichler, 1963), and have found that the 10–20 system does an adequate job in defining placement of electrodes across key cortical regions. However electrodes are distributed across the scalp, it is important to note that electrical activity is volume conducted at different rates through different materials (e.g., scalp, meninges, brain, cerebrospinal fluid). Thus, the scalp distribution of electrical activity only provides an approximation of the location of the source of the activity. High-density recordings likely increase the accuracy of these estimates; however, electrophysiological methods remain significantly less accurate for estimating the location of activity as they do the time course of that activity.

### EEG Data Reduction and Measures

The methods for recording “clinical” EEG and “quantitative” EEG are identical. Clinical EEG records are analog tracings that focus on the time domain. These clinical EEG records are inspected by visual analysis and yield valuable information regarding neuropathology in infants and children, as well as gestational age/maturation level of premature infants. Quantitative EEG is a digital record that is converted from the time domain to the frequency domain using fast Fourier transform. This is accomplished to assess mathematical changes in brain electrical activity and corresponding psychological functions. Quantitative techniques can also be used to assess developmental changes in the EEG during infancy and childhood. This chapter focuses on quantitative EEG.

Theoretically, the EEG signal is composed of multiple sine waves cycling at different frequencies. The Fourier transform decomposes the EEG into these different sine waves and estimates the spectral power (in mean square

microvolts) at each frequency. The result is information regarding the contribution of each individual frequency to the entire EEG spectrum at a particular electrode site. Power is thought to reflect the excitability of groups of neurons. Increasing power values across age are considered indicative of brain development (Bell, 1998; Marshall, Bar-Haim, & Fox, 2002). The power data are normalized because EEG power data are usually positively skewed. The most common normalization for EEG data is the natural log (Davidson, Jackson, & Larson, 2000).

Power values are usually totaled across frequency bins to form measures of power in a specific frequency band. *Alpha* activity, so named by Berger (1929) because it was the first EEG rhythm he discussed, cycles at 8 to 13 Hz and is the predominant frequency band for adults. Activation of brain areas underlying specific scalp electrodes is assumed when alpha power values at those electrode sites are lower during stimulus processing than they were during resting baseline (Bell & Fox, 2003; Davidson, Chapman, Chapman, & Henriques, 1990). Similarly, activation of brain areas underlying specific electrodes also is assumed when alpha power values at those electrode sites are lower during rest than are alpha power values at corresponding electrodes sites on the opposite hemisphere (Davidson et al., 2000).

Interest in the normal developmental course of the EEG began with Berger's (Berger, 1932) report of EEG differences among infants, young children, and adults. This work immediately generated longitudinal studies of EEG development during infancy and childhood (Henry, 1944; Lindsley, 1939; Smith, 1938a, 1938b). These pioneering re-

searchers used visual inspection of EEG records to describe the appearance of a 3–5 Hz rhythm over the occipital area at 3 months of age that increased to a frequency of 6 to 7 Hz by 12 months of age. More recently, researchers have noted, based on these earlier studies, that by the second half of the first year of life the majority of infant EEG activity can be found in the 3 to 12 Hz band (Fox & Davidson, 1987, 1988). Furthermore, there appears to be a peak in EEG activity at 6 to 9 Hz during this same time period (Bell, 1998; Johnson et al., 2001; Molfese, 1989; Molfese, Wetzel, & Gill, 1993; Sato, Kochiyama, Yoshikawa, & Matsumura, 2001). This period of rapid EEG development during the first year of life continues into early childhood and is then followed by a more gradual change in EEG. In longitudinal studies of EEG development during childhood, frequencies of 9 to 10 Hz at occipital locations have been reported by 8 years of age (Bell, 1998; Lindsley, 1939; Smith, 1938b; see Bell, 1998, for a detailed review of the ontogeny of EEG during infancy and childhood). Thus, the pediatric EEG signal has different frequency, as well as amplitude, characteristics relative to the adult EEG signal (Fig. 7.2). Researchers must take care to examine frequency components that are appropriate for infant and child populations.

### ERP Data Reduction and Measures

As with EEG, ERP data are scored for artifact before data analysis is conducted. Some ERP data-collection programs include algorithms for detecting data that include eyeblinks, motor artifact, and environmental noise. Other researchers choose to manually inspect data, as is frequently

**Figure 7.2** Comparison of infant (top) and adult (bottom) EEG tracings. Note the differences in frequency and amplitude. Eyeblinks (arrows) are labeled in each tracing.

done in EEG recording. Regardless of which method is used, researchers should inspect averaged data from each individual subject for artifact.

After artifact detection, data from the raw EEG recording are averaged over some number of trials that are defined by the onset of some temporally-locked event (e.g., the presentation of a stimulus). In this way, the background EEG is removed over trials, and ERP components emerge. Several components are usually observed in developmental ERP research. A complete review of the components elicited in most ERP studies is beyond the scope of this chapter. We describe the components typically elicited and analyzed in visual ERP paradigms used with children, as this is the type of study we describe in a later section of the chapter. The reader should be aware that a number of other components are elicited in studies using auditory stimuli and in studies conducted with adults (see Fig. 7.3).

Visual ERP studies conducted with infant and child populations typically elicit characteristic ERP components. Characteristic ERP patterns seen in visual ERP studies with infants are shown in Figure 7.4. Among the first of these to be identified and the one that seems to be most pervasive in the developmental literature is the Nc component. This component was first identified by Courchesne (Courchesne, 1978; Courchesne, Ganz, & Norcia, 1981). The Nc component is a middle latency (peaking at about 500 msec after stimulus presentation) negative component. The scalp distribution of the Nc was first described as involving

frontal and central midline electrodes. Since the development of high-density recording methods, it has become clear that the Nc is broadly distributed over the frontal scalp. The Nc is thought to be related to the infant's attentional response to a salient stimulus (Courchesne, 1978; Courchesne et al., 1981; de Haan & Nelson, 1997, 1999; Nelson, 1994; Nelson & Collins, 1991). The more salient the infant finds the stimulus, the larger the amplitude of the Nc that is elicited. Thus, if an infant sees a novel object, and has a novelty preference, the amplitude of the Nc will be larger than that elicited by a familiar stimulus. However, if the familiar stimulus is highly salient (e.g., a picture of the infant's mother), the Nc can be larger to the familiar stimulus. In addition, early in development, the Nc can respond to the frequency with which a familiar stimulus is presented, so that the Nc is larger to a infrequently presented familiar stimulus than to a more frequently presented familiar stimulus (Nelson & Collins, 1990, 1991). The Nc component is typically elicited in young children and can be seen until at least 7 years of age (Courchesne, 1978). It is not typically seen in adults.

Other ERP components elicited in many developmental studies are also seen in adults. Early components thought to reflect sensory processing are elicited over occipital scalp locations and are similar in morphology to early sensory components seen in adults (Courchesne, 1978). These components are typically labeled in relation to their polarity and peak latency (e.g., P250) or by their polarity and

**Figure 7.3** Adult ERP waveform recorded at a posterior electrode site in a target/nontarget paradigm. The top arrow indicates the P300, which is larger in response to the target stimulus. The second arrow indicates the early sensory component, N200.

(a)

(b)

**Figure 7.4** Infant ERP waveforms at frontal (a, Fz) and posterior (b, O1) electrodes. The arrows indicate the Nc component (in [a]), the P500 component (positive peak in [b]), and the early sensory component N200 (in [b]). The Nc and P500 components are larger to a highly salient stimulus (in this case, a negative facial expression).

ordinal position (e.g., the second negative component would be referred to as N2). A large amplitude positive component (P500) has been observed over occipital scalp locations. This component has been described primarily in studies of face recognition, although it has also been elicited in studies of object recognition. The function of this component is not entirely clear; however, it appears to have some face-specific response characteristics, making it a potential candidate for a precursor to the face-specific component observed in adults (de Haan, Pascalis, & Johnson, 2002). Finally, slow-wave activity (activity that does not resolve in a clear peak) has been observed in studies of memory (Nelson & Collins, 1990, 1991). This slow-wave activity occurs late in the recording epoch, and its polarity may be related to memory updating, novelty detection, or recognition.

A final component that is important for the discussion of face processing is the N170. This is an early component that peaks over posterior parietal electrode sites and is sensitive to aspects of face processing (Bentin, Allison, Puce, Perez, & McCarthy, 1996). The N170 is larger in response to faces than other classes of stimuli and is sensitive to the orientation in which faces are displayed. The N170 is larger in amplitude and slower in latency for inverted faces than for upright faces. It is not clear whether the N170 can be identified in developmental studies. De Haan and colleagues (de Haan et al., 2002) suggested that early developmental precursors to the N170 are apparent in the P400 and the negative peak that immediately precedes it.

Typical dependent measures in ERP studies include the peak amplitude of the component and its latency, as well as the area underneath the curve formed by the component, and the average amplitude of the component. Principle components analysis (PCA) and independent components analysis (ICA) have also been used in some studies in attempts to isolate multiple underlying neural sources that could contribute to activity recorded at the scalp (Grice et al., 2001).

In ERP studies, the stimuli typically belong to two or several categories or conditions and are analyzed across these conditions, leads (i.e., activity at different electrode sites), and any grouping variables. Data from clinical populations are typically compared to that from a control group, although the choice of control group needs to be made with great care. For example, in studies of children with developmental delay, controls might typically be matched on mental age. However, there are significant maturational changes in children that could preclude the choice of a much younger control group. In such cases, it is often helpful to test a group of children who have developmental delay of a different etiology and thus are matched on both maturation and level of cognitive functioning.

### Limitations of EEG/ERP

EEG and ERP are among the more favorable brain imaging methods for use with infants and children; however,

these methodologies have some drawbacks. Although the EEG and ERP signals have outstanding temporal resolution, they have poor spatial resolution. There are at least three reasons for this shortcoming (Davidson et al., 2000). First, even with multiple electrodes, there are gaps between electrodes on the scalp. This prohibits a complete electrical mapping of the scalp. Second, the skull behaves like a low-pass filter and distorts the underlying brain electrical activity over a large area of the scalp. Finally, scalp potentials are likely generated by multiple groupings of cortical and subcortical generators spread across a relative wide area. Thus, an electrode is likely detecting electrical activity generated from nonlocal groups of neurons.

The accuracy of algorithms devised to localize electrical activity in the brain from scalp surface recordings is a source of debate (Dien, Spencer, & Donchin, 2003; Mosher, Leahy, & Lewis, 1999; Picton et al., 2000). These considerations are amplified in studies with infants, primarily due to challenges in electrode application, testing parameters, and physical differences between infants and adults (Johnson et al., 2001). These differences include myelination of certain brain areas and dendritic arborization (Greenough, Black, & Wallace, 1987; Greenough & Volkmar, 1973), and differences between adults and children in factors that affect the transmission of electrical signals, such as differences in skull and meninges thickness, and open fontanels in infancy. Our limited understanding of neural development in humans compounds the problem of accurate localization of source activity in the young infant. Johnson and colleagues (2001) reported that reasonable source localization can be estimated in about half of infant subjects. Thus, improvements in methods for both analyzing source information and recording brain electrical activity are needed before we can accurately estimate the source of such ERP activity in infants.

Another drawback is that the EEG is prone to distortion because of motor movement. Artifact may result from such gross motor activity as waving of the arms and legs or from motor activity as fine as a blink or a slight eye movement. Although adult research participants are generally cooperative when requested to sit without moving, young children often have great difficulty in refraining from gross motor movements. Researchers must ensure that their expectations for the behavior of young children in EEG and ERP paradigms are developmentally appropriate.

## CLINICAL APPLICATIONS OF EEG STUDIES

EEG methodology has proven very useful in studies of cognitive and socioemotional development. We have highlighted the use of the EEG in research on cognitive development elsewhere (Bell & Wolfe, 2004). Here we focus on the use of the EEG in research on socioemotional development and specif-

ically examine EEG correlates of behavioral inhibition. Behavioral inhibition is a childhood temperament profile of great interest to developmentalists because of its association with later developing anxiety disorders (Biederman et al., 2001; Kagan, 1997; Ollendick & Hirshfeld-Becker, 2002; Schwartz, Wright, Shin, Kagan, & Rauch, 2003). In this selective overview, we describe the development of behavioral inhibition, briefly discuss the neural circuitry hypothesized to be involved in behavioral inhibition, and then detail EEG correlates of behavioral inhibition in children. Although the EEG cannot be used as a diagnostic tool for behavioral inhibition, its inclusion in research projects may help provide a convergent piece of evidence toward the goal of understanding the biological underpinnings of behavioral inhibition.

### Development of Behavioral Inhibition

Temperament refers to relatively enduring individual differences in affective moods and behaviors observed during infancy and early childhood. Current theories of temperament consider these individual differences to have a biological basis and most likely a genetic basis as well (Kagan, 1998; Rothbart & Bates, 1998; Schmidt, Polak, & Spooner, 2001). Much of the work on individual differences in temperament can be delineated along the behavioral dimensions of approach and withdrawal (Fox, 1994; Schmidt & Fox, 1999). Thus, behavioral inhibition, more specifically “inhibition to the unfamiliar” (Kagan, 1994, 1999), is a temperament profile that describes children who tend to withdraw from unfamiliar people, objects, and situations, whereas uninhibited children tend to approach under these circumstances.

The term “behavioral inhibition” is most often associated with the work of Jerome Kagan and his colleagues at Harvard, who have reported that behavioral inhibition is associated not only with behavioral withdrawal but also with negative affect (Garcia-Coll, Kagan, & Reznick, 1984) and physiological arousal (Kagan, Reznick, & Snidman, 1987). In longitudinal studies from infancy to adulthood, Kagan and colleagues have focused on individuals who are at the extremes of approach and withdrawal profiles because these were the groups of children who displayed the most consistent behavior across laboratory tasks, although this consistency was not acute (Kagan, 1999; Kagan, Reznick, Snidman, Gibbons, & Johnson, 1988). Others also have noted that behavioral inhibition can be moderately stable throughout childhood for some individuals (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001; Scarpa, Raine, Venables, & Mednick, 1995).

Although temperament profiles are considered to be rather enduring individual differences in affective moods and behaviors, it is probably *not* the case that specific, microscopic behaviors are permanent. Kagan (1998) holds that infants are born with a particular temperamental profile that undergoes change as a result of experiences with parents, teachers, and peers. Because of all these changes, the actual descriptive names of temperament profiles in in-

fancy should differ from those used to describe older children. Thus, it appears that the most notable temperament profile in infancy is distress or irritability (Kagan, 1998; Rothbart, Derryberry, & Posner, 1994), whereas the most notable temperament profile in childhood is shyness or, more aptly, fearfulness (Kagan, 1998). These different temperament profiles at different times in development may be related to the development of behavioral inhibition.

In Kagan’s work, as well as the work of others, infant predictors of inhibited and uninhibited behaviors in childhood center on motor and affective reactivity to sensory stimuli (Calkins, Fox, & Marshall, 1996; Fox et al., 2001; Kagan, 1997; Kagan & Snidman, 1991). Highly reactive infants have been shown to display high motor activity and high negative affect to visual, auditory, and olfactory stimuli at 4 months of age. Low-reactive infants remained motorically inactive and display little affect to sensory stimuli at 4 months. During the toddler period (ages 14 and 21 months), many (but not all) of these high-reactive infants exhibited fearful behavior to unfamiliar people, objects, and situations. The low-reactive group typically exhibited minimal fear (e.g., Kagan, 1997). By age 4, members of the original high-reactive group were less likely to talk and smile to an unfamiliar adult than were members of the low-reactive group. With unfamiliar peers, the original high-reactive group were avoidant and quiet (Kagan, 1998).

This temperament profile was not rigidly stable, however. Only a small percentage of the original high-reactive and low-reactive infant groups exhibited consistent inhibited or uninhibited profiles across each age and at each assessment period (Fox et al., 2001; Kagan, 1998). Maternal behavior (Schmidt et al., 2001) and possibly day care experience (Fox et al., 2001) have been implicated in the instability of the behavioral inhibition temperament profile. Thus, it appears that experience may be able to dampen, or perhaps even enhance, original temperament quality (Kagan, 1998).

Of most interest to developmentalists is the evidence that individuals with stable behavioral inhibition profiles across childhood are at risk for social anxiety disorder (Biederman et al., 2001; Schwartz et al., 2003). Social anxiety disorder is the most common anxiety disorder in adolescence and adulthood. It is the third most common of all neuropsychiatric disorders, following major depression and alcohol dependency (Ollendick & Hirshfeld-Becker, 2002). Most models of social anxiety hypothesize interactions between biological and psychological variables, as well as genetic influences. Children with behavioral inhibition from the original Kagan studies had parents with higher rates of social phobia than the parents of the uninhibited children (Rosenbaum et al., 1991). Similarly, in another parent-child sample, behavioral inhibition was associated with social anxiety among children whose parents had panic disorder. Furthermore, behavioral inhibition predicted childhood social anxiety beyond what could be predicted from parent panic disorders (Biederman et al., 2001). Kagan has emphasized, however, that most children with behav-

ioral inhibition will not develop an anxiety disorder. It is more likely that behavioral inhibition in childhood will be associated with introverted, or shy, adult personality (Kagan, 1998).

### Neurological Basis for Behavioral Inhibition

Many developmentalists propose that individual differences in behavioral inhibition may reflect variation in excitability of the limbic system, specifically the amygdala and its neural circuitry (Kagan, 1997, 1998; Marshall & Stevenson-Hinde, 2001) or perhaps even dysregulation of this neural circuitry (Schmidt & Fox, 1999, 2002; Schmidt et al., 2001). In particular, the central nucleus of the amygdala is associated with fear (LeDoux, 1996; Nader & LeDoux, 1999), the most distinguished temperament profile in childhood (Kagan, 1998). As noted previously, fearfulness is the primary behavioral component of behavioral inhibition in childhood, and this has led Kagan and others to propose that behavioral inhibition is associated with the functioning of the amygdala and associated circuitry (Davidson & Rickman, 1999; Kagan, 1997, 1998; Schmidt & Fox, 1999, 2002). Indeed, recent fMRI evidence lends support to this hypothesis. Young adults who had been categorized as having behavioral inhibition when toddlers exhibited greater amygdalar responses to novel versus familiar faces compared with young adults categorized as uninhibited as toddlers (Schwartz et al., 2003).

Data from animal studies have been used to suggest that the frontal cortex is also an integral part of the fear system (see Schmidt & Fox, 2002, and Schmidt et al., 2001, for overviews of the neural circuitry of the fear system). In humans, the frontal cortex is associated with emotion expression, regulation, and associated processes (Davidson, 1992, 1995; Fox, 1991, 1994). Functional connections have been demonstrated between the frontal cortex and the amygdala, and this is of importance for any model of behavioral inhibition. Communication between these two brain areas may be important for regulating withdrawal responses to aversive stimuli and approach responses to appetitive stimuli (Davidson & Rickman, 1999; Marshall & Stevenson-Hinde, 2001).

Both Fox (1991, 1994) and Davidson (1992, 1995) have proposed two basic circuits involving the frontal cortex and associated affects and motivations. The approach system focuses on positive emotions that are implicated in pregoal attainments. This system involves reduced negative affect and active social approach and is associated with left hemisphere frontal functioning. The withdrawal system involves negative emotions that are implicated in aversive situations. This system has reduced positive affect and active social withdrawal and is associated with right hemisphere frontal functioning (Davidson & Rickman, 1999).

These two affect/motivation circuits have major implications for EEG work in studies of behavioral inhibition. One could readily hypothesize that behavioral inhibition would be associated with functioning of the right frontal

cortex relative to the left frontal cortex. As previously noted, EEG methodology is especially suited for research with infants and children (Casey & de Hann, 2002; Taylor & Baldeweg, 2002). Thus, the EEG is an excellent research tool for examination of the biology/physiology associated with behavioral inhibition.

### Frontal EEG and Behavioral Inhibition

A difference in EEG power values between left and right frontal EEG scalp electrodes is assumed to reflect relative differences in neuronal activity between the left and right hemispheres of the frontal cortex. Evidence presented by Davidson and colleagues (Davidson, 1992, 1995; Davidson & Rickman, 1999; Davidson, Schaffer, & Saron, 1985) indicates that within a normal adult population differences in tonic or baseline EEG alpha (8–13 Hz) hemispheric activation are associated with affective style. EEG alpha values are inversely related to cortical involvement. Thus, lower power values in a hemisphere (or region) reflect greater cortical activation of that hemisphere (or region) relative to the other hemisphere (Davidson et al., 2000; Lindsley & Wicke, 1974). For example, adults rating themselves high on the Beck Depression Inventory exhibit greater right frontal activation (i.e., lower EEG alpha values) during a resting baseline condition than adults rating themselves low on the inventory. Likewise, adults who are clinically depressed also exhibit right frontal activation during baseline (Henriques & Davidson, 1990). Conversely, left frontal activation is associated with higher positive affect on self-report measures (Sutton & Davidson, 1997; Tomarken, Davidson, Wheeler, & Doss, 1992).

In the adult EEG literature, Davidson has reported that asymmetries in frontal cortical functioning also are associated with variations in emotional behavior during tasks designed to evoke different emotion responses (Davidson, 1992, 1994, 1995; Davidson et al., 1990). Specifically, greater levels of left frontal activation relative to right frontal activation are associated with positive affect or approach behaviors. Greater levels of right frontal activation, relative to left frontal, are associated with negative affect or withdrawal behaviors.

Developmental evidence seems to suggest that electrocortical differences in affective style or temperament can be evident as early as the first year of life. The EEG power values used for infants are at developmentally appropriate lower frequency (i.e., 6–9 Hz) than the traditional 8 to 13 Hz adult alpha levels and may reflect similar processes as the adult alpha frequency band (Marshall et al., 2002). Fox and colleagues have shown that infants who cry at maternal separation are more likely to exhibit right frontal EEG activation during rest or baseline (Bell & Fox, 1994; Davidson & Fox, 1989; Fox, Bell, & Jones, 1992; Fox, Calkins, & Bell, 1994; Fox & Davidson, 1987). Dawson (Dawson, 1994a, 1994b; Dawson, Panagiotides, Grofer Klinger, & Hill, 1992) has reported that type and intensity of

emotional expression during emotion-eliciting tasks is related to specific patterns of left and right hemisphere frontal EEG activation in infants. Infants exhibited frontal activation relative to baseline during a brief maternal separation. Furthermore, during emotion-eliciting situations, infants exhibited right frontal activation during sad, or withdrawal, situations and left frontal activation during more positive, or approach, situations. Others have reported similar EEG findings with infant populations (Buss et al., 2003; Davidson & Fox, 1982). All this infant emotion reactivity research has implications for EEG work on behavioral inhibition.

Using Kagan's methodology to select infants who may later on be high or low on behavioral inhibition, Fox has reported that infants who display negative affect and high motor activity at age 4 months exhibit right frontal EEG activation at age 9 months and inhibited behavior at age 14 months (Calkins et al., 1996). Infants who exhibited a pattern of stable right frontal activation across the 9- and 14-month time period were more likely to be inhibited at both age 14 and 24 months relative to those infants who exhibited a pattern of stable left frontal EEG activation (Fox et al., 1994). Schmidt has speculated that infants may have a temperamental bias toward the emergence of behavioral inhibition in very early childhood. These bias features appear early in the first year of life and remain stable during the first 2 years of life (Schmidt et al., 2001). The frontal EEG indicators of this temperament bias may be indexing individual differences in forebrain and limbic sensitivity (Schmidt & Fox, 2002).

For many infants, these individual differences in affective style and EEG activation persist throughout the preschool years and early school age years. Fox has reported that when these same infants were 4 years old, those who displayed a high level of behavioral inhibition during play groups with three unfamiliar peers exhibited greater relative right frontal EEG activation during baseline rest compared with children displaying less behavioral inhibition behaviors (Fox et al., 2001; Henderson, Fox, & Rubin, 2001; Henderson, Marshall, Fox, & Rubin, 2004). It is of note, however, that not all behavioral inhibition toddlers exhibited behavioral inhibition behaviors at age 4 years (Fox et al., 2001), much like the data reported by Kagan and colleagues (see Kagan, 1998, for a review of this work). Schmidt reported that by age 7 years, these children who displayed high levels of behavioral inhibition at the preschool years exhibited an increase in right, but not left, frontal EEG activity during a self-presentation task as the task became more demanding (Schmidt, Fox, Schulkin, & Gold, 1999). The self-presentation task was used with the school-age children because issues of self-evaluation appear to be at the crux of many social anxieties (Schmidt & Fox, 1999).

Davidson and colleagues have reported similar EEG data for children at age 3 years (Davidson & Rickman, 1999; Finman, Davidson, Colton, Straus, & Kagan, 1989). Children were exposed to a play session during which mild

stressors were presented (e.g., talking robot, adult stranger). Play sessions were experienced with an unfamiliar same-gender peer. Later the children who exhibited the most behavioral inhibition behaviors and those exhibiting the least behavioral inhibition behaviors returned for EEG baseline recordings. The group of 3-year-old children with the highest levels of behavioral inhibition had relatively more right than left frontal EEG activity, whereas the children with the lowest levels of behavioral inhibition had relatively more left than right activity. EEG power was calculated on a slightly higher frequency band than that used in the Fox studies. Power was formulated for 7 to 11 Hz.

Returning at age 9 years for more behavioral testing and then at age 10 years for EEG recordings, these children mimicked the behavioral inhibition-EEG data at age 3 years (Davidson & Rickman, 1999). Comparison of the 3-year-old data with the 9- to 10-year-old data revealed no stability in either behavioral inhibition or EEG hemispheric activation for the entire group of children. Much like the previously noted reports of Fox and Kagan, however, there was a smaller group of children who exhibited greater relative right frontal EEG activity at both ages, and these were the children who exhibited behavioral inhibition behaviors at both ages. One possible explanation for this apparent lack of behavioral stability in behavioral inhibition is that the laboratory measures were not analogous, each being based on developmentally appropriate tasks (Davidson & Rickman, 1999). It is also the case that individual differences in EEG activation patterns and behavioral inhibition behaviors are influenced by maturational patterns of brain development (Davidson & Rickman, 1999).

In summary, these EEG studies indicate an association between behavioral inhibition and frontal EEG activation from infancy through the middle childhood years. These associations lend some credence to the hypothesis that behavioral inhibition can be linked to the dysregulation of some components of the fear system involving the frontal cortex and the amygdala (Schmidt et al., 2001). Thus, although these data provide evidence of a biological predisposition to behavioral inhibition in some children, there is also evidence that many children do not exhibit stability in behavioral inhibition-EEG associations (Davidson & Rickman, 1999; Fox et al., 2001). Likewise, there is the suggestion that there are environmental contributions to behavioral inhibition as well (Fox et al., 2001). The interested reader is directed to the writings of Schmidt (Schmidt et al., 2001) for a discussion of possible environmental correlates of childhood shyness or behavioral inhibition.

## CLINICAL APPLICATIONS OF ERP STUDIES

ERPs have been used to test a variety of types of function in populations with developmental disorders. Because they

are noninvasive, EEG and ERP can be used to understand a number of aspects of brain development and function in populations that might otherwise be difficult to test. We will describe studies that focused on measuring brain function related to social behavior in children with typical development, autism, Williams syndrome, and developmental delay. We will describe a paradigm that has proven highly useful in studying these populations, as well as children with typical development.

### Typical Development

Faces have long proved a powerful stimulus for use in ERP studies with infants and very young children. Because participants of this age cannot make verbal or motor responses, researchers depend on their attention to salient stimuli, which are then varied on some parameter (e.g., familiarity). Because infants like to look at faces from very early in development, they are more likely to reliably attend to presentations of face stimuli than almost any other type of stimulus. Thus, faces have been used to measure infants' ability to learn about faces through familiarization (Nelson, 1994, 1998, 2001). They have also been used in studies designed to elicit and differentiate ERP activity related to encoding, novelty detection, and memory updating in infancy (Nelson & Collins, 1991). Faces have also been used to measure infants' emotion recognition ability (Nelson, 1993; Nelson & de Haan, 1996; Nelson & Horowitz, 1983).

In most previous studies, infants typically viewed faces that, prior to the experiment, were entirely novel to them. Infants were typically familiarized with one face or emotional expression, and subsequent ERP activity was measured to that face or expression in contrast with a novel (unfamiliarized) face or expression. De Haan and Nelson (1997, 1999) devised a novel but elegant method by which infants' ERP responses to an already familiar stimulus could be compared to their responses to a new, novel stimulus. A digital image was taken of the infants' mother, and was shown paired with an unfamiliar face. De Haan and Nelson (1997) systematically varied the degree to which the unfamiliar face resembled the mother's face. In 6-month-olds, the similarity between the mother's face and the stranger's face affected infants' ERP responses to the mother's face. Thus, the context in which the familiar face was seen had an impact on how that face was processed.

In a second study, de Haan and Nelson (1999) compared ERP response to the mother's face versus a stranger's face to their responses to a very familiar object (a favorite toy brought to the lab from home) versus an unfamiliar toy (a toy provided by the lab and confirmed by the mother to be unfamiliar to the infant). This study revealed differences in the laterality of the Nc component for faces versus objects where faces elicited a greater Nc over the right hemisphere than the left. (Objects were bilaterally distributed across the scalp hemispheres.) These data provided

evidence of the lateralization of face processing mechanisms as distinct from general familiarity mechanisms.

A number of labs have adapted the mother's face recognition paradigm for use with both typically developing infants and children, and children with developmental disabilities. Carver and colleagues (2002) tested 13-month-old to 4-year-old typically developing children using the mother's face paradigm. The results indicated age-related changes in the differences between the amplitude of the Nc component to the mother's face and the stranger's face. Further analysis revealed that this correlation occurred primarily because the infants' Nc to the mother's face decreased over time, whereas the Nc to the stranger's face remained fairly constant. Based on the ages over which this change occurred, the authors suggested that the effect may be due to changes in the relative salience of the mother's face as infants emerge from the stage of attachment. Studies are currently under way to test this hypothesis.

### Autism

One of the key areas of impairment in autism is in social development. Children with autism fail to attend preferentially to faces as do other children, and adults with autism show impairments in face recognition tasks and unusual patterns of brain activity in response to faces. Thus, face recognition tasks provide an important avenue from which to explore the brain basis of the social impairments in autism. Dawson and colleagues (Dawson et al., 2002) tested 3- and 4-year-olds with typical development, developmental delay, and autism spectrum disorders using the mother's face paradigm and the very familiar object paradigm (de Haan & Nelson, 1997, 1999). The researchers noted that 3- and 4-year-olds with autism showed ERP patterns that were similar to those elicited for children with typical development in responses to very familiar versus unfamiliar objects. Children in both groups showed differences in the amplitude of the P500 component. The amplitude was larger for the unfamiliar object than for the very familiar object. Children with typical development also showed a difference in the amplitude of the Nc component to familiar and unfamiliar objects. The Nc effect was similar in children with autism, although it did not reach statistical significance (Dawson et al., 2002). A very different pattern was observed for faces. Children with typical development showed differences between responses to the mother's face and a stranger's face for the Nc component, the P500 component, and the slow wave component. Children with autism showed no differences between the ERP response to the mother's face and the stranger's face for any of these components. Interestingly, children with developmental delay showed a third pattern, in which ERP activity differentiated the familiar from the novel stimulus for both faces and objects, but only in the slow-wave activity. The authors interpreted these results as indicating that children with typical development and developmental delay both

were able to differentiate both social (faces) and nonsocial (objects) stimuli, although the components in which this differentiation occurred varied between these populations. Children with autism, in contrast, showed differential ERP activity only to objects, suggesting a specified impairment in the processing of social information. In future studies, the mother's face paradigm could be used longitudinally to examine the long-term effects of autism on face processing.

ERPs have also been used in a study of face processing in adults with autism (McPartland, Dawson, Webb, Panagiotides, & Carver, 2004). In this experiment, high-functioning individuals with autism were tested using standardized behavioral measures of face recognition ability, and ERPs to faces were tested using a paradigm described by Bentin and colleagues (1996). High-functioning volunteers with autism and typical control volunteers saw random presentations of upright and inverted pictures of unfamiliar faces and furniture. People with autism failed to show the usual inversion effect in the N170 (slower and larger amplitude to inverted faces). The N170 was also not lateralized to the right hemisphere in the patients with autism, whereas it was in the typical controls. Finally, slower latency of the N170 component over the left hemisphere predicted better performance on the face recognition task for people with autism, whereas faster N170 over the right hemisphere predicted better performance for typical controls. These data suggest that individuals with autism use a different brain system for processing faces than do controls. In addition, the results suggest that the extent to which such compensatory strategies are developed may relate to the severity of the face recognition impairment in autism.

### Williams Syndrome

Williams syndrome is a rare genetic disorder that, in many ways, seems to be the polar opposite of autism. Patients with Williams syndrome are hypersocial where patients with autism are asocial. Patients with Williams syndrome also show a pattern of severe impairment in spatial cognitive abilities with less impairment in verbal abilities. This pattern is the opposite of that typically seen in autism, where most patients show severe impairments in verbal abilities and less severe spatial cognitive deficits. In one area, however, patients from these seemingly disparate disorders are strikingly similar. Patients with autism and Williams syndrome show similar behavioral profiles in face recognition tasks. Both groups fail to show an inversion effect, in which inverted faces are recognized less well than upright faces. ERPs to faces have also been used to test patients with Williams syndrome. In one study, ERPs of individuals with Williams syndrome, autism, and typical controls were compared in a face processing task (Grice et al., 2001). Both of the patient groups showed different ERP patterns than did controls. Patients with autism showed an increased amplitude to inverted faces (which is a typical pattern) but did not show differential latency of the

activation. Patients with Williams syndrome showed a latency difference, but not an amplitude difference between inverted and upright faces. Thus, ERPs proved helpful in differentiating the underlying neurophysiology between autism and Williams syndrome, despite similar or identical behavioral profiles.

### Other Populations

In addition to studies of children with autism, ERP methods can be used with any number of other populations. Pollak and colleagues (Pollak, Cicchetti, Klorman, & Brumaghim, 1997) measured ERP responses to facial expressions of emotion in children who had or had not been physically abused. Children who had suffered abuse showed enhanced ERP activity to negative facial expressions, especially to angry expressions. The authors interpreted these results as indicating that the children's perception of emotions differed as a function of their abuse history. These results may prove important in future studies of children who have experienced any number of different environments (e.g., children raised by caregivers with major depression) and point to a potential aspect of brain plasticity that might be involved in their behavioral profiles.

## CONCLUSION

EEG and ERP studies have proven useful for investigating a number of aspects of development in typically developing children as well as in clinical populations. The results of these studies have provided important insights into the nature of the differences found in these populations, as well as providing information from which hypotheses about their brain bases can be generated. EEG has proven useful in our understanding of the brain basis of behavioral inhibition, in both its normative variance and clinical application. Electrophysiological methods can, in the future, provide even more information about both normal and atypical development. ERP methods would be even more powerful if used in conjunction with other methods. For example, functional imaging methods provide high-resolution spatial information. ERPs used in conjunction with imaging could provide important information about both the spatial and temporal characteristics of brain activity. ERP and EEG methods could also be combined to gain converging information from their relative strengths. Finally, electrophysiological methods should be used in conjunction with behavioral observations to provide the strongest possible estimate of the neural correlates of behavioral change.

# Mental Retardation

8

**Suzanne T. P. V. Sundheim, MD**     **Ruth M. Myers, MD**  
**Kytja K.S. Voeller, MD**

Mental retardation syndromes should be of great interest to those who study normal development and psychopathology. In the last decade molecular biological techniques and the stimulus of the Human Genome Project have made it possible to identify many of the genes that are involved in these disorders. Simultaneously, research in neuroscience has provided clues as to the role of these genes during brain development and in postnatal brain function. Studies in cognitive neuroscience, particularly in the area of neuroimaging, have made it possible to study the differences in information processing in individuals with a specific mental retardation syndrome compared to unaffected persons. In some cases, it has been possible to demonstrate an association between the genotype and cognitive function; as for example in the performance of individuals with fragile X on tasks demanding prefrontal executive resources. Moreover, it has become apparent that certain psychiatric disorders are strongly associated with certain mental retardation syndromes, such as the link between schizophrenia and velocardiofacial syndrome or Prader-Willi syndrome, or the fascinating association of Prader-Willi syndrome and obsessive-compulsive disorder. Although there remains much that needs to be learned about the precise mechanisms by which the genetic perturbations result in the neuropsychiatric phenotype, the mental retardation syndromes provide the neuropsychiatrist with a remarkable opportunity to understand how the neurobiological underpinnings of these disorders affect cognitive and emotional behaviors. In this chapter we have attempted to provide the reader with an overview of the genetics, cognitive, neurological and psychiatric features (and, where relevant, medical disorders), of several well-studied mental retardation syndromes.

## **CURRENT DEFINITIONS OF MENTAL RETARDATION**

Mental retardation is the term used to describe the condition of individuals with intellectual impairment and com-

promised adaptive behavior with onset prior to 18 years of age (in some situations, age 21 years). Three formal definitions of mental retardation are currently recognized. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition (DSM-IV) (1) definition (Table 8.1) establishes an IQ of approximately 70 as a cutoff-point. If, for example, an individual has an IQ of 75 but has adaptive functioning with impairment in two or more skill areas of onset prior to age 18 years, the criteria for mental retardation are met. This represents a change from the 1987 definition in DSM-III-R (2), which neither recognized that the classification was continuous nor attempted to integrate IQ and adaptive functioning. In the American Association on Mental Retardation (AAMR) definition, mental retardation is viewed not as an absolute trait, but rather as an interaction between the individual and the environment (3). The AAMR approach is multidimensional, involving a systematic, three-step evaluation of psychological/emotional, physical/health/etiological, and environmental factors, focusing on an individual's specific deficits and providing adaptive supports to optimize functioning. The International Classification of Diseases, 10th Revised Edition (ICD-10) (4) provides a description of each condition rather than a symptom menu as in DSM-IV. It clearly describes the same three qualitative features that are critical to the diagnosis of mental retardation in DSM-IV. Like the DSM-IV nosology, ICD-10 defines levels of mental retardation in terms of measured IQ level.

## **Individual Differences in Profile and Changes Across the Life Cycle**

Individuals with mental retardation have specific strengths and weaknesses in both cognitive and adaptive areas: one person might have strong spatial abilities but impaired language, whereas another might be independent in self-care skills and home management but have poor functional math skills and require help in money management. A thoughtful, multidimensional neuropsychiatric evaluation

**TABLE 8.1**  
**DSM-IV DIAGNOSTIC CRITERIA FOR MENTAL RETARDATION**

- a. Significantly subaverage intellectual functioning: an IQ of approximately 70 or below on an individually administered IQ test (for infants, a clinical judgment of significantly subaverage intellectual functioning).
- b. Concurrent deficits or impairments in present adaptive functioning (i.e., the person's effectiveness in meeting the standards expected for his or her age by his or her cultural group) in at least two of the following areas: communication, self-care, home living, social/interpersonal skills, use of community resources, self-direction, functional academic skills, work, leisure, health, and safety.
- c. The onset is before age 18 years.

Diagnostic Code	Degree of Severity of MR	IQ Level
317	Mild	50–55 to approximately 70
318.0	Moderate	35–40 to 50–55
318.1	Severe	20–25 to 35–40
318.2	Profound	Below 20 or 25
319	Severity unspecified	When there is strong presumption of MR but the person's intelligence is untestable by standard tests

mental retardation functions. An adequate evaluation should include a systematic review of the patient's developmental, medical, and family history, as well as cognitive function, daily living skills, and capacity for autonomous function. Temperament, social, emotional, psychosexual, and moral functioning also need to be explored. Moreover, these cognitive and behavioral profiles do not necessarily remain static, but may change across the life cycle in both a syndrome-specific and individual manner. For example, children with fragile X syndrome may reach a cognitive plateau in adolescence, whereas those with Williams syndrome start out with delayed language but then go on to develop a remarkably rich vocabulary. Each child's personal strengths and life experiences, physical health, and their family and educational environment will also affect how this basic pattern is manifested.

## COGNITIVE AND ADAPTIVE MEASURES

### Measurement of Intelligence

Intellectual functioning is measured by standardized tests that yield an intelligence quotient (IQ). Intelligence tests were originally developed to predict academic success and measure general intelligence. However, they do not necessarily provide much information about performance in real-world situations.

### Assessment of Adaptive Functioning

Adaptive functioning refers to an individual's ability to perform tasks of daily living compared to others of the same age and cultural group. It provides a real-life, practical measure of performance and a second source of information

about areas of competence and deficit. Without an assessment of adaptive functioning, the diagnosis of mental retardation is only provisional. What constitutes a significant impairment in adaptive behavior has not yet been tightly defined. The Vineland Adaptive Behavior Scales (VABS) (5) and the AAMR Adaptive Behavior Scales (6–8), are commonly used instruments. The VABS is restricted to four domains—communication, daily living skills, socialization, and motor skills—not the entire spectrum of adaptive behaviors, and is of limited use in longitudinal studies because of the fluctuation of means and standard deviations across age groups (9).

### Epidemiology

From a purely statistical point of view, mental retardation is defined by an arbitrary cut-off of two standard deviations below the mean on a continuum of intelligence test scores. In the Wechsler tests, which have a mean of 100 and a standard deviation of 15, the cutoff is 70. On the Stanford-Binet, with a mean of 100 and a standard deviation of 16, the cutoff is 68. When adaptive functioning criteria are considered, the prevalence drops to the 1 to 1.5% range (1, 10, 11). Depending on the specific criteria that are used to determine special education services, 0.3 to 2.5% of school-aged children are defined as being mentally retarded.

Approximately 85% of the mentally retarded population fall into the range of mild mental retardation, 10% have moderate, 3 to 4% to have severe, and 1 to 2% have profound mental retardation (1). Medical complications and mortality increase with severity of mental retardation, and contribute to the discrepancy between expected and identified prevalence rates.

## Psychiatric Assessment

Individuals with mental retardation are at high risk for psychiatric disorders. The term *dual diagnosis* is used for individuals with mental retardation and comorbid mental health disorders. Depending on the types of population sampling strategies used, between 10 and 40% meet the criteria for a dual diagnosis. (12)

Psychiatrists are often consulted to address an isolated behavioral symptom, such as self-injurious behavior, aggression, or destructiveness. These symptoms may arise from any number of different interacting neurobiological and environmental factors. Two pitfalls in the diagnosis of patients with mental retardation are especially worth mentioning. *Diagnostic overshadowing* refers to using the diagnosis of mental retardation as an explanation for the symptoms instead of applying more standard diagnostic approaches. As a result, a symptom that would be diagnosed and treated in an individual of normal intelligence is instead diagnosed and treated differently when it is associated with mental retardation. (13–15). *Diagnostic presumption* is a term coined by Sundheim to describe the phenomenon of assuming that a specific psychiatric diagnosis applies to an individual with mental retardation purely on the basis of its frequent association with the syndrome instead of systematically exploring the full range of other diagnostic possibilities. For example, assuming that a 20-year-old individual with Down syndrome who has increasing difficulty with day-to-day functioning is demented, rather than exploring the possibility of a depressive disorder.

Patients with mental retardation often have difficulty verbalizing the reasons for their distress. Otitis, dental pain, urinary tract infection, migraine headaches, or gastritis may lead to irritability, aggressive, or self-injurious behavior. Thus, in many cases it may be necessary to refer the patient for a medical evaluation. Medical conditions, such as hypothyroidism and epilepsy, are often associated with mental retardation syndromes and appropriate treatment may improve function. Adequate neuropsychiatric assessments of patients with mental retardation are optimally served in the context of a team of other physicians, educators, and behavioral specialists (16). In light of the emerging syndromal subtypes and their association with different psychiatric and behavioral manifestations, genetic evaluation is an essential part of diagnostic evaluation and treatment planning.

Although most people with developmental disabilities are able to communicate using words, it may be necessary to modify the interview to work around the linguistic limitations of the patient. Nonverbal individuals develop ways of expressing themselves (sometimes the strategy used is troublesome enough to be the reason for the referral!). Information must be obtained from parents, caregivers, and teachers about past and present functioning. When possible, direct, systematic observation of the individual in his

home or daytime environment can be extremely helpful for understanding the circumstances involved in problematic behaviors and the development of effective interventions.

Even for a patient who has difficulty communicating in words, the mental status examination remains critical. The nonverbal person may be able to utilize sign language, respond to yes-no questions, or use a picture book to facilitate the interview. Subjective experience may be cautiously inferred from facial expression and body language.

## GENETIC AND NEUROPSYCHIATRIC ASPECTS OF CERTAIN MENTAL RETARDATION SYNDROMES

In the following sections, six common, well-studied genetic mental retardation syndromes are reviewed, with the goal of exploring the diversity of medical and neuropsychiatric features associated with mental retardation.

### Fragile X Syndrome

#### Epidemiology/Phenotype

Fragile X syndrome, the most common form of inherited mental retardation, affects approximately 1 in 1,200 males and 1 in 2,500 females. Males with fragile X are more severely involved than females and have some phenotypic features which become more apparent with age—an elongated face, large mandible, long ears, head circumference > 50<sup>th</sup> percentile, hyperextensible metacarpophalangeal joints, soft skin over the dorsum of the hands, a hallux crease, and enlarged testicles (not noted in children under age 8 years). There is usually a family history of mental retardation (17–20). However, these phenotypic features are variable and do not reliably identify affected individuals. They should not be used as the only basis for deciding to conduct molecular DNA testing.

#### Genetics

In 1969, Lubs described a secondary constriction on the long arm of the X chromosome and noted the relationship between this anomaly and X-linked mental retardation (21). However, this “fragile site” as it was called, is apparent only when a folate-deficient culture medium is used and it was not until the early 1980s that the critical role of folate was appreciated (22). The fragile X mental retardation gene (*FMR1*) is located at Xq27.3 (23). Fragile X syndrome results from a large expansion (>200 repeats) of an unstable CGG trinucleotide in the 5′ untranslated region of the *FMR1* gene (24). In unaffected individuals, this repeat is less than 50. A “transmitting” (carrier) male who is normal in appearance, has CGG repeats in the range of 50 to 200 (termed a “premutation”) which are transmitted to his daughters with little change in size. However, the daughter’s children (both males and females) inherit CGG repeats that are significantly longer (ranging from 200 to over

1,000). This coincides with the appearance of the clinical phenotype (25). This large CGG repeat results in hypermethylation of the promoter region with transcriptional suppression of the *FMR1* gene, in turn shutting down the production of fragile X mental retardation protein (FMRP). FMRP is widely expressed in neurons (26), with highest levels of expression in the cholinergic cells in the nucleus basalis and the hippocampus (27–29). FMRP is involved in synaptic plasticity, and plays a role both in fetal brain development and learning in the mature brain (30). Although neurogenesis and neuronal migration are relatively normal, there is disruption of the later “pruning” phase. During normal brain development, the numerous, small synapses distributed along long, thin dendritic spines undergo a transition during pruning to fewer, larger synapses on broader and shorter spines. The immature pattern is retained in brains of individuals with fragile X as well as of knockout mice lacking the *FMR1* gene (31–34).

An intriguing finding is that there is a high level of FMRP expression in the magnocellular layers of the lateral geniculate nucleus in normal humans and monkeys, whereas a loss of the normal laminar structure of the lateral geniculate was noted in a male with fragile X. Clear evidence of magnocellular pathway pathology in fragile X was demonstrated by motion-perception deficits without impairment of function of the parvocellular pathway. The magnocellular pathway feeds into the dorsal visual stream/parietal lobe system which integrates visuospatial and motor processing, an area of significant weakness in individuals with fragile X (35).

### Medical and Neurological Disorders

About 28% of carrier females have premature ovarian failure, probably the result of decreased follicle number and function, (36) with a risk of osteoporosis (37). Males with premutations (CGG repeats <200) were long believed to be unaffected. However, neuroimaging studies have revealed clear differences in gray and white matter volumes were relative to controls (38). Approximately a third of male premutation carriers over the age of 50 develop fragile X-associated tremor/ataxia syndrome (FXTAS), characterized by cerebellar ataxia, intention tremor, cognitive decline, peripheral neuropathy, lower-limb proximal muscle weakness, and autonomic dysfunction (39, 40). Female premutation carriers may develop a more subtle presentation but are not demented (41, 42). Diffuse eosinophilic intranuclear inclusions are found in both neurons and astrocytes and MRI studies have revealed atrophic changes (43, 44). Thus, when reviewing family history in a child in which fragile X is considered a diagnostic possibility, it is helpful to explore late-onset progressive motor dysfunction in older relatives.

Dysregulation of hypothalamic/pituitary/adrenal axis and neuroendocrine functions can be seen, with a blunted response to thyrotropin releasing hormone (45). The exaggerated hormonal response to stress and elevated glucocor-

toid hormones under basal conditions described in fragile X is relevant because of the difficulties affected individuals manifest in managing stress and anxiety. Hessler et al. conducted an in-home evaluation of a large group of children with fragile X full mutation and their unaffected siblings. Children with fragile X (in particular the boys), had higher levels of salivary cortisol and increased cortisol was significantly associated with behavior problems. Lauterborn also demonstrated an exaggerated response to stress in FMR1 knock-out mice compared to wild-type mice (46).

### Neurocognitive Profile

Intellectual ability in fragile X ranges from frank mental retardation in males to bright normal intelligence in females. In a study of 144 families neurocognitive status was significantly correlated with the amount of FMRP present. However, the genetic variance accounted for less than half of the total variance in full scale IQ (47).

There is evidence of a decline in IQ in fragile X which becomes apparent during early puberty (48–56). Young boys with the full mutation typically have IQs in the borderline-to-mild mental retardation range, whereas the IQs of adult males fell in the moderate-to-severe range (57, 58). The decline in IQ is correlated with the methylation status of *FMR1* (with a resulting decrease in FMRP) (56, 59–61). Even male premutation carriers have significant deficits in executive function and memory compared to controls (62).

Although the cognitive profile of women with full expression of fragile X syndrome is similar to that of males (58, 63–68), there are significant enough differences to warrant treating them separately in the following discussion.

### Males with the Full Fragile X Mutation

#### Language

Although language is a relative strength in boys with fragile X, their linguistic age ends up being roughly equivalent to that of a 4-year-old (69, 70). In fact, fragile X should be a diagnostic consideration in any preschool child with delayed language (71). Receptive language lags behind expressive language (72). Adolescent and adult males with fragile X have a characteristic rapid, perseverative, jocular, tangential, “cluttered,” and echolalic speech (64, 73–76). It may be a way of managing social anxiety (77) or allowing more time to process verbal information.

#### Psychiatric and Behavioral Features in Males

Fragile X has been reported to be associated with a broad range of psychiatric disorders. Schizotypal features are prominent enough to warrant molecular testing even in males with relatively normal IQs (78). In adults, dysthymia, abusive verbal behaviors, and antisocial personality disorder behaviors have been reported (79). Self-injurious behaviors, usually restricted to hand- or finger-biting, occur in 58% of boys with fragile X (80). These behaviors appear before age 3 years and are triggered by

changes in routine or when the child is asked to perform a difficult task. Selective mutism (81), social phobia (82), Tourette syndrome, and OCD have been reported (83, 84). Hagerman (65) suggests that complex stereotypies are only vaguely differentiated from motor tics and that the bursts of pressured speech represent complex vocal tics, which increase with anxiety.

Hyperactivity is common in fragile X syndrome, and although prominent in early childhood (69, 85), it is also present in adolescents and adults in somewhat diminished form (58, 86–89). There is a high level of sensitivity to sensory stimuli, often labeled “tactile defensiveness” which can be quite impairing (90). Young males with fragile X have deficits in prepulse inhibition (an indicator of impaired sensory gating in rodents), which is strongly associated with intellectual deficits, impaired attention and adaptive skills as well as autistic behaviors (91). Curiously, FMR1 knock-out mice show enhanced prepulse inhibition which would suggest a different compensatory mechanism in that species.

In the 1980s, a series of papers appeared that drew attention to the similarities between fragile X syndrome and autistic disorder (69, 73, 92–98). The atypical social interactions, stereotypies, hypersensitivity and bizarre responses to sound and other sensory stimuli, self-injurious behaviors, smelling of nonfood objects are all strongly reminiscent of autism spectrum disorders. Moreover, depending on the sample, up to 16% of males with autism manifest the fragile site (99). Autism is more prevalent in males (6.5%) than in females with fragile X (4%) (65).

Current information suggests that individuals with fragile X and autistic-spectrum behaviors represent a distinct subgroup. Autistic behaviors were significant predictors of slower development (100, 101), greater cognitive, adaptive, and social impairment (102), and increased age-related cognitive decline (60). Autistic behaviors occur more frequently in individuals with the full mutation (103), although Bailey et al. were unable to demonstrate a relationship between autistic behavior and the level of FMRP expression (100). On the other hand, children without autistic features and higher levels of FMRP expression features also demonstrated higher levels of adaptive behaviors (104).

The diagnosis of autistic disorder in individuals with fragile X must be approached cautiously because many of the “autistic” behaviors are qualitatively quite different. The social indifference that is the hallmark of autism is not seen in boys with fragile X: they are aware of the feelings of others and capable of reciprocal interactions, and their social skills improve with maturation (95, 105, 106). Men with fragile X are more likely to achieve adaptive functional levels commensurate with IQ than those with nonspecific mental retardation or autism (107). Males with fragile X syndrome are shy, socially awkward, anxious, and have a characteristic approach-withdrawal interactive style with an invariant set of mannerisms (108, 109). They have

peculiar greeting behaviors (such as looking away and making repetitive, out-of-context comments while also putting out a hand to shake) (92, 93, 110, 111, Cohen, 1991 #2395; Hatton, 2002 #5108; Merenstein, 1996 #7757; Wolff, 1989 #12464;). This “go away closer” quality is quite perplexing to those who are interacting with them. In social contexts their speech is more perseverative and less echolalic than observed in autism (112). These stereotypical utterances may serve to increase processing time (105, 113).

The neurobiological factors underlying gaze avoidance in fragile X also appear different from those involved in autistic disorder. Gaze avoidance in autistic disorder has been attributed to attentional factors or an inability to integrate eye contact into social interactions (94, 105). Individuals with autism appear to be indifferent and unaware of gaze but do not find it aversive, whereas individuals with fragile X are highly aware of gaze but disturbed by it (93). As discussed below, individuals with fragile X appear to have atypical activation neural activation patterns in regions subserving face and gaze-processing.

### **Females With the Fragile X Gene**

Although once believed to be unaffected, fragile X carriers also manifest the somatic and neurobehavioral features of the disorder, albeit in attenuated form (114–116). The IQ of female fragile X carriers typically falls in the normal to mildly mentally retarded range, and there is a gradient of severity, with those with the full FMR1 mutation having greater cognitive deficits than those with the premutation. Women with the premutation did not differ from sibling controls (117). The verbal IQ is higher than the performance IQ. Subtests that are usually impaired include the Arithmetic, Digit Span, Block Design, and Object Assembly subtests (55). Short-term memory deficits, visual memory deficits, and impaired prefrontal executive function are typically seen (118–121). Girls with fragile X are often diagnosed as learning disabled. The typical academic profile of women with fragile X is characterized by relative strengths in reading and spelling and weakness in arithmetic (122).

Despite their relative strength in language, and even in the presence of average- to above-average intelligence, women with fragile X manifest deficiencies in expressive language and have conceptual disorganization with unusual thought content. This is accompanied by deficits in the expression and modulation of affect. Stereotypes are often observed. Compared to controls, they are more prone to schizophrenia-spectrum diagnoses, in particular schizotypy (115, 123). They are also more likely to have a diagnosis of avoidant disorder, mood disorder, as well as greater impairment in social interactions than controls (124–126). Mood disorders occur in 40% of the women with the premutation and are three times more common than in the control groups. Women with fragile X are shy, socially anxious and avoidant (127). They are often quite disorganized, inattentive, distractible, and impulsive (121, 125, 126, 128, 129).

Keysor and colleagues (130) noted a heightened level of baseline physiological arousal in 12- to 22-year-old girls with the full mutation. The length of the CGG repeat (therefore a lower level of FMRP) and inheritance of the gene from the mothers are associated with increased severity of psychiatric symptoms (75, 123, 125, 131). The cognitive and neuropsychiatric profile presented by women with fragile X is similar to that of nonverbal learning disability (125).

### Neuroimaging Studies

In some ways, brains of children with fragile X are not different from brains in normally developing children. There is no significant difference in total cerebral volume in fragile X and it remains relatively stable after the age of 5 years. As in normal subjects, males have larger total cerebral volumes than females, with larger gray matter volumes in the male accounting for the difference, and there is the normal pattern of a decrease in gray matter volume with age, with an increase in white matter volume (132–134). However, there is evidence of disruption of the frontal and parietal white matter pathways in females with fragile X compared to controls (135).

Interestingly, the age-related decrease in gray matter volumes in boys with fragile X is slower than that in affected girls (136). In normal populations, total cerebral volume (specifically prefrontal and subcortical gray matter) explain 20% of the variance in IQ (134, 137). However, although there was a highly significant difference in IQ scores between fragile X males and females (mean full scale IQ  $85 \pm 18$  for females versus  $54 \pm 15$  for males), there was no evidence of a relationship between gray matter volumes and IQ, even after correcting for total brain volume difference. The volume of the lateral ventricles is increased and is also correlated with IQ. An atypical pattern of hemispheric asymmetry was noted, with larger right-sided cortical gray matter volumes (132).

Significant regional morphometric differences between individuals with fragile X and normal individuals have been noted in several studies. The cerebellar vermis is smaller in fragile X (males more so than in females) compared to both normal controls and other subjects with developmental disabilities. This reduction in size appears to be due to a failure of normal brain growth rather than atrophy (138, 139). The growth impairment is particularly prominent in cerebellar lobules VI and VII and correlates with lower IQ (140) as well as increased stereotypy (126). An age-related increase in hippocampal volume is observed in the fragile X group by some investigators (136, 141) but not by others (118). Interestingly, FMRP is highly expressed in both the cerebellum and hippocampus and further research is required to understand this differential effect (26, 29). A decrease in size of the superior temporal gyrus, also age-related, has been reported (136). Subcortical structures have been reported to be enlarged, possibly as a result of increased dendritic density (142). Enlargement of the thalamus was also observed in females.

The caudate nucleus is enlarged in males and is correlated with methylation status and IQ (143), in contrast to the decrease in size observed in normally-developing children (144).

Although previously thought to be unaffected, adult males with premutations also manifest significant reduction in grey and white matter voxel densities across a broad range of cerebral structures. These reductions were correlated with increased CGG repeat size and decreased percent of FMRP positive lymphocytes (38).

Functional neuroimaging studies, largely restricted to females with fragile X, are particularly instructive as they not only provide valuable information about the recruitment of prefrontal cortex in the performance of difficult tasks, but also demonstrate that women with fragile X have particular difficulty with this process compared to controls. Highly relevant to these studies is the concept of *deactivation* (that is the control or baseline condition minus the cognitive task condition, which is the opposite of activation, cognitive task condition minus baseline). Deactivation may be viewed as the suspension or inhibition of ongoing background neuronal activity in specific brain regions during the performance of tasks requiring increased cognitive activity (145). A number of studies have demonstrated that women with fragile X differ from control groups not only in activation patterns but also in their inability to deactivate or turn off this ongoing background activity and impairment in performance is correlated with diminished FMRP levels. Thus, anomalous activation and inactivation MRI patterns were noted in fragile X females and controls while they performed a STROOP interference task (146). In an arithmetic task with two levels of difficulty, women with fragile X showed less activation and did not increase activation in response to greater task difficulty in contrast to the controls. FMRP expression was positively correlated with activation of a number of frontoparietal structures. (147).

In an fMRI Go–No Go study, the accuracy and reaction time of females with fragile X did not differ significantly from that of the controls, despite a lower mean IQ score. However, FMRP expression was positively correlated with activation in a number of areas, including the hippocampus, cerebellum, and frontostriatal regions. Controls manifested an *increased* level of activation in prefrontal ventromedial cortex area during the baseline “Go” task compared to the “No Go” task. A markedly different pattern was noted in the women with fragile X (148).

In an fMRI study examining visuospatial working memory in females with fragile X (149), similar anomalies in the activation and deactivation patterns were noted in comparison to controls. Although they were able to perform the simple version in a manner similar to the controls, on the difficult task, the performance of the fragile X females deteriorated significantly and they activated a number of prefrontal areas, suggesting that they were unable to recruit neural areas in a coherent manner on the more difficult

task. The lack of FMRP may impair the transcriptional machinery required for rapid protein synthesis of protein in synapses, which underlies learning. In a study of visual memory encoding (150), girls with fragile X showed significantly less activation in the hippocampus and the basal forebrain.

In a study examining accuracy in identifying the direction of facial gaze, females with fragile X syndrome were less accurate and did not manifest enhanced left superior temporal sulcus, or the differential activation in the fusiform gyrus in response to forward faces relative to angled faces, as was seen in controls (151). This study provides a somewhat different perspective on the issue of gaze aversion in individuals with fragile X. It would suggest that there is an underlying impairment in the neural systems for processing faces and direction of gaze.

### Management

One of the “take home” messages in this section about fragile X is that when a child comes for psychiatric evaluation and treatment, it is unusual to have just one affected individual in the family. It is likely that management of the child will need to take into consideration the neurocognitive status of the parents. It is also apparent that there is a broad range of variability in the cognitive and neuropsychiatric features so that a careful assessment of the child is indicated. This assessment should include evaluation of the child’s temperament, ability to interact in social situations, and function in school.

Individual assessment of temperament, and functional analysis with subsequent parent counseling and environmental modification is an important first step that can help delay the use of medications very early in life (152–154). A careful initial evaluation will provide the basis for a treatment plan, which may include appropriate psychopharmacology. In some cases, sensorimotor integration therapy may be helpful in managing the high arousal level (155), and cognitive behavioral therapy may be useful in selected cases (81, 156–158, Sundheim, unpublished data). Assisting the parents in finding an appropriate school setting and anticipating the type of educational difficulties that the child is likely to encounter (poor grasp of arithmetic and difficulty making inferences) will be beneficial. Providing structured, supportive settings for learning socially appropriate behaviors is helpful. Parents benefit from counseling regarding the longterm outcome and assistance in locating vocational training opportunities tailored to their child’s abilities. Some patients will require considerable structure and support to function adequately, whereas others will be able to manage with relative independence.

### Future Avenues in Treatment

Learning and memory are regulated by a delicate balance between the creation functional and stable synapses and the elimination of redundant synapses. There is a considerable body of research which supports the role of long term

potentiation (LTP) in establishing and maintaining such functional synaptic connections, whereas long term depression (LTD) is one of the processes involved in the pruning of non-functional connections. There are several different pathways leading to LTD. One pathway involves the activation of group 1 metabotropic glutamate receptors (Gp1 mGluRs) by mGluR agonists which in turn results in the translation of preexisting mRNA in the postsynaptic neuron leading to a rapid increase in dendritic protein synthesis (158a), as well as the rapid (and, importantly, irreversible) loss of both AMPA and NMDA receptors from synapses, a putative antecedent of synaptic elimination (158b). Importantly, the activation of Gp1 mGluRs also stimulates the synaptic synthesis of FMRP. One might expect that in fragile X syndrome, the absence of FMRP at the synapse would result in a decrease in protein-synthesis dependent LTD. Surprisingly, in the *Fmr1* knockout mouse model, LTD is *enhanced* rather than diminished (158c). This finding makes sense in the context of research that shows that FMRP is a translational repressor—part of the RNA-induced silencing complex (RISC) that mediates the degradation of mRNAs and stops transcription (158d). These findings have led Bear et al. to propose that the neuropsychiatric profile of fragile X is the result of a failure of FMRP to silence synthesis of specific proteins at an appropriate developmental stage with an ensuing pathological exaggeration of LTD (158e). Thus, at a time when the developing brain should be generating and strengthening synaptic connections, the fragile X brain is slowing and eliminating synaptic connections with a predictable and devastating impact on learning and memory. Anatomically, the anomalous long, thin dendritic spines seen in fragile X brains would fit with this model. This opens an exciting therapeutic possibility, namely that Gp1 mGluR antagonists may serve to treat or mitigate the symptoms observed in fragile X. These agents (one of which is lithium) have been used in mouse and drosophila models of fragile X and have materially decreased the pathological behaviors seen in these mutant animals (158f; 158g). These mGluR antagonists are being actively investigated because of their role in the treatment of other neuropsychiatric disorders— anxiety, addictive and bipolar disorders. The challenge here will be to select an appropriate time window as LTD induced by mGluR functions differently at different phases of development (158h). Moreover, the mechanisms of LTP and LTD vary depending on brain region and function.

### Down Syndrome

Down syndrome (DS)(trisomy 21) is the most common genetic mental retardation syndrome, occurring in 1 in 660 live births (159). Very young mothers and those over age 40 years are at increased risk of having a child with DS (the risk increases to 1 per 50 live births over age 40).

The individual with DS is short and has a small, brachycephalic head. Atypical facial features include hypotelorism, midface hypoplasia, epicanthal folds, upturned

palpebral fissures, small ears, an enlarged tongue, and a high-arched palate. Hands are broad with short fingers and an incurved fifth finger. They are hypotonic, with hyperextensible joints. DS is associated with serious congenital anomalies of the heart and gut, both congenital and acquired thyroid disease, and a 19-fold increase in risk of acute leukemia (160, 161). Children with DS are at increased risk for celiac disease (162). Epilepsy occurs in about 8% of children with DS; with close to a third having infantile spasms of infancy (163, 164).

### Genetics

Trisomy (three copies of chromosome 21) occurs in 95% of individuals with DS. About 5% have a translocation (165, 166). Two to 4% of cases are mosaics (167). The DS critical region has been mapped to a 5 Mb area on chromosome 21(168–172). Some genes are overexpressed, such as C21orf2, synaptojanin, and the Minibrain (Mng) gene (183, 184, 185). Others are unchanged, and some, such as HACSI1, a signaling pathway mediator, are underexpressed. As a result, there is a dysregulation and “misexpression” in the balance of protein products (173–185). Many of the dysregulated genes play important roles in neuronal function and connectivity. At 19 gestational weeks samples of fetal cortex from patients with DS revealed significant reduction in proteins associated with synaptogenesis and dendritic tree arborization (186). Examination of DS fetal brains also reveals marked reduction of protein products associated with genes on other chromosomes (179).

### Neuroanatomical Aspects

Brain weight is reduced to about 76% of normal, although in some studies, the cerebellum and brain stem are disproportionately small (187–189). The convolutional pattern is simple, with a narrow superior temporal gyrus and gaping insula. Frontal cortex, anterior corpus callosum, and limbic structures (uncus, amygdala, hippocampus, and parahippocampal gyrus) are disproportionately reduced in volume, with relative sparing of the parietal cortex (190, 191). The amount of gray matter is proportional to the volume of the cerebrum (192). However, thalamus, putamen and globus pallidus, but not caudate are increased in size compared to normal controls (190, 192, 193).

### Brain Development

Given the fact that several of the genes essential for normal brain development are disrupted in DS, one would expect to see anomalies in the earliest stages of brain development. Surprisingly, evidence of abnormal brain growth is apparent, albeit relatively subtly, only around the 22<sup>nd</sup> gestational week (194, 195). Despite the fact that in the DS mouse, there is evidence that the normal sequence of neuronal migration is disrupted (196) the DS brain is not particularly aberrant at birth. Dendritic differ-

entiation in infants with DS at 2½ months is similar to that of controls (197), but there is a 20–50% decrease in neuronal density with maturation (189, 195, 198, 199). Myelination is delayed, particularly fibers linking frontal and temporal cortices as well as U-fibers, and particularly in infants who had congenital heart lesions (200). Deceleration in brain growth and emergence of the characteristic foreshortening of the DS brain becomes apparent by 6 months of age (195).

The dendritic and synaptic structure within the DS brain is quite anomalous (200). Dendritic arborization is curtailed and there is a decline in the number of dendritic spines with age (201, 202). In a mouse model of DS, dendritic spines and synaptic boutons are markedly enlarged with abnormal internal membranes. There are shifts in the pattern of spine density and inhibitory inputs (203).

### Neurocognitive Profile

Forty-five years ago, the developmental picture for children with DS was bleak, and institutionalization was recommended. Today, it is not uncommon for individuals with DS to be married, live and work independently, raise children, and even attend college (204). Several young persons have been able to pursue careers as television actors. In 1976 the average IQ of persons with trisomy 21 was 52, and the average for the mosaic DS subject was 67. It is now recognized that the IQ can extend into the normal range (205). A trend to higher academic achievement scores from 1986 to 2000 has also been documented (206).

This shift toward higher functional ability reflects two major factors: First, birth defects and medical conditions are now treated early and effectively. Second, the discouraging prognoses have been replaced by much more positive attitudes, now infant stimulation programs and educational mainstreaming are the norm (189).

Children with DS are at risk for decreased visual acuity as well as hearing impairment, secondary to anomalies of the external auditory canal, and otitis media (207, 208). These preventable sensory impairments interfere with normal development and the child benefits immensely from early evaluation and treatment.

Children with DS typically manifest relatively rapid acquisition of skill in early childhood (albeit at a slower rate than normally developing peers), but the developmental pattern is asynchronous and skills are not consolidated, so that a plateau occurs at different points in different cognitive domains (209).

Overall, children with DS are weak in language and have somewhat greater strengths in processing visuospatial information. They acquire language at a slower rate than their normally developing peers (210). Adolescents with DS continue to manifest impoverished vocabulary and grammar, word meanings, appropriate contextual use, and syntax (211, 212). Working memory is impaired in these children and is associated with acquisition of receptive vocabulary. As a group, children with DS have a better

understanding of word meanings than their grasp of grammar and syntax and their comprehension is better than expression (213–216). Their narratives are wordy and complex and lack cohesion (217). A well-designed longitudinal study has shown that teenagers continue to acquire receptive vocabulary (albeit at about half the rate of normal peers), but comprehension of grammar begins to plateau in early adolescence (218). Comprehension at the initial evaluation and the rate of growth in comprehension provided the best predictors of expressive language (219).

Despite the expressive language delays, children with DS use gestural communication effectively and to the same extent as peers matched for mental age, although like other areas of development, they acquire gestures at a slower rate than normally developing children (205, 220, 221).

Visuospatial function is a relative strength in children with DS. Performance on visuospatial tasks continues to improve in adolescence, whereas several aspects of language acquisition either plateau or decline (218). Compared to children with Williams syndrome, children with DS perform better on visuospatial short-term memory tasks, even though they are impaired in auditory working memory (222). The deficits in working memory (due to limited storage capacity) and grammar would suggest that prefrontal functions are mainly compromised (223). Children with Williams syndrome have great difficulty with global processing, whereas those with DS grasp the gestalt more readily than the details (i.e., they see the “forest” but not the “trees”) (212, 224).

### **Social-Emotional Development**

Children with DS are described as having pleasant, easy-going personalities. However, there are two developmental features of young children with DS which may hinder social interactions with parents and social development. First, children with DS appear to make little effort to learn new skills, and fail to consolidate and use skills already acquired (225, 226). Their decreased engagement in a task may reflect attentional and intentional deficits (227). Infants with DS appear to have difficulty shifting attention from one target to another (228) and persisting in continuous goal-directed exploratory behavior (227). These attentional features may reflect an early manifestation of prefrontal dysfunction in infants with DS. Children with DS respond empathetically to facial emotional signals and gestures of distress but in tasks which involved processing of more abstract information about emotional states of others, their performance began to plateau at age 4 years (229, 230). This is somewhat unexpected, given the apparent sociability of these children and their relative strengths processing visuospatial information (212). Nonetheless, children with DS have considerable awareness of their social environment. Preverbal children with DS vary gestural patterns depending on social context. Patterns of visual checking also vary with the social context (more social checking occurs with a peer).

Symbolic play does not appear to be particularly delayed in children with DS (231). Although they may engage in more play acts than their normally developing peers, they are less likely to request objects or assistance (231, 232).

### **Academic**

Children with DS can decode single words but have difficulty comprehending what they have read (233). They have difficulty grasping mathematical concepts, lack a well-developed number concept and have difficulty applying their mathematical knowledge to novel problems (205, 234).

### **Brain Function in DS**

Functional neuroimaging studies on healthy, non-demented adults with DS have demonstrated elevated global cerebral glucose metabolism (235), particularly in inferior temporal/entorhinal cortex (236), and functional disruption of neural circuits involved in attentional processing (237). Several studies have described age-related decreases in regional gray matter of temporal lobe structures in nondemented adults with Down’s syndrome. Amygdala and hippocampal volumes were positively correlated with memory measures (193, 238). Neuroimaging studies in nondemented adults with DS indicate that there are progressive changes in the structure and function of various areas of the brain before the appearance of clinical evidence of dementia.

### **Neuropsychiatric Disorders**

The overall incidence of psychiatric disorders in children, adolescents, and adults with DS is around 20% (239–244). The pattern of psychiatric disorders shifts with age. Externalizing behaviors—ADHD, oppositional defiant disorder, conduct disorder, and aggression—are prominent in the school age child. Adolescents and young adults manifest more internalizing behaviors—withdrawal, shyness, impaired self-confidence. Depression is very common in older adolescents and adults with DS and should be considered before attributing a functional decline to dementia (245–248). It can lead to potentially lethal suicidal behavior (249). Obsessional slowness has been reported in individuals with DS who can spend hours performing daily routines (250). Anorexia nervosa is not unusual in DS (251–254) and has been reported in association with obsessive-compulsive disorder and depression (255). Other anxiety disorders, phobias, autistic disorder, stereotypy, and self-injurious behaviors are relatively rare. Dementia of the Alzheimer’s type appears as early as age 40 and 77% receive the diagnosis after the age of 60 years.

### **Management**

The neuropsychiatric management of patients with DS depends in part on the age of the patient. Counseling the parents of young children with DS can provide support while they struggle with any of the early medical complications. They need encouragement to provide early social and

developmental stimulation. Wishart recommends that parents and teachers focus on consolidation of existing skills and on dealing with the child's tendency to avoid challenging tasks (which may compromise performance on cognitive assessments) (226). There are multiple treatable etiologies for neuropsychiatric symptoms in DS patients that are unrelated to dementia (e.g., hypothyroidism).

### Williams Syndrome

Williams syndrome (WS) occurs in 1 per 25,000 to 1 per 50,000 live births. Individuals with WS are short (256) have a characteristic "elfin" facial appearance—a depressed nasal bridge with anteverted nares, medial eyebrow flare, stellate irides, small, low-set ears with prominent lobes, thick lips with a wide mouth, and curly hair. The voice is low-pitched, hoarse, and metallic (257–261). There is an exaggerated lumbar lordosis with flexion at the knees and hips (262, 263). Infants with WS are often of low birth weight and gain weight slowly. They are constipated, irritable, and overreactive to noises (264). Hypercalcemia, usually mild, occurs in the neonatal period and resolves spontaneously by age 2 years (265).

Neurological examination reveals esotropia (266), hypotonia, cerebellar signs and corticospinal tract signs as well as a higher incidence of left-handedness than in the general population (211).

Recurrent otitis media occurs in over 60% of children with WS (267), with the associated risk of a conductive hearing loss. Decreased visual acuity and strabismus occur frequently (268). Serious cardiac and vascular problems are associated with WS. In one series, 59% of children and adults with WS had a structural heart defect (supravalvular aortic stenosis, pulmonic artery stenosis, coarctation of the aorta, and cardiomyopathy) or vascular disease (vasospasm and stenoses resulting in stroke) (269). The vascular problems are the result of a deficiency of elastin in vessel walls (270). Thus, individuals with WS are at high risk for cerebral infarction at a young age (271). Hypertension occurs in about 50% of individuals with WS, likely secondary to the generalized arteriopathy discussed above, and increases the risk of stroke (274).

### Genetics

The WS critical region is composed of some 30 genes at 7q11.23. Over 99% of the DNA sequence of human chromosome 7 has now been identified and the orthologous sequences on mouse chromosome 5G have also been mapped with high accuracy (275). Identifying the genes responsible for WS challenges conventional mapping techniques because of the high density of repetitive sequences and the large (~300 kb) duplicated DNA sequences, which are nearly identical and vary from individual to individual (276). These result from the misalignment and crossing over of these low-copy repeat sequences which flank the WS critical region, and lead to chromosomal instability. Identifying

the genes responsible for the cognitive and behavioral features of WS phenotype has been particularly challenging. A number of different reports describing rare individuals with small deletions and only some of the somatic and cognitive phenotypic features characteristic of WS have appeared but definitive information is not yet available (277–279).

Many of the vascular features of WS results from haploinsufficiency of the elastin gene (ELN) (280–285). The decreased production of elastin alters the structure and mechanical properties of arterial walls (286). LIM kinase-1 has been considered a candidate gene for the cognitive deficits seen in WS (279, 285, 287, 288). It is a component of an intracellular signaling pathway, which regulates neuronal cytoskeleton, synapses and apoptosis through formation of actin fibers (289–291). LIM kinase-1 is expressed in fetal development, including neuronal differentiation of hippocampal progenitor cells (292, 293). It is also involved in hippocampal long-term potentiation (LTP), which is critical to memory formation (294). LIM kinase-1 knockout mice exhibit significant abnormalities in spine morphology, synaptic function, including hippocampal long-term potentiation and show altered fear response and spatial learning (295, 296).

Other candidate genes include those in the general transcription factor family, which are widely expressed throughout the brain during fetal brain development (297) and maybe related to mental retardation (279). Syntaxin 1A (STIX) and the gene for the human homologue of the *Drosophila* gene "frizzled", *FZD9*, were considered potential candidates but some patients with the classical WS phenotype have small deletions which spare these loci (298–302).

### Neurocognitive Profile

The IQ of most individuals with WS falls in the mild to moderate range of mental retardation (mean of 55; range 40 to 90) and remains stable across the lifespan (303, 304). Thus, the clinician can expect to encounter considerable variability in cognitive functioning among patients with WS.

There are several fascinating aspects of the neurocognitive profile of WS. As these children develop, an uneven cognitive profile emerges, characterized by relative strength in language, impaired visuospatial abilities, and a strong drive to engage in social interactions. In the preschool years, expressive language, and motor skills are often delayed. By school-age, the child with WS appears fluent and articulate, if not "verbose and pseudo-mature" (305). By the time that they are adolescents, children with WS have large, sophisticated vocabularies, consisting of unusual words. To give the flavor of these remarkable linguistic abilities of some individuals with WS, the following quote (the response of one of Dr. Bellugi's patients when asked what he would want other people to know about WS) is cited:

It is what you're born with, it is what you have to accept, and it is something that you go on day to day, year to year, month to month with. And no matter how people treat

people with Williams syndrome, you always have to stand tall and ignore the things that are said because they are, they don't understand the things that we go through every day that we wake up. We should be treated the same way somebody else should be treated. Even when times are bad we still try to shine a light upon other people, and to give that sense of glow to our friends . . . You have to accept things you cannot change. (306).

The language in WS has been a focus of considerable interest for linguists, as it is relevant to theories of the neural representations of language. Despite the relatively strong vocabulary of individuals with WS (albeit below that of controls) the way they organize their lexical information differs from that of normally developing individuals. (307–311). They use unusual low-frequency words both in spontaneous speech and when performing verbal semantic fluency tasks (e.g., words such as “brontosaurus” and “yak”) (211). Words are also used by individuals with WS in unusual ways; for example, “I have to evacuate the glass,” a phrase uttered by a girl with WS as she emptied a glass of water (210, p. 13). The WS profile has been the subject of considerable controversy. Bellugi maintains that individuals with WS have intact morphosyntactic rule and grammar systems and a deviant lexicosemantic system (307, 312), whereas others believe that the morphosyntactic abilities are in fact impaired (313). Clahsen has reported that individuals with WS performed as well as controls when inflecting regular forms but had difficulty on irregular forms, applying regular inflection forms to the irregular verbs; (for example, *ring*→*ringed*) (314). Based on the assumption that regular inflections are computationally-based and irregular inflections are lexically-based and stored in longterm memory, the investigators concluded that these children understand the rule-based systems of language (and thus are quite good in terms of managing regular syntax) but have difficulty with the items requiring access to the associative memory (lexical) system, required for manipulation of irregular forms. Cross-linguistic studies have tended to support this view (309).

Working memory is a relative strength in WS (mean digit span 4.6), (222, 309). Subjects with WS who had good working memory showed particular strength in producing irregular grammatical forms. Working memory was also associated with use of low-frequency words, suggesting that children with WS rely on phonological working memory to a much greater degree than normal children in the process of learning language. It would also explain their deficits in manipulating irregular syntax (315).

In comparison to relative strength in working memory which persists into adulthood, most individuals with WS have deficient episodic memory, particularly in the visuospatial domain, which becomes increasingly impaired as they age (222, 305, 307, 316–318).

Performance on visuospatial, graphomotor, and constructional tasks are significantly impaired in individuals with WS (312, 319–321). Children with WS have difficulty

integrating visual features into a global configuration—they see “the trees” rather than “the forest” (210, 211, 224). Drawings lack coherence and spatial orientation, perspective or depth, consisting of parts of objects scattered across the page. These deficits are not secondary to either fine motor or vision impairment per se (268, 322). Rather, the deficit involves the integration of visuospatial information and motor programming, thus implicating the dorsal parietal and frontoparietal functions (323).

Although verbal mediation can be used to compensate for these deficits, language describing spatial relationships is also impaired in individuals with WS (210, 324). They have difficulty understanding terms describing spatial relationships, in contrast to their relative strength in other conceptual areas (325).

Some individuals with WS have been reported to have a higher frequency of perfect pitch (1 per 20) compared to the general population (1 per 10,000) (326, 327).

### **Hypersociability**

The hypersociability of individuals with WS is a distinctive attribute. Babies with WS will stare intensely at faces for long periods of time (328). They tolerate brief separations from their mothers with few manifestations of distress (329). Older children with WS approach strangers in a fearless manner and engage them in conversation, a trait which is particularly concerning to mothers of adolescent girls (277, 329).

In story-telling tasks, children with WS demonstrated a remarkable ability to engage their audience. They changed their voices and used exaggerated prosody to enhance the story, provided interpretations of the mental states of the characters in the stories, and employed “audience hooks” (e.g., “Guess what happened next?” “What do you know?” and “Lo and behold, the frog was gone!”). These devices were utilized to a much greater extent than normal controls. Similar behaviors were noted in the course of a semi-structured interview (329).

The performance of persons with WS on Theory of Mind tasks (i.e., the ability to make inferences about another individual's perspectives and motivations) is again uneven. Older children and young adults with WS were able to make appropriate inferences about the intention of others at a level comparable to that seen in normally developing controls. They were able to deal with more difficult tasks, such as the interpretation of sarcasm, and 44% passed second-order knowledge questions, but some had difficulty discriminating lies from jokes (330).

However, despite their apparent sociability, children and adults with WS are not very successful in developing and keeping friendships (331). They typically relate to adults better than to peers (329, 332).

Although some aspects of the WS profile resemble that of individuals with nonverbal learning disorder or right-hemisphere dysfunction, individuals with WS are more attuned to the emotional state of others and more able to

describe their own emotions in detail. They lack the prosodic flatness that is often seen in persons with right hemisphere dysfunction. Their performance on the Facial Recognition and Noncanonical Views tasks (i.e., a test in which one is given views of an object in different lighting and from different vantage points) is surprisingly proficient. However, the strategies they use are different than those employed by controls, suggesting that facial processing follows an abnormal course of development (311, 333, 334).

### Academic Achievement

Children with WS remain in special education classes throughout their educational exposure (335, 336). Although they perform as well as controls (matched for reading and verbal mental age) on most phonological awareness tasks and are able to link a word's orthographic form to its phonological representations, they do not necessarily associate the word with its meaning (337, 338). Thus, in some ways they are hyperlexic—they may perform better in single word reading than would be predicted by IQ, but their comprehension is poor (339, 340). Writing and arithmetic are areas of weakness, which persist into adulthood (210, 341).

### Neuropsychiatric Disorders

Children with WS are rated by parents and teachers as being fussy, fearful, anxious, shy, distractible, and hyperactive (342–347). One interesting aspect of the attention problem is “sticky fixation”—difficulty disengaging and shifting attention from one target to another. This may reflect dysfunction in the dorsal (parietal) pathway (323). Sticking fixation is seen in normally developing infants aged 3 to 5 months, but not after 6 months. In the child with WS, it may persist until the age of 5 to 6 years. These children also have particularly difficulty modulating incoming stimuli and regulating their levels of arousal. This is particularly true with regard to loud noises which provoke great distress—crying, rocking, and self-injurious behaviors (267, 348). As many as 95% have hyperacusis, which tends to improve with age (263). Clinically significant anxiety, obsessions, and phobias often persist into adulthood (349, 350). Depressive symptoms tend to increase with age (351).

Difficulty initiating and sustaining sleep, associated with frequent nocturnal arousals and difficulty settling back to sleep is a common problem. Parents often need to soothe the child who cannot otherwise settle down to sleep. The arousals may be related to periodic limb movements (352).

### Brain Structure and Function

The brain in WS is small (800 to 1000 grams; MRI morphometric studies reveal a reduction of 13% in total brain volume compared to controls). There is relative preservation of cerebellar volume: lobules VI-VII and VIII-X are enlarged and the posterior vermis is significantly larger, after controlling for the reduction in the size of the WS brain

(353). Brainstem tissue volume is reduced by 20%. In general, there is relative sparing of frontal regions and a selective reduction in posterior areas of the WS brain (188, 190, 211, 354–356). In an MRI study using much thinner slices and better resolution, this observation was only partially replicated: decreased occipital gray matter volume, particularly on the right and increased parietal gray matter volume was noted (300). Schmitt et al. described the distinctive shape of the WS brain, characterized by less of a curve in the corpus callosum as well as in the angulation of the anterior/posterior areas relative to frontal areas in the sagittal plane which may reflect the decrease in the ratio of frontal to parietaloccipital volumes (357).

There is a disproportional reduction of cerebral white matter with relative sparing of gray matter (300). In particular, gray matter in the superior temporal gyrus (STG) volumes in subjects with WMS were proportionally larger compared to controls. The corpus callosum is noted to be decreased in size, particularly in the isthmus and splenium (358, 359). However, women with WS were noted to have decreased gray matter volumes bilaterally in the superior, not the inferior parietal lobule (360). This finding would implicate specific involvement of dorsodorsal stream which control “on line” motor behaviors. Lesions in this area result in optic ataxia (361), and would be consistent with the deficits in visuomotor integration observed in individuals with WS. Corroborating information from functional neuroimaging studies have demonstrated that the parietal segment of the dorsal stream is hypoactivated in WS (362).

Anomalous patterns of cortical gyrification have been noted. Increased gyrification was noted most prominently in the left frontal and right parietal and occipital areas (363). Shortening of the central sulcus with relative hypoplasia of the occipitoparietal regions has been observed. The cytoarchitecture of cortical forebrain areas is relatively normal (354).

During face perception tasks, WS subjects show a pattern of activation of the fusiform gyrus that is similar to controls (364). However, in an ERP study of face processing, individuals with WS demonstrated an abnormally small negativity at 100 msec (N100) and an abnormally large negativity at 200 msec (N200) to both upright and inverted faces. The small N100 /large N200 ERP may represent an electrophysiologic marker for abnormal face perception in WS (334).

These structural and functional neuroimaging studies provide further evidence for the anomalous anatomical features of the WS brain. However, at this point in time, the genes in the WS critical region that result in these aberrant morphological features have not been identified. The aberrant gyrification patterns, reduction of gray matter in the parietal lobe, and the relative decrease in white matter suggest that brain development is affected at different points in time and by different mechanisms across development. The relationship between the structural and functional anomalies in the dorsodorsal parietal region provides a pathophysiological basis for the visuospatial deficits seen in WS.

### Management

The management of persons with WS starts with a detailed assessment of intellectual and functional ability. The high rate of medical complications associated with WS, particularly with aging, requires close collaboration with other physicians.

Young children with WS are often particularly handicapped by a combination of visuospatial deficits, deficient expressive language, hyperacusis, severe ADHD, and an array of anxieties, phobias, and a lower threshold for arousal. Tomc suggests that parents should be counseled regarding these difficult temperamental characteristics and supported in their attempts to deal with a difficult child who “should be easy”; (that is, they appear friendly and outgoing) (365). ADHD may respond to treatment with psychostimulants (366). Sensory integration techniques aimed at helping the child to modulate arousal level and hypersensitivity to environmental stimuli (particularly auditory stimuli) may be helpful. The use of auditory filters has been suggested (348). It is helpful for the parents, teachers, and mental health professionals to understand the developmental trajectory of children with WS—namely, that as they mature they may develop relative strengths in the area of expressive language but continue to have severe intellectual and academic deficiencies. The school-age child will require selection of an appropriate class placement and learning disability support.

The remarkable language skills of persons with WS and their engaging way of relating may lead caretakers into erroneously assuming that the individual’s functional ability is comparable to their linguistic skill. In fact, the individual with WS has a simplistic understanding of the functional aspects of day-to-day living (e.g., the purpose of going to the bank is to get money). They continue to struggle with fine motor skill deficits (they need help in tying shoelaces), visuospatial deficits, and difficulty with social relationships. Most adults with WS live a solitary existence; are restless, anxious, and fearful; and continue to be troubled by hyperacusis. Fewer than 5% are employed in the general work force. Most live and work in sheltered environments (335, 367).

### Turner Syndrome

#### Epidemiology

Turner Syndrome (TS) is the most common sex chromosome abnormality in females, occurring in 1 in 1,500 to 2,500 live born females (368, 369). Two to three percent of all females conceived have an XO karyotype. Only 1 to 1.5% survive to term (370).

Characteristic features include short stature, low posterior hairline, lymphedema of the hands and feet, anomalous ears, and a narrow maxilla. A webbed neck and increased chest diameter (“shield chest”), are strong predictors of aortic and pulmonary venous anomalies (371). Gonadal dysgenesis, apparent in the 20-week fetus, results in ovarian failure which can occur either before puberty or later. Most (85 to 95%) of the girls with monosomy (45X)

and 60% of mosaic TS fail to enter puberty spontaneously (372). Women with TS are at high risk for osteoporosis and other medical complications associated with estrogen deficiency. Spontaneous pregnancy is rare and the rate of fetal wastage and birth defects is very high (373, 374).

Serious medical problems in TS include cardiac anomalies (17 to 45%), prominently coarctation of the aorta and bicuspid aortic valve (375), aortic dissection (373), hypertension (in 7 to 17% of children and 24 to 40% of adults) (375), and congenital renal anomalies (25 to 43%) (373, 376–378). A mild conductive hearing loss (as a result of chronic otitis) occurs in over 50% of girls with TS. A progressive sensorineural hearing loss may also occur (379–381). Impaired glucose tolerance, insulin resistance with Type 2 diabetes mellitus, (382), hyperlipidemia, ulcerative colitis, Crohn’s disease, and autoimmune thyroid disease are frequently associated with TS (383). Growth failure secondary to a primary bone defect, and possibly a relative growth hormone deficiency result in slow growth in childhood. The height of adults with TS falls two standard deviations below the mean (373).

#### Genetic Features

TS is characterized by the absence of part or all of the second X chromosome (in some cases, absence of part of the Y chromosome). Approximately half of the girls with TS have monosomy X- (45, XO), which is associated with the most severe anomalies (373, 384). In 70%, the single X chromosome is of maternal origin.

Two copies of the X chromosome are required for normal development of the female (385). Early in the normal embryonic development of females, one X chromosome in each cell is transcriptionally silenced (or “inactivated”), with the exception of the genes in the pseudoautosomal region 1 (PAR-1), located in a 2.6 Mb region—Xp11.2–p22.1—at the distal end of the short arm. (In males, the short arm of the Y chromosome contributes a similar set of genes from PAR-1). Thus, deletion of one copy of PAR-1 genes can result in the TS phenotype (380, 386). Genes associated with ovarian failure, high-arched palate, and autoimmune thyroid disease have also been mapped to this region (386).

The X-inactivation site (XIST) is located at Xq11.2–q21 on the long arm of the X chromosome. It is required for the transcriptional silencing of the second copy of the genes on the X chromosome, except for those in PAR-1. Inactivation typically involves any faulty genes. Genes (specifically paternal genes) are initially silenced well before cellular differentiation, later reactivated, and then randomly silenced again (387). Deletion of the XIST site, which occurs in some cases of small ring chromosomes in TS, may be associated with severe anomalies or retardation (388–390).

Imprinting, that is, whether the X chromosome comes from the father ( $X^+$ ) or mother ( $X^m$ ), may also result in different cognitive and behavioral phenotypes.

Somewhat different genetic patterns are associated with different TS phenotypes. Seven to 18% of individuals with

TS have an isochromosome (46,Xi(Xq), that is, two identical chromosome arms due to duplication of one arm and loss of the other arm. This genotype is linked to increased risk of deafness and autoimmune disorders. Mosaicism (45, X/46, XX) occurs in 10% and is associated with a milder neurocognitive phenotype, less growth impairment, and less ovarian dysfunction (391). Approximately 2% of women with TS have 46,XXp- and 46,XXq- genotypes with variable phenotypes. Ring chromosome, 46,Xr(X), sometimes associated with a severe phenotype, occurs in 6 to 10% of TS subjects (388–390). In about 7% of TS cases, Y chromosome material is present as a result of deletion of the Y chromosome (45,X/46,XY) as demonstrated by polymerase chain reaction (392, 393). There is a significantly increased risk for gonadoblastoma; virilization is inconsistently present (392, 393).

### Neurocognitive Profile

The TS cognitive profile is characterized by average-range verbal skills and impaired visuospatial/motor/perceptual skills, visual memory, prefrontal executive function and processing social-emotional interactions (394–408).

A study was undertaken comparing the neurocognitive performance of women with TS to those with premature ovarian failure (409). Both groups had early estrogen deficiency and both had received estrogen replacement therapy (410). The performance of the women with premature ovarian failure did not differ from that of normal controls; whereas the women with TS manifested the characteristic visuospatial perceptual skills deficit, suggesting that the cognitive deficits in TS are the result of anomalous brain development rather than estrogen deficiency. In a study in which adolescent girls with TS were randomly assigned to placebo and androgen (oxandrolone) treatment groups for two years, there was a small but significant improvement in working memory in the treatment group (411).

In the academic sphere, reading skills in TS are relatively intact. Individuals with TS are able to read irregular words, and manifest strength in phonological awareness and comprehension (412). Despite the strength in phonologic awareness, they are impaired in nonword reading, which is an unusual pattern and may be a manifestation of executive function deficits (394).

Poor performance in the area of arithmetic, especially numerical ability, mental calculation, geometry, and reasoning are characteristic of the TS population (403, 413–415) and is apparent in kindergarten and shows little improvement. They perform poorly on tasks involving cognitive estimation and rapid enumeration of small quantities which depends in part on storing a specific configuration in memory and calculation ability (400, 414, 416).

Girls with TS have difficulty with facial affect recognition, particularly identifying fearful facial expressions. Their deficit is as impaired as that seen in patients with bilateral amygdalectomies (397, 417, 418). Similar impairment was noted in a study in which they were asked to

identify mental state from images of the upper face (“reading the mind in the eyes”) (419). Some studies evaluating their ability to detect small shifts in gaze have indicated impairment as well (420).

The TS neurocognitive/behavioral profile (in 70% of females with TS)— verbal ability superior to visuospatial ability, motor impairment, prefrontal executive function deficit, relative strength in language-based academic tasks compared to weakness in arithmetic coupled with difficulty in the social-emotional sphere— bears a strong resemblance to nonverbal learning disability (421).

There is considerable variability in individuals, and the degree of impairment on task performance depends, in part, on the complexity of the task and the cognitive load that is placed on frontal-executive system resources (407, 408). In addition, the specific pattern of affected genes may determine the neurocognitive profile, although more data will be required before firm conclusions can be drawn. The genes related to the TS neurocognitive profile have been mapped to the PAR-1 region (380). Overall, TS subjects with monosomy perform more poorly than mosaic TS subjects, who may perform within the range of controls on some verbal tasks. Both the mosaic and monosomic TS groups are significantly impaired on visuospatial and memory tasks compared to controls, suggesting specific impairment of association neocortex (422). Imprinting may contribute to the TS cognitive phenotype. Skuse found the women with 45,X<sup>P</sup> to have superior verbal and executive function and better social adjustment (423). Moreover, 40% of the subjects with 45,X<sup>m</sup> had been in special education settings in comparison to only 16% of the subjects with 45,X<sup>P</sup>. Autistic disorder in TS occurs in association with the 45,X<sup>m</sup> phenotype more frequently than would be expected in the general population (424). Severe social problems, significant obsessive features, aggression, impulsivity, and attention problems have been reported in patients with small ring X chromosomes (425).

### Psychiatric and Behavioral Aspects

The social difficulties of girls with TS require sensitive handling. As children, they are at risk for being teased and marginalized by peers because of their unusual appearance, short stature, and poor motor skills (381, 426, 427). They have few friends and are often socially isolated (427). Their impaired social skills, which arise in part because of difficulties processing emotional signals, may also result from their decreased emotional arousal and restricted emotional facial expressions, and need to be addressed in their management (428–430). Not surprisingly, girls with TS have serious deficits in self-esteem (369, 427, 431, 432).

Inattention, hyperactivity, and impulsivity are often severe enough to meet formal criteria for ADHD, and impair academic performance and social interactions. When compared to their sisters who do not have TS, affected girls had higher ratings of social, attention or thought problems on

the Child Behavior Checklist (126). Anxiety has been reported but is not consistently found (428, 433).

### Neuroimaging Studies

Total brain volume of individuals with TS does not differ from that of controls (434). However, as might be predicted from the neurocognitive profile, neuroimaging studies demonstrate abnormal structure and function in areas subserving visuospatial and executive functions. The structural anomalies in the TS brain are prominently in the occipito-parieto-temporal regions. These include regional decreases in tissue volumes in the parietal areas, particularly the superior parietal and postcentral gyri (435), as well as occipital white matter (with some imprinting effects) (436), and reduced size of the genu of the corpus callosum (408). Anomalies of the right intraparietal sulcus have been reported (407). Reiss noted increased proportions of white and gray matter in the right posterior area (434). White matter pathways in the temporal lobe, the gray-white interface of superior temporal sulcus, and the inferior interparietal region are disrupted (406–408). Full-Scale IQ scores showed a significant positive correlation with postcentral tissue volume (435).

Anomalous structural and functional features of the superior temporal gyrus, which plays a crucial role in the processing of social-emotional signals, have been noted. Gray matter volumes in this area are larger than observed in controls (an effect particularly obvious in the 45,X<sup>m</sup> suggesting that neuronal pruning is differentially regulated in some way) (437). In a sample limited to 7- to 12-year-old girls with XO monosomy, (not on estrogen replacement, thus, eliminating issues of age or hormonal effect), an increase in temporal lobe gray matter was noted (394). Magnetic resonance spectroscopy findings were also consistent with a possible failure of normal neuronal pruning, which may also be reflected in the disturbed gyrification and sulcation that is prominent in the superior temporal sulci (407). The size of temporal gyri was correlated negatively with performance on auditory rhyme and semantic fluency (394).

The amygdala, a structure implicated in the recognition of fearful facial expression (438) is significantly larger in TS females than normal XX females and interestingly, even larger than in 46,XY males (417). It is a sexually dimorphic structure: normal 46,XY males have significantly increased amygdala volumes in comparison to normal 46,XX females, so that the finding of the larger amygdala in TS females is a distinct anomaly. The amygdala is tightly interconnected with orbitofrontal cortex and forms one of the functional neural units involved in emotion-processing. The finding that the orbitofrontal cortex is larger in TS females than in normal XX females or XY males provides a possible explanation for the deficits that TS women manifest in the processing of facial emotional displays, particularly in the recognition of fearful emotional expressions. Good et al. suggest that the amygdala and orbitofrontal cortex constitute a functional unit which is specifically affected in TS.

Although hormonal factors are a possible explanation, Good et al. did not note any clear relationship between ovarian function and neuroimaging or neuropsychological findings. Enlargement of the left amygdala was also noted in a study involving younger subjects suggesting that rather than any hormonal effects, it is X-linked genes gene dosage effects that influence amygdala development (439).

Decreased hippocampal gray matter volume is associated with memory deficits on neuropsychological testing in TS (434, 436, 439, 440). Smaller volumes of the caudate, lenticular, and thalamic nuclei were noted in women with TS (441). Some studies have noted abnormalities in the cerebellum and brainstem, but the findings are inconsistent and may be explained by different technical methods (406, 408, 436, 442–445).

Functional neuroimaging studies have demonstrated that women with TS not only fail to activate the cortical areas employed by normally developing individuals during the performance of certain specific cognitive tasks, but also fail to employ frontal resources when required to deal with increased task difficulty (406, 407, 444, 445). For example, subjects with TS activated the same frontal-parietal network as normal controls when performing simple computational tasks, but decreased activation in these areas when they were required to perform exact calculation of large numbers, (406, 444). They performed more poorly than controls on both the easy and hard versions (1-back and 2-back) of a visuospatial working memory task, and, unlike controls increased activation bilaterally in the supramarginal gyrus during the 1-back task, and during the 2-back task decreased supramarginal gyrus activation as well as dorsolateral prefrontal cortex, and caudate (446). Thus, cognitive function in TS appears to result from dysfunction of posterior association cortices, possibly as the result disturbance of neuronal pruning as well dysfunctional connectivity as a result of disruption of the underlying white matter pathways.

### Management

The array of cognitive and executive function deficits presents a formidable challenge for the treating psychiatrist. The problems surrounding social competence and sexuality in combination with numerous medical disorders make the girls and women with TS particularly vulnerable to emotional problems. The medical problems associated with TS continue throughout the life span. Parents of young children need guidance in understanding the cognitive and psychosocial implications of the diagnosis and making reasonable choices with regard to growth hormone and estrogen replacement. The psychiatrist will play an important role in helping the girl with TS who is approaching puberty understand the implications of ovarian dysfunction and the absence of pubertal development and child-bearing potential as well as working through the risks and benefits of estrogen replacement therapy. In addition, assisting the girl

with TS in dealing with the difficulty in reading social cues and developing effective coping strategies is beneficial.

## Prader-Willi Syndrome

### Epidemiology

The prevalence of PWS has been estimated as falling between 1 per 10,000 and 1 per 52,000 (447–450). There is no specific racial preponderance. Boys and girls are equally affected, except for one particular genetic subtype, uniparental disomy, in which there is a male predominance (451).

### Physical and Behavioral Phenotypic Features

Persons with PWS are typically short, obese, with small hands and feet, delicately, tapering fingers, a narrow bifrontal diameter, full cheeks and almond-shaped eyes. About 75% of patients are hypopigmented relative to other members of the family (452–454). Ocular hypopigmentation has been found in about half of patients with PWS and is often associated with strabismus and nystagmus (455). The physical and behavioral features of PWS change with maturation. Even before they are born, mothers report diminished fetal activity (456). Newborns are small, profoundly hypotonic, have hypoactive reflexes, severe feeding problems, failure to thrive, and may have apnea. During the first year of life, the feeding problems resolve. Initially pleasant and rather docile in the second to third years of life, the PWS child develops rampant food-seeking behaviors which leads to gross obesity around 6 years of age (457, 458). Anger, aggression, and obsessive-compulsive behaviors also emerge during the preschool years.

Thus, when making a diagnosis of PWS, the child's age must be taken into consideration. The following criteria for genetic testing, DNA methylation analysis, which take the age-related shift in the phenotypic profile into account were proposed by Gunay-Aygun in 2001 (459). In the birth to 2-year old age range children presenting with hypotonia and poor suck in the neonatal period should be tested. Similarly, in the 2- to 6-year range a child with this neonatal history, hypotonia, and global developmental delay should undergo testing. Those in the 6- to 12-year range with this neonatal and developmental history, coupled with excessive eating with central obesity are candidates. Adolescents and adults with this history, mild mental retardation, excessive eating with central obesity, hypothalamic hypogonadism, and/or the typical PWS obsessive-compulsive behaviors and temper outbursts should be screened (459). The parent-specific DNA methylation imprint is present in the PW critical region in over 99% of patients with PWS. Once the diagnosis is confirmed by methylation analysis, the specific type of mutation is identified.

### Genetic Features

The PW critical region is on chromosome 15q11–q13 encompasses 4 million base pairs containing 50 to 100

genes/transcripts, some of which are highly relevant to the neuropsychiatric features. There are several different genetic subtypes of PWS. The most common (70% of cases) involves an interstitial deletion (absence of the paternal genes), 25% have maternal disomy (that is, two copies of the maternal gene, and none from the father), and 2 to 3% have a mutation of the imprinting center or other anomalies of the imprinting process. There is evidence that suggests that maternal disomy results from the "correction" of a trisomy 15 state.

There are some differences in the somatic and cognitive/behavioral phenotypes depending on the particular genetic subtype. The typical phenotype is seen in children with paternal deletions. Individuals with mosaic trisomy 15 have the most severe phenotype, whereas those with maternal uniparental disomy have a milder phenotype (460). The oculocutaneous albinism II (OCA2) gene (formerly the P gene) is located at 15q 11.2–12 and is deleted in most patients with paternal deletions. These children are hypopigmented relative to other members of their families. Less than half of those with uniparental disomy are hypopigmented (451, 452, 454). Highly relevant to the psychiatric manifestations of PWS is the fact that the genes encoding the alpha (5), beta (3), and gamma (3) subunits of the gamma-aminobutyric acid type-A (GABA(A)) receptor lie within the PWS critical region (461–465). There are rare cases of patients with the PWS phenotype who on genetic testing have a chromosome 15 deletion and imprinting defect typical of Angelman's syndrome (a genetic disorder which involves the same region of 15q as PWS but disomic individuals have two copies of the maternal chromosome) (466).

A number of genes which regulate various aspects of brain development have been mapped to the PW critical region (in the mouse orthologous genes are located on mouse chromosome 7C). Although a number of genes have been identified in this region the molecular features of PWS have not as yet been fully identified. One of the genes is the small nuclear ribonucleoprotein particles (*snRPN*) gene, which is maternally imprinted. Mutations of this gene might affect RNA-splicing (467). *Magel2* is specifically expressed in developing hypothalamus. Other genes, such as the highly conserved genes NIPA 1 and NIPA 2, which may function as transporters or receptors, have also been identified. The precise role of these genes has yet to be identified. Loss of expression of small nucleolar RNAs, involved in various aspects of RNA-processing, has been suggested to be an important factor in the PWS phenotype (468).

### Neurocognitive Profile

Individuals with PWS have intelligence quotients ranging from average to severe mental retardation. In a population-based study the IQ distribution was normal, but shifted downward by about 40 points (469). Typically there are relative strengths in visuospatial ability and relative weakness

in the verbal sphere, although not all persons follow this pattern (470, 471). PWS children may perform as well as peers of normal intelligence on word searches and outperform them on puzzles (472).

Speech and language deficits are prominent. In the preschool child, oral motor and articulation difficulties are primarily affected (473–475). Kleppe et al. reported that in their sample of children with PWS, 88.9% fell below the 6<sup>th</sup> percentile on tests of receptive language (474). This may be related to the behavioral problems that are characteristic of PWS children, as receptive language delays contribute to oppositional, angry, aggressive outbursts and academic frustration (469, 476). Developmental language disorder also contributes to impaired reading comprehension. It is thus of interest that Burd and Kerbeshian described such a hyperlexic adult with PWS with an IQ of 75 who was able to read fluently but with poor comprehension (477). It is common, however, for the academic performance of children with PWS to fall considerably below the level of their measured intelligence. Whittington et al. attributed it to placement in restrictive educational environments because of behavior problems (469).

Cognitive and behavioral profiles appear to be related primarily to the particular genetic subtype (478). Subjects with uniparental disomy had better verbal abilities but impaired coding ability, compared to the deletion group. Some subjects in the deletion group had strong visuospatial skills. Cassidy compared 37 individuals with paternal deletion to 17 individuals with uniparental disomy and noted that the group with uniparental disomy had less skill with jigsaw puzzles, and had a more normal pain threshold and less skin picking (453). Butler et al. (479) examined PWS subjects with large deletions (500 kb or more), those with smaller deletions, and those with uniparental disomy. Large deletions were associated with lower adaptive behavior scores, and more academic difficulty compared to the smaller deletions. Those with the large deletions also manifested more OCD behaviors than subjects with disomy 15. Butler et al. noted that four recently identified genes are deleted in the large not the small deletion and that these genes are implicated in OCD behaviors. Somewhat different conclusions were reached by another group, who conducted a telephone survey using the Autism Screening Questionnaire (ASQ) and the Vineland Adaptive Behavior Scales. These investigators found that subjects with maternal uniparental disomy manifested more autistic symptomatology (480).

### **Psychiatric and Behavioral Aspects**

The toddler with PWS is often friendly, charming, well-intentioned and generous. However, during the preschool years, there is a dramatic change in behavior. The child develops incessant food-seeking behavior, aggressive rages and tantrums, becomes stubborn and perseverative, and has repetitive skin-picking, and obsessive-compulsive behaviors. Children with PWS tend to be rigid and inflexible in their thinking. These behaviors reach a peak in adolescence and

young adulthood, and start to decline in intensity around age 30 years (481–484). A variety of psychiatric disorders have been described in patients with PWS—obsessive-compulsive disorders, conduct disorder, depression, bipolar disorder, ADHD, psychosis, and self-injurious behavior.

Obsessive-compulsive symptoms are prominent in patients with PWS and include hoarding, ordering and arranging, repetitive concerns, and symmetry (485, 486). Anger and irritability are extremely common, occurring in 84.8% of subjects with PWS. Nearly half (42.1%) meet DSM-III-R criteria for conduct disorder in childhood (486).

Depression is also noted in some patients with PWS. In one study 16.4% had a history of depressed mood for more than 2 weeks (486). More boys than girls appeared to be affected (481). Attempted suicide was reported in 4.9% (486). ADHD is seen in pre-adolescents (487). Anxiety disorder or panic attacks/panic disorder occur rarely (in less than 10% of subjects with PWS) (486).

Psychosis has also been described in patients with PWS. In a longterm study, 6 of 59 patients with PWS experienced a psychotic episode during adolescence (488). The presenting features included agitation of sudden onset, abnormal beliefs, and auditory hallucinations and severe affective disorder (488–492). Virtually all of these cases of psychosis occurred in patients with maternal uniparental disomy and were not associated with paternal deletions.

Self-injurious behavior (repetitive skin-picking and hair pulling) is a common problem and a source of constant stress for parents (80, 493, 494). The sores heal very slowly and sometimes not at all because of repetitive injury. Rectal digging is a variant of this behavior and has been misdiagnosed as inflammatory bowel disease (495). It has been suggested that picking behaviors may be an attempt to increase sensory input, or may represent a behavior in the OCD spectrum (486, 496–498).

Gamma amino butyric acid (GABA) is a widely distributed inhibitory neurotransmitter which plays an important role in neuropsychiatric function. GABA(A) receptors are ligand-operated chloride channels assembled from five subunits, which mediate fast inhibitory neurotransmission (499). The physiological and pharmacological properties of these receptors are related to the particular combination of receptors. This permits flexibility in signal transduction and allosteric modulation, enabling neuronal networks to detect pre- and postsynaptic signals, and select and stabilize response patterns. This changing pattern of sensitivity in receptors enables the synapse to respond differentially to the same type of stimulus and thus permits remarkable response modulation (500, 501). Different brain regions are associated with specific GABA(A) receptor subunit configurations, suggesting that there are functional differences depending on the combination of receptor subunits in that region (499, 502).

There is a remarkable structural heterogeneity in the GABA (A) receptor family. Twenty-one GABA(A) receptor subunits have been identified at this point, distributed

among 8 different subunit “families.” (502–506). Genes encoding the alpha (5), beta (3) and gamma (3) subunits of the gamma-aminobutyric acid type-A, GABA (A), receptor have been mapped to the PWS critical region. Given the crucial role of GABA (A) in receptors in brain development and neuronal signaling, one would expect that the absence of these subunits of the GABA (A) receptor would have a profound effect on neuronal connectivity, cognition, and behavior. These subunit types are concentrated in the neostriatum, lateral geniculate nucleus, amygdala, hypothalamus, and hippocampus in a rat brain— all regions shown to be involved in the regulation of social behaviors, mood, autonomic regulation, memory, and motor behaviors (499, 507–510).

Although GABA is viewed as an inhibitory neurotransmitter in the adult brain, it is expressed in the fetal brain and plays a crucial role in brain development (511–514). During the early phases of fetal brain development, GABA (A) receptor subunits regulate cell proliferation in neocortex (515, 516) and hippocampus (517). As brain development progresses, they play a role in the regulation of neuronal migration (518), as well as synaptogenesis (519–521). Thus, GABA (A) is an important regulator of neuronal plasticity (522).

In the adult brain, the finely-tuned GABAergic activity in hippocampal inhibitory interneurons contributes to synaptic plasticity and thus to learning and memory (523, 524). The GABA (A5) subunit is expressed abundantly in the hippocampus and only minimally in other areas of the brain. A number of studies have demonstrated that in the GABA (A5) knock-out mouse in which GABA (A5) activity is decreased, performance on hippocampus-dependent learning tasks, particularly those involving visuospatial memory, is enhanced (525, 526). Similarly, when the alpha 5 subunit binds inverse agonists (that is, agents which shifts the equilibrium of the receptor toward its inactive state), enhanced memory is observed with improved spatial learning (527, 528).

What are the observed effects of the deletion of these GABA (A) receptors in PWS? Plasma GABA levels are much higher than normal in individuals with PWS and Angelman’s syndromes (in which the same area is deleted) but not in obese or mentally retarded control subjects, possibly because of increased release of presynaptic GABA as a compensation for the decrease in GABA-A receptor units (529). However, since not all GABA receptor types map to the region of the deletion, the remaining GABA receptors are exposed to much higher neurotransmitter levels than is normal. Given the important role that GABA (A) plays in early brain development, neuronal connectivity and neuronal transmission may be affected. Certainly, many of the behaviors seen in PWS—aggression, arousal, impaired motor function, decreased response to pain, and impaired satiety mechanisms—could be attributed to this sequence of problems. Moreover, given the role of GABAergic interneurons in binding and synchronizing the neuronal activity of various cortical networks and, on a cognitive level,

conscious experience, GABA has been postulated to play a role in the development of psychosis (530–532).

Overeating and food-seeking behaviors in patients with PWS result in severe obesity and all the secondary medical problems that are associated with obesity (including cardiovascular disease, obstructive sleep apnea, diabetes, and degenerative joint changes). The behavioral problems associated with food-seeking pose formidable challenges for parents in their day-to-day management of these children. Behavioral problems are positively correlated with body mass index (482, 483). There is little question that persons with PWS can ingest enormous quantities of food when left to their own devices. In one study, subjects with PWS ate steadily for an hour and consumed more than three times as much food as did normal controls (1,292 vs. 369 calories) (533). Satiety was reached only when subjects became markedly hyperglycemic (534). Moreover, individuals with PWS, even underweight infants, have proportionately more body fat than controls, as measured by skin fold thickness (535). Abnormal fat metabolism is, in part, related to growth hormone deficiency (536). Although it appears likely that the overeating is related to hypothalamic dysfunction, the precise pathophysiological mechanism has yet to be identified. An fMRI study demonstrated that hypothalamic activation in PWS subjects in response to a glucose load occurred only after a 24-minute delay, in contrast to healthy lean subjects who showed this activation in 10 minutes, and obese subjects in 15 minutes. The activation of other areas (prefrontal cortex, insula, ventral basal ganglia) which regulate hunger and satiety was also delayed (537). Considerable attention has been focused on ghrelin, a peptide expressed in the stomach and hypothalamus that stimulates both growth hormone and prolactin secretion. In normal individuals, increased plasma ghrelin concentrations are associated with increased subjective ratings of hunger. Individuals with PWS have markedly elevated ghrelin levels compared to other obese patients (538–540). However, two short-duration studies failed to demonstrate that lowering ghrelin levels effectively inhibited food-seeking behavior (540, 541).

Other evidence of hypothalamic dysfunction is suggested by extremely high fevers in young infants with PWS, deficient growth hormone production (542), decreased size of the adrenal glands (543), and decreased bone mass density probably as a result of high bone turnover and in males appeared to be related to lower levels of sex steroids (544). The posterior hypothalamus is involved in the regulation of wakefulness and REM sleep (545–547), and dysfunction in this area may underlie the sleep disturbance frequently noted in PWS.

### Management

Treatment of persons with PWS requires broad behavioral, medical and neuropsychiatric approaches. Interventions should include control of weight including restriction to foods in all environments (548), management of sleep apnea, if present, exercise (549, 550), hormone replacement,

and psychopharmacological treatment of self-injurious behaviors, and psychiatric issues.

Receptive language impairment can have a negative impact on social interaction. Taking time to understand what the individual understands in a given conversation is essential. Furthermore, the use of visually-based communication (for example, gestures and visual cues), the more effective, successful, and helps the person with PWS with a greater sense of being understood and self-control.

Limiting access to food in all environments, as well as exposure to food-related stimuli (e.g., viewing pictures of food, working in food preparation, having access to leftovers and garbage) is the foundation of effective weight management. Foods should be prepared by others in limited portions, and in most households it is necessary to lock cupboards and the refrigerator. Limiting access to food is much more effective than any other approach. (533, 551, 552). Hormonal replacement with growth hormone improves growth, body composition (decrease in fat mass and increase in lean body mass), physical strength (including respiratory muscles), agility, bone density and fat utilization in children with PWS, as well as improvement in depressive symptoms and behavior (487, 553–556), although there are also reports of adverse events associated with growth hormone therapy (487, 553).

## Velocardiofacial Syndrome

### Epidemiology

Velocardiofacial syndrome (VCFS), originally described by Shprintzen, is a genetic syndrome found once in every 2,000–4,000 live births (557, 558, 559).

### Physical Features

The VCFS phenotype is extremely variable. Some affected children have major cardiac defects and thymus aplasia, so severe as to be fatal, whereas others may have only subtle craniofacial dysmorphic features. Patients are often of short stature. There is a typical facial appearance—narrow palpebral fissures, prominent tubular nose, narrow alae nasi, low-set, dysplastic ears, and retrognathia. Cardiovascular malformations include anomalies of the aortic arch, pulmonary arteries, defects of the infundibular septum, and malformations of the semilunar valves (560). These congenital heart defects require surgical repair in early childhood (561). Renal anomalies may also occur (561). Cleft palate and velopalatal insufficiency result in feeding problems in infancy, and speech and articulation problems later in childhood (562–564). Absent or hypoplastic adenoids and laryngotracheal anomalies and laryngeal stenosis also contribute to communication problems (561). Congenital ear anomalies result in middle ear infection in almost 50% of children with VCFS, with a secondary conductive hearing loss. About 11% of individuals with VCFS also have a sensorineural hearing loss (562). Hypocalcemia or immune disturbances may occur (561). Although VCFS is

associated with a high rate of birth defects and dysmorphic features, one third of individuals with VCFS do not have such anomalies (565). Thus, the absence of these congenital anomalies is not a reason for not performing genetic testing (565–567).

### Genetic Aspects

VCFS results from a microdeletion at 22q11.2. Most deletions are de novo, sporadic deletions. There is considerable phenotypic overlap between VCFS, DiGeorge syndrome, and conotruncal anomaly face syndrome, all of which involve deletion of the same region of 22q11.2. In DiGeorge syndrome a developmental anomaly of the derivatives of the 3<sup>rd</sup> and 4<sup>th</sup> pharyngeal pouches is associated with the absence or hypoplasia of thymus and parathyroid glands. Conotruncal heart defects include truncus arteriosus, transposition of the great arteries, double outlet of the right ventricle, and tetralogy of Fallot. These three syndromes are sometimes grouped under the acronym CATCH-22 (for Cardiac defects, Abnormal facies, Thymic hypoplasia, Cleft palate, and Hypocalcemia) (568).

The genetic anomaly in VCFS is complex and there are a variety of deletions in the 22q11 region that result in the VCFS phenotype. A large (3 Mb) deletion is found in about 87% of the cases, whereas 8% have a smaller (1.5 Mb) deletion within that region, 4% have other deletions, and a small percentage have unique deletions (569). After examination of patients with more restricted deletions, the critical region has been narrowed to a 250 kb area at the proximal end of the larger deletion (570). In some cases, microduplication of the del(22)(q11.2q11.2) results in a similar phenotype (571).

The 22q11 region is highly susceptible to chromosomal rearrangements, which has been attributed to a set of common chromosomal breakpoints, called low copy repeats (569, 572, 573). Low copy repeats are rich in palindromic AT repetitive sequences, which may result in a hairpin turn of the chromosomal material, facilitating more frequent chromosomal rearrangement (573–575). These exchanges of chromosomal material occur during meiosis I and seem to happen more frequently than in deletions on other chromosomes, suggesting a difference in the meiotic behavior of chromosome 22 (576). This has made it hard to pinpoint the mechanism by which haploinsufficiency results in the VCFS phenotype. Even monozygotic twins do not always have the same phenotypic presentation (577).

A number of genes in the VCFS region are expressed in the brain during early development, although some are not unique to developing brain (578). Genes of the latter type include the goosecoid-like homeobox gene (579, 580), *Tbx1*, a gene encoding transcription factors involved in developmental processes (578), ubiquitin fusion degradation 1-like (*UFD1L*) gene (581), and *PIK4CA*, a member of the phosphatidylinositol 4-kinase family (582).

Some genes in the VCFS deleted region have been implicated in psychiatric disorders (schizophrenia and bipolar

disorder), which occur in very high frequency in VCFS. However, controversy remains considerable and none of these genes have been demonstrated to be involved in the psychiatric symptoms in all populations. These include the proline dehydrogenase (PRODH) gene (583), the NoGo (RTNF4) gene, a glycosylphosphatidylinositol-linked protein, which inhibits axonal growth, is involved in myelination, and is also a factor in hippocampal neuronal plasticity during development (584, 585). The claudin gene (CLDN5), is involved in myelination (586).

An important gene in this area is the catecholamine-O-methyltransferase (COMT) gene that codes for the COMT enzymes, which inactivates catecholamines. There are two polymorphisms, the val and met forms, resulting from a G-to-A transition at codon 158 (thus, a valine-to-methionine substitution). Individuals, who have two copies of the met allele, have a three to fourfold reduction in COMT activity, with a marked increase in catecholamines.

### Neurological Features and Neurocognitive Profile

Some patients are microcephalic and have severe cognitive dysfunction. Spina bifida and hydrocephalus have been described in VCFS (587). Unprovoked seizures are more frequent in VCFS than in the general population, and are not explained by any associated medical problems (588). Children with VCFS are hypotonic and delayed in acquiring motor milestones, and have poor coordination (589). IQs range from profound mental retardation to the average range. About half of the patients have an IQ below 70. The typical VCFS patient is mildly mentally retarded—mean IQ of 70, (range 46 to 100) (590).

Language development is often significantly impaired and severe articulation difficulties are prominent. The situation is made more complicated by the global developmental delay often seen in these children, as well as the craniofacial anomalies (cleft palate or nasopharyngeal insufficiency which results in hypernasality and audible nasal air emission). Hearing deficits also contribute to the slow language acquisition of these children. However, a number of studies comparing children with VCFS to other groups with similar birth defects and developmental delays have suggested that the delay in language is not simply the result of these physical anomalies or developmental problems (591–593).

One study examined 27 subjects with VCFS (6 to 19 years of age) matched to a group of children with idiopathic developmental delay, and for certain tasks, typically developing children. The parental origin of the deletion was confirmed in 21 of these subjects. The assessment, which included the *Clinical Evaluation of Language Fundamentals–III*, revealed that Receptive Language scores were significantly lower than Expressive Language scores in the VCFS group. In contrast, the reverse pattern was seen in the developmentally delayed group. The mean full scale IQ was 69.4 (range 40–105) (those with maternally-derived deletions had a mean full-scale IQ of  $64.4 \pm 23.7$ ; range 46 to 81) whereas those with a deletion of paternal origin had a

full-scale IQ score of  $76.2 \pm 18.56$  (range 40–105). The VCFS children in which the deletion was of maternal origin scored significantly lower in receptive language than those whose deletion was paternally derived; a trend in the same direction was also noted in expressive language. These findings are also intriguing because of the possibility that there is an imprinting effect, namely that the parental origin of the deletion affects the phenotype. The authors, noting the lack of congruence with the findings reported by others (594, 595), suggested that their findings might be related to the specific test instruments used, or to the increasing demands for abstract reasoning with age. They suggested that their findings are consistent with the volume reduction noted in cortical language area on morphometric MRIs (596, 597).

Despite the early language deficits and uniformly poor cognitive profile in the young child with VCFS (598), the cognitive profile in older children and adolescents is characterized by low-normal to borderline-range Full-Scale IQ with a Verbal IQ in the range of 80 and a Performance IQ of about 70. The gap between the Verbal Comprehension and Perceptual Organization indices is even greater. In about 90% of individuals with VCFS, reading and spelling achievement scores (high 80s) are higher than arithmetic achievement scores (low 80s) (594). Moss et al. point out that this is an unusual pattern as one usually sees poor academic performance on language-based tasks in children with early language impairment (594).

Gross and fine motor skills are impaired. Visuospatial skills, visual attention, and visual-spatial memory are deficient and affected individuals have difficulty grasping new and complex information (599). Adults with VCFS have a cognitive profile characterized by deficits in visual working memory, visual recognition, attention, certain aspects of social cognition, and frontal executive deficits, a profile resembling that seen in nonverbal learning disability particularly in view of the deficits in social-emotional behaviors (600, 601). Moreover, patients who were hemizygous for COMT-met performed better on executive function tasks (set-shifting, verbal fluency, attention, and working memory tasks) than did those who were hemizygous for the val allele (602).

### Psychiatric Aspects

High rates of attention deficit hyperactivity disorder (ADHD), aggression (603), anxiety disorders (specifically obsessive-compulsive disorder and separation anxiety disorder), mood disorder, in particular, bipolar disorder, schizotypal features, and schizophrenia have been noted in persons with VCFS (604).

ADHD (both with and without hyperactivity) has been reported in 35 to 50% of children with VCFS (the higher prevalence occurring in those children whose first degree relatives also had ADHD). There was no apparent relationship to dysmorphic features, perinatal problems, or developmental delay (603). Based on the pattern of errors on the

Attention Network Test, Sobin et al. concluded that the attentional disturbances in the VCFS group are consistent with executive function deficits (605, 606).

Behavioral disorders typically emerge in prodromal form in the preschool years. Several studies involving different populations of youngsters with VCFS have described them as having difficulty with attention/concentration, and atypical thinking (607). They are also withdrawn and retiring (589, 607), and compared to children with learning disabilities, less aggressive (589, 608). However, these internalizing, withdrawn behaviors do not appear to be related to craniofacial abnormalities. Compared to a matched control group of children with craniofacial abnormalities, VCFS children had significantly higher scores on the internalizing scale of the Achenbach Child Behavior Checklist and Teacher Rating Scale, as well as significantly higher scores on the thought problems, attention problems, and social problems scales (609).

Bipolar disorder has been reported to occur more frequently in persons with VCFS. Based on a study involving a structured interview, review of records, and a clinical interview by two research psychiatrists, Papolos et al. concluded that 64% of an unselected series of children and adults with VCFS (age range 5 to 34 years) met DSM-III-R diagnostic criteria for bipolar disorder (610). Moreover, they suggested that homozygosity for the COMT-met allele could predispose to the ultra-ultra or ultradian cycling form of bipolar disorder (611). Mean age of onset was 12 years standard deviation = 3 years. None of the patients in this series met diagnostic criteria for schizophrenia, and only four had psychotic symptoms which emerged in their 20s or 30s. However, approaching the association from the other direction—namely, genotyping patients with bipolar disorder, Lachman et al. were unable to find any association between bipolar disorder and the COMT-met polymorphism (612).

Approximately one third of individuals with VCFS also have Obsessive-Compulsive disorder (OCD). Gothelf noted that 32.6% of their subjects met diagnostic criteria for OCD using the YBOCs (613). The disorder appeared relatively early and responded to fluoxetine. The symptoms included contamination concerns, somatic preoccupations, hoarding, repetitive questions and cleaning. Comorbid ADHD was present in 37.2% of the subjects in this series. Psychosis was present in 16.2%.

Difficulty in the realm of social-emotional functioning is quite prominent in older children and adults with VCFS, ranging from disorders in the autistic spectrum (590) to a cognitive/behavioral phenotype reminiscent of nonverbal learning disorder characterized by delayed motor development, Verbal IQ > Performance IQ, coupled with academic deficits in arithmetic, impaired visuospatial skills, and social withdrawal and anxiety (589). Some, (55%), of children with VCFS fit into this diagnostic category. Language is often more impaired than is typical in most children with nonverbal learning disorder. In one study it was noted that even in persons with VCFS who were of normal intelligence, there

was often a behavioral profile resembling prefrontal dysfunction, characterized by apathy and difficulty with initiation (590).

Individuals with a 22q11 deletion are at particularly high risk for schizophrenia—as many as 25% may develop schizophrenia—a rate substantially higher than that of the general population (0.025%) (614, 615). In fact, only the offspring of two parents with schizophrenia are at higher risk (616). Bassett et al. compared a group of patients with the 22q11.2 deletion to a sample of patients with familial schizophrenia. The groups did not differ in age of onset, positive/negative schizophrenic symptom scores, severity of anxiety-depression or cognitive symptoms. The subjects with VCFS had more problems with impulse control, uncooperativeness, and hostility. These symptoms were not secondary to mania. The conclusion was that the schizophrenic phenotype in VCFS is essentially indistinguishable from other forms of schizophrenia. However, there were significant differences in that 75% of the VCFS group had either congenital cardiac defects and/or palatal defects, whereas none of the comparison subjects had a congenital birth defect. A family history of psychosis was present in only one of the 16 patients with VCFS (6.3%) (a result of the high rate of spontaneous deletion in VCFS) compared to 82.6% in the comparison group (565). Although the *absence* of dysmorphic features cannot be used to eliminate the possibility of a 22q11 deletion (617, 618), the *presence* of dysmorphic features, cardiac abnormalities, or mental retardation would make the diagnosis of VCFS well worth considering. In short, at this point in time, a careful review of developmental, medical and family history in a person with schizophrenia may be helpful in determining whether genetic testing for VCFS is indicated.

A relatively dense genetic map of single nucleotide polymorphisms in the entire 1.5 Mb schizophrenia critical region on 22q11 was extensively studied by Liu et al. (619, 620). They identified two subregions in this area suggesting that the 22q11 microdeletion schizophrenia phenotype might be a contiguous gene syndrome. In the proximal ~ 30 kb segment the only two genes identified at that time were PRODH2 and DGCR6 and this region appeared to be associated more closely with childhood and early onset schizophrenia. In the distal subregion, measuring 80 kb, a number of genes were identified and appear to contribute to schizophrenia independently of the timing of onset. In addition, numerous other genes have been suggested as possibly involved in schizophrenia, but none have as yet been consistently shown to be related.

### Neuroimaging studies

An overall reduction in total cerebral volume in patients with VCFS has been reported (621, 622). This is not surprising, given the prevalence of microcephaly in the VCFS population. In the study by Eliez et al. there was even greater (9%) reduction in volume when the deletion was on the paternal chromosome (621). In adults with both

with both schizophrenia and VCFS the reduction in total cerebral volume is quite striking. A significant reduction in cerebellar volume (particularly the vermis) compared to controls has been noted in most studies (621–624). Eliez also noted a reduction in the size of the pons and in vermal lobules VI–VII (621). Lynch reported an adult with VCFS with evidence of cerebellar atrophy of unknown origin (625). Decreases in frontal and temporal lobe volumes have also been noted, although this does not reach statistical significance when corrected for multiple comparisons (626).

A spectrum of neuromigrational abnormalities has been described in VCFS ranging from lissencephaly to abnormal gyrification (627, 628). Regional anomalies, such as widening of the sylvian fissure have been reported (629). Midline abnormalities such as cavum septum pellucidum are more frequent in persons with VCFS than in controls (622, 623, 626, 630). Anomalies of the septum pellucidum have been reported in subjects with VCFS with and without schizophrenia. However, anomalies of the septum pellucidum are found in subjects with schizophrenia without the 22q11 deletion, particularly in schizophrenia of childhood onset (631, 632) and may reflect the close embryological and functional relationship of the septum pellucidum to limbic structures (633). (In individuals with schizophrenia, an enlarged cavum septum pellucidum has been associated with reduced volumes of the parahippocampal gyrus) (634). The finding of other midline anomalies in the VCFS population suggests that there may be a specific disturbance in the formation of midline structures (635).

A number of studies have reported decreased white matter volumes, particularly in the frontal area, and particularly in those with schizophrenia and the VCFS deletion.

White matter hyperintensities and cysts in the vicinity of the frontal horns have been noted (624, 626). Van Amelsvoort compared patients with VCFS without schizophrenia to those with schizophrenia and to a group of IQ-matched controls who did not meet criteria for psychiatric disorders or conditions that might affect the brain. The group with schizophrenia and VCFS had a significant generalized reduction in total brain volume and total white matter (626). A diffusion tensor imaging study revealed disruption of white matter connectivity in fronto-temporal-parietal pathways (636). Deep frontal white matter was reduced significantly (by about 23%) in VCFS subjects compared to controls (637). Kates et al. noted that it was not clear if this was related to a disturbance in myelination or simply reflected delayed myelination.

The reduced volumes in the frontal area have been associated with increased volumes of the caudate nucleus (left > right) (638). Kates et al. reported increased volume of the right caudate nucleus in the VCFS group (637). In that study, the VCFS group did not show the association between the right caudate and right frontal region which was present in the controls, providing anatomical support

for the frontostriatal dysfunction that is clinically noted in the VCFS population.

Shashi et al. noted that total area of the corpus callosum was significantly increased in the group with VCFS, in particular the isthmus (which includes interhemispheric fibers from posterior parietal and superior temporal cortex) (639). In the NIMH study of very early onset schizophrenia, increased ventricular volume and increased midbody area of the corpus callosum was noted in the subjects with VCFS when compared to persons with non-VCFS childhood-onset schizophrenia and healthy controls (640).

Relatively few functional imaging studies have been performed on patients with VCFS. Eliez et al. studied children with VCFS and controls as they performed a mathematical computation task and noted increased activation of the left supramarginal gyrus in children with VCFS compared to controls which correlated with increased task difficulty (621, 641).

### Management

Children with VCFS pose a challenge to the neurologists and psychiatrists who are caring for them. In early childhood, children with VCFS often require multiple surgical procedures for congenital heart lesions and/or palatal defects. In addition to the emotional problems often experienced by children who have been subjected to multiple surgical procedures and hospitalizations at an early age, they also have multiple neurodevelopmental problems. Thus, early identification and treatment of any hearing and speech problems, as well as language impairment requires sophisticated evaluations. Proactively identifying and helping the child, the child's parents and teachers to work with the social-emotional problems that are typically associated with VCFS is extremely helpful. Being aware of the significant psychiatric morbidity that this diagnosis is associated with can hopefully mitigate some of these problems.

Children with VCFS are likely to be functioning below the average range and supporting the parents and assisting in finding appropriate educational settings will be highly beneficial. Children with VCFS often have strong aptitudes for music and computers. Educational interventions which use music and computers often meet with greater success in reading and math and socially with improvements noted in self-esteem, motivation, and confidence (642, 643). Success is also facilitated when information is presented in small increments that can be successfully mastered.

Clinicians should be aware of the increased risk of bipolar disorder, schizophrenia, and obsessive-compulsive disorder in this population. There are several genes which map to the VCFS critical region which potentially play a role in bipolar disorder. One of these genes, PIC4CA, is involved in the synthesis of phosphatidylinositol 4,5-bisphosphate, a phosphoinositide that regulates signal transduction and synaptic vesicle function. Some patients with bipolar disorder show an atypical response to lithium, which is a non-competitive inhibitor in this metabolic pathway. There is a

suggestion that this gene may be involved in bipolar disorder and schizophrenia (582).

Patients with VCFS who have the COMT-met polymorphism (with reduced levels of COMT and high levels of catecholamines) may be at high risk for mania, particularly if treated with psychostimulants. In the case of psychiatric symptoms that are refractory to more standard psychological treatment, the possibility that the deletion of the COMT gene results in high levels of circulating catecholamines should be considered. The use of alpha-methyl-tyrosine, a competitive inhibitor of tyrosine hydroxylase, which lowers the concentration of homovanillic acid, and in turn decreases endogenous levels of catecholamines, has been reported to improve function and have minimal side effects (644). O'Hanlon described a case in which seizures and hallucinations were controlled with improved cognitive function (645). Selective serotonin reuptake inhibitors for OCD have been useful in this population (613). Given the possibility that COMT levels are decreased, and therefore the inactivation of catecholamines is compromised, concern has been expressed regarding the use of psychostimulants, the fear being possibly precipitating or exacerbating mood disorder or psychotic symptoms. One small-n, 4-week study reported that treatment with low-dose (0.3mg/kg) methylphenidate resulted in significant behavioral improvement in patients with VCFS, without any evidence of increased cognitive dysfunction and only mild side effects (646). However, given the fact that the dose level was relatively low, the treatment of short duration, and the COMT genotype of the subjects unknown, the results of this study should be taken with caution. Gothelf et al. have suggested that some patients with VCFS and schizophrenia respond poorly to standard neuroleptics (although two of the four responded to clozapine) (567).

## Conclusion

In this chapter we have reviewed the neuropsychiatric features of some of the common mental retardation syndromes, and the importance of making a diagnosis not only on the basis of IQ but also in terms of adaptive functioning. Given the variability in neuropsychiatric presentation in mental retardation syndromes as well as the variability in individuals who carry the same diagnosis, it is important to be aware of the characteristic neuropsychiatric features associated with these syndromes while at the same time having a diagnostic approach that is sensitive to this variability. Although the relationships between the genetic factors and neurobehavioral profile are still incompletely delineated, there is a burgeoning research literature that will make it possible to understand more clearly the pathophysiology of these syndromes and ultimately provide a rational approach to management. At this point, neuropsychiatric diagnosis and management should include a detailed history and examination that takes into account the medical and neuropsychiatric features associated with these syndromes

but is flexible enough to evaluate the psychosocial and medical issues of each patient on an individual basis.

# Genetic Syndromes

# 9

**Chiara Pantaleoni, MD   Stefano D'Arrigo, MD**  
**Sara Bulgheroni, DN   Daria Riva, MD**

Genetic syndromes, also called dysmorphic-genetic syndromes, are complex conditions characterized by the association of genetic abnormalities with severe or mild dysmorphisms, in which staturo-ponderal growth problems, psychomotor delay, mental retardation, and behavioral disorders are frequent (1,2). Patients presenting these characteristics are often referred to a specialist in pediatric neurology or to a child psychiatry unit. Clearly, those operating in such settings need to possess specific diagnostic expertise, not only to ensure targeted therapeutic and rehabilitative interventions (3), but also to be able to inform families as to the risk of recurrence (4).

On a causal level, the various genetic syndromes can be secondary to chromosomal abnormalities, numerical or structural, or to the mutation of a single gene (5). Frequently, the underlying abnormality is not known and, without the opportunity for laboratory confirmation, the diagnosis is based exclusively on clinical data (6). Thus, diagnosing these syndromes means following a rigorous procedure in which the first step is collection of a detailed history of the family (reconstruction of the family tree must go back at least three generations) and of the patient himself: prenatal, neonatal, physiological, and pathological (7). This is followed by the clinical investigation, which involves not only neurological examination (including exploration of intellectual and behavioral aspects), but also assessment of dysmorphological features; that is, measurement of auxological parameters and careful detection of all those minor abnormalities (dysmorphisms) that constitute the gestalt of dysmorphic syndromes (8). It must be pointed out that the presence of a single minor abnormality cannot be deemed to have clinical significance; at least three are needed (9). It is also important to stress that the collection of photographic evidence is useful for reassessing a patient over time (10).

Once collection of the history is complete, a diagnostic hypothesis can be formulated, also with the help of special

computerized systems such as the Possum database (11) and London Dysmorphology (12). These systems are undoubtedly important diagnostic aids but they are intended to be used by experts; that is, by those with specific expertise in selecting search criteria and in interpreting results (13).

At this point, instrumental investigations can be carried out, the choice of investigations being guided by the clinical suspicion. Of the various available instrumental tests, brain magnetic resonance imaging (MRI), to verify the presence of structural abnormalities of the central nervous system (14), and an electroencephalogram (EEG) are, in our view, indispensable. Neurophysiological investigations (evoked potentials, electromyography) may also be useful for diagnostic purposes and again must be performed to investigate a definite clinical suspicion. Similarly, the choice of tests for the diagnosis of metabolic diseases must be guided by the patient's clinical picture (15).

With regard to the more strictly genetic analyses, all patients with a suspected dysmorphic-genetic syndrome should undergo standard karyotype analysis at 500-band level (16). Importantly, given the rapid evolution of cytogenetic techniques, it may be deemed opportune to repeat this analysis if the last one performed dates back more than 5 years (17).

Cytogenetic analyses, such as high-resolution karyotype, fluorescence in situ hybridization (FISH), and karyotype analysis of dermal fibroblasts, are indicated only if performed in order to confirm a clinical suspicion (18).

Molecular analysis of DNA or RNA samples, conducted to identify the gene defect responsible for the disease, should be performed only to confirm a clinical hypothesis: the only exception to this is, in our view, molecular analysis for fragile-X syndrome, which is warranted in all cases of unclassified mental retardation, regardless of the sex of the patient (17).

The most recent evolutions in molecular cytogenetics and molecular biology have been directed toward two

groups of genetic abnormalities: uniparental disomies and subtelomeric rearrangements. Uniparental disomy is present when a patient has inherited both copies (or parts thereof) of a particular chromosome from only one parent. In addition to patients suspected of having a clinical condition in which uniparental disomy is a known feature (Angelman syndrome, Prader-Willi syndrome), testing for uniparental disomy is also indicated in patients presenting association of mental retardation, dysmorphisms and growth delay (pre- or postnatal) of unknown etiology (17).

According to the most recent data, subtelomeric rearrangements are responsible for around 5% of cases of mental retardation (19). Screening for these rearrangements is indicated in the presence of several factors: family history of mental retardation, intrauterine growth delay, postnatal growth abnormalities (excessive or deficient growth), at least two facial dysmorphisms, one or more nonfacial dysmorphism and/or congenital malformations (19).

Recently a new technique, called microarray-based comparative genomic hybridization (array CGH) has been introduced, enabling analysis of the whole genome in a single experiment. It can be used for the screening of known submicroscopic aberrations in human genetic diseases, but is also suitable for identification of yet unidentified abnormalities (20).

Let us now consider the dysmorphic-genetic syndromes most frequently encountered by the pediatric neurologist.

## FRAGILE-X SYNDROME

Fragile-X syndrome is the most frequent inherited cause of mental retardation: its prevalence has been estimated at around 1/2,000–1/3,000. The syndrome is caused by a mutation of the FMR1 (Fragile-X mental retardation 1) gene on chromosome X (X q27.3). The mutation is associated with expansion CCG repeats, which determines a deficit of FMR1-protein (21). FMR1 is, to date, the only gene known to be associated with fragile-X syndrome. Genetic tests for mutation of the gene generally focus on the number of CCG repeats, and the FMR1 alleles are usually categorized according to this number:

- (a) Normal alleles: the number of repeats ranges from 5 to 44: normal alleles are transmitted without modification of the number of repeats
- (b) Intermediate alleles: the number of repeats ranges from 45 to 58: transmission of intermediate alleles can (occasionally) result in slight modification of the number of repeats
- (c) Premutation alleles: the number of repeats ranges from 59 to 200: females in this group are considered to be at risk of having affected offspring, due to a potential expansion of the number of repeats
- (d) Full mutation alleles: over 200 repeats (22).

Fragile-X syndrome shows a clear genotype-phenotype correlation. In male full mutation patients (hemizygotes), the prepubertal clinical picture is characterized by psychomotor retardation, prevalently affecting language, and by craniofacial dysmorphisms: long face, prominent forehead, large or prominent ears, prognathism. Mental retardation is moderate (IQ 30–50). It is often associated with behavioral disorders: hypersensitivity to sensory stimuli, hyperactivity, stereotyped movements (hand flapping, hand biting), gaze avoidance, social anxiety. Some patients present some or all the symptoms of autism: Rogers et al (23), investigating a series of 27 fragile-X children, found that 8% fulfilled the diagnostic criteria for autism. On the other hand, the incidence of fragile-X syndrome in autistic patients has been reported, in different studies, to be between 2.5 and 6%. Although some of the symptoms appear very reminiscent of autism, one important behavioral difference does in fact separate these two groups of children: the ability of fragile-X children to recognize human facial expressions of emotion (an ability severely impaired in autistic children) has been shown to be comparable to that of the general population. This explains the tendency of the fragile-X child to maintain an adequate preferential relationship with his main caregivers.

Epileptic seizures are present in around 20% of patients (24): typically these have onset in early infancy, with children presenting generalized tonic-clonic, absence, partial motor, and temporal lobe seizures. The seizures generally respond to common antiepileptic medication and they occur less and less frequently over time, usually disappearing in adolescence (even though they can occasionally persist until adulthood). The main postpubertal phenotypic characteristics are macrocrania, strabismus, prognathism, macroorchidism, joint hyperextensibility, subluxation of the thumb, flat foot. The cognitive deficit persists and, from the behavioural point of view, it is possible to observe an increase of the hyperactivity and social anxiety, and onset of obsessive-compulsive disorder and, in the most severe cases, psychotic symptoms (25). Mitral valve prolapse has been observed in 50% of adult patients.

Female full mutation patients (heterozygotes) show similar (but less severe) physical and behavioral characteristics (26). Premutation patients generally have a normal appearance and normal intelligence. Some may present slight cognitive or behavioral disorders, learning difficulty and social anxiety.

Female premutation carriers can have a premature menopause, while a late-onset ataxic syndrome with tremor has been reported in premutation male carriers (27). Brain MRI can reveal cerebellar vermis hypoplasia and, more rarely, malformations of other areas: enlarged hippocampus, caudate nucleus and thalamus (28).

Finally, another condition, characterized by less severe mental delay and by less marked somatic traits, has been described in males with expansion of CCG repeats in the FRAXE fragile site (clearly distinct from FRAXA, the fragile

site associated with the more common fragile-X syndrome) in the FMR2 gene. Given that mutations in FRA2E are far less common, routine testing for them in subjects with mental retardation is not deemed opportune. (29)

## ANGELMAN SYNDROME

Angelman syndrome is a disease associated with a chromosome 15 (15q11–13) abnormality. In most cases this abnormality is a deletion of the maternal derived chromosome, while in 3 to 5% it is a paternal uniparental disomy (i.e., both the alleles of that specific location on chromosome 15 have been inherited from the father). In 4 to 6% of cases it is due to an imprinting center defect or to a defect of the E6-P ubiquitin-protein ligase (UBE3A) gene (30). The region 15q11–13 contains the genes for the subunits  $\beta$ 3,  $\alpha$ 5 and  $\gamma$ 3 of the receptor of the main inhibitory neurotransmitter system, gamma-aminobutyric acid type-A receptor (GABA(A)R.) (31). A link between the  $\beta$ 3 subunit gene and susceptibility to autism has recently been suggested (32). In 20% of cases, no genetic abnormality is demonstrated and the diagnosis remains clinical. The prevalence of the disease is estimated at around 1/12,000. From a clinical point of view (33), patients present severe psychomotor retardation and gait ataxia: gait is stiff, extremely hesitant, and irregular. Impairment of language, mainly expressive language, is again a feature: nonverbal performances can vary widely; some children are able to learn sign language and to use alternative methods of communication. A frank behavioral disorder constitutes another constant feature: these children have been dubbed “happy puppets” on account of their manner; they are typically cheerful, excitable, hyperactive and inattentive, a profile associated with stereotyped “hand fluttering” movements. More than 80% of patients also present acquired microcephaly, epilepsy and a characteristic EEG pattern (high-amplitude slow-wave activities prominent in the frontal region and spike-and-slow-wave multifocal activity prominent in occipitofrontal areas). Epileptic seizures generally have onset after the first year of life, usually after the age of three years. Patients with the deletion may present drug-resistant epilepsy, characterized by atypical absence or myoclonic seizures (34). Brain MRI generally confirms the finding of microcephaly, but fails to reveal other abnormalities, with the exception of mild cortical atrophy, mild ventriculomegaly, and thin corpus callosum. Other findings occasionally described include cerebellar hypoplasia, unilateral temporal lobe hypoplasia, and vermian cysts (33).

Less common signs (20 to 80% of cases) include flat occiput, strabismus, macrostomia, widely spaced teeth, prominent jaw and hypopigmentation of skin and eyes.

From a behavioral point of view, these subjects display hypersensitivity to heat, attraction to water, and a sleep disorder characterized by reduced need for sleep and altered sleep-wake rhythms. Some behavioral aspects of the

syndrome fulfill perfectly two of the DSM-IV classification’s three essential criteria for autism: stereotyped behaviors and absence of language (35). Social interaction appears to be relatively conserved in these children, and they seek relationships with others. Williams et al. (36), in a report on the differential diagnosis of the syndrome, maintains that children with a clinical diagnosis of Angelman syndrome who give negative results in genetic laboratory tests for the four known types of genetic anomaly must be considered affected by a pervasive developmental disorder not otherwise specified (PDD NOS), in accordance with the criteria of the DSM-IV. Longitudinal evaluation of these children in fact revealed that the phenotypic characteristics of the syndrome became less clearly defined over the years, while the opposite was true of the behavioral disorder.

## WILLIAMS SYNDROME

Williams syndrome is due to a submicroscopic deletion of a segment of chromosome 7 (7q11.23): the deleted region spans approximately 1.5 megabases and 14 genes have been mapped to it. Many of the syndrome’s clinical manifestations are caused by the deletion of the elastin (ELN) gene, which results in abnormal elastin production and thus connective tissue alterations (37). LIM kinase 1 (LIMK1), a gene contiguous to ELN, is the second gene recognized as implicated in the syndrome. In particular, the cognitive profile of the syndrome seems to be attributable to the deletion of LIMK1: the gene is expressed at brain level and could be involved in the development of the neural pathways responsible for visuospatial integration. The true prevalence of the syndrome is not known, although it is estimated to be between 1/10,000 and 1/20,000. Clinical diagnosis is made on the basis of the presence of a characteristic pattern of facial dysmorphisms, mental retardation, short stature, connective tissue abnormalities, a distinctive cognitive profile and typical behavioral phenotype. The facial characteristics are distinctive: younger children present a broad forehead with bitemporal narrowing bilaterally, periorbital edema, stellate iris, strabismus, low-set nasal root, bulbous nasal tip, flattened cheekbones, prominent earlobes, long philtrum, wide mouth and full lips, patho-occlusion with small widely-spaced teeth, and micrognathia. In older children and adults, there are other distinctive features (prominent supraorbital ridge, narrowing of the nasal root and long neck) and the face has, overall, a less chubby appearance. The main connective tissue abnormality is a cardiovascular alteration, in most cases supra-aortic stenosis; other possible findings include vesical or intestinal diverticula, hernias, joint laxity, phonation disorder (i.e., deep voice), and loose skin. The earliest reports consistently described idiopathic hypercalcemia, but this is actually documented in only 15% of cases.

From the neurological viewpoint, hypotonia is a common early sign, which can be followed at a later stage by

limb hypertonia and hyperreflexia. Brain MRI can reveal reduced cerebral volume, while the cerebellum is normal size; it is even possible to observe hyperplasia of the cerebellar vermis lobules VI-VII and VIII-X (38); sporadic cases of associated Chiari I malformation (39) and of cerebrovascular accidents attributable to multiple intracranial arterial stenoses (40) have also been reported. We described a personal case of Williams syndrome with oligogyric microcephaly (41).

Most affected subjects present mental retardation ranging from severe to mild (the latter being relatively more frequent). The cognitive phenotype is extremely distinctive (42): in intelligence scales, high scores are recorded on the verbal subtests, exceeding IQ-based expectations, good scores on the sentence repetition memory tests, and lower-than-expected scores on the nonverbal tests; there also emerges a significant impairment of visuospatial organization and integration (43). Writing and drawing skills are found to be significantly impaired, as is the ability to reconstruct models. Since visuomotor skills are processed by the occipital-parietal visual pathway, it is possible, in this syndrome, to hypothesize gene involvement in the development of this neural circuit. Conversely, visuo-perceptual abilities, processed by the occipital-temporal pathway, are relatively spared (44).

The behavioral profile is distinctive: a high percentage of cases present an attention disorder which may or may not be associated with hyperactivity (45) and an excessively sociable and friendly attitude to strangers. Compared with other children of similar intelligence, the incidence of behavioral problems (such as anxiety, worry, attention deficit) in these subjects is high; they also show impaired capacity for autonomy.

## VELO-CARDIO-FACIAL SYNDROME

This syndrome, which shows marked phenotypic variability, is caused by a microdeletion of Chr 22q 11.2, and characterized by involvement of the face, palate and heart, as well as possible involvement of other organs (46). Its prevalence is difficult to establish, partly because the condition has been called by different names (DiGeorge sequence, CATCH 22, Shprintzen syndrome); nevertheless, its prevalence is estimated to be around 1/4,000. Although more than 150 clinical characteristics have been reported in connection with this syndrome, none has been found to be present in 100% of the cases and thus pathognomic; but several characteristics do give rise to clinical suspicion: in particular, in small children, the association of palatoschisis with conotruncal cardiac defects. The most common cardiac malformations are alterations of the aortic arch, ventricular septal defects, pulmonary atresia or stenosis, and tetralogy of Fallot. The suspicion becomes stronger if these signs are associated with other malformations such as facial asymmetry, hypocalcemia, equinus foot, laryngoma-

lacia, inguinal or umbilical hernias, and hypospadias. Later on, the clinical phenotype becomes even more evident, thanks in particular to the appearance of the classic behavioral and personality traits. Mental delay is found in only a minority of patients, and IQ is generally borderline or slightly below normal. Children initially present psychomotor retardation, but good recovery around the age of four years. A language delay is also present, attributable in part to the phonation and articulation problems caused by the malformations. The psychiatric disorders evident in the affected adult are preceded by prodromes in childhood: attention deficit with hyperactivity, obsessive-compulsive disorder, dysthymia and cyclothymia. Bipolar disorder and schizophrenia have also been reported in adults and in general it is estimated that around 20% of affected subjects present psychosis in adulthood. In a recent study (47), brain MR investigations in patients affected by the syndrome have revealed structural abnormalities in the temporal and temporomesial regions also involved in schizophrenia. It is thus suggested that the effects of deletion 22q11.2 and the complex pathogenetic alterations underlying schizophrenia share a common etiology.

From the neurological point of view, epileptic seizures can present even as an early manifestation of the syndrome, generally symptomatic of hypocalcemia, stroke or cortical atrophy; febrile convulsions are also common. Other common neurological signs are chronic lower limb pain and nocturnal leg cramps; tethered cord has been found in some cases, while equinus-varus deformity of the foot is present in around 10%.

## SMITH-MAGENIS SYNDROME

Smith-Magenis syndrome is due to an interstitial deletion of the short arm of chromosome 17 (17p11.2); its prevalence is estimated to be around 1/25,000. The symptomatic phenotype varies with age: in infancy (0–3 years), facial dysmorphism is very mild, the face having a characteristic “cherubic” appearance, with full, prominent cheeks, upslanting palpebral fissures, depressed nasal root, and micrognathia (48). The shape of the mouth is very distinctive, with a “Cupid’s bow” upper lip and pronounced philtrum. In childhood (3–10 years), the facial traits become coarser and “Down’s-like” owing to hypotonic facial muscles, brachycephaly, flattened face, and short broad nose. After the age of 10 years, the facial traits become even more distinctive: facial hypoplasia and a wide, prognathic jaw (49). The cognitive phenotype is characterized by mental retardation of extremely variable degree: patients with borderline IQ have been reported, but also ones with very low IQ. As regards to language, impairment of expressive language predominates. The behavioral phenotype is very distinctive: maladaptive disorders are reported, such as self-harm, impulsivity, rage attacks, and onychotillomania. These are also associated with stereotyped behaviors: the self-

hugging phenomenon is common, but these subjects can also present body rocking and object spinning. Udwin et al. (50), studying 50 patients, and Willekens et al. (51), studying a sample of just 3, both encountered very clinging and dependent behaviors, toward both family members and strangers: this finding allows this syndrome to be distinguished from classic autism.

Epileptic seizures are present in 10 to 30% of cases, while EEG abnormalities in the absence of seizures are reported in around 20%. In 75% of cases, there are clinical signs of peripheral neuropathy: anatomical-pathological studies highlight a picture of segmental demyelination and remyelination similar to that found in hereditary Carchot-Marie-Tooth 1A (CMT1A) neuropathy, although the PMP22 mutation typical of CMT1A is not found in patients with Smith-Magenis syndrome. Brain MRI can reveal cerebral malformations: ventriculomegaly, mega cisterna magna, cerebellar vermis hypoplasia (49).

## CHROMOSOME 15 INVERSION-DUPLICATION SYNDROME

Chromosome 15 inversion-duplication (inv-dup 15) syndrome is a genetic condition that can, in most cases, be diagnosed with standard karyotype analysis. The syndrome is characterized by psychomotor retardation, ranging from mild to severe, hypotonia, and ataxia and dyspraxia. Many affected subjects are epileptic, presenting generalized myoclonic or atonic seizures, or focal seizures. These patients show a measure of resistance to antiepileptic drug therapy. Not all patients have epileptic seizures, but even those who do not present them typically have an electroencephalogram showing diffuse rapid activity and focal paroxysms bilaterally (52). These patients are also characterized by mild facial dysmorphism: flat nasal root with upslanting nostrils, downslanting palpebral fissures, micrognathia, low-set ears, and flat occiput. These patients typically show an autistic-like behavioral phenotype. A recent study (53) examined six patients with inv-dup 15 syndrome: two fulfilled the diagnostic criteria for classic autism, while the other four were diagnosed with PDD NOS in accordance with the DSM-IV criteria. These patients indeed presented severe impairment of social interaction and communication, but no repetitive or stereotyped behaviors were either reported or observed. Brain MRI in these patients generally gave normal findings, even though there exist sporadic reports of mild cerebral atrophy (53).

## OTHER SYNDROMES

We will now describe some of the peculiar characteristics of syndromes sometimes brought to the attention of pediatric neurologists due to the presence of neurological, cognitive, and behavioral signs: Rett syndrome, which the DSM-IV

classifies under Pervasive Developmental Disorders, and the syndromes of Turner, Sotos, Cohen, and Noonan.

Rett syndrome is a genetic condition associated with various mutations of the MECP2 gene on chromosome X. The syndrome has an estimated prevalence of 1/10,000, and typically (but not exclusively) affects females, who, in the classic form, present a typically autistic phenotype (54). These patients' most striking phenotypic characteristic is their gentle gaze and dreamy expression. Their laughter is distinctive, typically having a circadian pattern of manifestation and occurring prevalently in the evening, which contrasts with the laughter in patients with Angelman syndrome in whom it is practically constant (throughout the day). In classic Rett syndrome, language is absent, but there exists a variant form in which patients do acquire, over time, the ability to produce simple or even more structured sentences; this growing ability being accompanied by a reduction in their stereotyped hand movements (55).

Turner syndrome, which has a prevalence of 1/5,000, is due to the loss of part or all of the second X chromosome (45X0), frequently accompanied by cell-line mosaicism. Features of the syndrome are: low birthweight, neonatal lymphoedema of the extremities, low stature, pterygium colli, broad chest, valgus deformity of the upper limbs, cardiac malformations (bicuspid aortic valve, mitral valve prolapse, coarctation of the aorta), kidney malformations, primary amenorrhoea and sterility. IQ is generally normal, although visuospatial organization difficulties have been reported. Brain MRI gives normal findings (56).

Sotos syndrome (prevalence 1/100,000) is characterized by accelerated somatic growth, which is most marked in the first five years of life. Children affected by Sotos syndrome present dolichocephaly and macrocephaly, frontal bossing, high forehead, downslanting palpebral fissures and prognathism. Bone age is typically, although not necessarily, higher than chronological age. Patients can be cognitively normal or present an intellectual impairment of varying degree (ranging from mild to severe). From the behavioral point of view, they can present phobic traits, sleep disorders, hyperphagia, and aggressiveness. Morrow et al. (57) described an autistic disorder in a child with Sotos syndrome. Around 50% of patients present a genetic abnormality (deletion or intragenic mutation) of the long arm of chromosome 5 (5q35). The neuroradiological findings include ventriculomegaly and midline defects (hypoplasia of the corpus callosum) (58).

Howlin (59) found a diagnosis of autism in 19 out of 33 patients affected by Cohen syndrome, a condition characterized by low birthweight, microcephaly and psychomotor retardation of varying degree (ranging from mild to severe). The prevalence of Cohen syndrome is 1/100,000. Patients present maxillary hypoplasia, large ears, prominent upper incisors, tapered fingers, trunk obesity and scoliosis. They may also present neutropenia and chorioretinal dystrophy or optic atrophy. The syndrome is caused by a mutation in the COH1 gene on chromosome 8 (8q22).

Central nervous system abnormalities are not generally reported, even though a case with focal polymicrogyria was recently described (60).

Another frequent syndrome is Noonan's syndrome. Known to have a prevalence 1/2,000, it is characterized by short stature, pterygium colli, epicanthic folds, low-set and malformed ears, micrognathia, and association, in 50% to 80% of cases, with congenital cardiopathy (frequently pulmonary stenosis). Patients are cognitively normal, or may present a mild-moderate cognitive deficit. Behavioral disorders include sleep disorder and aggressiveness, anxiety, and an association with autism has also been described (61). Fifty percent of cases present a missense mutation of the PTPN11 gene on chromosome 12 (12q24.1). From the neuroradiological point of view, the syndrome may present associations with syringomyelia, Chiari I malformation, Dandy-Walker syndrome, and arteriovenous malformations.

# Childhood-Onset Schizophrenia

10

*Natacha Akshoomoff, PhD*

The autistic spectrum disorders and childhood-onset schizophrenia are complex disabling neuropsychiatric disorders. Children with schizophrenia share some symptoms with, and may be mistaken for, children who suffer from autistic spectrum disorders, which are more common. The pervasive and disabling symptoms associated with these disorders typically necessitate lifelong specialized educational, family, and adult services which cost billions of dollars each year. Early identification and effective interventions can potentially reduce human suffering and costs with the potential of significantly improved functioning and personal independence for individuals with these disorders. As will be discussed in this chapter, recent studies have identified a number of brain development abnormalities and genetic factors associated with these disorders.

Childhood-onset schizophrenia (COS) has been recognized since before the time of Kraepelin (1). It is a rare but disabling condition. Both Kanner (2) and Asperger (3) independently provided the first accounts of autism, describing children with a “disturbance of contact,” unusual communication skills, and movement stereotypes, with an onset of symptoms before age three. Despite the notice paid to Kanner’s landmark paper, autistic disorder was not formally distinguished from COS for many years. In the

DSM-II (4), the diagnosis of childhood-onset schizophrenia included all psychiatric disorders in children as well as autistic disorder. Autistic disorder and childhood-onset schizophrenia were separately classified with the publication of the DSM-III (5) after studies made it clear that the symptoms of childhood schizophrenia are much more similar to those of adult-onset schizophrenia than autistic disorder (6, 7). The history of the concept of COS has been reviewed in more detail elsewhere (e.g., 1, 8, 9).

## **AUTISTIC SPECTRUM DISORDERS**

In the past, autism was viewed as a very rare disorder (estimated 4 to 5 per 10,000 births). Autism is now more commonly seen as part of a spectrum of disorders with significant social deficits and the presence of repetitive behaviors and restricted interests (10–12). Variations in severity, particularly with regard to a history of early language delays and degree of communication difficulties, are the primary differences in the criteria for the autistic spectrum disorders, which include Autistic Disorder, Asperger’s Disorder, and Pervasive Developmental Disorder-NOS (PDD-NOS) and which are included as pervasive developmental disorders in DSM-IV-TR (13).

Recent epidemiological studies suggest that the prevalence of autistic spectrum disorders is approximately 60 per 10,000, while the prevalence of Autistic Disorder specifically is estimated to be 8 to 30 per 10,000 (14–17). From a clinical and service perspective, there are many more children identified with “autism” today than 10 or 20 years ago. This increased rate of referrals has led parents, clinicians, researchers, and the public to question a possible “epidemic” of autism. Although recent epidemiological studies have generally been in agreement regarding the best estimate for the prevalence of autism and related disorders (15), the precise estimate is difficult to determine due to changing definitions of the disorders and differences in survey methodology (e.g., studies using multiple sources of ascertainment and direct diagnostic procedures yield higher rates). The National Center on Birth Defects and Developmental Disabilities (a division of the Centers for Disease Control and Prevention) is developing a surveillance system which will ultimately provide more reliable epidemiological data (18).

### Diagnosis and Appropriate Assessment Strategies

The DSM-IV-TR (13) criteria for autistic disorder require that the individual exhibits six (or more) symptoms, with at least two in the area of social interaction (e.g., impaired use of nonverbal behaviors to regulate social interaction, such as eye-to-eye gaze or gestures; failure to develop peer relationships appropriate to developmental level), one in the area of communication (e.g., delay in the development of language; impaired ability to initiate or sustain conversation), and one in the area of restricted repetitive and stereotyped patterns of behavior (e.g., motor mannerisms; restricted interests; inflexible adherence to routines). Prior to age 3, the child must have exhibited abnormal functioning in social interaction, language as used for social communication, or symbolic/imaginative play. Lower functioning and younger individuals tend to be more aloof in social interactions (such as those described by Kanner), while higher functioning and older individuals are more likely to be described as passive or odd (19). Autistic disorder is more common in males than females (approximately 4:1) and the majority of individuals have Intelligence Quotient (IQ) and adaptive behavior skills that fall in the mentally retarded range (IQ <70).

The diagnosis of PDD-NOS (or “atypical autism”) is used with those individuals who do not meet criteria for autistic disorder but exhibit at least two symptoms in the area of social interaction and one in the area of communication or one in the area of restricted repetitive and stereotyped patterns of behavior. This diagnosis is often used to describe very young children who appear to have autism. As children get older, it does appear to be a fitting description for children with the social deficits common to Autistic Disorder and Asperger’s Disorder but who have fewer

repetitive behaviors, or high functioning children with early language delay or mild cognitive impairment (20).

The DSM-IV criteria for Asperger’s Disorder require that the individual does not meet criteria for Autistic Disorder but exhibits at least two symptoms in the area of social interaction and one in the area of restricted repetitive and stereotyped patterns of behavior. Additional requirements are that the individual did not exhibit significant delays in language (i.e., single words used by age 2 years, communicative phrases used by age 3 years) and does not have delayed cognitive skills. If strict DSM-IV-TR criteria are applied, a diagnosis of Asperger’s disorder becomes unlikely (21–24). This issue has led researchers and clinicians to adopt the term *Asperger syndrome* to distinguish those individuals who share many of the features of autism but who had relative preservation of language and cognitive abilities early in life. The direct clinical or educational benefits of this distinction from “high functioning autism” are not yet clear (25–27). Most individuals with Asperger syndrome are not identified with significant difficulties until after age 3, most commonly after having attended school (28). While formal language skills are normal and may develop early, individuals with Asperger syndrome have more difficulty understanding the nuances of language and the use of language in social interactions (“pragmatics”). These children typically appear to want to interact with others but tend to do so in odd, unusual, awkward, and inappropriate ways. Most of these individuals are highly verbal and have a tendency to become very interested in and preoccupied with particular subjects, which can interfere with other activities and social relationships. They are often less anxious when they can adhere to specific routines and may have difficulty with change.

The American Academy of Neurology and the Child Neurology Society have jointly developed a guideline on screening and diagnosis for autism (29). Based upon the empirical evidence, the guideline gives specific recommendations for a dual process:

1. Routine developmental surveillance screening specifically for autism should be performed (using recommended instruments) on all children to identify those at risk for any type of atypical development (especially siblings of children with autism), and to identify those specifically at risk for autism:
  - a) screening (with either the CHAT (30) or the Social Communication Questionnaire (31) specifically for autism should be performed on all children failing routine developmental surveillance.
  - b) recommended laboratory investigations for any child with developmental delay or autism should include audiologic assessment and lead screening.
2. Specific assessments should be performed to diagnose and evaluate autism, including genetic testing (e.g., karyotype and DNA analysis for fragile X) and selective metabolic testing as indicated by clinical findings. Routine clinical brain imaging is not recommended (even in

the presence of megalencephaly) and EEG should be reserved for patients with a regression (see below) or possible seizures. There is inadequate evidence supporting other laboratory studies.

Much progress has been made in the early identification of children with autism so that most children today are identified during the preschool period (29, 32–34). Earlier identification is related to improvements in the recognition of the early features of autism among primary health care providers and other professionals who interact with very young children, as well as the development of appropriate screening tools (16, 35, 36). Research has demonstrated that the use of standardized test instruments by experienced clinicians results in a relatively stable early diagnosis in children as young as two years (37). Another apparent reason behind the decrease in the age of referral and diagnosis for autism is due to a general consensus that appropriately targeted early intervention improves outcome (38).

While the National Research Council's Committee on Educational Interventions for Children with Autism recommended that early diagnosis should be emphasized, children under the age of four who appear to have an ASD should be considered to have a "provisional diagnosis" (38, 39). Although a clinical diagnosis of autism is often sensitive and stable over time in children, stability increases when a spectrum approach is used (37, 40, 41). That is, a proportion of the children identified with possible autism before age three years may not meet criteria for DSM-IV-TR Autistic Disorder at later follow-up but are highly likely to meet criteria for PDD-NOS, a less severe form of autism. Alternatively, a proportion of children under the age of three who do not meet criteria for autism on a standardized parent report measure, such as the Autism Diagnostic Interview-Revised (ADI-R (42)) may nonetheless receive a clinical diagnosis of Autistic Disorder at a later follow-up (37, 40, 41). Studies of young children have demonstrated that the use of a standardized observation of social and communicative behavior and play, such as the Autism Diagnostic Observation Schedule (ADOS: WPS Edition; 43, 44), may be more sensitive and stable over time than a standardized parent report measure alone. It is also important to note that very young children with ASD may not show significant evidence of repetitive and stereotyped behaviors and restricted patterns of interest, as required to meet the cutoff for autism on the ADI-R or to meet DSM-IV-TR criteria. In one study of two-year-olds suspected of having autism, use of instruments that relied on the clinician's ratings of the child, instead of the ADI-R alone, allowed for the inclusion of children who appeared to meet the social and communication criteria for autism but did not yet show significant evidence of restricted or repetitive behaviors (45). A follow-up assessment confirmed the diagnosis of autism in the vast majority of these children. At the earliest ages, experienced clinical judgment using information from a variety of sources is more reliable for deter-

mination of diagnosis than the use of standard assessment instruments alone (14, 33, 37).

Although impairments in social interaction, communication, and a restricted repertoire of interests, behaviors, and activities are core domains in ASD, there are several additional domains that can be affected and influence the manifestation of the disability. It is therefore often recommended that an evaluation for ASD should include a formal multidisciplinary evaluation of social behavior, language and nonverbal communication, adaptive behavior, motor skills, atypical behaviors, and cognitive status by a team of professionals experienced with autistic spectrum disorders (29, 33, 38, 46). This evaluation will typically include an experienced clinical psychologist or school psychologist, a speech/language pathologist, and an occupational therapist. A complete physical examination is critical to rule out any other possible explanations for delayed and abnormal behavior. Many children with ASD experience difficulties with fine motor coordination, low muscle tone, behavior control and aggression, and/or the presence of a seizure disorder, warranting a consultation with an experienced pediatric neurologist or child psychiatrist (29).

Both the ADI-R and the ADOS operationally define current DSM-IV and ICD-10 criteria, and quantify separately the three domains that define autistic spectrum disorders: social reciprocity, communication, and restricted, repetitive behaviors and interests. The ADI-R is a semi-structured interview that is conducted with the parents or primary caregiver and is designed to elicit a full range of information needed to produce a diagnosis of autism or an autistic spectrum diagnosis (42, 47). The assessed individuals can be of any age, as long as their mental abilities are at a developmental level of at least 24 months. Diagnostic decisions are based on algorithm items. The ADOS is a standardized observation of social behavior in naturalistic and communicative contexts, with different modules and tasks for children of different ages and language levels (43, 44, 48, 49). The ADOS yields scores that fall within a range from autism to autism spectrum disorder, and so may be particularly helpful with difficult to diagnose cases. Inter-rater and test-retest reliability as well as internal validity have been demonstrated for both instruments and they, and their previous versions, have been widely used in research and in academic centers for about 15 years. The authors of the ADI-R and ADOS originally intended that experienced clinicians would use them after obtaining training in their use and achieving administration and scoring reliability.

The Gilliam Autism Rating Scale (GARS; 50) is another standardized instrument that can be used to assist in diagnosis. The GARS appears to have limited use for diagnostic purposes and appears to be better used as a screening device. The child's primary caregiver or teacher can complete the GARS. Screening questionnaires were never intended to be a diagnostic gold standard, particularly for low base rate disorders (51). The Social Communication Questionnaire (SCQ; 31) is a brief instrument that helps evaluate

communication skills and social functioning in children who may have autism. This instrument, formerly known as the Autism Screening Questionnaire, has good discriminative validity with respect to the separation of ASD from non-ASD diagnoses at all IQ levels (52, 53). It can be used with any individual over 4 (with a mental age exceeding 2 years of age). An experienced professional rates the child's behavior on the GARS (54), which requires direct observation of the child but does not provide guidelines on a standardized method of observation. The GARS has fair agreement with the ADI-R (55). Some argue that the GARS may be best used as a screening measure (46).

### Neuropsychological Findings and Theories

Although the majority of children with autistic disorder are mentally retarded, this is less often the case when one looks across children with diagnoses in the autistic spectrum (16). By definition, individuals with Asperger syndrome have intellectual abilities that are within the average range. Some individuals may have IQs that fall in the superior range and yet they have significant social disability. It is thought that while children with ASD are able to perform a variety of tasks, they may do so in ways different from typically developing children.

Neuropsychological studies have demonstrated that individuals with autism are able to perform certain types of tasks better than others. Using standardized intelligence tests, such as the Wechsler Intelligence Test for Children (56, 57), children with autism were reported to perform better on tests of visual pattern matching and rote auditory memory and more poorly on tests of commonsense social reasoning (58, 59). However, more recent studies suggest that a variety of profiles exist, such that some children may have more even nonverbal and verbal skills and some may perform better on verbal tests compared to nonverbal tests (60). Older children with nonverbal skills that are significantly higher than their verbal skills tend to have more social difficulties.

It appears that individuals with autism tend to disregard context and use this to their advantage on certain types of cognitive tests and in certain situations. This is in contrast to individuals with less formal schooling, who tend to perform poorly on tests with relatively little context (61). Even less able children with autism may have remarkable rote memory skills. The difficulty is that they are not able to use these skills to extract meaning as needed for learning important skills and procedures. This difficulty has been termed weak central coherence (61).

It is important to note that while ASD is typically associated with developmental delays and even mental retardation, the social deficits distinguish this disorder from more general cases of learning disability or mental retardation. Reciprocal social skills develop early in life and contribute to the development of a variety of cognitive skills, particularly language. Individuals with ASD appear to have early

difficulties in understanding the mental states of other individuals, specifically that others have a mind capable of understanding things the same way they do. This ability has been termed *theory of mind* (62) or *mentalizing* (61). In the time since first described by Simon Baron-Cohen and colleagues as a deficit in autism, many studies have replicated this finding. However, while individuals with ASD are significantly delayed in mentalizing, they are not incapable of acquiring knowledge about mental states. Difficulties with mentalizing may explain why young children with autism typically do not appear interested in sharing things that interest them with others or respond infrequently when others try to attract their attention to things of interest. As they develop, children with ASD may approach others to share things, particularly related to their restricted interests, but have limited interest in learning about the interests of others.

Some children with ASD appear to compensate for this difficulty in mentalizing by employing logic to understand why other people respond in certain ways to certain situations. However, in real-life situations or when under stress, they may continue to have significant difficulties. It is important to note that while many individuals with ASD want companionship and often approach others, they typically have significant difficulty interpreting the actions of others and responding appropriately in different situations. When others do not respond in the expected manner, individuals with ASD often have limited insight regarding how their actions affected the situation. This may lead to social withdrawal, anxiety, or mood disturbance.

Several of the diagnostic features of autism, as well as findings from psychological testing and experiments, have pointed toward deficits in executive function in autism. Executive abilities are not required for routine events or actions but rather when one has to switch between tasks or deal with the unexpected. Difficulties with tests of executive functioning such as the Wisconsin Card Sorting Test, the Tower of Hanoi, and the Trail Making Test have been reported for high functioning individuals with autistic disorder and Asperger syndrome (63–70). Individuals with ASD often exhibit repetitive actions, restricted interests, and have a desire for the “maintenance of sameness.” Difficulty with flexible thoughts and actions, reflecting deficits in executive functions, may help to explain why these behavioral features are so prominent and problematic for individuals with ASD.

### Etiology

Although autistic characteristics are associated with some neurodevelopmental disorders (e.g., fragile X and other chromosomal abnormalities), the etiology in the vast majority of cases is unknown. There is some evidence of increased prenatal and perinatal risk factors, although how these may relate to the etiology of the disorder is not clear (71).

### Neuroanatomy

The neuroanatomical abnormalities associated with autism have been the focus of many investigations that have included the use of structural brain magnetic resonance imaging (MRI), neuropathology, as well as neurophysiological and functional brain MRI techniques. Most studies have included older children, adolescents, and adults, although a few recent studies have focused on children who were studied soon after initial diagnosis.

Although head circumference at birth generally falls within the average range, recent evidence suggests that the trajectory of head growth occurs more rapidly than normal in the first few years of life in children with autism (72, 73). Figure 10.1 shows that head circumference measurements at the time of birth for children later diagnosed with autism were close to or slightly below the population mean. However, head circumference measurements taken between 6 and 14 months of age for those same children were more typically above the population mean, indicating that the relative rate of head growth was abnormally large during the first year of life. It is interesting to note that the abnormally rapid increase in head circumference in the first year of life in children with autism was strongly correlated with abnormal cerebral and cerebellar volumes from brain MRI data by two to five years of age (72). Whole brain volume has been found to be significantly larger than normal in two- to five-year-old children with autism (73, 74). More specifically, cerebellar white matter volume was abnormally large, and within the cerebral cortex, there was an anterior to posterior gradient in degree of abnormality: largest at the frontal lobes and closer to normal in the occipital lobes (75). Head circumference measures are strongly correlated with brain

size in the first few years of life while abnormally large head circumference measures later in life is less likely to be correlated with underlying brain volumes (76).

The degree of overgrowth abnormality during early life may be correlated with later outcome for children with ASD. Two- to five-year-olds with signs of ASD were scanned and sorted into three groups, when diagnoses were confirmed after age five: lower functioning children with autism, higher functioning children with autism, and higher functioning children with PDD-NOS (77). Discriminant function analysis revealed that the groups could be successfully discriminated from typically developing children using a combination of brain MRI measures. Cerebellar white matter volume was significantly larger in all three patient groups compared to the control group, but the posterior cerebellar vermis was smaller than normal in the lower functioning children and the anterior cerebellar vermis was larger than normal in the higher functioning children with autism. Brain MRI studies of high functioning older children and adults with autism have reported no significant differences in the size of the anterior and posterior cerebellar vermis from normal (78, 79) while studies that included both low and high functioning individuals consistently report decreased size of the posterior cerebellar vermis (80–82). Less loss in the posterior cerebellar vermis early in life may therefore be associated with better functional outcome, while early abnormalities in terms of increased white matter in the cerebellum and early overgrowth of the cerebrum may be associated with the persistent autistic symptoms observed across children.

In terms of gross anatomy, there appears to be a changing process with age, with rapid growth early in development preceding the onset of symptoms, and later changes

**Figure 10.1** Increase in head circumference from birth to 6 to 14 months of age in infants later diagnosed with autistic disorder. Modified from Courchesne, Carper, & Akshoomoff (2003) with permission from the American Medical Association.

that may include abnormally slow brain growth, compensatory overpruning of connections, or abnormal neuron loss (83–86). Rapid growth is only one possible explanation for these findings. Abnormally large brain volume may reflect an excessive number of neurons or glial cells, an excessive number of minicolumns, an excessive and early expansion of dendritic and axonal arbors, an excessive number of axonal connections, premature myelination, or an excessive rate of growth of the neurons or glial cells (72, 87, 88). These abnormal processes could reflect an abnormal acceleration of postnatal growth processes and/or a failure of the late prenatal and early postnatal regressive or “pruning” processes.

Abnormally large brain volume is not a typical finding among school-age children and adolescents with autism (73; for review, see 89). Cerebellar white matter volume also generally falls within the normal range, as well as measures of cerebral gray and white matter volume (73). Cerebellar pathology has been found in 21 of 22 postmortem (primarily adult) cases and appears consistent with prenatal or early postnatal abnormalities in neuronal development (90–93). Specific structures may be affected early in development and appear abnormally small in size compared to normal throughout development. Brain MRI data suggests that the cross-sectional size of the posterior corpus callosum is reduced compared to normal (94–96). Inconsistent findings have been reported with regard to amygdala (97–99) and hippocampal (100, 101) volumes, although there is postmortem evidence of abnormalities at the cellular level in the hippocampus and amygdala (90, 91, 102, 103). A recent study of 7 to 11 year-old high-functioning children with autism found white matter volume was larger than normal while measures of the cortical gray matter and hippocampus/amygdala were smaller than normal (104). Inconsistencies in volumetric abnormalities across studies are likely due to a number of factors. These include the ages of participants, relative sample sizes, the level of functioning of participants (i.e., level of mental retardation), selection criteria for control groups, and other potential confounds (e.g., history of seizures, long-term medication use).

### Neurofunctional Findings

Early widespread neuroanatomic defects in autism, including white matter overgrowth and hypoplasia of specific structures, would likely lead to abnormal development of functional systems. Neurophysiological and functional brain MRI studies have revealed abnormal patterns of brain activity during attention and other cognitive tasks, even when relatively high-functioning adolescents and adults with autism are normal in their behavioral performance in these tasks (for review, see 89). For example, individuals with autism have reduced activation in the brain regions typically associated with performing attention, motor, and face processing tasks while showing increased activation in other regions not primarily utilized by normal subjects

(105–109). In a  $H_2(15)O$  PET study of five high-functioning adults with autism, brain activation patterns were evaluated while the participants were listening to tones and sentences, and generating sentences (110). Reduced or reversed dominance activation was found over temporal regions associated with language perception and reduced activation of auditory cortex and cerebellum were found during acoustic stimulation. Further analysis showed that during sentence generation, the left dorsolateral prefrontal cortex (Brodmann area 46) and left thalamus and the right dentate nucleus of the cerebellum showed less activation in the males with autism (111). During sentence repetition, greater increases in blood flow in the left frontal cortex and right dentate nucleus were found in the males with autism compared to controls.

Many of the structures that are affected in autism mediate the development of more than one function. Since typical brain development involves competition between functions (or functional inputs) as the natural process of functional specialization, the early neural defects in autism may differentially affect the cerebral and cerebellar organization of different functional domains, with greater abnormalities for some functions than for others, and to a greater degree in some individuals than others (89). It has been hypothesized that the early development of basic skills, such as rapid shifting of attention, are affected to some degree in autism, leading to delays in the development of other skills reliant on these skills, such as joint social attention. As the child develops, these basic skills improve but behavioral and functional neuroimaging data suggest that the development of these skills occurs in an atypical fashion (105, 112, 113).

Functional neuroimaging studies have provided information about abnormal brain metabolism in autism. These studies are useful not only in improving our understanding of structure-function relationships but also to understand developmental changes in biochemistry and therefore lead to more rational design of drug treatments of children of different ages (114). In a positron emission tomography (PET) study using  $\alpha[^{11}C]$ methyl-L-tryptophan, whole brain serotonin synthesis capacity in children was over 200% of adult values until 5 years of age when it declined to adult values (115). In contrast, serotonin synthesis capacity in children with autism increased gradually from 2 to 15 years of age, reaching 1 to 1.5 times adult normal values. It thus appears that in normal brain development, there is a period of high brain serotonin synthesis capacity during childhood. There is also evidence that serotonin regulates neuronal differentiation, neurite outgrowth and synaptogenesis (116). These data, in conjunction with the brain MRI volumetric data from young children with autism, suggest that the normal developmental process, specifically the regulation of trophic effects, is disrupted in autism. In another study that included a subset of these participants, regional brain alterations in brain serotonin synthesis were observed, namely gross asymmetries in frontal cortex, thalamus, and cerebellum (117). Decreased serotonin synthesis was observed in the left frontal cortex and thalamus

accompanied by increased serotonin synthesis in the right cerebellum.

In a study of 14 medication-free children with autism, dopamine metabolism was studied with PET using 18F fluorodopa (118). There was a 39% reduction of dopamine activity in the anterior medial prefrontal cortex compared with activity in the occipital cortex in the children with autism compared with healthy children.

A 31P magnetic resonance spectroscopy (MRS) study of phosphorus metabolites in dorsal prefrontal cortex was conducted with 11 high-functioning adolescent and young adult men with autism (119). Decreased levels of phosphomonoesters, increased levels of phosphodiesteres, and decreased levels of ATP were noted. In the autism group, alterations in brain energy and phospholipid metabolism were correlated with neuropsychological and language test scores. The authors suggested that the findings indicate a hypermetabolic energy state and undersynthesis of brain membranes in autism. *N*-acetylaspartate (NAA) was significantly lower in the cerebellum of 9 children with autism compared to sibling control subjects using MRS (120). NAA levels in the frontal and temporal lobes did not differ between the two groups. An MRS study of 3- and 4-year-olds with ASD revealed widespread alterations in brain chemistry (121). Compared to age-matched developmentally delayed and typically developing control children, decreased metabolism of NAA, creatine plus phosphocreatine, and myo-inositol were found in a variety of brain regions, including the frontal and temporal lobes, cingulate gyrus, and a number of subcortical structures. Another recent MRS study of 5- to 16-year-old children with autism revealed altered metabolism in the left anterior cingulate gyrus, caudate nucleus, and right occipital cortex of NAA, choline compounds, and creatine plus phosphocreatine (122).

Additional studies are needed to determine how metabolic rates are related to cerebral volume increases in young children with ASD and how regional abnormalities may vary as a function of techniques, age, and level of functioning. While direct correlations between measures of brain structures and rates of metabolic activity have not been conducted, many of these findings are consistent with the results from neuroanatomical studies of autism. Measures of levels of activation in specific brain structures using functional MR imaging, PET, and SPECT, may eventually be used in drug treatment trials to assess changes in neural activation patterns in conjunction with behavioral changes (114).

### Genetics

Identification of the biological defects has significant implications for quantitative trait genetic linkage analyses and animal models of the neurodevelopmental abnormalities in ASD. These findings may also serve as a component of subject characterization in clinical treatment trials with young children to assist in determining how a child's level

of functioning and biological characteristics may be predictive of treatment response (114).

Data from twin and family studies indicate that genetic factors play an important role in the development of autistic spectrum disorders (123, 124). Concordance among dizygotic twins range from 0 to 25% while the rate of concordance for a diagnosis of autism or an ASD diagnosis among monozygotic twins is higher (40–90%). The concordance rate among siblings (2–6%) is significantly higher than the estimated population prevalence. It is clear that the autistic spectrum disorders are complex and the result of a number of genetic and environmental factors.

A number of recent studies have focused on identifying the specific genes that appear to be important in the development of autism and related disorders. For example, a genomewide scan with DNA markers was conducted in 345 multiplex families, each with at least two siblings affected with autism or an ASD phenotype (125). Evidence for linkage was found on chromosomes 17, 5, 11, 4, and 8. It is important to note that the linkage region implicated on chromosome 17q included the serotonin transporter (5-HTT) gene locus (SLC6A4), which has previously been implicated as a candidate gene for autism on the basis of some association studies (126–129). There is also some evidence of elevated blood serotonin levels both in patients with autism and in their unaffected first-degree relatives (130). A recent study sought to identify a susceptibility gene for autism in the chromosome region 2q24–q33 (131). Linkage and association was identified between two single nucleotide polymorphisms and autism. This region is known to be important for mitochondrial function and ATP synthesis in neurons. Future studies to identify the genes that act together to cause the autism phenotype would be improved by a focus on larger samples, more homogeneous samples, detailed phenotype information that is collected in a consistent manner, selection of candidate genes on the basis on recent neurobiological findings, and the use of knockout models (132, 133).

### Other Theories

The first report of an unexpected intestinal lesion associated with gastrointestinal problems in a group of 12 children with pervasive developmental disorders has been associated with a great deal of controversy (134). Specifically, the authors of the report raised the possibility of a link, on the basis of parental and medical histories, between the newly described syndrome of bowel disease and autism and the measles, mumps, and rubella (MMR) vaccine. This suggestion led to a great deal of concern in the United Kingdom and the United States, among other countries, regarding the safety of the MMR vaccine (135). Of particular concern was the suggestion that the MMR vaccine was a contributing factor to early loss or regression (134).

Regression is typically used to refer to the losses of already established skills (136). This is a phenomenon that has been documented for several decades and occurs in

approximately 20 to 33% of all cases of autism (136–138). Regression is most commonly identified as occurring between 18 and 24 months of age (137–143). One of the most striking features of regression is word loss. That is, the child may have produced several words and then stopped saying those words altogether for months or even years (142, 144). Children with word loss are also more likely to be described by their caregivers as showing more gestures, greater participation in social games and better receptive language before the time of the word loss (145).

A possible causal relationship between vaccines and autism has been of concern to some clinicians and parents, particularly with reports of increasing prevalence of autism and the increasing number of vaccines given to infants. However, epidemiological studies have not supported the relationship between prevalence of autism and the MMR vaccine (140, 146–149). Ten of the authors of the original study that suggested the possibility between the MMR vaccine and autism (134) have recently published a retraction of that interpretation of their data (150).

## Treatment

### *Behavioral and Educational Treatment*

The majority of evidence-based interventions for children with ASD are behavioral and educational in nature (38). Early intervention programs (between 2 and 4 years of age) are the most effective for helping improve the outcome in children with autism (151). Several intensive behavioral treatments are supported by empirical investigations, such as behavior modification or the “Lovaas method,” discrete trial training, incidental teaching, and pivotal response training, as well as structured programs such as TEACCH and the Denver Model (152–154). A large number of other treatment programs exist, such as “floor time” developed by Greenspan and colleagues (155). It is important to note that outcome data are limited making it difficult to adequately evaluate the effectiveness of the treatment programs available and in use (156). It is also important to note outcome among children with ASD is variable, in part due to the fact that the needs and strengths of these children are very heterogeneous (38). Speech and language therapy is essential for assisting young children who are delayed in their use of language, as well as older, higher-functioning children in assisting them with pragmatics and the social use of language. Occupational therapy is often helpful for assisting with sensory integration issues as well as the development of fine motor coordination and self-help skills. Physical therapy is often needed, as well as adapted physical education programs.

The Individualized Education Plan (IEP) and the Individual Family Service Plan (IFSP) should be utilized for planning and implementing the educational objectives of children with ASD (38). Learning objectives should be observable, measurable behaviors and skills that are accomplished within one year, including the development

of social skills, language and communication skills, developmentally appropriate tasks and play, cognitive skills, and fine and gross motor skill development. The National Research Council’s Committee on Educational Interventions for Children with Autism recommended that educational services should include a minimum of 25 hours a week, 12 months a year, and be based on an individualized plan. Until more data are available, particularly with regard to the relative merit of one program model over another, a wider range of outcome variables, and specific approaches for specific needs, the Council suggested that it may be more important to consider how the environment and educational strategies associated with a particular program allow implementation of the goals for a child and family.

### *Medications*

The medications most commonly used in the treatment of individuals with ASD are directed toward ameliorating the associated rather than core symptoms of the disorder (157). Medications may be prescribed when children are having significant difficulty with hyperactivity, aggression, irritability and agitation, repetitive behaviors, and so on to increase the likelihood that the individual will benefit from behavioral and educational programs. Some aspects of social behavior may also improve as a result of the reduction in these problematic symptoms (158).

Early drug treatment studies included the use of fenfluramine, haloperidol, and naltrexone (158). Haloperidol, in doses of 1 to 2 mg/day, was more effective than placebo for relieving temper outbursts, hyperactivity, withdrawal, stereotypy, anger, and affective lability but acute dystonic reactions and withdrawal and tardive dyskinesias occurred relatively frequently (159, 160). Large controlled studies of naltrexone failed to find improvement of maladaptive behaviors except for motor hyperactivity (161). More recent, well-controlled studies have focused on the atypical antipsychotics, including clozapine, risperidone, olanzapine, and quetiapine (162). Risperidone has received the most attention. In the largest controlled drug treatment study in autistic disorder to date, the National Institute of Mental Health (NIMH)-sponsored Research Units on Pediatric Psychopharmacology (RUPP) Autism Network completed a randomized controlled trial of risperidone in 101 children with autistic disorder (163). Treatment for eight weeks was effective in reducing tantrums, aggression, or self-injurious behavior in children with autistic disorder. An average weight gain of 2.7+/-2.9 kg (as compared with 0.8+/-2.2 kg with placebo) was observed; increased appetite, fatigue, drowsiness, dizziness, and drooling were also associated with risperidone. In an open-label, naturalistic study of preschoolers with autistic disorder or PDD-NOS, low-dose risperidone was associated with reducing behavior problems and affect dysregulation in the short-term, but also in the long-term period (164). Increased prolactin levels

without clinical signs and increased appetite were the most frequent side effects. Response was associated with higher doses and weight gain. In general, risperidone appears favorable in reducing symptoms of most concern to parents (165).

Serotonin reuptake inhibitors have also been the focus of investigations on clinical response and side effects in children, adolescents, and adults with ASD. Although a number of studies of clomipramine have been published (166) the selective serotonin reuptake inhibitors (SSRIs) have received more recent attention due to the less severe side effects associated with the SSRIs (158). Few controlled studies have been completed. Studies of fluvoxamine suggest that it may be less efficacious and less tolerated in children and adolescents with ASD than adults (167). Studies of fluoxetine indicate favorable results, although drug-induced side effects, such as hyperactivity, agitation, decreased appetite, and aggression, led to discontinuation in some cases (168). Fewer studies have been conducted to date with sertraline and paroxetine.

Some individuals with a diagnosis of autistic disorder or other ASD may also meet the DSM-IV-TR criteria for attention-deficit/hyperactivity disorder (ADHD). However, the DSM-IV-TR specifies that in order to meet criteria for ADHD, the symptoms do not occur exclusively during the course of a pervasive developmental disorder or schizophrenia. Hyperactivity and impaired attention are more prominent in younger children and can interfere with the implementation of critical early intervention programs. The use of psychostimulants for the treatment of motor hyperactivity and poor attention in ASD has generally resulted in mixed results (169). While these symptoms may improve in some children, adverse effects, notably aggression, irritability, have been noted in children with autism as a result of methylphenidate. There is some interest in the use of clonidine and other  $\alpha$ -adrenergic agonists such as guanfacine, particularly for those children and adolescents with ASD who are nonresponders to methylphenidate and other psychostimulants (169).

There has been a great deal of interest in more novel types of treatment strategies for children with ASD, particularly those directed toward gastrointestinal and immune functions. Secretin is a hormone that is secreted in response to food passage by the gut and stimulates the pancreas, resulting in decreased gastrointestinal motility. It is commonly used in gastrointestinal endoscopies. It became a focus of much interest after a report indicated that three boys with ASD demonstrated improvement in autistic symptoms following secretin injection associated with an endoscopy procedure (170). Many children with ASD received treatment with secretin before formal research studies were conducted. A series of double-blind placebo-controlled studies with single dose secretin in children with ASD (with more than 300 children total) have indicated no consistent significant differences in primary outcome measures (171–177). While there is some speculation that

multiple doses are perhaps needed, or secretin may prove helpful with a certain subset of children with ASD (178), others believe that the results indicate that there is a strong placebo effect associated with secretin and no scientific evidence to support its use as a treatment for autism (179).

A limited number of studies have been conducted with drugs that have direct effects on immune function that may warrant further investigation. The use of alternative treatments is increasing among families who have a child with an ASD and therefore physicians should discuss the efficacy and potential side effects of such treatments with parents (180). Although no comprehensive scale has been developed to date to assess change in maladaptive behaviors during treatment, a number of scales have been utilized by the (RUPP) Autism Network (158, 181). These include the Aberrant Behavior Checklist, the Clinical Global Impressions scale, and the Children's Yale–Brown Obsessive Compulsive Scale. There are currently no measures available to adequately assess changes in core symptoms, such as social behavior or restricted/repetitive behaviors, appropriate for drug treatment trials (182). Current information about the individual's cognitive and adaptive skills is also helpful.

### Course and Mortality

It is important to consider issues related to outcome and long-term care when working with individuals with ASD. The symptoms of ASD differ over the course of life. These differences reflect developmental interactions with the core symptoms of autism, environmental influences, and individual differences in background variables. The patterns of autism were assessed using the ADI-R in 405 individuals with ASD, ages 10 to 53 years (183). Although the patients met criteria for autistic disorder based on childhood criteria, only 54.8% would have met criteria based on their current behavior. The greatest amount of improvement was observed in development of phrase speech while there was limited change in having friendships.

Individuals with autism are subject to increased mortality risk (184). A database study revealed the causes of mortality and relative risk for individuals who were diagnosed with autism and received any services from the California Department of Developmental Services between 1983 and 1997 (185). Among those with no or mild mental retardation, deaths by seizures, nervous system dysfunction, drowning, and suffocation were all more than three times higher than expected in the general population. Excess mortality was marked for individuals with severe mental retardation but life expectancy was also reduced for individuals who were fully ambulatory with only mild mental retardation.

## CHILDHOOD-ONSET SCHIZOPHRENIA

The onset of symptoms in schizophrenia most commonly occurs during late adolescence and early adulthood (13).

Onset of symptoms between the ages of 5 and 14 is commonly referred to as “childhood-onset schizophrenia” (186, 187). Kraepelin reported that only about 6% of his sample of more than 1,000 cases with schizophrenia had an onset of psychotic symptoms before 15 years of age (61). Although epidemiological data are limited, it is estimated that less than 1 child in 10,000 suffers from COS, making it a rare disorder compared to adult schizophrenia, which affects approximately 1 in 100 (188). COS is more common among males than females until adolescence, when the ratio of males to females is more similar. Although this is a rare developmental disorder, COS has increasingly become the focus of research investigations because it is thought that enhanced understanding of developmental changes in the brain could lead to an improved understanding of the neurobiology of schizophrenia.

### Diagnosis and Appropriate Assessment Strategies

The DSM-IV-TR (13) criteria for schizophrenia are as follows. The characteristic psychotic symptoms must be present for a significant portion of the time during a one-month period (or less, if successfully treated). Two or more of the core symptoms of schizophrenia must be present, namely delusions, hallucinations, formal thought disorder, grossly disorganized behavior, and negative symptoms (flat affect and anhedonia). However, only one symptom is required if delusions are bizarre or hallucinations consist of a running commentary on the person’s behavior or thoughts or two or more conversing voices. There must be deterioration in functioning or failure to achieve the expected level of interpersonal, academic, or occupational achievement. The boundaries between schizophrenia and mood disorders, schizoaffective disorder, organic disorders, and pervasive developmental disorder are specified and should be carefully considered in making a diagnosis. The duration of disturbance, prodromal features, and residual features are also defined in DSM-IV-TR.

Several independent studies have concluded that schizophrenia in childhood can be reliably diagnosed using the same criteria for adults (for review, see 189). However, developmental differences do exist in symptom presentation. Hallucinations, delusions, and formal thought disorders are rare or difficult to diagnose in children younger than age 7 (190). The distinction between schizophrenic symptoms and features of typical children can be difficult in some cases, such as distinguishing between delusions and the imaginative fantasies typical of young children. Of concern is a more persistent pattern of such behaviors, such as a child who often hears voices saying derogatory things about him or her, or hears voices conversing with one another, talks to himself or herself, imagines seeing scary things (such as snakes, spiders, or shadows), and shows no interest in friendships (191). It is important to note that a child with more limited language and cognitive skills may

have difficulty accurately describing their experiences and distinguishing them from pretend or fantasy (1).

After age 7, hallucinations are the most common symptom of COS, with auditory hallucinations more common than visual hallucinations (192). It may be difficult to accurately assess disorganized speech or formal thought disorder in children and adolescents with schizophrenia. Blunted affect is fairly common.

Childhood-onset schizophrenia typically presents with an insidious rather than acute onset, with a number of associated symptoms and problems (1, 192). The prodromal symptoms are similar to those observed in adult-onset schizophrenia but language impairments and transient autistic-like and nonspecific symptoms are more common (187). The onset of psychotic symptoms is often preceded by social abnormalities; many children are described as odd prior to the onset of psychotic symptoms. Developmental disturbances are common, such as lags in motor and speech/language development (193). Children with more pronounced early developmental abnormalities tend to have a poorer outcome. The most common type of communication difficulty is poor pragmatic skills. During the early school-age period, difficulties with attention and behavior often affect school functioning (194). Other symptoms include depression, oppositional behavior, and conduct problems.

Researchers have identified other disorders that fall within or similar to the schizophrenia spectrum. Children with “multidimensionally impaired syndrome” exhibit psychosis, poor affect regulation, and difficulty with attention and impulse control (187). These children can be distinguished from children with schizophrenia. Although they are likely to develop more specifically defined psychiatric disorders, such as bipolar disorder, schizoaffective disorder, or a disruptive behavior disorder, longitudinal follow-up studies do not suggest they are likely to be diagnosed later with schizophrenia. Follow-up of children with schizoaffective disorder or schizotypal personality disorder reveals that although the development of full-blown schizophrenia is rare, the majority of children will continue to exhibit a schizophrenia spectrum disorder (195).

The outcome of children with schizophrenia is generally poor and possibly worse than those with adult-onset (196). Eggers and Bunk (197) conducted a 42-year follow-up of a group of 44 patients with COS. They found that 50% of the sample had continuous symptoms and 25% had partial remission. Studies with shorter follow-up periods have reported similar results.

Uncertainty about diagnosis is common among children with schizophrenia and therefore it is important to consider a variety of factors to reduce the misclassification of cases. Although it may appear that the distinction between childhood-onset schizophrenia and an autistic spectrum disorder is fairly apparent, the differential symptoms and similarities should be considered. Childhood-onset schizophrenia is distinguished from autism by the persistence of hallucinations and delusions for at least 6 months,

and a later age of onset. Autistic Disorder is most typically identified before age 5 and results in more major intellectual deficits than COS (6, 7). It is interesting to note that in adulthood some individuals with autism exhibit, in their surface behavior, some symptoms characteristic of schizophrenia (61). They may show negative signs, such as little or no speech or facial expressions, little or no interest in social contact or communication, and they may exhibit simple movement stereotypies. However, articulate individuals with autism who have reported their experiences give accounts quite different from those of individuals with schizophrenia; most notably the absence of hallucinations and delusions. Furthermore, in schizophrenia, phases of acute illness often alternate with long periods of symptom remission, which is different from autistic spectrum disorders. It is interesting to note that the term autistic was first coined by Ernst Bleuler to apply to thought processes in schizophrenia. Both autism and schizophrenia result in some sort of social impairment. If children show any interest in friendships, even if they fail at maintaining them, it is unlikely that they have schizophrenia (191).

As part of the ongoing study of childhood-onset schizophrenia at the NIMH, more than 1,300 children and adolescents have been referred to the study since 1990. After the initial screening process, 215 cases were interviewed to identify those that met criteria for COS (198). Many of the cases referred to the study were judged to have psychotic mood disorders rather than schizophrenia. The clinical presentations included mood-congruent hallucinations, the absence of grossly disorganized behavior or speech, and comorbid disorders commonly seen in patients with mood disorders (e.g., anxiety disorders, attention-deficit/hyperactivity disorder). As the authors discuss, it is important to note that the rarity of COS makes it difficult for clinicians to have the experience of the NIMH team in diagnosing COS, as well as the time needed for a comprehensive, structured diagnostic assessment. These results also suggest that it is not uncommon for children with bipolar disorder or major depressive disorder with psychotic features to be diagnosed with schizophrenia initially. The distinction between schizoaffective disorder and schizophrenia was more difficult to achieve reliably, as has been noted in previous studies (199, 200). The acute onset of manic episodes in bipolar disorder may be mistaken for schizophrenia. Children who have experienced abuse or who suffer from posttraumatic stress disorder may sometimes claim to hear voices or see visions associated with abuse or a traumatic event. Due to these issues in misdiagnosis, clinicians should not rely on cross-sectional assessments of children and adolescents with psychotic symptoms (187). It may also be important to consider whether a child develops additional symptoms that may signify an additional diagnosis or perhaps different subtypes. These distinctions are important considerations for neurobiological studies.

A number of standardized assessment tools exist for use with children and adolescents with suspected psychotic dis-

orders (for reviews, see 201, 202). The diagnostic interviews have been developed in order to obtain a categorical diagnosis according to the DSM or ICD systems. These tools include the Schedule for Affective Disorders and Schizophrenia for School-age Children (K-SADS) (203), the Interview for Childhood Disorders and Schizophrenia (ICDS) (204), and the NIMH Diagnostic Interview Schedule for Children (NIMH DISC) (205). Symptom rating scales are broader in focus and assess severity of psychopathological symptoms on a continuous scale. These scales include the Positive and Negative Syndrome Scale for Children and Adolescents (K-PANSS) (206), the Children's Psychiatric Rating Scale (CPRS), the Brief Psychiatric Rating Scale, and the Children's Global Assessment Scale (C-GAS) (207). Caplan and colleagues developed the Kiddie Formal Thought Disorder Rating Scale and Story Game (K-FTDS), which provides a structured evaluation of thinking disturbance (208).

It is essential to obtain information from parents and teachers as well as careful observation of the child (209). The most valid diagnosis is likely to be obtained using a "best estimate" approach, taking into consideration all sources of information and using a prospective approach (202).

The American Academy of Child and Adolescent Psychiatry published a practice parameter for the assessment and treatment of children and adolescents with schizophrenia (210). Based upon the empirical evidence, the practice parameter gives specific recommendations:

#### 1. Assessment

- (a) A comprehensive diagnostic assessment, which includes, when possible, interviews with the child/adolescent and the family, plus a review of past records and other available ancillary information.
- (b) Physical assessment to rule out general medical causes of psychotic symptoms.
- (c) An intellectual assessment or cognitive testing to evaluate possible developmental delays and degree of impairment associated with the illness.
- (d) Recognition of the various phases of the disorder (prodrome, acute phase, recovery phase, residual phase, and chronic impairment).
- (e) Psychiatric formulation to establish diagnosis and rule out other disorders. Reassessment longitudinally is recommended.

#### 2. Treatment

- (a) Antipsychotic agents are recommended for the treatment of the psychotic symptoms associated with schizophrenia. Guidelines are provided for the procedures for medication administration and management.
- (b) Psychoeducational therapy for the patient (e.g., education about the illness, social skills training) and for the family.
- (c) Specialized educational program and/or vocational training programs may be indicated.

## Etiology

Schizophrenia in childhood appears to have a particularly strong biological predisposition and may possibly represent a more homogeneous genetic form of the disorder. Data from various medical disorders indicate that unusually early onset is associated with greater heritability and disease severity (211). Also the excess of males in younger age groups may indicate a particular biological vulnerability. Childhood-onset schizophrenia may be a more severe and familial variant of schizophrenia, giving hope that the etiology may be more easily discerned in cases with childhood rather than adult-onset. Studies of children with schizophrenia may also provide more information about etiology due to limited history of neuroleptic treatment and years of dysfunction. It is important to note, however, that the children who participated in the NIMH study were selected because they did not respond to traditional neuroleptic medications and therefore have a history of multiple medication use.

The causes of schizophrenia are still unknown. Weinberger (212) proposed a "neurodevelopmental model" of schizophrenia. While COS is rare compared to the typical profile of onset during late adolescence and early adulthood, Weinberger's neurodevelopmental model may be particularly applicable to the early onset cases. Children with schizophrenia are more likely to manifest impairments in language and motor development before the onset of psychotic symptoms, which may reflect early manifestations of the underlying brain abnormalities. Children with schizophrenia often exhibit difficulties with social behavior early in development, more so than children with major depression and other psychiatric conditions (195, 196). It is important to note that these early developmental difficulties in language and social development appear to be distinguishable from the early symptoms of autism.

## Genetic Risks

Two classic studies suggested significantly higher rates of schizophrenic disorders (schizophrenia, schizoaffective disorder, schizotypal disorder, schizotypal personality disorder, and paranoid personality disorder) among the first-degree relatives of children with schizophrenia compared to those of adults with schizophrenia (7, 213). Using a larger sample and more rigorous methods, the UCLA Family Study (214) compared the diagnoses of first-degree relatives of probands with COS (N=148) with those of first-degree relatives of probands with attention-deficit hyperactivity disorder (ADHD; N=368) and community control probands (N=206). The families of probands with COS were significantly more likely to have at least one first-degree relative with a diagnosis of schizophrenia, or schizotypal or paranoid personality disorder than the other two groups. An unexpected finding was that the parents with a diagnosis of schizophrenia had an early age of first onset

(mean = 20.8 years) compared to the typical age of first onset for schizophrenia.

The results from the UCLA Family Study (214) suggested that the relative risk for schizophrenia in the parents of probands with COS was higher than that observed in adult-onset schizophrenia. This finding was directly compared as part of the study of COS at the NIMH (215). Indeed, the parents of patients with COS had a significantly higher risk of schizophrenia spectrum disorders (24.74%) than parents of patients with adult-onset schizophrenia (11.35%). The rates of mood disorders, substance use disorders, and schizoid personality disorder did not differ among the two groups and the control group. These results suggest that there is a more specific risk, rather than risk of psychopathology in general. It is also interesting to note that the patients with COS in the NIMH study who had relatives with schizophrenia or spectrum disorder were more likely to have a premorbid language disorder (187). The authors from both the UCLA and NIMH studies conclude that COS may be a more familial, possibly more genetic, form of schizophrenia than adult-onset schizophrenia.

In addition to a family history of a schizophrenia spectrum diagnosis, other factors are useful for developing a clinical phenotype of schizophrenia for genetic linkage studies. In one study, performance on neurocognitive tests was compared in three groups: parents of probands with COS, parents of probands with ADHD and parents of community controls (216). Only parents without a diagnosis of psychosis were included. Parents of probands with COS performed worse than parents of probands with ADHD and community controls on the Degraded Stimulus Continuous Performance Test and the Trail Making Test. The results suggest that neurocognitive impairments index the liability to schizophrenia in nonpsychotic relatives but neurocognitive impairments are not a significant factor among relatives of children with ADHD.

## Neuropsychological Findings

Neuropsychological studies indicate that children with schizophrenia have difficulty allocating attention, have limited processing resources, show deficits on tests of executive functions, and have deficits in both verbal and nonverbal memory (187, 217). They also show difficulty with visual-motor coordination and fine motor speed. Other anomalies associated with adult schizophrenia, such as smooth pursuit eye movement abnormalities, are also found in children with schizophrenia and their first-degree relatives (187, 218, 219). The abnormal leading saccade phenotype may prove useful as a marker that is present by age 6 for individuals at risk for developing schizophrenia. A number of studies have been conducted with adolescents and adults at risk for schizophrenia in order to identify neurobehavioral markers associated with risk. Studies have implicated a specific type of eye-tracking dysfunction that is associated with prefrontal cortex function and appears to

be specific to schizophrenia (220). Prospective neurobehavioral studies of the children of schizophrenic parents have identified variables that may be associated with the genetic liability of schizophrenia and related disorders, including anticipatory saccades (221). It is also important to note that the early course of neuropsychological dysfunction in patients who have not yet received antipsychotic medication treatment suggests that the neuropsychological dysfunction associated with schizophrenia is neurodevelopmental, rather than neurodegenerative, in nature (222).

### Neuroanatomy

MRI abnormalities have been found in many of the same brain regions in childhood-onset schizophrenia as in adult schizophrenia. The ongoing NIMH study of childhood-onset schizophrenia includes children who experienced an onset of psychotic symptoms before the age of 12 and were selected because they did not respond to traditional neuroleptic medications.

In a series of publications, brain MRI data from these children has revealed significant differences in brain anatomy compared with age-matched typically developing children (223–225) (for reviews, see (187, 226). Most notably, the volume of the lateral ventricles is enlarged, and the area of the midsagittal vermis of the cerebellum and the area of the midsagittal thalamus is significantly

smaller than normal in the children with schizophrenia. It is important to note that reduction of the thalamus is a consistent finding in adult patients with schizophrenia, including those who have not received neuroleptic medications, as well as the healthy relatives of patients with schizophrenia.

The UCLA group has also reported significant ventricular volume enlargement in their sample, particularly in the poster region of the ventricles (227, 228). Results from the UCLA group, using statistical parametric mapping, are shown in Figure 10.2. Both research groups have also reported reductions of total gray matter volume. These differences appear to be more striking for the cases with COS than has been reported in adults with schizophrenia (226). Both the UCLA and NIMH groups have reported volume increases in basal ganglia structures. This finding may be related to exposure to typical neuroleptic medications. One study reported that after two years of clozapine treatment, the volume of the caudate decreased to normal (229). Differences in caudate volume as a function of age are not clear. Decreased caudate volumes have been reported in adult patients with schizophrenia who did not have a history of neuroleptic medication treatment (230).

Longitudinal data from the NIMH sample of patients with COS have revealed progressive changes in volumetric measures during childhood and adolescence. The volume

**Figure 10.2** Statistical parametric mapping (SPM) results from the UCLA childhood-onset schizophrenia study. The top panel shows the three-dimensional renderings of the significant clusters from the gray matter (blue), white matter (red), and CSF (green). SPMs mapped into the average brain space of the nine subjects with COS. Significant voxels from the gray matter (in blue; voxel threshold  $p < .01$ , corrected at  $p = .05$ ), white matter (in red; voxel threshold  $p < .01$ , corrected at  $p = .05$ ), and CSF (in green; voxel threshold  $p < .01$ , corrected at  $p = .10$ ) SPMs are mapped onto three orthogonal slices from the average schizophrenic brain (middle panel) and over the same three slices of the average control brain (bottom panel). From: Sowell ER, Toga AW, Asarnow R. Brain abnormalities observed in childhood-onset schizophrenia: A review of the structural magnetic resonance imaging literature. *MRDD Res. Rev.* 2000;6:180–185. Copyright © 2000. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. (For color detail, see full color insert.)

of temporal lobe structures may not differ from normal when children COS are scanned in late childhood or early adolescence (224, 231). However, a two-year follow-up of brain MRI data from the NIMH study revealed significantly greater decreases in temporal lobe volume, even after taking the 4.6% decrease in total cerebral volume into consideration (232). Reduction of right posterior superior temporal gyrus volume was also associated with increased symptom severity. Longitudinal data obtained from 55 patients with COS also revealed abnormal changes in the corpus callosum (233). At the time of the initial scans, no differences from normal were seen. However, among the patients with schizophrenia the developmental trajectory of the area of the splenium was significantly different from normal. The splenium was significantly smaller than normal in patients with COS.

In a study of a small sample of the children with COS from the NIMH study, healthy controls, and a comparison group of nonschizophrenic patients matched for IQ and drug treatment status, three-dimensional maps of brain change were derived from high-resolution longitudinal brain MRI scans (186). By early adolescence, a “dynamic wave” of gray matter loss occurred. The loss started in the parietal association cortices and continued to the dorsolateral prefrontal cortex and temporal cortex. Significant progressive loss of cerebellar volume has also been reported from the longitudinal NIMH study (234). The loss appears to occur at the same time as cerebral volume loss, despite the fact that the cerebellum appears to reach its peak in total volume later than total cerebral volume. These data suggest that structural changes continue after the early onset of psychotic symptoms and continue well into adolescence. The changes observed in cortical volume are consistent with changes in ventricular enlargement.

These results, as well as a recent report of progressive gray matter volume loss in a larger sample of longitudinal subjects from the NIMH COS study (235), support the concept of schizophrenia as a progressive neurodevelopmental disorder with both early and late developmental abnormalities. While these brain MRI results do not have any immediate clinical implications, they may provide useful information for understanding the underlying pathophysiology.

The progressive loss of neural tissue seen in COS does not appear to be common to other developmental disorders. For example, although there is evidence for early developmental abnormality of cerebellar-striatal-prefrontal circuitry in ADHD, longitudinal data indicate that the developmental trajectory of brain volume is normal in children with ADHD (236, 237). Rapoport and colleagues speculate that in COS, the earlier tissue loss may trigger the onset of psychosis in childhood.

The underlying causes of the brain MRI abnormalities are not clear. There may be abnormalities in neuronal migration, or a disturbance in the process of normal synaptic pruning that follows the peak of synaptic production during the preschool period (212, 238, 239), particularly the

prefrontal corticocortical, and corticosubcortical synapses (240). The progressive loss may indicate a late neurodevelopmental disorder that may be correlated with clinical symptoms and pathophysiology of the illness. It is interesting to note that healthy siblings of patients with COS share some of the brain MRI abnormalities as their affected siblings (241). The healthy siblings had smaller than normal total and parietal gray matter volumes than normal comparison subjects. Unlike the patients, however, there was no evidence of ventricular enlargement. These results may suggest that some of the brain abnormalities associated with COS are genetic trait markers, just as has been suggested from similar results from siblings of patients with adult-onset schizophrenia.

Two MRS studies (Bertolino et al., 1998 and Brooks et al., 1998) suggest anterior cingulate and frontal metabolite abnormalities in childhood-onset schizophrenia, including below-normal NAA/Cr (242, 243). In a MRS study of 11 patients with childhood-onset schizophrenia, above-normal levels of creatine plus phosphocreatine were found in the superior anterior cingulate, and above-normal levels of choline compounds were found in the superior anterior cingulate, frontal cortex, and head of the caudate nucleus (244). In the thalamus, NAA was lower in male but not female subjects with COS. Elevated creatine suggests abnormal local cell-energy demand and elevated choline may indicate that patients with COS exhibit phospholipid membrane disturbances (244). Low NAA may reflect diminished neuronal integrity.

## Treatment

Patients with childhood-onset schizophrenia appear to be less responsive to medication treatment than adults with schizophrenia and may experience more adverse drug side effects. It is possible that these effects reflect the earlier, more severe nature of their neurodevelopmental abnormalities (188).

As with adults, antipsychotic medications may be beneficial in reducing hallucinations and delusions. The newer generation “atypical” antipsychotics, such as olanzapine and clozapine, may also reduce negative symptoms, such as improving motivation and emotional expressiveness (187). Due to the increased risk of side effects associated with the typical antipsychotics, atypical antipsychotics are preferred in the initial treatment of COS (202, 245). However, side effects are also associated with these newer medications, including excess weight gain, neutropenias, and seizures, and therefore all children should be carefully monitored and administered the lowest effective dose possible. The majority of studies conducted with children and adolescents have been open label studies. The largest number of studies included clozapine or olanzapine. Less data are available on the effectiveness of risperidone (two open label studies), amisulpride (one controlled study), and quetiapine (one open label study) (202).

The NIMH group has conducted studies with patients with COS who were neuroleptic nonresponders. In a double-blind comparison of haloperidol and clozapine, clozapine was found to be superior in reducing both positive and negative symptoms (246). Other studies have also reported positive effects with clozapine (187, 202). Studies comparing clozapine with olanzapine have revealed that olanzapine has a more benign side effect profile but clozapine has superior efficacy for positive and negative symptoms (187). Due to the increased risk of serious side effects, clozapine is not recommended as a first-line antipsychotic medication (1). Clozapine requires daily monitoring. In this era where several atypical neuroleptic medications are available to target negative and positive symptoms, traditional neuroleptic medications, such as haloperidol, are not typically thought of as first line medications.

Schizophrenia impacts a wide range of domains therefore treatment must be multimodal. In addition to medication treatment, it is important to consider the benefits of psychosocial intervention for children and adolescents suffering from schizophrenia (1, 202). An integrated intervention package that combines psychotropic medication to reduce acute symptoms and vulnerability, and psychosocial interventions to reduce stress and build coping strategies is ideal but has not been systematically investigated (209). It is important to consider the impact of developmental level on the treatment process, the necessary case management skills in working with family members and school systems, potential comorbid symptoms, and the chronic nature of this disorder. Given the deficits in attention, verbal learning, and executive functions among children with schizophrenia, neuropsychological assessment can be helpful for treatment and academic planning. Special school programs are often needed. Social skills training and improvement of problem-solving skills may also be warranted (1). Currently, more children are treated within their families and communities rather than long-term hospitalization. The attributes of the family may have an impact on the child's illness, and the needs of the child can also have a significant impact on the rest of the family. Behavioral family treatment is therefore an important consideration.

## **EPIDEMIOLOGY OF ATTENTION DEFICIT–HYPERACTIVITY DISORDER**

---

Attention deficit–hyperactivity disorder (ADHD) is the most common neuropsychiatric disorder in the pediatric age group, with a worldwide prevalence in the range of 7 to 17% of school-aged children (1,2). This disorder has a long history. The first description of ADHD is attributed to Sir George Still, who in 1902, described children with “morbid deficits in moral control” (3). The disorder was also described in association with the residual effects of encephalitis and traumatic brain injury. In 1937, the efficacy of psychostimulants in the treatment of hyperactivity was described (4). Terms such as “minimal brain damage/dysfunction, minimal/minor cerebral dysfunction and hyperkinetic syndrome or hyperactive child syndrome” were also common descriptors at the time. The diagnosis of ADHD has undergone considerable evolution since the first clinically-based behavioral descriptions were put forth. It has now been recognized as a neuropsychiatric disorder with a strong genetic basis.

Two large-scale studies have provided considerable information about the clinical presentation of ADHD. The first, sponsored by the National Institute of Mental Health, was undertaken as part of the DSM-IV field trials. The study was based on 380 clinic-referred children and adolescents, ranging in age from 4 to 17 years. Structured diagnostic interviews were conducted with multiple informants and standardized clinician’s diagnoses of ADHD were obtained to assess agreement. The study was also

directed at definitional criteria for “impairment” (8). A second study, the NIMH Collaborative Multisite Multimodal Treatment Study of Children with ADHD, was conducted at six different sites across the country and enrolled 579 children with ADHD combined type, aged 7 years to 9 years 9 months. The subjects were randomly assigned to one of four different treatment conditions and followed for a period of 14 months. Both of these studies, although not without some limitations, provide a rich source of data regarding the clinical presentation of ADHD.

## **DIAGNOSIS AND CLINICAL PRESENTATION OF ATTENTION DEFICIT–HYPERACTIVITY DISORDER: INATTENTIVE, HYPERACTIVE/IMPULSIVE, AND COMBINED SUBTYPES**

---

Currently, DSM-IV defines three subtypes of ADHD: the predominantly inattentive type, the predominantly hyperactive/inattentive type, and the combined type. To be given a specific diagnosis, a child must meet six of nine criteria for each of the subtypes. However, this is of questionable clinical utility, particularly if ADHD is a biological phenomenon with gradations of severity. A child would technically not be considered to have met diagnostic criteria of ADHD if only five of the nine behaviors were identified, even in the presence of serious impairment in daily life. Moreover, even though there is often relatively good

agreement between observers, the diagnosis is based on behavioral manifestations and these observations are, of course, subject to observer bias and definitional criteria. (Some raters have a much lower threshold for “hyperactivity” or “impulsivity” than others.) The inattentive and hyperactive/impulsive subtypes differ in terms of age of onset, gender, and associated comorbid psychiatric conditions and learning disabilities. In general, the agreement between DSM-III-R and DSM-IV criteria is high (positive predictive power 93%) (9).

In 1987, Lahey and colleagues described a group of children, with a “sluggish cognitive tempo.” These behaviors are typically seen in children who fall into the inattentive group and are not hyperactive or impulsive. They had difficulty initiating behaviors and were often disorganized and, if anything, apathetic (10). Although these symptoms demonstrated high positive predictive power in the DSM-IV field trials, they did not have high negative predictive power; that is, they were strongly associated with inattention but their absence did not predict absence of inattention. In addition, because the sluggish cognitive tempo subtype had a low base rate (that is, it was observed relatively infrequently in the study population), it was not included in the final symptom list (8).

Since the publication of DSM-IV in 1994, this issue has been reconsidered by several research groups. Several studies supported the validity of the sluggish cognitive tempo subtype. In a study of 692 clinic-referred children, a factor analysis indicated that the sluggish cognitive tempo items were most strongly associated with the severe end of the inattention spectrum. When the hyperactive/impulsive items and the inattention items were analyzed separately, the inattention symptoms could be broken down into two components: the sluggish cognitive tempo items plus forgetfulness and the DSM inattention items. These authors noted that their results challenged the two factor structure of DSM-IV (hyperactivity/impulsivity and inattention) and also observed that DSM-III inattention and DSM-IV inattention were not necessarily the same disorder. They concluded that DSM-IV inattention was a “perhaps overly heterogeneous group of children” and the inclusion of the sluggish cognitive tempo criteria might be helpful (11).

Carlson and Mann constructed a sluggish cognitive tempo scale based on the Achenbach Teacher Rating Scale (Achenbach 1991) and compared children with the combined ADHD subtype and the inattentive type. The sluggish cognitive tempo group was more prominently apathetic, underactive and day-dreaming, and prone to more social-emotional difficulties and withdrawal. Not surprisingly, they received lower teacher ratings for externalizing behaviors (12).

In contrast to the two previous studies, a large population-based study of 2,944 Australian twins, based on parent report found little selectivity for sluggish cognitive tempo symptoms based on latent class analysis. However, using a principal components factor analysis, there

were striking gender differences. In boys, the sluggish cognitive tempo symptoms formed a separate factor, whereas in girls the sluggish cognitive tempo items loaded strongly on an inattentive factor. They concluded that the overall pattern of ADHD behaviors was not altered by this factor, but there were distinct gender differences (13).

In a study on a school population based on teacher ratings, Gaub and Carlson observed that children with DSM-IV combined type were severely impaired in academic and behavioral spheres, whereas those with the inattentive type had fewer externalizing behavior problems than those with the hyperactive/impulsive or combined types. The hyperactive/impulsive type had externalizing and social problems but did not have learning problems or internalizing problems (14). This study was based on teacher ratings. In some cases teachers attribute poor school performance to behavior problems but, there may also be a subtle comorbid learning disability. In a chart review comparing 143 cases of ADHD-inattentive type and 133 cases of combined type, the inattentive group tended to be older, have a higher proportion of girls, had more comorbid internalizing disorders, more academic difficulty and learning disabilities, particularly in the realm of speech and language problems. Although some of these children also had clinically significant hyperactivity and impulsivity, they did not meet formal diagnostic criteria (15).

A different approach to categorization of ADHD subtypes has been suggested by researchers in the Colorado group. Chhabildas examined the neuropsychological profiles associated with the three ADHD subtypes (inattentive, hyperactive/impulsive, and combined) as well as nonADHD controls. Subjects were drawn from a community sample of twins evaluated for reading disability, ADHD, and comorbid disorders. Somewhat counterintuitively, every dependent measure was best predicted by symptoms of inattention. The hyperactive/impulsive type resembled the controls in many respects, whereas the inattentive type performed more poorly than the other groups on almost all of the neuropsychological tasks (16). In another study by this group, extreme scores on the hyperactivity/inattention dimension were highly heritable only when the proband also exhibited a concurrent elevation of inattention. If the child did not meet criteria for inattention the hyperactive/inattentive scores were not heritable (17).

Electrophysiological studies also provide some support for these different subtypes. In boys with ADHD, two distinct electroencephalography (EEG) clusters were identified in the boys with ADHD of the inattentive type. One was characterized by high-amplitude theta with decreased delta/beta activity, and the other by increased slow-wave and decreased fast-wave activity. These different patterns of EEG activity were felt to reflect two physiologically different subgroups: those who were hypoaroused and those who had a more immature pattern (“developmental lag”) (18). In an event-related potential study in which children and adolescents with ADHD were compared to controls, a

stepwise discriminant function analysis demonstrated different response patterns between the combined type, inattentive type, and controls. The discrimination of the adolescent groups was not at all as robust, but it would appear that event-related potentials might be combined with other clinical information to enhance differentiation (19). A time-frequency analysis revealed event-related slow-wave activity that was reduced in the combined type group but not the inattentive group. Activity in the 1- to 12-Hz range was different in the control group and the ADHD group but not between the ADHD subtypes (20).

### Age of Onset

There are significant differences between the hyperactive/impulsive type and the inattentive type in terms of the age at which symptoms emerge. Based on a retrospective parent report, children with ADHD become noticeably impaired around the age of 3½ years, with the median age of onset of the first ADHD symptom appearing around 1 year of age. The age of onset of the hyperactive type (mean = 4.21 years) is earlier than that of the combined type (mean = 4.88 years), and both are considerably earlier than the inattentive type. Virtually all (193 of 199 children in the DSM-IV field trials—98%) of the children with the hyperactive-impulsive type of ADHD, and 82% of those with the combined type are considered impaired before they reach the age of 7 years. By age 9 years, all would have met formal ADHD diagnostic criteria.

In contrast, the developmental pathway characterizing the inattentive type is quite different: ADHD of the inattentive type is often not apparent until around the first grade (mean age = 6.13 years) and in the DSM-IV field trials, some subjects did not become symptomatic until age 14 years. In the preschool years, symptoms of inattention without hyperactivity and impulsivity are less obvious and become impairing in half of the children with inattentive type at some point in the first grade. Based on the Great Smoky Mountains Study, Willoughby and colleagues noted a similar pattern of age of onset (21). Although most (85%) of children with the inattentive type manifest at least one symptom before the age of 7 years, only about half (43%) are considered impaired after age 7 years. (Moreover, astute clinicians not infrequently identify an adult with the inattentive type who may have been able to function adequately enough to miss detection until they embark on a demanding academic program in graduate school or in a profession or they change professions.)

Using appropriate assessments, the characteristic motivational and cognitive profile seen in the older individual with ADHD can also be observed in the preschool child (22). Moreover, children who meet full DSM-IV criteria for ADHD in the preschool years continue to manifest these symptoms into the school years (23). In one study involving 156 preschool children (aged 3 to 5½ years) executive dysfunction (working memory, planning, and set shifting)

as well as aversion to delay of gratification were predictive of ADHD symptoms (24).

These findings are of considerable importance to the clinician. One should be able to make the diagnosis of ADHD with hyperactivity/impulsivity in the preschool child. On the other hand, the age-of-onset criteria specified in DSM-IV for ADHD of the inattentive type, which indicates that some symptoms are “present before age 7 years,” should not be taken too seriously, as evidence of impairment may not be apparent until much later, when the child is required to perform in an autonomous fashion (25). Thus, the way the symptoms are expressed may differ with age. Children with ADHD present in preschool with hyperactivity and impulsivity. As the demands for autonomous self-regulation increase, the inattentive profile becomes more prominent and more impairing.

### Gender

It is only in the last decade that it has been recognized that boys and girls are at much the same risk for ADHD and that the clinical manifestations of the disorder are not gender-related. If anything, they may be an artifact of referral source. In earlier studies, substantial differences with ratios of boys to girls ranging from 6 to 12 to 1 were reported. In epidemiologic samples, the ratio is closer to 3 to 1. With more finely tuned diagnostic strategies, the ratio may become even lower. The clinical presentation of boys and girls with ADHD has also appeared to be different. In clinic-referred populations, girls with ADHD are more likely to have inattention and internalizing behaviors, and less peer aggression than boys with ADHD. Gaub and Carlson conducted a meta-analysis comparing ADHD symptoms, intellectual and academic functioning, comorbid behavior problems, social behavior, and family variables in boys and girls. They found no differences in impulsivity, academic performance, social functioning, fine motor skills, parental education, or parental depression. Girls with ADHD were not as hyperactive, and had fewer externalizing behaviors, but were more intellectually impaired. In some cases these differences were attributable to referral source (26). Boys manifest much higher rates of conduct disorder and oppositional defiant disorder than girls, which may explain the higher rate of referral to mental health clinics. In contrast, girls are more likely to have higher rates of depression and anxiety, poor self-esteem, a sense of limited control, and significant difficulties in the social sphere (27). Based on a large non-referred sample (577 subjects), Biederman and colleagues were unable to identify gender-based differences in full scale IQ, rates of learning disabilities, school performance, or social adjustment (28).

There are no gender differences in prefrontal executive function in boys and girls with ADHD (29, 30). When girls with ADHD are compared to controls, their ratings on the Global Assessment of Functioning Scale, cognitive

functioning, and academic performance are all impaired. They have higher rates of disruptive behavior disorders, are vulnerable to alcohol and drug dependence, and are at risk for academic failure (31, 32). In a study of girls aged 6 to 12 years, 93 with ADHD-combined type, 47 with inattentive type, and 88 controls, the ADHD group had more speech and language problems and academic problems (repeating grades), externalizing/internalizing behaviors, and psychiatric comorbidities than the controls, and were more likely to be adopted. Girls with the combined type were more likely to be abused. Although girls with the inattentive type were more likely to be socially isolated, those with the combined type suffered more social rejection (33). In terms of performance on a neuropsychological test battery, there were robust differences between the girls with ADHD-combined and the control group, but differences between girls with the inattentive type and controls were much less prominent, and few differences were noted between the combined and inattentive types (34).

In a review of the effects of gender on ADHD, Biederman and Faraone concluded that ADHD is expressed similarly in both boys and girls. The differences in comorbid psychiatric disorders, learning disability, and inattention in boys and girls was not the result of effect modification of ADHD but rather were features of gender differences per se. Gender and ADHD were felt to be independent risk factors for comorbid psychopathology. The only significant gender-by-ADHD interaction that was identified in this study was the higher risk of alcohol or drug-dependence in females with ADHD compared to males with ADHD (35). However, in the study described previously, consisting of somewhat younger subjects, the propensity for drug dependence in girls with ADHD was not replicated (28).

### Comorbid Disorders and Attention Deficit–Hyperactivity Disorder

There is a very high rate of comorbid psychiatric disorders in children and adults with ADHD. Conduct disorder, oppositional defiant disorder, depression and bipolar disorder, anxiety disorder, obsessive-compulsive disorder (OCD), Tourette's disorder, and learning disabilities are present in many children with ADHD. This risk is not limited to affected children, but also extends to the first-degree relatives of children with ADHD who are also at higher risk for neuropsychiatric disorders than control families (36, 37). Moreover, when followed over a number of years, comorbid conditions can emerge in children who previously did not meet diagnostic criteria.

The specific comorbidity is related to the subtype profile. Children with comorbid oppositional defiant or conduct disorder are rated as more impulsive than inattentive. Children with comorbid anxiety disorder have higher inattention than impulsivity ratings (38). Children with ADHD of both sexes are at risk for oppositional and conduct disorder.

In a follow-up study in which 207 caucasian boys (ages 6 to 12 years) who did not have a conduct disorder diagnosis in childhood were then re-evaluated at age 18 years by clinicians who were blind to childhood status. A control group of nonADHD adolescents was also evaluated. There was no specific single conduct disorder or oppositional disorder behavior which predicted later outcome. However, even the boys who had minimal evidence of conduct disorder in childhood were at significantly increased risk in adolescence. In addition, the presence of conduct disorder and oppositional defiant disorder also was associated with antisocial personality in adulthood (39).

Mood disorders are also associated with ADHD and tend to cluster in families. Depression and anxiety do not appear to be related to the particular subtype of ADHD and are present in both the combined and inattentive types to the same degree (40). However, Vance and colleagues reported that dysthymic disorder and ADHD combined type contributed in the multiple regression analysis to the prediction of oppositional defiant disorder (41). They made the point that dysthymic disorder often emerges in early childhood and might be regarded as a risk factor. Bipolar disorder is also not only a comorbidity of ADHD but can be part of the differential diagnosis. However, the association of bipolar disorder and ADHD is still somewhat controversial. In a study comparing well-functioning youths with bipolar disorder, unipolar depression, and normal controls, only 6.8% of those with bipolar disorder, 10% of those with depression and none of the controls reported a previous diagnosis of ADHD. Results of a test battery involving neuropsychological assessments of attention, did not reveal any objective differences in performance between the groups. However, the patients with bipolar disorder reported subjective attentional disturbance (42). In contrast to these observations, in a study of young adults with bipolar disorder, 67% had impaired performance on the Wisconsin Card Sorting Test when previously assessed as adolescents, in comparison to those with unipolar depression (19%) or those without major mood disorder (17%). Attention problems in adolescence were not associated with later bipolar disorder (43).

Anxiety disorder is also associated with ADHD and often makes treatment challenging as some children become more anxious on psychostimulants. In the MTA study, 33% of the children with ADHD met DSM-III-R criteria for an anxiety disorder (excluding simple phobias). More than half of these children also met DSM-III-R criteria for comorbid oppositional-defiant or conduct disorder (44). In one study, 146 medication-naïve elementary school children with ADHD combined type were grouped into those with and without dysthymic disorder. The group with dysthymic disorder had a higher incidence of anxiety disorder (41, 45).

Epidemiological studies have revealed a consistent and rather complex association between ADHD, OCD, and Tourette's disorder. When viewed in longitudinal studies,

tics in early childhood and adolescence were associated with increasing OCD symptoms with maturation. ADHD in adolescence predicted an increase in OCD symptoms in early adulthood, and OCD in adolescence predicted more ADHD symptoms in adulthood (46). This close association is not surprising, given that all three disorders involve frontal-subcortical pathways and disruption of catecholamine neurotransmission (47).

Many individuals with mental retardation and autistic-spectrum disorders (that is pervasive developmental disorder, autistic disorder, Asperger’s disorder, and nonverbal learning disability) are found to have associated attention deficit and impulsivity although these are considered exclusionary criteria.

## NEUROLOGY OF ATTENTION DEFICIT–HYPERACTIVITY DISORDER

ADHD is a disorder of self-regulation reflecting dysfunction in frontal-subcortical systems that control attention, intention, and emotional arousal. Children and adults with ADHD have great difficulty following through on their intention to perform certain tasks. Although they typically know what needs to be done, they have difficulty initiating work on a task (in fact, they are often skilled procrastinators) and do not complete the task in a satisfactory manner. They may perform the task so slowly or ineffectively that they are quite frustrating to those around them. They may rush through the task in a sloppy manner. Parents complain that a child with ADHD requires constant monitoring when performing routine tasks, and disrupts family functioning by being unable to get dressed or complete homework without constant supervision. This is often accompanied by a striking lack of awareness of the difficulty.

In this section, some of the brain mechanisms that underlie the regulation of attention, motor intention (activity, response time, inhibition and intention), and arousal and motivation will be discussed.

### Attention

We are bombarded by stimuli all the time, but not everything in the world around us is of equal importance at a given moment. Attention is an active process which enables organisms to screen out irrelevant stimuli and to focus on (or pay attention to) stimuli that are relevant. The metaphor that attention is like a spotlight has been used—one may scan the environment with a broad beam but then focus the beam very narrowly on a few important details, or shift from one aspect of the scene to another. Shifts in attention can be *overt*—that is a shift in direction of gaze, or *covert*—changing the focus of attention without shifting gaze. Attentional behaviors also need to be relatively constant during wakefulness (vigilance). Thus, adequate function, if not survival, depends on being able to detect important stimuli, identify

new stimuli, shift attention as necessary, and ignore irrelevant stimuli. In the classroom, a child is expected to attend to the teacher and the task at hand and *not* pay attention (or at least pay less attention) to what Jimmy is doing in the next seat, or what is happening in the hall. This also involves regulating one’s own cognitive processes. One child that we worked with talked about his “green ideas”; namely, a flood of rich associations about the topic at hand, or possibly other matters, which, although undeniably brilliant and creative, definitely impaired his ability to concentrate on the immediate task. In addition, the child is expected to be aware of important internal and external stimuli—a precipitous dash to the bathroom is appropriate in a three-year-old, but would suggest inadequate monitoring in an eight-year-old.

The best model for understanding the neurophysiological processes underlying attention involves the visual system, which has been extensively studied. The essential feature of the processing of sensory information is that there are top-down attentional control functions at all levels of the system.

Visual information flows from the retina, through the optic nerve, to the lateral geniculate nucleus. In the lateral geniculate, a six-layered structure, visual information is sorted into two systems. One system is specialized for motion detection (analysis of speed and direction or movement, and depth perception and is closely linked to the extraocular system that controls eye movements). This system, the magnocellular system, feeds into layers one and two which have large cell sizes. The other system, which feeds into the other four layers consisting of smaller size neurons (“parvocellular”), is specialized for the analysis of shape, color, fine details, and fine depth perception. Both of these streams then project into different layers in primary visual cortex (V1 or Brodmann’s area 17). The magnocellular system projects into area 4B and the parvocellular system to area 4A. Neurons in V1 do not identify objects or movements, but rather bars of light. The information then flows into visual association cortex—initially areas 18 and 19. The motion detection pathway (also called the dorsal pathway) is divided into two separate streams. The dorsodorsal stream arises in area V6 and projects to the superior parietal lobule. This is part of a broader system involved in the integration of sensory motor information; there are a multitude of connections to motor cortex and subcortical structures, involved in the guidance of arm movements, and the integration of arm, eye, and head movements. Damage results in optic ataxia. The ventral dorsal stream flows from the middle temporal visual area (area MT) and projects to the inferior parietal lobule, and processes visual motion (48). The ventral pathway (or “what?” pathway travels into the temporal lobe where information relating to objects and faces is processed. By the time a stimulus reaches the level of awareness, it has been cataloged as to identity (*what* it is), location/orientation (*where* it is), the features relevant to

its movement, familiarity (memory), and significance (its motivational/emotional valence). The stimulus itself may be subjected to closer inspection (selective attention). In real-world situations, the attentional focus must be constantly readjusted to either scan a broad area or focus in on a small detail. This has been referred to as “the zoom lens model” (49).

During this sequential process of visual stimuli, attention plays a critical role (50–52). *Enhancement* is a term used by neurophysiologists to label this effect of attention on the firing pattern of neurons. Attention increases the firing rate of certain neurons and decreases the firing of others. In a classical experiment, monkeys were trained to release a lever when the light dimmed to receive a juice reward. The firing of a single neuron in the visual system was increased if the stimulus (a central spot of light) was important to the monkey, because upon release of the lever, the monkey would get the juice. A second neuron responded with only a brief burst of firing when another light stimulus, not linked to the juice reward, was presented to the monkey. However, when the second spot of light was then linked to the juice reward, the firing rate of the second neuron increased significantly. Thus, the rate of neuronal firing was modulated by the motivational significance of the stimulus specific to a given context (53). In humans, a combination of functional magnetic resonance imaging (fMRI) and evoked potential techniques have demonstrated that the initial arrival of visual information to primary visual cortex is not attended, but within 70 to 75 milliseconds, attentional modulation becomes engaged (54). In a fMRI study, subjects were asked to fixate on one target and pay covert attention (that is, without shifting gaze) to another location. Activation (or enhanced neural activity) was observed in the brain area corresponding to the attended location and was greater in parietal and frontal areas than in visual areas (55). Moreover, in a difficult task in which subjects were required to detect specific patterns, there was a clear relationship between the extent of activation in visual cortex and adequacy of task performance (56). However, attention is not an infinite resource and there are distinct limits to attentional capacity. As attentional resources are deployed over a broader area, the capacity of the attentional system is taxed and task performance became more difficult. This was demonstrated in an fMRI study. As the size of the attended field increased, the activation in the visual cortex decreased, and subjects made more errors and reaction time was increased. The investigators felt this provided substantiation of the “zoom lens model” as well as the limited capacity notion (57).

Attention involves different processes that are instantiated in different brain areas. A large, widely distributed neural network, which involves posterior and frontal association cortex, is involved in guiding visual spatial attention as well as linking working memory into the attentional system. Voluntary attention is controlled by superior frontal, inferior parietal, and superior temporal cortices (58). The interparietal sulcus contains four different areas, each

integrating a specific aspect of attention, sensory input, and representations of movement through space as well as motor exploration of space. Frontal eye fields are more involved in the motor exploration aspect. This region appears to play a crucial role in processing the sensory aspects of covert spatial attention. In a study in which some of the confounding variables were controlled, it was apparent that the parietal lobe was involved in the representation of sensory information (the banks of the interparietal sulcus and the temporo-occipital region were activated to a much greater extent than frontal areas), whereas the frontal areas were involved in the motor aspects of visual exploration. There was also evidence that the parietal cortex may engage visual and frontal cortex in the attentional processes (58).

Selective attention involves anticipatory attending to a specific location before presentation of a visual target. It is associated with activation of the intraparietal sulcus. When an unexpected target is detected, there is activation in the right temporoparietal junction (59). In another study, a group of neurons in area 7a of the parietal lobe responded preferentially to stimuli that require reorienting attention (60). In addition to the posterior parietal areas, attending to representations of external space involves lateral premotor, dorsal prefrontal, and cingulate cortices. Working memory is intimately linked to the efficient deployment of selective attention and is subserved by a distributed system involving intraparietal sulcus and frontal eye fields that mediates the on-line storage of location information (61).

However, attention is also directed to internal mental representation in the absence of any “real” extrapersonal object. In one fMRI study, subjects were asked to orient attention to a location that existed only as a mental representation held in working memory. (The task was complex in that a spatial array was presented which then disappeared and the subjects had to hold both color and location characteristics in working memory.) The neuroanatomical areas that were activated in this study overlapped to a great extent with those related to attending to spatial locations, but the mental representation also resulted in activation of frontal regions (62).

Lesions of the parietal lobe and transcranial magnetic stimulation of the parietal lobe both produce *neglect*—unawareness of stimuli in contralateral space—or deficits in disengaging visual attention from one location and shifting it to another (63–65). Similarly, transcranial magnetic stimulation of the parietal lobe results in neglect in contralateral hemispace (Fierro 2000; Bjoetomt 2002). When ADHD children were tested using paradigms that had been sensitive to neglect in adults, the children’s profile was similar to that to adults who had sustained right hemisphere lesions (66).

To summarize, attention is an active process that includes detecting important stimuli in the environment, being able to focus on it, controlling distractibility, and shifting attention rapidly when it is necessary to do so. Thus, long before one becomes conscious of a specific item in one’s environment, the nervous system has surveyed the

environment, selected relevant stimuli, and decreased attention paid to unimportant stimuli. One can see that if the attention system is not working well, an important stimulus might not be recognized (neglect), or attending to an important stimulus may be disrupted by distraction, or the inability to sustain attention as long as is necessary.

### Hyperactivity

Hyperactivity is a common manifestation of ADHD; children can show high levels of motor activity, fiddle with objects, and move and shift their bodies. Older children can appear very restless and adults with ADHD can have an uncomfortable sense that they have to move. Hyperactivity in children with ADHD has been documented in numerous studies using a variety of motion detection devices (67–69). From a neurological perspective, patients with lesions in orbitofrontal cortex are restless and engage in random and purposeless movements. Some children with ADHD manifest “utilization behavior.” This is behavior that is initiated by a common object (such as a pencil or a knife) and the patient performs the activity even when it is grossly inappropriate (70). It is important to emphasize that not all frontal lobe lesions result in hyperactivity. Patients with lesions in the anterior cingulate area are often hypoactive and abulic. Lesions involving the caudate nucleus and the mesolimbic system also result in hyperactivity (Davis, 1958; Koob et al. 1981). In rodents, the hippocampal-accumbens-subpallidal circuit appears to be associated with increased locomotor activity (Mogenson, 1984). In a study involving the selective breeding of mice with a propensity to “voluntary” wheel-running, a total of 11,904 genes were screened using high-density oligonucleotide arrays. Increased wheel-running was associated with a significant increase in expression of 30 genes (primarily involved in transcription and translation) and, more specifically, a 20% increase in the expression of dopamine D2 and D4 receptor mRNA in the hippocampus (71). The major neurotransmitter implicated in hyperactive behaviors is dopamine; for example, akathisia is noted in patients with Parkinson’s disease (Lang and Johnson 1987). Tassin and colleagues (1978) reported that motor restlessness in rats was inversely correlated with prefrontal cortical dopamine. The “knockout” mouse that lacks the dopamine transporter gene, which then results in increased extracellular dopamine, manifests a remarkably high level of motor activity (Giros et al. 1996). Jucaite and colleagues conducted a PET-scan study that involved adolescents with ADHD and young adults, who served as controls. The study used selective radioligands to assess the relationships between the binding potential of dopamine transporter and dopamine receptor D2 density in various brain regions to levels of attention and hyperactivity. There were no group differences noted in radioligand binding in the striatum, but the binding potential of the dopamine transporter in the midbrain was significantly lower in the ADHD group. Dopamine receptor D2 binding in the right

caudate showed a significant positive correlation with hyperactivity (72). Thus, although the neural circuitry underlying hyperactivity has not been as clearly defined in humans, it appears to be related to several different areas all of which involve dopaminergic neurotransmission.

### Impulsivity

In DSM-IV, impulsivity is defined by three criteria—blurting out answers before questions have been completed, having difficulty awaiting turn, and interrupting or intruding on others. More broadly, impulsivity involves not waiting for complete information before plunging into a task, not considering undesirable consequences, proceeding with an action based on limited information, and difficulty inhibiting an inappropriate response. Psychiatrists include an even broader array of complex behaviors such as suicide, pathological gambling, kleptomania, intermittent explosive disorder, and addiction under the rubric of impulsivity. Impulsivity also includes a broad range of behaviors such as inability to tolerate delays, and a tendency to perseverate. From a neurological viewpoint, impulsivity is a deficit in controlling responses to stimuli. In this context, impulsivity is defined as a deficit in response inhibition. However, on analysis, in addition to inhibitory control, impulsivity can also be viewed as an aversion to delay.

There are a number of experimental paradigms that are used to measure impulsivity in individuals with ADHD. The Stop Signal Paradigm assesses inhibitory control. The Choice-Delay Task monitors delay aversion. The Go–No Go task assesses the ability to withhold a response, particularly in a situation in which a prepotent response pattern has been established. The Gambling task monitors delay aversion in a context which requires weighing highly motivating factors. Solanto and colleagues studied a group of 7.0- to 9.9-year-old children with ADHD using the Choice-Delay and Stop Signal tasks. ADHD subjects performed significantly more poorly on both tasks, and both were associated with ADHD, suggesting that aversion to delay and inability to inhibit responses were features of ADHD. The Choice-Delay task correlated with teacher ratings of impulsivity, hyperactivity, conduct problems, and aggression as well as the ADHD composite score. This suggests that delay aversion is associated with a broad range of ADHD behaviors. In contrast, the Stop Signal task correlated with the behavioral observations, and appears to tap executive control. One neurological experimental model involves the inability to inhibit gaze to a visual target. In this context, distractibility would be considered an intentional motor deficit rather than an attentional deficit. Deficits on contrasaccade tasks are associated with medial frontal lesions (Butter et al. 1988, Guitton et al. 1985). Difficulties inhibiting gaze have been described in children with ADHD. In a study which required subjects to delay before shifting gaze to a target held in working memory, children with ADHD performed more poorly

than controls in the inhibition component of the task, but had no difficulty in response preparation or in the memory component (Ross et al. 1994). Similarly, children with ADHD had much greater difficulty in contrast to controls in inhibiting gaze to a visual stimulus (Voeller et al. 1990).

There is a strong link between impulsivity and dysfunction of the frontal-subcortical circuits, particularly the right orbitofrontal area (73). The amygdala, which is highly interconnected with prefrontal cortex, is also involved with impulsivity (74). Lesions of the subcortical nuclei, which receive orbitofrontal projections, are also associated with impulsive behaviors. For example, individuals with Sydenham's chorea manifest significant impulsivity (75). In a study of the Go–No Go task performed by normal subjects who had undergone extensive assessments of impulsive traits, neural response inhibition activated right lateral orbitofrontal cortex and was strongly correlated with Eysenck's impulsivity score. Other cortical areas—the superior temporal gyrus, medial orbitofrontal cortex, cingulate gyrus, and inferior parietal lobule, more on the right than left—were also activated. Subjects who had higher impulsivity ratings and made more errors had greater activation of paralimbic areas during response inhibition, while less impulsive individuals and those with least errors activated higher order association areas.

In terms of neurotransmitters and pharmacology, numerous reports have linked decreased central nervous system serotonin to impulsive behaviors. However, Winstanley, in a study on rats that had depleted forebrain serotonin levels, noted only a subset of behaviors that could be construed as impulsive, suggesting that impulsivity is not a unitary construct (76). However, there also appears to be a role for dopamine as one of the neurotransmitters involved in impulsive responding (77). Hershey and colleagues studied eight neuroleptic-naïve adults with tic disorders and controls on a Go–No Go task before and during IV levodopa infusion. In the baseline condition, higher cerebellar activations were associated with faster reaction times and higher parietal activation with higher error rates. There was no difference in actual task performance, but the study indicated that lower levels of activation were required in the presence of this dopamine agonist (78).

In summary, impulsivity is a less well-defined entity, both behaviorally and neurologically than other aspects of ADHD. There is a body of research indicating that it is instantiated in orbitofrontal cortex and related subcortical circuits. There is evidence that impulsive behaviors are at least in part related to genetic makeup. Serotonin likely plays an important role in regulating impulsivity. However, both dopamine as well as other neurotransmitters interact in a complex way with serotonin.

### Regulation of Arousal

Arousal refers to a state of physiological readiness that enables the organism to respond to incoming stimuli and develop appropriate responses. Although arousal is often

triggered by novel or exciting environmental stimuli, the ability to regulate one's level of arousal with relative autonomy so that it is appropriate to the situation is an important adaptive strategy. If a child is working on a long and boring task, maintaining alertness and persevering is very helpful. On the other hand, the ability to remain calm and decrease the impact of unpleasant and distracting stimuli in certain situations is also an advantage. Arousal is closely linked to motivation and the ability to sustain attention and persist in performance when confronted with a difficult or boring task. The regulation of one's internal arousal is not one of the DSM criteria for ADHD, but it has considerable clinical relevance, particularly when dealing with children in an educational setting. Children with ADHD appear to have difficulty regulating their internal emotional states.

The concept of "sensory integration," a term used by occupational therapists, is another aspect of arousal. Occupational therapists note that some children are hypersensitive whereas others are quite unaware of stimuli in some or all sensory modalities. Some children may find tactile stimuli such as rough carpet, sand or grass on bare feet, or scratchy clothing tags or sweaters particularly unpleasant. Noises and visual stimuli can be particularly distracting. Other children appear to have very high sensory thresholds and are often unaware of stimuli. Some of these children may use motor activity to enhance stimulation. A preferred term for "sensory integration disorder" might be "sensory modulation disorder," which would include sensory overresponsiveness, sensory underresponsiveness, and sensation seeking/craving (personal communication, L. Miller). From the point of view of a clinician who deals with children with ADHD as well as those sensory modulation disorders, they appear to be close cousins, if not reflections of the same dysfunctional attention/sensory processing system that is seen in ADHD. Sensory overresponsiveness could be viewed from a neurological perspective as an impairment in the ability to downregulate incoming sensory stimuli and would be related to a failure to not only modulate and habituate to sensory stimuli, but to inhibit response, which would map on to distractibility. Sensory underresponsiveness, like inattention, is a failure to detect stimuli. This lack of awareness of external stimuli is often coupled with underarousal. These children clinically resemble Lahey's "sluggish cognitive tempo" type. One might speculate that sensation seeking/craving is another manifestation of inattention and underarousal, and these children are attempting to enhance sensory input and maintain arousal by movement. Some children with ADHD manifest extreme restlessness and are in constant motion at the same time they appear quite drowsy and underaroused (they yawn profusely).

### Representation and Awareness of Time

Although the representation of time is not a DSM-IV diagnostic criterion for ADHD a number of studies have presented evidence that individuals with ADHD have

difficulty with time estimation. This idea was introduced by Barkley (79), and although there has been some controversy, a number of subsequent studies have supported this notion (80). A widely distributed neural network is involved in time estimation, which includes the frontal, parietal, cortices basal ganglia, and the cerebellum (81, 82).

### Subtle Deficits in Motor Performance in Attention Deficit–Hyperactivity Disorder

There is a considerable body of information relating to motor performance in children with ADHD. In the absence of any classical neurological deficits, children with ADHD as a group manifest deficits in the regulation of motor performance. In one study, a discriminant function analysis classified 89% of boys who were hyperactive versus controls based on speed, rhythm, and overflow (83). Differences in velocity, coordination, and accuracy were observed in children with ADHD and controls during the performance of bimanual movements (84) as well as when programming goal-directed arm movement, particularly in the absence of visual feedback (85). In a prospective study of 5- and 6-year-old children, those who, when assessed several years later met criteria for ADHD, manifested much greater difficulty in regulating motor performance (86). They were more inaccurate and much more variable in performance. It may be that this type of variability in motor performance is more prominent in the preschool child with ADHD and becomes less apparent with age. Adults with prefrontal lesions typically manifest variability in motor performance (87).

## NEUROIMAGING STUDIES

There are numerous morphometric MRI studies that have identified relatively consistent differences in the brains of children with ADHD compared to normal controls. A particularly informative study is a large, longitudinal NIMH study involving children with ADHD and age- and gender-matched controls (Castellanos, 2002). The mean total cerebral volume in children with ADHD is slightly (approximately 5%) but significantly smaller than controls (88–93) (Filipek 1997). In one study in which unaffected sibling of boys with ADHD were examined, the unaffected siblings also showed a slight (but statistically significant trend) amounting to 3.4% reduction in total cerebral volume (89).

Various components of the cortical-striatal-thalamo-cortical circuits and cerebellum have been reported, with fair consistency, to be affected in most studies. These include frontal lobe (88, 91, 93–95) (Castellanos 2002), caudate nucleus (88, 96) (Castellanos 2002, Filipek 1997) as well as other basal ganglia structures (97, 98) and cerebellum (88, 90, 99, 100) (Castellanos 2002, Filipek 1997). In normally developing children, the caudate appears to decrease in size as the child matures (consistent with neuronal pruning, which is seen in many different areas in the course

of normal development) (88, 101) (Castellanos 2002). The decrease in size of the caudate is present early in development, suggesting that there is specific disruption of normal neuronal growth. Moreover, there is evidence that right hemisphere structures are affected to a greater extent than left hemisphere structures (88–90, 98, 102, 103) (Castellanos 2002, Filipek 1997). This is interesting, given the role of the right hemisphere in regulating sensory attention and motor intention in the majority of humans (66, 104).

Functional neuroimaging is consistent with the morphometric findings in that these studies reveal anomalous patterns of function in the prefrontal-subcortical circuits, often more prominent in the right hemisphere (105, 106). Early studies, which were not consistently replicated, suggested a complex interaction between gender, age, and hormonal effects (107–109).

When children are asked to perform a task that places demands on the frontal executive system, those with ADHD have atypical patterns of activation. In one study, children with ADHD and controls were studied using fMRI during a Go–No Go task. In general, fMRI scans on children performing tasks that demand executive function control have somewhat different patterns of activation than those seen in adults (110). However, when compared to age-matched controls, children with ADHD do not activate frontostriatal networks to the same extent as those without ADHD, but rather manifest a more diffuse activation pattern, suggesting a delay in the development of frontostriatal circuits (111). In another fMRI study involving children with ADHD and controls performing two somewhat different types of Go–No Go tasks, children with ADHD made more errors than controls. In one task, children with ADHD activated frontal areas to a greater extent than controls. Although this is not consistent with the findings in other studies, it is possible that in that specific paradigm, subjects with ADHD had to exert more effort than controls. (In this study, other brain regions were not examined so that there was no opportunity to see the diffuse activation pattern described in the Durston study.) After receiving methylphenidate, there was a decrease in the number of errors, particularly in the ADHD group. Both the controls and the children showed increased frontal activation. Striatal activation was increased in the children with ADHD, but decreased in the controls (112).

Schulz and colleagues examined male adolescents who had been diagnosed with ADHD at an earlier age, and divided them into “persisters” (those who continued to meet DSM-IV diagnostic criteria), “remitters” (those who no longer met DSM-IV criteria), and a group of matched controls who had never had ADHD. The subjects performed a Go–No Go task with fMRI monitoring. All groups activated ventrolateral prefrontal cortex to some extent, but there was a difference between the groups in both the number of commission errors and extent of activation. Commission errors ranged from 33% in the subjects who continued to meet full DSM-IV diagnostic criteria, to 13% in the control group. The remitters made 24% errors. There

was much greater activation in the persister group than in the controls (113–115).

In a study comparing adolescents with ADHD, those with dyslexia, those with ADHD and dyslexia, and controls, subjects with ADHD and dyslexia activated left ventral basal ganglia significantly less than did the controls. Methylphenidate decreased the level of activation but did not significantly change performance (116).

A technical issue of relevance to the interpretation of these studies is the concept of *deactivation*: the suspension or inhibition of ongoing background neuronal activity during the performance of tasks requiring increased cognitive activity (117). The computation involves subtracting the cognitive task condition from the control or baseline condition. This is the opposite of activation (cognitive task condition minus baseline) and is observed in normal individuals.

In a Go–No Go study, a number of methodological issues in the paradigm were carefully controlled so that it was possible to discriminate activation during the segments of the task in which inhibition was required. There were significantly more omission and commission errors made by the ADHD subjects than by the controls. This was accompanied by marked hypoactivation of the anterior/midcingulate cortex extending to the supplementary motor area. It was also noted that the left temporal gyrus was hyperactivated (118).

Dysfunction in the frontal-subcortical system has been supported by magnetic resonance spectroscopy (MRS) studies. Two of these studies have revealed an increase in the glutamate/glutamine/ GABA ratio in frontal-striatal circuits of children with ADHD (Macmaster et al. 2001; Courvoisie et al. 2004). This can be interpreted as reflecting an imbalance between excitatory (glutamate) and inhibitory (GABA) neurotransmission, particularly at various nodes in the frontal-striatal system, which has been implicated in ADHD. This imbalance can be interpreted as either due to increased excitation or reduced inhibition. There has been less consistency related to N-acetylaspartate with some investigators reporting no difference (McMaster et al. 2003), a unilateral (right frontal) increase (Courvoisie et al. 2004) or a bilateral decrease in the basal ganglia (Jin et al. 2001; Sun et al. 2005). Jin et al. (2001) suggested that there might be a neuronal loss in the striatum as well as an increase in cholinergic activity. N-acetyl aspartate is generally considered a marker for neuronal viability, although, arguably, it may reflect formation and maintenance of myelin. In the study by Sparkes et al. (2004) there was a positive correlation between N-acetyl aspartate /creatinine and mean reaction time in the controls which was significantly different from the negative correlation of the same magnitude in the ADHD group (Sparkes 2004). Interestingly, the subgroup of children with ADHD whose N-acetyl aspartate /creatinine ratios were close to that of controls still had longer reaction times than controls. In one study, a decreased N-acetyl aspartate/creatinine ratio in girls with ADHD was noted relative to both controls and boys (Yeo et al. 2003). These studies

are intriguing but should be interpreted with caution because of the relatively small sample sizes and resulting limited statistical power.

## NEUROTRANSMITTERS, TRANSPORTERS, AND RECEPTORS RELATED TO ATTENTION DEFICIT–HYPERACTIVITY DISORDER

Synapses are the basic structures underlying neurotransmission and brain function. A synapse is composed of a presynaptic neuron and a postsynaptic neuron which are separated by a synaptic cleft. Neurotransmitters are synthesized and packaged into synaptic vesicles in the presynaptic neuronal terminal. In response to a nerve impulse, the vesicles are extruded into the synaptic cleft; approximately 1,000 molecules of neurotransmitter per terminal. The neurotransmitter then binds to the cell membrane of the postsynaptic neuron, triggering a nerve impulse. Neurotransmitter in the synaptic cleft is then either recaptured by specialized monoamine transporter proteins, located in the plasma membrane of the presynaptic neuron and repackaged into synaptic vesicles; or the neurotransmitter is degraded by enzymes, such as the monoamine oxidases, or catechol-O-methyltransferase. These transporters and enzymes are the targets for many psychiatric drugs, which modify the amount of neurotransmitter available and modify brain function. Dopamine, norepinephrine, and serotonin belong to a family of monoamine transporters, part of a larger group of Na<sup>+</sup>- and Cl<sup>-</sup>-dependent transporters. This section will focus on dopamine and norepinephrine, which have been extensively studied in relation to ADHD. However, it is apparent that a number of other neurotransmitters (glutamate, gamma-aminobutyric acid (119), and acetylcholine) figure prominently in modulating dopaminergic and adrenergic neurotransmission. In addition, growth factors, such as brain-derived neurotrophic factor, and other regulators of synaptic function play an important role in regulating the neural networks that are involved in ADHD.

### The Dopaminergic System

Dopamine has long been thought to be a neurotransmitter that plays an essential role in the pathophysiology of ADHD. Dopamine is evolutionarily a highly conserved neurotransmitter, being found in very primitive organisms. Dopaminergic neurons are involved in learning, as well as maintaining trained/conditioned responses, and motivated, goal-directed behavior (120–122). (Schultz 1986, 1993). Dopamine appears to serve a special function in the extraction of reward-related information from an array of environmental stimuli and in using this information in programming goal-directed behaviors (123, 124). Dopamine also plays an important role in the prefrontal circuits that subserve working memory; the ability to “keep

something in mind” for a brief time (125, 126). Prefrontal cortex is highly dependent on a relatively narrow range of dopamine for adequate functioning: too little dopamine impairs working memory (127), too much dopamine disrupts cognitive function (128). However, in contrast to the abundant dopaminergic innervation of the striatum, dopaminergic neurons are not as dense and have a high firing rate and a much higher rate of dopamine turnover than dopaminergic neurons in the striatum (129, 130). Moreover, the dopamine transporter is not at all as prevalent as it is in other areas.

There are two dopaminergic systems: the nigrostriatal system, which arises from the substantia nigra and projects to the caudate and putamen (relay stations in the cortical-striatal-thalamo-cortical circuits); and the mesolimbic system, which arises from cell bodies in the mesencephalic ventral tegmental area of Tsai (A10), the substantia nigra pars compacta (A9), and the caudolateral cell group (A8), and projects to the nucleus accumbens and the ventromedial sector of the striatum, which in turn receives projections from the limbic system (131). Dopaminergic projections to the cortex involve primary motor cortex, and association neocortex (dorsomedial prefrontal cortex and inferior parietal cortex) (132), with relatively sparse innervation of primary visual, auditory, and somatosensory cortices (133, 134).

The human dopamine transporter is a protein consisting of 620 amino acids forming 12 putative transmembrane domains. It maps to chromosome 5p15.3 (135, 136). The coding region of the DAT-1 gene (also referred to SLC6A3) is of fixed length—a 2-kb coding region, consisting of 15 exons distributed across an over a 64-kb gene, that has little genetic variability (137). However, there is considerable variation in the length of the 3′-untranslated region (3′UTR) due to a variable number of tandem repeats (VNTRs) (135, 136, 138).

The dopamine receptors are part of a family of “G-proteins” (guanosine triphosphate binding proteins). These proteins traverse the cell wall membrane of the neuron and contain seven transmembrane domains. Once dopamine is bound to the receptor, it activates a cascade of biochemical events inside the cell, which either enhance or inhibit cyclic adenosine monophosphate (cAMP) production. In this complex sequence transcription factors are activated and early immediate genes are expressed, which in turn activate the expression of other genes. It is likely that the dopamine in humans originally arose from two gene subfamilies, the D1-like (consisting of D1 and D5) and the D2-like (D2, D3, D4) receptor genes. D1-like receptor genes do not contain introns in their protein coding regions, whereas the D2-like genes do. D1 and D5 receptors are excitatory, whereas D2, D3, D4 receptors are inhibitory. Based on positron emission tomography (PET) scan studies using radioligands as well as the distribution of mRNAs, it has been observed that dopamine receptor subtypes types are concentrated in different brain areas: D1 and D2 receptor mRNAs are found

in the caudate and putamen, whereas the D3 and D4 receptors are clustered in limbic areas, and D5 receptor distribution is restricted to hippocampus, the hypothalamus, and the parafascicular nucleus of the thalamus (139–141).

However, there is yet an additional level of variability. Each receptor subtype also has different genetic variants, which behave in physiologically different ways, with different binding affinities. For example, there are three dopamine D5 receptor subtypes. The “standard” dopamine D5 receptor, which consists of 477 amino acids, and two other dopamine D5 receptor subtypes coded by “pseudogenes.” These shorter D5 receptor variants are composed of only 154 amino acids and likely function very differently. There are “short” (414 amino acids) and “long” (443 amino acids) versions of the D2 receptor, as well as several other D2 receptors which vary because of different amino acids inserted at different points in the protein. Similarly, there are several different variants of the dopamine D3 receptor. Ten different D4 receptor subtypes have been identified; they differ in the number of 48 base-pair repeats in the putative third cytoplasmic loop, ranging from one to ten repeats. These various receptor subtypes also show differences of variable clinical significance. Two examples of this phenomenon should provide some insight into the complexity of the process. One patient, with the D4Valine194Glycine variant was reported as being strikingly less sensitive to dopamine, clozapine and olanzapine (142). Similarly, the long and short dopamine D2 receptor variants show different patterns of response to prior activation of protein kinase C without changing dopamine-induced inhibition (143). In rats, Martres and colleagues demonstrated a 70% increase in striatal D2 mRNA levels following a 15-day treatment with haloperidol, but no change in mRNA levels in cerebral cortex or brainstem. In contrast, the amount of long D2 receptor mRNA was decreased to a greater extent than the short D2 receptor following 6-hydroxydopamine treatment in the substantia nigra (144).

Several polymorphisms of the dopamine D4 gene have been identified. There have been numerous studies (145–153) and several meta-analyses (154, 155) supporting the association between the dopamine D4 48 base-pair seven-repeat allele in exon 3 and ADHD. However, some studies did not support the association (156–160). Another 120 base pair repeat promoter polymorphism, upstream of the 5′ transcription initiation site, may be associated with ADHD, particularly the inattentive type (161). Leung and colleagues conducted a study in the Chinese Han population. Rather than the expected increase in the seven-repeat allele, they found an unexpected 1.65 times increase in the two-repeat allele, which can be interpreted as supporting the association between the dopamine receptor D2 and ADHD, but with differences in the number of repeats that are specific to a given ethnic group (162).

Recently a series of studies examined the relationship between performance on cognitive tasks assessing attention and impulsivity, independent of a specific diagnosis

of ADHD. This approach has yielded some interesting results and provided evidence that specific genotypes are related to specific cognitive profiles. Langley and colleagues examined the effect of the dopamine D4 receptor seven-repeat allele in 133 drug-naïve children ranging in age from 6 to 13 years on a series of neurological tasks sensitive to inattention, impulsivity, response inhibition, and monitored activity level. The patients were divided into two groups: those with one or more dopamine D4 receptor seven-repeat alleles (38.3%) and those without (61.7%). The groups did not differ significantly in age or IQ. Although the children with the seven-repeat allele had a significantly higher total number of ADHD symptom than those without, the groups did not differ when the symptoms were subdivided into inattention or hyperactivity/impulsivity. The children with the seven-repeat allele showed significantly higher rates of oppositional defiant disorder and conduct disorder than those without. The children with the seven-repeat allele also tended to trade speed for accuracy (they were faster but more impulsive and more error-prone) and were more hyperactive. Interestingly, there was little difference between children with ADHD and the seven-repeat allele and those with ADHD without the seven-repeat allele, but these subjects differed significantly from the nonADHD control subjects (163).

### Norepinephrine

Norepinephrine (noradrenaline) is involved in regulating alertness and attention. Norepinephrine neurons arise from the locus coeruleus and innervate the dorsomedial and anterior cingulate regions (cortical regions heavily involved in attention) (164–166). Norepinephrines are also preferentially found in layers V and VI, which receive thalamocortical afferent fibers (167). Prefrontal cortex is reciprocally connected with the locus coeruleus, which enables prefrontal cortex to exert top-down control on attention (168). There is also a peripheral noradrenergic system, which regulates the cardiovascular system controlling blood pressure and heart rate (the “fight or flight” response).

The norepinephrine system plays a key role in stimulus detection and alertness. Neurons in the locus coeruleus respond to environmental stimuli (particularly novel stimuli), are quiet during sleep, and do not respond to automatic grooming and feeding behaviors (169, 170). There are four main types of central noradrenergic receptors: alpha-1, alpha-2, beta-1, and beta-2. Alpha-1 and the beta-1 and -2 receptors are primarily postsynaptic, whereas alpha-2 receptors are found at both presynaptic and postsynaptic sites. The presynaptic receptors are *autoreceptors*; that is, in response to an agonist, they downregulate noradrenergic activity by a negative feedback mechanism.

Although it was previously believed that a nerve terminal could store only one neurotransmitter, it is now recognized

that two neurotransmitters may be colocalized in one neuron (e.g., dopamine 1 and dopamine 2 may colocalize in neostriatal neurons) (171). In prefrontal cortex, Sawaguchi observed that about one-third of the neurons in prefrontal cortex responded to both dopamine and norepinephrine. However, the two neurotransmitters elicited quite different responses: dopamine was involved in the modulation of goal-directed motor performance guided by external cues, whereas norepinephrine appeared to modulate visual perception and behavioral arousal (124).

The norepinephrine transporter (NET1) functions to block the reuptake of norepinephrine into the presynaptic neuron, thus increasing available norepinephrine at the synapse. Atomoxetine is a selective NET1 inhibitor. Thus, the norepinephrine transporter is an attractive susceptibility factor in ADHD. A transmission disequilibrium test revealed a significant association between two *NET1* single nucleotide polymorphisms (SNPs) and ADHD (172). However, another study yielded what might be a small effect, but no evidence of a significant association (173).

### Serotonin

Serotonin has been implicated in a broad range of neuropsychiatric disorders, mood disorders, OCD, drug abuse, and impulsive/aggressive behaviors, all of which are also frequently observed in children and adults with ADHD. The serotonin transporter is the target for the selective serotonin reuptake inhibitors, which have become central to the treatment of many psychiatric disorders. Serotonin modulates the function of dopaminergic neurons (174), as well as that of other neurotransmitters (175). Dysregulation of the serotonergic system results in hyperactivity (176). Moreover, in DAT-1 knockout mice who are markedly hyperactive, reduction in hyperactivity following psychostimulant treatment requires a functioning serotonergic system (177). For all these reasons, a number of studies assessing the relationship of the serotonin transporter and specific serotonin receptors to ADHD have been conducted.

Susceptibility to ADHD has been linked to various polymorphisms of the serotonin transporter. A common 44 base pair deletion in the promoter region of the serotonin transporter gene (*5-HTTLPR*) results in reduced transcription and lower transporter protein levels. The homozygous L/L polymorphism results in higher levels of serotonin, which is associated with severe hyperactivity in animal studies. Several studies have reported a significant association between the long allele of the *5-HTTLPR* gene and ADHD (178–183). In some studies, there was also an association of the L/L polymorphism with conduct disorder as well (180).

A possible association between polymorphisms of the serotonin *HTR2A* receptor and the *5-HT1B* receptor genes and ADHD has also been reported (184–186). In a study of the T102C polymorphism of the *HTR2A* gene in a group of older women with seasonal affective disorder, those

women who were homozygous for the C polymorphism had a significantly higher score for retrospectively assessed ADHD behaviors than those with the T/T or T/C genotype (187). However, these associations vary with the particular ethnic group studied, and, not surprisingly, some studies have failed to show associations between these genes and ADHD (188–190).

### Glutamate

L-Glutamate, the most abundant excitatory neurotransmitter is involved in prefrontal-striatal and as thalamocortical projections. There are two types of glutamate receptors: metabotropic and ionotropic. Metabotropic receptors are members of the G-protein family (guanine nucleotide binding proteins) and trigger neural impulses through a biochemical cascade that is slower and longer-lasting than ionotropic receptors. Ionotropic receptors are ligand-gated ion channels and mediate rapid transmission. They consist of N-methyl D-aspartate (NMDA) receptors and closely related alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPA) and kainate receptors. These receptors play a crucial role in enhancing cognition by promoting synaptic plasticity and increasing the production of trophic factors. Glutamate has been implicated in ADHD in a number of clinical and preclinical studies. The glutamatergic and dopaminergic systems have a complex pattern of interaction. Glutamate may also be involved in the treatment response to psychostimulants, as magnetic resonance spectroscopy studies have revealed a significant decrease in the striatal glutamate/glutamine/GABA-to-creatine ratio following treatment with psychostimulants (191) (Carrey 2003).

The ionotropic glutamate receptor N-methyl D-aspartate 2A *GRIN2A* (*NMDA-2A*) gene that encodes the N-methyl D-aspartate receptor subunit 2A (*NMDA2A*) maps to chromosome 16p13. One study reported linkage between 16p13 and ADHD (192) Other studies have reported a positive association of the *GRIN2A* exon 5 polymorphism with ADHD (160), whereas others have not (193). Another study demonstrated linkage between the *SLC1A3* (Solute Carrier Family 1, member 3) gene (encoding a glial glutamate transporter), which maps to chromosome 5p12 (194). Genome-wide scans have also implicated this region as one possibly related to ADHD. (However, this is also close to the locus of the dopamine transporter gene.) This locus is thus both a functional and positional candidate for ADHD.

### Gamma-Amino Butyric Acid

GABA is an inhibitory neurotransmitter in the mature brain. There are numerous types of GABA receptors. GABA (A) receptors in prefrontal cortex regulate prefrontal cortical neurons by continuous “silent” task-related inhibition, which appears to contribute to behavioral organization

(195). There are also an array of GABA polymorphisms that have a variable effect on behaviors mediated by prefrontal cortex, particularly dopamine. Although GABA plays an important role in the regulation of these networks, it has not been examined in relation to ADHD. The noteworthy aspect of this neurotransmitter is its double life: in the developing brain, it is the first neurotransmitter to become functional and at that time, it behaves as an *excitatory* neurotransmitter through a diffuse, paracrine nonsynaptic mode of action. At this early stage, it plays an important role in neuronal proliferation, migration, dendritic arborization, and synaptic modeling. GABAergic synapses also interact with developing glutamatergic synapses (196).

### Other Aspects of Synaptic Function Possibly Related to Attention Deficit–Hyperactivity Disorder

An important aspect of synaptic function involves the formation of synaptic vesicles and the extrusion of neurotransmitter into the synaptic cleft. Numerous factors regulate synaptic function in addition to the transporters and receptor–vesicle docking proteins, agrins, which control clustering of receptors, and synapsins, which regulate neurotransmitter release.

One of the important components of this process is synaptosomal protein synaptic vesicle docking fusion protein 25 kDa (*SNAP-25*), which belongs to a family of soluble N-ethylmaleimide-sensitive factor attachment (*SNARE*) proteins that form complexes bridging the two cellular membranes and play an important role in presynaptic neurotransmitter release in association with the other vesicle-associated membrane proteins (*VAMP*)—syntaxin and synaptobrevin. Any disturbance of *SNAP-25* would thus be expected to impair neurotransmitter release. The hyperactive coloboma mouse is hemizygous for a deletion of the *SNAP-25* gene. These mice have a selective deficit of dopamine release in the dorsal striatum coupled with a significant increase in norepinephrine concentration in the striatum and nucleus accumbens (Jones 2001; Wilson 2000). A number of studies in humans have supported the association between *SNAP-25* (on 20p11.2) and ADHD. There is some evidence that the gene is imprinted and preferentially inherited from the father (198, 199; Barr 2000, Mill 2002, 2004). However, not all studies have supported this association.

### Dopamine- and cAMP-regulated phosphoprotein of 32 kDa (*DARPP-32*)

*DARPP-32* integrates various neurotransmitter, neuromodulator, and neuropeptide signaling pathways in the striatum and, depending on the state of phosphorylation, serves as a molecular switch. There is a very complex response to glutamate (201). *DARPP-32* is thought to play a central role in dopaminergic reward pathways and to be involved in response to a number of drugs of abuse (202).

Although DARPP-32 has been postulated as possibly being associated with ADHD, studies in humans have not been conducted (203).

### **Brain-Derived Neurotrophic Factor**

Brain-derived neurotrophic factor (BDNF), which is involved in neuronal plasticity and survival, increases spine density on pyramidal neurons and enhances the synaptic efficacy of glutamate, has been mapped to 11p14 (204). BDNF is found in high concentration in the hippocampus and prefrontal cortex, and appears to play an important role in memory and prefrontal function. A number of studies have implicated *BDNF* polymorphisms in mood disorders (particularly bipolar disorder), schizophrenia, and OCD (205). An MRI morphometry study on a group of normal individuals indicated that the val66met polymorphism results in anomalies in prefrontal cortex and hippocampus (206). Kent and colleagues reported preferential transmission of the *BDNF* valine (G) allele to offspring with ADHD. There were significantly more paternal than maternal transmissions (207).

### **Catecholamine-O-methyl Transferase**

Catecholamine-O-methyl transferase (COMT) degrades catecholamines by converting dopamine to 3-methoxytyramine, thus playing a major role in prefrontal function. This gene is located on chromosome 22q11. The polymorphism in which there is a valine to methionine substitution results in a three- to fourfold difference in enzyme activity. Individuals who are homozygous for the methionine allele degrade dopamine more slowly and therefore have higher levels of dopamine in prefrontal cortex. In one study they made significantly fewer perseverative errors on the Wisconsin Card Sorting Test than subjects with one or two valine alleles (208). In a study examining the effect of these two polymorphisms on attentional control and anterior cingulate activity, monitored with fMRI, there was a distinct gradient noted, with those homozygous for the valine allele performing more poorly and showing more activation of cingulate cortex than the heterozygotes, who performed more poorly and manifested greater fMRI activation than subjects homozygous for the methionine allele (209).

In another study performance of subjects with these different genotypes was monitored following administration of dextroamphetamine. Subjects were initially tested on the Wisconsin Card Sorting Test and then performed a working memory task while undergoing fMRI scanning. On the Wisconsin Card Sorting Test, subjects who were homozygous for the methionine alleles made fewer perseverative errors in the baseline condition than those who had two copies of the valine alleles, but their performance deteriorated following administration of dextroamphetamine, whereas those with two valine alleles showed a slight improvement. On the less demanding working memory task, subjects who were homozygous for the methionine allele did not show any change following

dextroamphetamine, but their performance deteriorated on the most demanding working memory task and there was an increase in prefrontal cortical activation indicating a less efficient performance. In contrast, subjects with two copies of the valine allele showed improved performance and enhanced prefrontal efficiency relative to baseline in response to dextroamphetamine (210).

Diamond and colleagues examined children who were 8.2 to 14.6 years old on tasks demanding working memory and inhibition. Children who had two copies of the methionine polymorphism performed far better on a task requiring both working memory and inhibition, whereas there was no difference on the self-ordered pointing or recall memory tasks. On the mental rotation task, children with two copies of valine polymorphism performed better (211). However, in another study that assessed working memory, attention and speed, impulsiveness and response inhibition in children with ADHD, no association with COMT was identified (212).

### **Monoamine Oxidase**

Monoamine oxidase (MAO-A, MAO-B) genes are mapped to Xp11.23 and code for enzymes that deaminate catecholamines. Brunner and colleagues described a large Dutch kindred in which affected males presented with mild mental retardation and impulsive, aggressive, antisocial behavior (arson, attempted rape, and exhibitionism) (213). This was related to a point mutation in the eighth exon of the *MAO-A* gene, which changed a glutamine to a termination codon (214). In a Chinese population, there is evidence of an association and linkage between ADHD and the monoamine oxidase genes (215, 216). In an Irish population, no association was noted with *MAO-B*, but certain *MAO-A* markers were significantly associated with ADHD (217). Children with certain *MAO-A* alleles who have been abused in early childhood are at greater risk for subsequent aggressive behaviors (218).

### **Enzymes Involved in the Biosynthesis of Catecholamines**

This section would not be complete without a brief mention of the enzymes that are involved in the production of catecholamines. The rationale for including these enzymes is that if the pathways leading to dopamine and norepinephrine are not totally functional, this might result in decreased levels of neurotransmitter. Enzymes in this pathway include tyrosine hydroxylase (mapped to 11p15.5), which is involved in the synthesis of dihydroxyphenylalanine (DOPA) from tyrosine. Deficiency of tyrosine hydroxylase in its autosomal dominant form results in L-dopa responsive dystonia, and involves the basal ganglia. DOPA decarboxylase (gene locus 7p11) converts DOPA to dopamine. A possible relationship to ADHD and a paternal pattern of transmission suggesting imprinting has been described (219). DOPA concentration is elevated in the right

brainstem areas of children with ADHD compared to controls, which may be the result of dysfunction in this system (109, 220). Dopamine  $\beta$ -hydroxylase (on 9q34) catalyzes the production of norepinephrine from DOPA and is associated with a disorder of cardiovascular regulation that is particularly severe in the young infant. Some studies have supported an association with ADHD (221–224) (Roman 2002), whereas others have not (225, 226).

## ETIOLOGY OF ATTENTION DEFICIT–HYPERACTIVITY DISORDER

### Genetic Factors

There is little question that genetic factors are extremely important in the etiology of ADHD. There are now well over 200 studies, consisting of relatively small samples, using different genetic tests of association, and carried out in different ethnic populations. As is clear from the previous review, there is far from total agreement across all these studies. However, there is evidence across many of these studies that some genetic perturbation of catecholaminergic systems is involved in the pathogenesis of ADHD. In addition to the issues of varying strategies in approaching the association, there is also the problem that one would not necessarily expect different ethnic populations to have the same gene pool. It is also unlikely that a single gene will be identified as the cause of ADHD. Like most neuropsychiatric disorders, it is likely that the disorder is polygenic. Thus, there is now an emerging trend to sample multiple candidate genes simultaneously and to increase the size of the population and use a variety of tests to determine if an association exists. Moreover, the inclusion of genes other than the classical neurotransmitters may strengthen these studies as patients may manifest symptoms of ADHD only when function of the transporters or the receptors is compromised by other factors. Moreover, it is possible that some of these genetic factors may interact with psychosocial or biological environmental factors.

### Nongenetic and Acquired Forms of Attention Deficit–Hyperactivity Disorder

ADHD has an undisputed genetic basis, but can also be the result of acquired brain injury or dysfunction of the frontal-subcortical system. In some individuals, both factors can be operative. DSM-IV diagnostic criteria do not distinguish between these various etiologies for ADHD. For the clinician, this distinction may not appear to be totally relevant because there appears to be no consistently different response to psychostimulant medications. However, as information relating to pharmacogenetics expands, different etiologies of ADHD are likely to become increasingly important to the treating physician.

### Prenatal Factors

A number of prenatal factors appear to place a child at risk for ADHD-like behaviors. Maternal cigarette smoking during pregnancy is one such factor. Twenty-two percent of the children with ADHD had a history of maternal smoking during pregnancy, compared with only 8% in the control group (227). This is an interesting association, given the effect of nicotine on the dopaminergic system and its effect on improving inhibition (228). Moreover, one cannot eliminate the possibility of a potential genetic confound, given the association of cigarette smoking and the DRD2 TaqI A1 allele (229). However, in a study in which the contribution of genetic factors (that is, maternal ADHD) was assessed in comparison to exposure to cigarette smoke in utero, Milberger demonstrated that maternal smoking was associated with a fourfold higher risk of ADHD in the offspring than in controls, even after controlling for maternal ADHD (230). A subsequent study by Mick and colleagues, using Milberger's data and adding information from girls, reported a 2 to 1 risk. In 2003, Thapar and colleagues also noted that maternal smoking increased the risk of ADHD in the offspring in addition to any specific genetic effect (231).

Fetal alcohol syndrome is also associated with ADHD but typically occurs in the context of neurocognitive deficits and microcephaly. In a meta-analysis of studies on maternal smoking, alcohol ingestion, caffeine and psychosocial stress published between 1973 and 2002, the authors reported that the findings on alcohol were contradictory, and studies on caffeine inconclusive. There was a possible modest contribution of stress to ADHD symptoms in offspring. However, maternal smoking during pregnancy appeared to place offspring at a greater risk for ADHD. Sowell and colleagues reported MRI morphometric studies in children exposed to heavy maternal alcohol ingestion that reveal widespread effects, including decrease in size of prefrontal cortex (232).

### Prematurity

Prematurity is often associated with ADHD. This can be relatively subtle in older children. In one study, very-low birth-weight prematures who were free of major cognitive or neurological impairment and did not manifest a classical ADHD-profile when tested on a CPT task at the age of 17 years nonetheless continued to show lingering emotional and neuropsychological deficits (233). A number of factors might explain the high incidence of ADHD-spectrum symptoms in this population.

First, the dopaminergic system, particularly in the developing brain, is easily damaged by hypoxia. Small premature infants are at high risk for recurrent apneic attacks. In a study on hypoxia in neonatal rats, Dell'Anna and colleagues reported that exposure to a hypoxic environment resulted in alterations in dopamine, norepinephrine, and serotonin in various areas of the brain (234, 235) and also observed that hypoxia affected the mesotelencephalic pathways involved in sleep, wakefulness, locomotion, and executive function. A

small group of ex-premature infants who had been examined with cerebral blood flow measures at birth and in whom ADHD later developed were re-examined at the age of 12 to 14 years. Dopamine receptor binding was examined, using PET with [<sup>11</sup>C] raclopride, which preferentially binds to dopamine receptors. They found that low neonatal cerebral blood flow was associated with increased dopamine receptor availability in adolescence (“empty receptors”) (236). In other words, damage to the dopaminergic system early in development resulted in the availability of an increased number of “empty receptors.”

Damage to white matter pathways also occurs in the small premature infant. Periventricular leukomalacia involves focal cystic necrosis of axons and white matter tracts lying deep in the brain around the lateral ventricles. There is also a more diffuse injury to white matter resulting from damage to oligodendrocytes, which ultimately are the source of the myelinated pathways (237). This diffuse white matter damage also disrupts normal gray matter growth. Inder and colleagues conducted an MRI study on premature infants and observed that gray matter abnormalities were correlated with the extent of white matter abnormality, so that cortical atrophy and immature gyral development were found in the vast majority of infants born at less than 26 weeks’ gestational age. Factors that contributed to this picture included infection in the perinatal period and hypotension requiring inotrope use (238).

Hyperbilirubinemia (jaundice) occurs in children who are premature as well as those who have blood group incompatibility. Bilirubin appears to function as a specific neuronal poison for neurons in the basal ganglia. Although the mechanism by which bilirubin damages neurons is not entirely clear, one possible mechanism is the excitotoxic effects of NMDA. The basal ganglia, certain brainstem nuclei, and the Purkinje cells are highly sensitive to damage. Before the use of exchange transfusions and RhoGAM, hyperbilirubinemia could result in devastating choreoathetoid cerebral palsy and deafness. Hyperbilirubinemia is a particular problem in the small premature infant, who lacks the ability to conjugate bilirubin and is at risk for hypoxia, which increases the potential for neuronal damage. Even full-term infants who are jaundiced at birth may have subtle attentional dysfunction, suggesting that in susceptible children, hyperbilirubinemia may not be all that benign (239).

Finally, focal lesions early in development may affect more distant cerebral regions and result in an ADHD-like picture. Saunders and Merjanian found that temporal lobe lesions in monkeys in the neonatal period disrupted dopamine regulation in the dorsolateral prefrontal cortex (240). Interestingly, Milichap described ADHD-like symptoms in children who had temporal lobe cysts (241).

### **Epilepsy**

ADHD is also more prevalent in children with epilepsy. Although there has been some controversy surrounding this point, whether or not it is a side effect of treatment, there is

evidence of an association between epilepsy and ADHD. One study from Iceland reported by Hesdorffer found that ADHD was 2.5 times more common in children with newly diagnosed seizures than in controls. This was most prominent in ADHD, predominantly inattentive type whereas the hyperactive impulsive or combined types were not as closely associated. There was no particular relationship to seizure type, ideology, gender, or seizure frequency at the time of diagnosis. In a study of 175 children ranging in age from 9 to 14 years with at least a 6-month history of epilepsy, Dunn and colleagues noted that 24% met DSM-IV criteria for ADHD, predominantly inattentive type. This was unrelated to gender, seizure type, or seizure focus (242). Holtmann and colleagues described a group of children who had ADHD-like symptoms and had an unusually high incidence of Rolandic spikes. The subjects included 483 patients between the ages of 2 and 16 years who met DSM-IV criteria for ADHD. Rolandic spikes were observed in the electroencephalographs of 5.6% of the children (243).

### **Medical Illness**

Another disorder that has been associated with ADHD is celiac disease, a multisystem autoimmune disorder, which has been associated with a broad spectrum of central nervous system symptoms. In adults, celiac disease is an important cause of cerebellar ataxia, and white matter lesions and cerebellar atrophy are often noted (244). In children, epilepsy, occipital calcifications surrounded by hypodense areas on CT scan, and diffuse white matter lesions have been reported (245, 246). This may be related either to an autoimmune demyelinating process or a vasculopathy. Celiac disease has been implicated in stroke in children (247). Developmental delay, ataxia, and hypotonia are prominent, but more subtle presentations, such as inattention and other ADHD-like symptoms, may be noted in approximately 20% of children (248). Although many of these children typically have gastrointestinal symptoms and failure to thrive, cases with few of these GI symptoms have also been observed. There are several possible explanations for the association between celiac disease and ADHD-like symptoms; the vasculopathy, white matter lesions, and cerebellar involvement (with secondary effects on frontal-executive function) come to mind.

ADHD has also been associated with other autoimmune disorders involving a vasculitis. Following a Group A beta-hemolytic streptococcal infection that appears to specifically involve the basal ganglia, ADHD, often in association with Tourette disorder and OCD, have been reported. This syndrome is called Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcus (PANDAS). There is controversy whether PANDAS and Sydenham chorea are different entities.

Phenylketonuria (PKU) is an inborn error of metabolism that results in significant ADHD symptoms. Although there are numerous gene mutations that disrupt the metabolism of phenylalanine, classically the absence of

phenylalanine hydroxylase, the enzyme involved in the conversion of phenylalanine to tyrosine which is an important step in the production of dopamine, results in varying degrees of hypodopaminergia. Any factor that reduces dopamine in prefrontal cortical neurons is likely to result in an ADHD-like picture. A gradient effect was noted in that exposure during fetal development (occurring in phenylketonuric mothers) resulted in hyperactivity/impulsivity and inattention while postnatal exposure was associated with inattention (249). Despite very tight control of phenylalanine during pregnancy, children with PKU who are then treated early and vigorously perform poorly on tasks demanding frontal executive resources and manifest hyperactivity, impulsivity, and inattention. Diamond observed that preschool children with elevated phenylalanine levels showed deficits in working memory and inhibitory control functions dependent upon dorsolateral prefrontal cortex, suggesting that dopamine played an important role in the maturation of that area (250).

### Environmental Toxins

Environmental toxins have received relatively little attention as contributing to the ADHD phenotype. The issue is complex because of the need to untangle various other factors, for example, socioeconomic and genetic. Probably the most extensively studied environmental toxin is lead. The severe encephalopathy that occurs in children with blood levels in the range of 60 mcg/dL has been well documented, but the more subtle effects of exposure to lower lead levels have been less obvious. Moreover, lead poisoning usually is found in specific populations and in restricted geographic areas. There is evidence that relatively minimal blood lead levels (above 10 mcg/dL) puts a child at risk for hyperactivity and subtle impairment of executive function (251, 252). In lead-exposed rats, striatal dopamine uptake as well as behavioral changes have been noted (253). Increased mercury ingestion also appears to target dopaminergic systems (254). Other environmental toxins such as polychlorinated biphenyls (PCBs) may also contribute to ADHD-like behaviors, particularly since exposure occurs not only during fetal development, but also during breastfeeding. Nigg has provided a thoughtful review of the issue of the role of environmental contaminants in ADHD (255).

### Acquired Brain Injury

Traumatic brain injury, particularly when there is damage to frontal subcortical circuits also produces ADHD-like behaviors (256–259). Because many types of traumatic injury involve damage to the frontal poles or shearing of white matter tracts, this is not an uncommon outcome.

Similarly, children who have suffered strokes not infrequently manifest ADHD-like behaviors, which had not existed before the stroke, and typically involve inattention and apathy. Max and colleagues noted that in their sample

of children with stroke, compared to matched controls with clubfoot or scoliosis, nearly half (46%) had ADHD-like traits following stroke. They performed poorly on a task that required alert, sensory orientation. Two factors were also important in determining severity of attentional disturbance: size of lesion in the attention/arousal network (but not executive attention) (260–264).

Castellanos and colleagues recruited nine carefully studied monozygotic twin pairs discordant for DSM-IV ADHD. Total caudate volume of the affected twin was significantly smaller than that of the unaffected co-twin. No significant differences within the twin pairs were found with regard to volume differences in other brain regions. The caudate volume differences did not correlate significantly with parent/teacher Conner's rating of hyperactivity severity, differences in birth weight, or duration of stimulant exposure (265).

Meningitis and encephalitis can result in ADHD-like behaviors, particularly when the basal ganglia are affected. Autoimmune disorders have also been implicated in triggering ADHD-like symptoms in susceptible patients. PANDAS are linked to Tourette disorder, OCD, and ADHD (266, 267). Lyme disease has also been associated with a number of neuropsychiatric symptoms, including those of ADHD (268).

### Psychosocial Factors

Although environmental factors may not directly cause ADHD, there is little question that the more adverse the environment, the more severe the symptoms are likely to be. Children who grow up in "adverse" environments (i.e., poverty, maternal psychopathology, paternal criminality) are at much greater risk for ADHD, and the risk is in proportion to the number of adverse factors that are present (269). Children with reactive attachment are often hyperactive and inattentive, and ADHD is one of the differential diagnostic considerations in these children. Children who are genetically at risk for ADHD would seem to be much more likely to be severely impaired if they grow up in chaotic, unstructured households. However, there is clearly a need for further research in this area (270).

## TREATMENT OF ATTENTION DEFICIT–HYPERACTIVITY DISORDER

The impressive effect of psychostimulants on ADHD symptoms has been known since 1937 when Bradley observed its remarkable effect on a classroom of children with ADHD (4). At present there are now a variety of drugs and delivery systems available for the treatment of ADHD. The most thoroughly studied and those that have been used for the treatment of ADHD for half a century or more are dextroamphetamine and methylphenidate. Both of these drugs increase available dopamine and norepinephrine at central synapses through somewhat different mechanisms.

Volkow and colleagues have provided a convincing demonstration that dopamine release at central synapses is enhanced when presented in the context of a salient stimulus. Methylphenidate, in the absence of such a stimulus, does not reliably enhance dopaminergic release (271, 272).

Not all patients respond equally well to these medications. Some show dramatic positive responses, whereas others are helped to some extent but often continue to experience unacceptable side effects. The most common side effects are decreased appetite and disrupted sleep, although some patients report improved sleep. Other side effects include dyspepsia, autonomic arousal and increased anxiety, and headache. Rare side effects include vermification or hallucinations.

Although a carefully executed double-blind crossover study reported a response rate of 98% to methylphenidate and/or dextroamphetamine (25% responded to only one agent) (273), this does not seem to concur with clinical experience, nor does it explain the substantial number of patients who drop out of treatment. A more reasonable estimate, based on 155 controlled studies involving 5,768 subjects, indicated a response in the 70% range (274). However, longterm adherence to psychostimulant medication can range from 52% to close to 90%. Adherence does not appear to be related to the effectiveness of the treatment. In a multicenter study involving 407 children treated with OROS MPH, 71% of the subjects remained on medication after 12 months. This is surprising as the children were responders and had been titrated to an appropriate dose and were followed closely (275). In the NIMH Collaborative Multisite Multimodal Treatment Study of Children With ADHD (MTA), 88% of the 198 children for whom MPH was the optimal treatment remained on medication. These children were followed monthly and received dose adjustments as needed (276). In a longterm follow-up study of children treated with methylphenidate, 52% continued to take medication at least 5 days a week at the 3-year mark. Adherence was predicted by absence of oppositional defiant disorder and more ADHD symptoms (based on teacher ratings), as well as a younger age at the start of program (277). Although continued treatment is associated with good response, side effects do not change. In a somewhat longer (5-year follow-up study) involving 79 children treated with methylphenidate with annual evaluations for 5 years, subjects who remained on medication had consistently greater improvement in teacher-reported symptoms than those who took medication inconsistently or took none at all. However, side effects in these treated children continued to persist (278).

In the past few years, a number of new drugs and new delivery devices have become available so that the physician now has an array of options. A number of extended release forms with a duration of action ranging from 8 to 12 hours are now available in an array of doses. The purified D-isomer of methylphenidate (dexmethylphenidate hydrochloride, D-MPH) is available in a variety of doses

(279, 280). Transdermal methylphenidate has also been used in experimental settings with good results (281).

Atomoxetine, a specific norepinephrine transport inhibitor, was originally developed as an antidepressant but was never marketed as such. It was then later reevaluated as a potential treatment for ADHD. A desirable feature is that once a day dosing provides 24 hour coverage. Atomoxetine has a low abuse potential and is considered a nonstimulant approved by the US Food and Drug Administration for treatment of ADHD. An important metabolic pathway for atomoxetine involves cytochrome P450 (CYP) 2D6. In extensive metabolizers, atomoxetine has a plasma half-life of 5.2 hours, while in poor metabolizers, atomoxetine has a plasma half-life of 21.6 hours. Once a steady state has been reached, the average steady-state plasma concentrations are approximately ten times higher in poor metabolizers than in extensive metabolizers. However, on the same dose, the incidence of side effects does not seem to differ in the two groups. Atomoxetine does not inhibit or induce the clearance of other drugs metabolized by P450 (CYP) 2D6 enzymes (282). In one study, the discontinuation rate was 3.5% and appeared to be dose-dependent, with higher discontinuation rates at dosages over 1.5 mg/kg day. In children and adolescents, nausea, vomiting, decreased appetite, and weight loss are common side effects. Several interesting preclinical studies have supported the use of atomoxetine as a treatment for ADHD. In the model of neonatal 6-hydroxydopamine lesions in neonatal rats, atomoxetine resulted in marked reduction of motor activity in these animals. In contrast, there was only a transient sedative effect in sham controls. The important aspect of atomoxetine is its effect on CYP 2D6 (283).

Another drug that has shown some promise in the treatment of some individuals with ADHD is modafinil, originally developed as a treatment for narcolepsy. This is also a nonstimulant and its mechanism of action is largely unknown. It has a different mechanism of action than psychostimulants, and does not increase dopamine or norepinephrine either by inhibiting reuptake or enhancing release. The mechanism of action that promotes alertness is not related to the locus coeruleus projections to the forebrain, but rather involves the hypothalamus, probably the tuberomammillary nucleus and hypocretin/orexin neurons in the perifornical area (284). These hypocretin/orexin neurons play an important role in hypothalamic arousal. Interestingly, low-dose modafinil also appeared to affect neurons in the amygdala as well. The input to the hypothalamic neurons appears to involve dopamine-dependent norepinephrine signaling (285), although the hypocretin/orexin neurons are also modulated by glutamatergic input (286).

## Behavioral Treatment

Behavioral treatments are also of value. Many children with ADHD need to have "accessory frontal lobes" and benefit

immensely from being provided with routines and scripts and being given tools that enable them to organize themselves. Pelham and colleagues reported that the combination of behavioral treatment and low doses of medication has been successful (281). The MTA study provided strong support for the efficacy of psychostimulants in the treatment of ADHD. In the short range, medication alone appeared to be more efficacious than the combination of medical and behavioral treatment, but the combination of medicine and behavioral management was associated with a better 2-year outcome than the medication group alone. In the long run, the difference (68% versus 56%) was relatively small but was significantly better compared to behavioral treatment alone and community care. The behavioral treatment was extremely intense and involved (1) parent training, (2) individual work with the child, (3) integration of the school into the behavior program, and (4) a daily report card completed by the teacher that was then used by the parents to deliver consequences. This large, well-designed study strongly supports the use of medication integrated with a behavioral program.

### Pharmacogenomics

Given the variability in the clinical responses of patients and the burgeoning information in the genetics of ADHD, the notion of developing systematic pharmacogenomic approaches to the treatment of ADHD is especially attractive. Unfortunately, this undertaking is still in its infancy. Current research studies involve small sample sizes, varying ethnic gene pools, and thus may not be applicable to all populations. Nonetheless the information available is tantalizing.

Most studies in this area have been limited to methylphenidate and most have involved the *DAT-1* gene. There are two common alleles, the 9-9-repeat and the more common 10-repeat. The *DAT-1* 10-repeat (480-base pair) polymorphism and the D4 dopamine receptor-7-repeat allele have been the subject of many genetic studies. Both of these genes have been demonstrated (albeit not consistently) to be associated with ADHD. The efficacy of methylphenidate is related to its ability to inhibit the function of DAT-1 to recycle dopamine from the synaptic cleft back into the presynaptic neuron. In a single photon emission spectroscopy study, using a ligand for the dopamine transporter, subjects with the 9-9 repeat or 9-10 repeat genotype had significantly higher DAT availability in the caudate and putamen than those homozygous for the 10-repeat (287).

With regard to D4, a preclinical study has suggested that the D4 dopamine receptor -7-repeat allele is less responsive to dopamine. (The assumption that the *DRD4-7* repeat polymorphism responds differently is based on a study by Asghari and colleagues that indicated that there was a twofold reduction in the D4-7 repeat polymorphism in the inhibition of cAMP formation compared to the dopamine 4 receptor with 2- and 4- repeats. [288]). The question

addressed in these pharmacogenomic studies is whether patients with these different genotypes manifest a differential response to methylphenidate.

In 1999, Winsberg and Cummings evaluated the interaction between genotype (*DAT-1*, and dopamine receptors D2 and D4) and response to methylphenidate in a group of 30 African American children. Methylphenidate was titrated to the point that a behavioral change was achieved, or a maximum tolerated dose was reached (the dose did not exceed 60 mg [approximately 0.7 mg/kg]). Eighty-six percent of nonresponders were homozygous for the 10-copy allele of the *DAT-1* gene in contrast to 31% of responders. The response rate in this group of children was only 53%, much less than that reported in most studies. No difference in response pattern was detected for the Taq 1A dopamine D2 receptor or the dopamine D4 receptor (289).

The lack of response to methylphenidate in children with two copies of the 10-copy allele of the *DAT-1* gene was replicated in a study on 50 male Brazilian youths. More (75%) of the boys who were not homozygous for the 10-repeat allele showed improvement compared to 47% of those who had two copies (290). In a single photon emission computerized tomography (SPECT) study involving children who demonstrated at least a moderate response to methylphenidate, those with the 10-repeat *DAT-1* allele showed significantly higher regional blood flow in the medial frontal and left basal ganglia (291). In a study on a small group of Korean children with ADHD, only about one third (28.6%) of the children homozygous for the 10-repeat *DAT-1* manifested a good response to methylphenidate. In contrast, all children without the 10/10 genotype manifested a good response to treatment. Moreover, the children homozygous for the 10/10 genotype also showed a significantly greater increase in DAT density in the basal ganglia compared to those without the 10/10 genotype (292).

However, the exact opposite finding was reported in a study involving 119 Irish children; namely that individuals with two copies of the 10-repeat allele showed a good response to methylphenidate in comparison to those who did not. The hypothesis on which this study was based was that the 10-repeat *DAT-1* allele resulted in an overactive transporter, and the investigators suggested that this might heighten the response to methylphenidate (293).

In a study of 47 children with ADHD treated with a placebo-controlled, double-blind crossover dosing schedule that involved three dose levels of OROS methylphenidate (18 mg, 36 mg, and 54 mg), it was noted that children who were homozygous for the *DAT-1* 9-repeat 1 3' UTR genotype (this is relatively rare) did not show a linear improvement as the dose was increased (294).

In a study comparing the magnitude of methylphenidate dose required to achieve behavioral responses (measured by rating scales), subjects with the *DRD4* receptor 7-repeat polymorphism required 1.5 times as much methylphenidate (with doses up to 1.70 mg/kg) compared to those without

that polymorphism (295). This study supports the hypothesis that the 7-repeat *DRD4* allele results in a less efficient dopamine receptor.

Tahir and colleagues reported that the *DRD4* 7-repeat allele was associated with a better response to methylphenidate. This Turkish study population included 104 trios and 7 dyads, and the analysis involved the transmission disequilibrium test (296).

Given the importance of serotonin and dopamine in psychopathology, and the possibility that serotonin is associated with ADHD (178), as well as the complex interaction of these two neurotransmitters at a neuronal level, examination of the methylphenidate response in individuals with differing dopamine and serotonin receptors is an important undertaking. Individuals who are homozygous for the long allele (L/L) manifest increased serotonin levels compared to the heterozygous (L/S) or those with two short alleles (SS). Prolactin release is inhibited by dopamine and enhanced by serotonin. Seeger and colleagues examined the methylphenidate response in 47 children with ADHD whose *DRD4* and *5-HTT* genotypes were known. Those who were homozygous for both the 7-repeat dopamine *DRD4* polymorphism and the long serotonin receptor had the smallest response to methylphenidate and the highest level of prolactin release. Moreover, children with the two long alleles had a higher incidence of conduct disorder (180).

Several other genes have been evaluated with regard to response to methylphenidate. One study reported a significant association between the norepinephrine transporter gene *G1287A* genotypes and response to methylphenidate. Chinese Han children with ADHD with the G/G or G/A genotype showed highly significant reductions in hyperactive/impulsive scores but not inattention scores. Those with the A/A genotype showed minimal response (297). There is also some support from preclinical studies for the specific reduction of hyperactivity/impulsivity in these children. In rats with 6-OHDA-induced lesions in the neonatal period, there is a marked reduction in hyperactivity following administration of atomoxetine, a specific norepinephrine inhibitor (283).

# Conduct Disorder and Sociopathy

12

**Markus J. P. Kruesi, MD    Kevin Gray, MD**

This chapter reviews the neuropsychiatry of conduct disorder/sociopathy (CD). The term *conduct disorder/sociopathy* emphasizes the life course persistent nature of some conduct disorders and their continuity with antisocial personality disorder (ASP) (Robins 1966; Moffitt 1993).

## **HISTORICAL OVERVIEW**

The emergence of near universal schooling in the early 20<sup>th</sup> century brought children under the eye of institutions and professionals and the subsequent detection of more subtle forms of disturbance than epilepsy, mental retardation, and gross psychosis (Neve & Turner 2002). This led to a need to deal with troubled or delinquent children as seen in the work of William Healy (1917), an obstetrician, who founded juvenile court clinics in Chicago and Boston. Healy viewed delinquents as suffering from a “psychic constitutional deficiency.” In contrast to this internal deficit perspective, conduct disorder has also been viewed as an ecological adaptation to a harsh family or community environment (Steiner et al. 1997). As psychodynamic perspective grew influential, August Aichorn, the principal of Austrian reform schools, described delinquents whose actions were attempts to assuage neurotic guilt via seeking punishment (Aichorn 1935). Although Cleckley in *The Mask of Sanity* (1941) described psychopathy as driven by both environmental and hereditary factors, nature and nurture generally remained oppositional conceptualizations of CD (Steiner et al. 1997).

The groundbreaking evidence for the continuity of conduct disorder and antisocial personality disorder came from the serendipity of juvenile clinic records being stored in space that Lee Robins was to move into. Rather than

dispose of the records, she had the perspicacity to investigate those children’s outcome. Her longitudinal follow up of those youths, *Deviant Children Grown Up* (1966), provided valuable missing descriptive data analogous to the observations of Kraepelin about psychiatric disorders in adults. Subsequent longitudinal studies of Loeber et al., Trembley et al., Raine et al., and McCord et al. supported the concept that CD is not purely a transient reaction to circumstance. Gradually an appreciation of the costs of the disorder is beginning to emerge along with an interactive perspective on nature nurture relationships.

## **DEFINITIONS AND NOSOLOGY**

Conduct disorder is a psychiatric disorder in the category of disruptive behavior disorders, with criteria listed below. However, a number of other potentially overlapping constructs are pertinent. Many studies use related but non-interchangeable criteria. CD, crime/delinquency, psychopathy, and/or aggression are related but not entirely the same concepts. Delinquency is a legal term. Juvenile delinquents may present with no psychiatric diagnosis at all or with many different diagnoses (Quay 1979). Similarly, aggression has considerable overlap with conduct disorder, but there are conduct disordered individuals who do not display other directed physical aggression. Psychopathy refers to a disorder characterized by two features—an antisocial behavioral dimension which includes instrumental aggression and a wide variety of offenses plus a dimension of emotional impairment such as a lack of guilt and emotional shallowness (Cleckley 1941; Hare 1993). Most psychopaths qualify for an antisocial personality disorder diagnosis, but only 1 in 3 persons who meet

criteria for antisocial personality disorder diagnosis meet criteria for psychopathy (Hart & Hare 1996). It is not surprising that inconsistency in findings exist given these discrepant inclusionary criteria. A further potential confound is that some studies examine the broad band of externalizing or disruptive behavior. Although, evidence for the existence of this broad band is substantial, discriminating among the different typologies subsumed under the broad externalizing banner may have considerable prognostic import. For example, ADHD was thought to be a risk for later substance abuse. However, subsequent studies clarified it is comorbid conduct problems that drive the relationship, not ADHD per se (Disney et al. 1999; Chilcoat & Breslau 1999). Review of conduct disorder is complicated by the many studies which concentrate on aggregated measures of antisocial behavior and often include symptoms of ADHD, or more general behavior problems (Burke et al. 2002).

## EPIDEMIOLOGY

Prevalence rates for CD are generally reported to be between 1.5 to 3.4% in the general population (AACAP 1997, Manfred et al. 2002) and vary according to age, sex, geographic location, socioeconomic status, and familial structure and attributes. It is generally agreed that the prevalence of CD is greater among males (2.6–8.2%) than among females (0.8–2.8%) (Feehan et al. 1994; Offord et al. 1987; Rutter et al. 1970). The association between CD and age remains unclear. Previous findings (Cohen 1987) suggested higher prevalence rates among adolescents than among prepubertal children, but this has more recently come into question (Breton et al. 1999; Cohen et al. 1993; Lewinsohn et al. 1993; Nolan et al. 2001). Symptoms of both conduct disorder and various comorbid disorders fluctuate over time (Lahey et al. 2002). A greater prevalence of CD has been reported among youths from families of low socioeconomic status (Lahey et al. 1999; Rutter et al. 1975; Stanger et al. 1992) and from families with disrupted structure (Esser et al. 1990; Velez et al. 1989). Urban environment has been found to be a risk by some (Tolan and Henry 1996) but not by others (Rutter et al. 1970; Breton et al. 1999). Many youth with conduct disorder have reading problems (Hinshaw 1992), but it is unclear whether a causal relationship exists (Fergusson and Lynskey 1997; Maughan et al. 1996; Bennett et al. 2003).

Epidemiologic studies support a possible distinction between delinquency and conduct disorder. Of 478 individuals in the juvenile justice setting, less than 30% met criteria for conduct disorder in a study that took social, academic, and occupational impairment into account (Garland et al. 2001). In a randomly selected, stratified sample of 1,829 juvenile detainees, only about 40% had conduct disorder (Teplin et al. 2002).

## ETIOLOGY

### Genetic and Environmental Factors

The field of behavior genetics largely finds origin in the study of animals, as domesticated animals have been selectively bred for a variety of attributes, including temperament (Takeuchi and Houpt 2003). Despite selective breeding, it is well known that individual differences in temperament occur. Correlation with humans leads us to the concept of genetic and environmental interaction. Many individual characteristics may have origins in synergistic genetic and environmental effects, while others may be related solely to genetics or environment.

Twin (Simonoff et al. 1998; Slutske et al. 1997) and adoption (Cadoret et al. 1995) studies support a genetic liability for conduct disorder. In addition, variance in adolescent antisocial behavior may be accounted for in part by conflictual and negative parental behavior directed specifically toward the adolescent (Reiss et al. 1995).

Attempts have been made to correlate behavioral traits with genetic abnormalities of various neurotransmitters, including dopamine, serotonin, and noradrenaline. Behavioral traits often linked to conduct disorder include aggression and novelty seeking. Dopamine DRD2 and DRD4 polymorphisms have been found to associate with novelty seeking behavior (Noble et al. 1998; Ono et al. 1997). Polymorphisms of the gene coding for tryptophan hydroxylase, the rate-limiting enzyme in serotonin biosynthesis, were associated with individual differences in aggressive disposition among 251 adult subjects (Manuck et al. 1999). Comings and colleagues have examined 42 genes using multivariate regression analysis to determine associations with attention deficit hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), and conduct disorder among 326 subjects, 271 of which had a diagnosis of Tourette's syndrome (Comings et al. 2000a, 2000b). They report that some noradrenaline genes may share a role in all of these disorders, while hormone and neuropeptide genes may be linked to CD.

Recent twin studies of adults (Blonigen et al. 2003) and adolescents (Taylor et al. 2003) examined genetic and environmental influences on psychopathy. Both studies revealed a substantial genetic contribution to psychopathy and neither revealed a shared environment effect.

The measure most frequently utilized for evaluating the level of childhood and adolescent aggression in genetic studies is the Child Behavior Checklist (CBCL) (Achenbach 1983). Twin (Ghodesian-Carpy and Baker 1987) and adoption (van den Oord 1994) studies suggest that genetics account for 42 to 90% of variance in CBCL-rated aggression. It should be noted, however, that only two items on the CBCL aggressive subscale refer to physical aggressiveness and that, in a study of disruptive and aggressive children, CBCL aggressive scale scores did not correlate significantly with severity of physical aggressiveness (Kruesi et al. 1994).

### Birth Complications: Pre- and Perinatal Toxic Influences

Birth complications and pre- and perinatal toxic exposures can play a substantial role in the development of CD/ASP. Child and adolescent behavioral disturbances have been associated with low birth weight, prematurity, obstetric complications, physical anomalies, maternal illness, nutritional status, and substance and medication use (Rutter et al. 1998). Dutch military psychiatric examinations among those exposed prenatally to German army food supply blockade in 1944 and 1945 revealed that in utero malnutrition during the first and second trimesters is associated with an excess of Antisocial Personality Disorder in the offspring of those pregnancies (Neugebauer et al. 1999).

Toxin exposure is more controversial. Associations between maternal smoking and risk of conduct disorder, behavior problems, and crime have been reported in several studies (Brennan et al. 1999; Fergusson et al. 1993; Fergusson et al. 1998; Orlebeke et al. 1997; Rantakallio et al. 1992; Wakschlag et al. 1997; Weissman et al. 1999; Williams et al. 1998). Some question the role of direct causation and offer the alternative and increasingly accepted explanation that the associations may be attributed to the transmission of a latent conduct disturbance factor from mother to child (Maughan et al. 2001; Silberg et al. 2003). In a 1995 study, prenatal alcohol exposure contributed significantly to CD as an offspring outcome, but having an alcoholic biological parent did not (Cadoret et al. 1995). This finding implies that it was the actual alcohol exposure of the fetus in utero (not the genetic contribution from the parents' alcoholism) that resulted in the development of CD.

In a cohort of 4,269 consecutive live male births, infants who experienced both birth complications and early maternal rejection were more likely than those with only one of these risk factors to become violent offenders in adulthood (Raine et al. 1994). Although only 4.5% of the subjects had both risk factors, this small group accounted for 18% of all violent crimes committed by members of the original cohort. The interactive effect of maternal rejection and birth complications was specific to violence and was not observed for nonviolent criminal offending.

### Physical Characteristics

Historical attempts to correlate physical appearance with psychopathology have often come into question. The classic example was phrenology, wherein personality and mental characteristics were thought to be represented by the contours of the skull, and diagnostic interpretations were based on its palpation. With advances in genetic research, however, there has been a renewed interest in physical markers that may correlate with mental disorders. For example, hair whorl patterns and dermatoglyphic abnormalities have been studied in patients with schizophrenia (Alexander et al. 1993; Puri et al. 1995; Rosa et al. 2000) (Table 12.1).

**TABLE 12.1**

### PHYSICAL CHARACTERISTICS POTENTIALLY ASSOCIATED WITH CONDUCT DISORDER, DELINQUENCY, AND CHILDHOOD AGGRESSION

Mesomorphic body type (heavy-boned, muscular)  
Large body size  
Increased height  
Decreased fluctuating asymmetry

Investigation of physical characteristics of delinquents was undertaken in the mid-twentieth century. Sheldon described three major body types, including endomorphic, mesomorphic, and ectomorphic (1949). In both male and female populations, mesomorphs (i.e., heavier boned and muscular subjects) were more commonly found among delinquents than among controls (Epps and Parnell 1952; Glueck and Glueck 1956). A study of somatostatin in cerebrospinal fluid revealed lower levels among subjects with disruptive behavior disorders compared with age-matched subjects with obsessive-compulsive disorder (Kruesi et al. 1990). If the reduced somatostatin concentration correlated with hypothalamic levels, the resultant decreased inhibition of growth hormone might result in increased bone and muscle mass, and thus a more mesomorphic appearance. Large body size and increased height have been linked to child and adolescent aggression, violence, and conduct disorder (Farrington 1989; Ishikawa et al. 2001; Pine et al. 1997; Raine et al. 1998; Tremblay 1998).

Fluctuating asymmetry, which refers to a deviation from bilateral symmetry of physical characteristics, such as ear widths, ear lengths, elbows, wrists, finger lengths, ankles, and foot widths, is described as a reliable measure of developmental instability, defined as "the imprecise expression of a given developmental design because of untoward environmental or genetic perturbations that disrupt developmental processes" (Gangestad and Yeo 1994). Measures of developmental instability, including fluctuating asymmetry, "tell a historical tale of poor or disrupted design, random errors and accidents, or deleterious environments" (Lalumiere et al. 2001). Fluctuating asymmetry is recognized to correlate negatively with fitness across a wide range of taxa other than our own species (Moller 1997). Two recent studies revealed a negative correlation between fluctuating asymmetry of morphological traits and aggression and fighting history among male children and college students (Furlow et al. 1998; Manning and Wood 1998). Given that fluctuating asymmetry reliably measures developmental instability, those male subjects with higher aggression ratings might be seen as more developmentally stable. The implications of these studies may include viewing aggression as a developmentally adaptive behavior in some contexts. Lower rates of fluctuating asymmetry and

obstetrical problems were found among male offenders with psychopathy when compared with nonpsychopathic offenders (Lalumiere et al. 2001). These results may support the theory of psychopathy as an evolutionarily stable strategy (Harpending & Sobus 1987; Mealey 1995). Another symmetry analogy, a study comparing successful (e.g., not caught) psychopaths versus unsuccessful psychopaths, found that the successful psychopaths had greater hippocampal symmetry (Raine et al. 2004).

## REPRODUCTIVE ADAPTATION

An early attempt to address the evolutionary biologic fit of ASP (MacMillan & Kofoed 1984) proposed that ASP, in sociobiological terms, represented an alternate reproductive strategy—a minimal investment reproductive strategy. A continuum of reproductive strategies ranges from maximal investment characterized by protracted care of the young and minimal numbers of offspring to minimal investment characterized by lack of care for the young and greater numbers of offspring. Larger numbers of offspring, more promiscuous matings (Robins 1966), more abuse/neglect/abandonment of partners and offspring (Robins 1966), and a “cheating” reproductive strategy wherein males misrepresent their position in the dominance hierarchy to mate were cited (MacMillan & Kofoed 1984) as evidence of that alternate strategy. In contrast, nonantisocial individuals were said to be more likely to have a greater investment/fewer offspring strategy.

There is a growing consistency of evidence to support the idea that CD/ASP represents an alternate reproductive adaptation among humans (Kruesi & Showalter, in press). Individuals with ASP differ in their number of sexual partners and for their comparative lack of investment in their young. A study of 55 methadone patients found those with ASP were significantly more likely to be promiscuous—defined as having 10 or more sexual partners in the past year (Gill et al, 1992). A separate study of 351 cocaine abusers also found that those with ASP are more promiscuous (Compton et al., 1995). Another consistent finding is assortative mating among sociopaths: sociopaths tend to mate with other sociopaths (Krueger et al, 1998). Studies of the sexual behavior of juveniles are limited, but also support the theory. A study of 126 boys aged 5 to 11 years at increased risk for the development of conduct-disorder-related behavior re-evaluated 112 of them 15 months later (Meyer-Bahlburg et al, 1999). At both time points, the boys scored higher on the Sex Problems scale as well as on the nonsexual CBCL scales than Achenbach’s nonclinical norm sample. Data analyzed from 5,877 respondents aged 15–54 years in the National Comorbidity Survey, a nationally representative household survey, indicated that early-onset psychiatric disorders were associated with subsequent teenage parenthood among both females and males, with odds ratios of 2.0–12.0 and population attributable risk proportions of

6.2–33.7% (Kessler et al, 1997). Because of this risk due to the general category of early onset psychiatric disorder, it is important that studies address psychiatric comorbidity in order to parse out relationships to CD.

Recent studies have shed light on the association between CD and sexual/reproductive behavior by controlling for confounds. Girls with conduct disorder, girls with depression, girls with anxiety, and healthy girls (N = 459) who had been evaluated at age 15 years were followed up at age 21, when reproductive health was assessed (Bardone et al, 1998). After control for potentially confounding variables including prior health, adolescent conduct disorder predicted more medical problems, poorer self-reported overall health, lower body mass index, alcohol and/or marijuana dependence, tobacco dependence, daily smoking, more lifetime sexual partners, sexually transmitted disease, and early pregnancy. In a separate study, 83 girls, 8 to 13 years old at study entry with childhood-onset psychiatric disorders were repeatedly evaluated during an interval of up to 12 years (Kovacs et al, 1994). In the final model, childhood or adolescent onset conduct disorders (but not depressive disorders) were significantly associated with teenage pregnancy. Among the girls with conduct disorders, 54.8% became pregnant teenagers versus 12% of the rest. In addition to earlier sexual initiation, pregnancy and greater numbers of partners, there are indications that other aspects of sexuality differ as well. A birth cohort study of 930 New Zealand residents found that individuals with ASP have a risk ratio of 2.8 for early onset intercourse (prior to age 16), whereas those with depressive disorders have a risk ratio of 1.3 (Ramrakha et al, 2002). This is consistent with the idea that it is CD that is driving the early age of sexual initiation rather than other psychiatric disorders.

Sexual victimization, as victim or as perpetrator, is associated with conduct disorder in community as well as clinical samples. A study of 1,025 females and 1,087 males in grades 7 to 12 in Alberta (Canada) high schools found associations between experiencing a high number of sexual assaults and clinical profiles on measures of conduct disorder for both males and females (Bagley et al, 1995). CD was present in 94% of a clinical sample of 17 adolescents who sexually molested children (Galli et al, 1999). In a study of 499 mentally ill children and adolescents which grouped subjects in four mutually exclusive categories (no inappropriate sexual behavior (n=296), hypersexual (n=82), exposing (n=39), and victimizing (n=82)), an antisocial family history was associated with an increased rate of sexually inappropriate behaviors (Adams et al, 1995). One criterion symptom for conduct disorder is “has forced someone into sexual activity” (DSM-IV), therefore the “victimizing” group might be expected to be associated with antisocial family histories. However, hypersexuality and exposing behaviors were also associated with antisocial family histories suggesting that antisocial family history is associated with a broad range of sexual behavior that differs in qualitative and quantitative ways from that of other youth.

Another facet of reproductive adaptation, parenting, also differs between antisocial and other families: individuals with ASP tend to do less parental monitoring and have greater family conflict and lower family involvement (Patterson et al, 1989; Ary et al 1999). The predictive association between parenting and adolescent adjustment has been assumed to be environmental. However, one recent examination of genetic and environmental contributions suggests a need for greater consideration of genetic contributions. A study of 395 families with adolescent siblings who participated in the Nonshared Environment in Adolescent Development (Reiss et al., 1994) project indicates that the cross-lagged associations between parental conflict-negativity and adolescent antisocial behavior can be explained primarily by genetic factors (Neiderhiser et al, 1999).

## NEUROBIOLOGY

### Neurochemistry

The most studied neurotransmitter related to CD is serotonin and its major metabolite 5-hydroxyindoleacetic acid (5-HIAA). Recent meta-analysis (Moore et al, 2002) of 20 adult studies of cerebrospinal fluid 5-HIAA concentration where the experimental subjects included adults exhibiting outwardly directed antisocial behavior found a significant overall effect size ( $d = -.45$ ). Lower concentrations are associated with antisocial behavior. A significant moderating effect for age was found, with larger effect sizes for groups under age 30 (weighted  $d = -1.37$ ). The relative dearth of child CSF 5-HIAA studies necessitated a broader behavioral inclusion definition—the experimental group included children with disruptive behavior or whose parents evidenced antisociality. Again, a significant effect size was found ( $d = -.32$ ). Sixteen of 29 in the initial pediatric CSF 5-HIAA aggression study and follow-up (Kruesi et al 1990, 1992) had conduct disorder. A study of 29 boys with ADHD (11 with CD) did not find the expected low 5-HIAA concentration f aggression relationship (Castellanos et al., 1994). However, those subjects were significantly less aggressive (Kruesi & Jacobsen 1997). More recently, two studies investigated 5-HIAA concentrations in infants and behavioral variables. In one study, the investigators assayed monoamine metabolites in “leftover” spinal fluid from 167 neurologically normal infants (0–3 months of age), and later (at age 18–21 months of age) obtained their family psychiatric histories (Constantino et al, 1999). As calculated by Moore et al (2002), there was a significant but small effect size ( $d = -.261$ ) for the relationship between newborns CSF 5-HIAA and antisociality in the family in the expected direction (lower concentration—more antisocial). In a behavioral follow-up study, leftover CSF from 73 febrile infants (age  $\leq 3$  months) was assayed for 5-HIAA (Clarke et al, 1999). Subjects with 5-HIAA below the

median had higher externalizing behavior scores at 30 months than did subjects whose 5-HIAA levels fell above the median ( $P = 0.02$ ).

Relationships between serotonergic measures and psychopathy have been investigated in adults. In the first study, psychopathy as assessed by the Psychopathy Checklist-Revised (PCL-R) (Hare et al 1990) was associated with the ratio of CSF HVA/5-HIAA concentrations in 22 violent offenders undergoing pretrial forensic psychiatric assessment (Soderstrom et al, 2001). 5-HIAA alone was not significantly correlated with PCL-R scores. That finding was replicated in a new group of 28 violent and sexual offenders, where the HVA:5-HIAA ratio was strongly associated with psychopathic traits ( $r = 0.50$ ,  $p = 0.010$ ), (Soderstrom et al, 2003). Recently, fifty-one DSM-III-R personality disordered offenders who had a dynamic assessment of 5-HT function (prolactin response to 30 mg d-fenfluramine challenge) were rated on the Psychopathy Checklist: Screening Version (Dolan & Anderson 2003). 5-HT function did not correlate with psychopathy as a unidimensional phenomenon. The impulsive-antisocial component correlates negatively with 5-HT function while the arrogant/deceitful component correlates positively with 5-HT. In line with previous research findings, impulsive-antisocial conduct shows an inverse relationship with 5-HT function. The findings are consistent with genetic studies in supporting some degree of independence for the impulsive antisocial and callous unemotional factors.

Aggression and its associations with CSF 5-HIAA concentrations have been examined in adults, but pediatric age groups have not addressed aggression subtypes. An important early and replicated finding in adult samples is that it is impulsive, affect laden aggression in contrast to the “cold blooded” premeditated aggression that is associated with low concentrations of CSF 5-HIAA. It is *not* crime in general that is linked with low 5-HIAA concentrations, but rather only impulsive, affect laden violent crime that has an association. Pediatric CSF studies have not thus far systematically assessed predatory versus affective/impulsive aggression (Kruesi et al, 2003). However, studies of both youth and of adults indicate that impulsive and premeditated aggression are independent constructs (Dodge and Coie 1987; Vitiello et al, 1990; Barrat 1999).

Pediatric fenfluramine challenge studies present an inconsistent picture of serotonin aggression links. One study of boys with ADHD who were divided into aggressive and nonaggressive subgroups found the aggressive subgroup had a significantly greater prolactin response to the fenfluramine challenge (Halperin et al, 1994). However, another study found fenfluramine-induced prolactin release was not correlated with aggression rating scores in disruptive behavior disorder (DBD) patients and did not differ significantly between adolescent DBD patients and normal controls subjects (Stoff et al 1992). A study of 18 late adolescent/early adult individuals with early onset alcoholism use disorders who were impulsive and aggressive found no

significant difference in prolactin response to fenfluramine compared to 19 matched controls (Soloff et al, 2000). A study of 34 younger brothers of convicted delinquents found increasing degrees of aggressive behavior were positively correlated with the prolactin response to fenfluramine challenge (Pine et al, 1997). Furthermore, adverse-rearing circumstances conducive to development of aggressive behavior also exhibited positive correlations with the prolactin response. This association between adverse rearing and the prolactin response was statistically independent of that between aggression and the prolactin response. The inconsistent results may be a product of failing to address predatory versus affective aggression or presence/absence of psychopathy.

A significant caveat in examining relationships between monoamine metabolite concentrations and behavior is that age may alter the relationships. Studies of relationships of certain types of aggression (e.g., suicide and monoamine metabolites) suggest caution in generalizing across age. Although studies of adults are very consistent in finding relationships between low CSF 5-HIAA and suicide (Lester 1995), the two studies of adolescents to date (Kruesi et al, 1992; LL Greenhill personal communication) both found the dopamine metabolite, HVA, a better predictor.

### Hormonal Studies

Hormones of adrenal as well as gonadal origin have been implicated in the neurobiology of conduct disorder. In most species, androgens appear to exert a significant influence on the form and degree of aggressive behavior (Rubinow & Schmidt 1996). Steroid hormones are thought to play two distinct roles in modulating behavior: an organizational as well as an activational role. Gonadal steroids act around the time of birth in organizing which brain and other tissues will be steroid responsive. Later in life, the hormone will activate behavioral patterns such as mating behavior.

Body fluid findings have linked testosterone concentrations with aggression in humans. For example, higher CSF testosterone was associated with increased aggression among alcoholic offenders (Virkkunen et al, 1994). Yet, aggression testosterone relationships are not simple one to one linear relationships. Androgens interact with neurotransmitters in modifying or modulating aggression. For example, the increased aggression evident in genetically altered neuronal nitrous oxide negative male mice appears modulated by testosterone (Dawson 1997). Castration reduced aggression in neuronal nitrous oxide negative mice and wild type mice to equal low levels. Testosterone replacement restored aggression to precastration levels suggesting testosterone dependence. A study of plasma androgens in 15 boys with conduct disorder and 25 normal controls found significantly higher levels of dehydroepiandrosterone sulfate (DHEAS) but not testosterone in CD (van Goozen et al, 1998). Both aggression and delinquency correlated with DHEAS levels.

Another neuroendocrine abnormality associated with antisocial behavior is decreased cortisol secretion. The first study describing low cortisol response to a stressor compared adult male criminals in a maximum security hospital to a criminal control group (Woodman et al, 1978). More recently pediatric studies have documented associations. A study of 38 clinic referred boys with disruptive behavior found low salivary cortisol levels associated with early onset of and persistence of aggression (McBurnett et al, 2000). A study of 47 adolescent girls with conduct disorder and 37 control girls found the girls with CD had lower plasma cortisol levels (Pajer et al, 2001). Girls with CD, who did not have other psychiatric comorbidity, had lower cortisol than those with comorbidity or controls. Salivary cortisol had a significant negative correlation with CD symptom counts in boys and their parents (Vanyukov et al, 1993). However, not all studies have found decreases. Urinary free cortisol (Kruesi et al 1990) and plasma cortisol (Schulz et al 1997) did not differ in boys with ADHD (most of whom had comorbid CD or ODD) compared to normal controls.

### Electrophysiology

The most common psychophysiological measures recorded from antisocial populations have been electroencephalography (EEG), evoked potentials, event related potentials (ERPs), heart rate (HR), and skin conductance (SC) (Scarpa and Raine 1997). Adult psychopathy studies find three relatively consistent abnormalities: (1) Generalized excess theta activity; (2) foci of 6–8/second, 14–16/second bilateral or right temporal activity; (3) localized slow-wave activity in the temporal lobe (Dolan 1994). The comparatively slower EEGs are consistent with underarousal theories of psychopathy. However, often the EEG studies include psychopaths or criminals, but may not represent aggression or the diagnosis of conduct disorder. For example, two prospective studies by Volavka (1987) tracked Scandinavian boys who had had EEG recordings before age 16 and followed up their criminal records. These studies revealed relatively slower EEG frequencies in those with repetitive theft but do not mention a link to violence. However, study of 372 male maximum security mental hospital patients found more EEG abnormalities (slowing and/or sharp waves) in the temporal lobes of the most violent compared to the least violent: 20% versus 2.4% (Wong et al. 1994). Overall rates of EEG abnormalities (meaning without regard to location) were higher (43%) in the most violent compared to less violent patients (24–26%). Clinically, routine EEG screening is of limited value in childhood antisocial behavior problems without clinical evidence of neurologic disorder (Phillips et al. 1993).

### Evoked Potentials

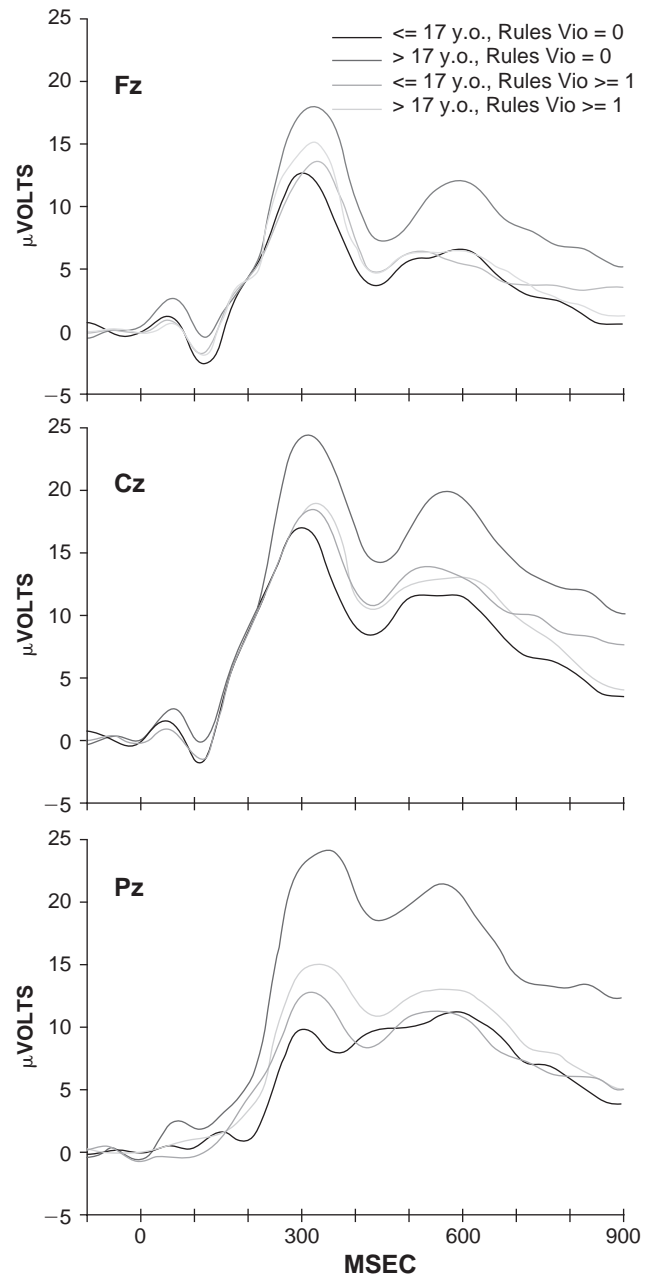

Event related potentials (ERP) are averaged changes of the brains electrical activity in response to specific stimuli. The

event related potential alternatively referred to as P 300 or P3 describes the third positive peak component of the ERP waveform that occurs at a modal time of 300 msec after presentation of a novel/deviant/unexpected stimulus (Fabiani, Gratton, & Coles 2000). Late, middle, and early components are believed associated with attention, cortical augmenting, and environmental filtering. Earlier studies reviewed by Raine (1993), largely in psychopathic subjects, support three findings: (1) enhanced late latency ERP P300 amplitudes to stimuli of interest suggesting enhanced attention for stimulating events; (2) heightened middle latency ERP amplitudes to stimuli of increasing intensity, consistent with sensation seeking; and (3) long early latency brain stem average evoked responses, consistent with decreased arousal and excessive environmental filtering.

A recent study (Iacono et al, 2002) using a statewide sample of 502 male youth about age 17, identified from Minnesota birth records as members of twin pairs, had their P300 amplitude measured, using a visual oddball paradigm. Structured clinical interviews covering attention deficit hyperactivity disorder, conduct disorder, oppositional defiant disorder, antisocial personality disorder, and substance use disorders were administered to the youth and his parents at the time of the P300 assessment and again to the youth 3 years later. Reduced P300 was associated with disorders and paternal risk for disorders, reflecting a behavioral disinhibition spectrum that included attention deficit hyperactivity disorder, oppositional defiant disorder, conduct disorder, antisocial personality disorder, alcoholism, nicotine dependence, and illicit drug abuse and dependence. Reduced P300 at age 17 predicted the development of substance use disorders at age 20. Most effect sizes associated with these group differences exceeded 0.70, indicating medium to moderately large group differences.

In another ERP study, the subjects were 94 community males, aged 14–19 years, who varied in the type and number of conduct problem behaviors exhibited prior to age 15. Groups were operationally defined by the number (0 versus  $\geq 1$ ) of DSM-IV conduct disorder diagnostic criteria within each of four categories: rules violations, aggression, deceitfulness/theft, and destructiveness. P300 electroencephalographic potentials were recorded while subjects performed a task in which rare auditory stimuli were used to signal a change in stimulus-response mapping during a succeeding set of trials. Analyses revealed that boys with a history of rules violations failed to exhibit the normal maturational increase in P300 amplitude. Topographic analyses suggest that the source of the maturational deficit involved P300 generators within the frontal brain. Parietal generators of P300 matured normally (Bauer & Hesselbrock 2003). See Figure 12.1 from Bauer & Hesselbrock 2003.

Heart rate (HR) reflects sympathetic and parasympathetic activity. The common view is that high HR is associated with anxiety, whereas low HR reflects underarousal. A recent meta-analysis of studies of heart rate and antisocial

**Figure 12.1** Group-averaged event-related potential (ERP) waveforms recorded at three representative electrode sites. The waveforms are sorted by severity of the Rules Violations subtype and age group. Note: Upon first examination, it appears that two late positive (P300) components are present in the group-averaged waveform. However, an examination of ERP waveforms obtained from individual subjects reveals only one prominent positive peak. The erroneous impression of two peaks is the result of averaging data across subjects whose P300 ERPs vary markedly in their peak latencies. (Reprinted from Bauer & Hesselbrock, 2003.)

behavior in children and adolescents found considerable support for relationships between low heart rate and antisocial behavior (Raine et al. 2004). Forty-five independent effect sizes of the resting heart rate–antisocial behavior relationship were obtained from 40 studies conducted between 1971 to 2002 using a total of 5,868 children.

Significant overall effect sizes were found for both resting heart rate ( $d = -0.44, P < .0001$ ) and heart during a stressor ( $d = -0.76, P < .0001$ ).

There appears to be some specificity to the low heart rate antisocial behavior relationship. Other psychiatric conditions such as hyperactivity, anxiety, depression, schizophrenia or PTSD either do not differ from normal controls or have higher rates (Raine 2002). The specificity of the low heart rate relationship may be greatest for crime/delinquency. The Ortiz & Raine meta-analysis examined broad band "antisocial" behavior. All the studies that used crime as their inclusion criteria reported significant effect sizes and had a 95% confidence interval for their effect size in the direction of lower HR associated with antisocial behavior. In contrast, studies which reported higher heart rate associated with antisocial outcome used samples where crime was not a clear inclusion criteria. For example, two studies which found effects (nonsignificant) in the opposite direction, higher rate associated with greater externalizing behavior used samples which may not have been crime predominant. Zahn & Kruesi (1993) studied a mixed group of ADHD, conduct disorder and oppositional defiant disorder. Pine et al. (1998) studied children at risk for delinquency. A third study (Van Hulle et al. 2000) which did not find a low heart rate association, used a young (age 7) twin sample that lacked significant criminal representation as evidenced by mean scores on the CBCL delinquent subscale that were significantly lower than published norms.

Skin conductance (SC), represents changes in the electrical activity of skin. Sweating increases SC. Resting skin conductance is thought to reflect arousal. There is some evidence for underarousal in antisocial spectrum individuals, but it is linked more to crimes of evasion than violence (Scarpa & Raine 1997).

## NEUROANATOMY AND NEUROIMAGING

Where is the neuropathology for conduct disorder localized? Despite the enormous public health impact of this condition (Vostanis et al. 2003; Mandel et al. 2003; Jones et al. 2002; Knapp et al. 2002; Kittelsen et al. 2001), there is relatively little direct anatomic data to answer the question. Most pediatric neuroimaging studies have focused upon diagnoses other than CD (Peterson 1995, Kruesi et al. 2004). Consequently, much of the information this section draws upon is from adult studies that address a variety of related conditions.

### Anatomic Evidence

Historically, lesions (often due to accident or tumor), trauma history, and findings on neurological exam or neuropsychological testing have furnished evidence regarding

localization. Two regions have most consistently been implicated: prefrontal cortex and temporal lobe.

The *Phineas Gage* case is well known as evidence of traumatic frontal lesion in adulthood leading to impulsivity and rage (Damasio et al. 1994). Subsequent cases, such as those from the Vietnam Head Injury Study offer some confirmation that frontal lesions are associated with hostile, impulsive, aggressive behavior (Grafman et al. 1996). However, that study of Vietnam veterans did not address or control for prehead injury aggression/conduct disorder rendering it unclear how much aggression should be attributed to the head injury (Brower & Price 2001). Violent adult psychopaths display orbitofrontal dysfunction on neuropsychological tests (LaPierre et al. 1995). However, clinical observation suggests that the social inappropriateness of patients with adult-onset prefrontal damage tends not to include violent and criminal behavior (Damasio 2000). Traumatic frontal lobe injury cases have been referred to as acquired sociopathy because of the pattern of irresponsible socially inept behavior seen in the face of normal intellectual abilities. In contrast, early childhood onset of prefrontal cortex lesions (before 16 months) is associated with defective social and moral reasoning in addition to the insensitivity to future consequences of decisions, defective autonomic responses to punishment contingencies and failure to respond to behavioral interventions despite normal basic cognitive abilities picture seen in adult-onset patients (Anderson et al. 1999).

It has long been recognized that temporal lobe epilepsy (TLE) can result in increased aggression (Bear & Fedio 1977). A study of 372 adult male maximum security patients found high violence scores correlated with CT scan and EEG abnormalities in the temporal lobes (Wong et al. 1994).

Frontal and/or temporal locations need to be thought of as interconnected rather than isolated independent structures. This is illustrated by a study of temporal lobe epilepsy patients. Analysis of MRI from 35 control subjects, 24 TLE patients with a history of repeated, interictal episodes of aggression, and 24 patients with TLE without episodes of aggression showed that patients with TLE with aggressive episodes had a decrease of gray matter, most markedly in the left frontal lobe, compared with each of the other groups (Woermann et al. 2000). Although the temporal lobe is a site of obvious pathology, the epileptic focus, findings suggest that structures elsewhere (frontal lobe) underlie the pathophysiology of aggression in TLE.

### Pediatric Neuroimaging Studies

There are only three MRI studies of groups of subjects with conduct disorders to date and all address anatomic features (Lyoo et al. 2002; Bussing et al. 2002; Kruesi et al. 2004). The first examined white matter hyperintensities (WMH) on MRI scans in 408 child and adolescent psychiatric inpatients. WMH are believed to represent regions of increased water density (Awad et al. 1986) and are reported to be in-

volved in the pathogenesis of cognitive impairment (Breteler et al. 1994). Study subjects were grouped according to a hierarchical diagnostic system as follows: schizophrenia ( $n = 42$ ), bipolar disorder ( $n = 56$ ), unipolar depression ( $n = 94$ ), conduct disorder/attention deficit disorder ( $n = 103$  of whom 80 met criteria for CD), and other neurotic disorders ( $n = 30$ ). Subjects without any level 2 diagnoses on structured interview ( $n = 83$ ) constituted the comparison group. Bipolar disorder, unipolar depression, and conduct disorder/attention deficit disorder groups were significantly more likely to have severe levels of WMH than the controls (prevalence rates: 17.9%, 13.8%, 13.6%, 1.2%). The frontal lobes were the most frequent location for WMH in the conduct disorder/attention deficit disorder group (35.7%). The Bussing et al. study examined a community sample of 12 children with combined subtype ADHD (aged 8–12, 7 of whom had comorbid conduct disorder) and 19 healthy controls matched for age, gender, and handedness. Volume measurements, including left/right asymmetries, were quantified from MRI of the total brain, caudate and cerebellar vermis. No significant differences in total brain volume, caudate volume, asymmetry of the hemispheres or asymmetry of the caudate were found between the groups. Another study used MRI imaging to compare brain anatomy in 10 early onset conduct disorders and 10 age, sex, and handedness matched controls free of psychiatric disorders (Kruesi et al. 2004). Right temporal lobe total and gray matter volumes were smaller in conduct disorder subjects before and after covarying whole brain volume. See Figure 12.2 for an illustration of MRI techniques used.

Smaller frontal lobe volumes were found, but did not reach statistical significance.

Two SPECT studies have examined mixed adolescent and adult subjects with aggression. One study examined a mixed group of 40 aggressive adolescents and adults with various psychiatric disorders (Amen et al. 1996). Findings include significant decreased activity in the prefrontal cortex and increased activity in the anteriomedial portion of the frontal lobe and left side basal/ganglia in the aggressive patients. Focal abnormalities were also seen in the left temporal lobe. The prefrontal cortex is involved in impulse control, critical thinking and concentration. Another SPECT study (Soderstrom et al. 2000) also includes a mixed adolescent and adult sample of 21 nonpsychotic violent offenders. In 16/21 of those subjects some hypoperfusion was noted in the frontal or temporal lobes. Importantly, the abnormalities were as severe in the subgroup ( $n = 7$ ) without major mental disorders or substance abuse as they were in those with those diagnoses.

### Adult Neuroimaging

Using MRI, Raine et al. (2000) found an 11% reduction in the prefrontal gray matter volume compared to controls in 21 subjects with ASP to 34 healthy controls, 26 substance abusers, and 21 psychiatric controls. The mean psychopathy scores for subjects suggest many, if not most, of the ASP subjects in that study also meet criteria for psychopathy. A study of 15 antisocial men with high psychopathy scores and 25 matched controls found a large effect size ( $d = 1.8$ ) for an increase in volume of the corpus callosum in the psychopaths compared to controls (Raine et al. 2003).

A growing body of literature is identifying activity differences in adult psychopaths. A study of 32 violent offenders found correlations between regional cerebral blood

**Figure 12.2** The figure (A) illustrates an unenhanced MRI coronal section through a midlevel of the temporal lobe (anterior thalamic nucleus visible). In (B) the temporal lobe has been defined by a boundary function. In the figure (C) a line perpendicular to the axis of the temporal stem connects the Sylvian fissure and the lateral ventricle. An automated edge detection technique defines the outer border of the temporal lobe and corresponding white matter (C and D). Used with permission from MJP Kruesi, et al. *Psychiatry Research: Neuroimaging* 132 (2004) 1–11.

flow and scores on the Psychopathy Checklist–Revised (Soderstrom et al. 2002). Significant negative correlations between frontotemporal perfusion and the interpersonal (callous, unemotional), but not the behavioral (antisocial, impulsive) aspects of psychopathy were seen. The most clearly associated regions of interest were the head of the caudate and the hippocampi. Decreased hippocampal perfusion may also reflect the anatomic finding of another Scandinavian group who reported decreased hippocampal volumes in psychopaths (Laasko et al. 2001). A study of 8 psychopathic criminals, 8 nonpsychopathic criminals and 8 controls used fMRI to examine localized brain activation during performance of an affective memory task (Kiehl et al. 2001). The psychopaths showed significantly less affect-related activity in the amygdala/hippocampus but overactivation in the frontotemporal cortex for processing affective stimuli. An fMRI study of 6 psychopaths and 6 controls found increased right prefrontal and amygdala activation in response to negative emotional pictures among the psychopaths (Muller et al. 2003). Another small sample study with 4 psychopaths, 4 social phobics, and 7 controls used fMRI to examine brain activity during an emotional learning activity (Veit et al. 2002). Results were indicative of hypoactive frontolimbic circuits among the psychopaths during the aversive conditioning.

One important caveat in examining neurobiologic studies of ASP is that substance abuse is a recognized confound. Uncertainty about primary versus acquired deficits is a problem in cross-sectional MRI studies (Franklin et al. 2002). For example in the Raine et al. (2000) MRI study of ASP, cocaine dependence was present in 67% of the ASP group but only 31% of the substance abuse group which raised questions as to whether the prefrontal volume reduction is related to ASP or a product of cocaine dependence (Franklin et al. 2002). Evidence mounts that state dependent brain changes due to substance abuse/dependence or abstinence occur. Brain shrinkage with chronic alcoholism is well acknowledged, but only recently have increases in brain size been shown with abstinence (Liu et al. 2000).

PET scan studies have also identified functional abnormalities associated with violence. Murderers ( $n = 41$ ) were characterized by reduced glucose metabolism compared to controls in the prefrontal cortex, superior parietal gyrus, left angular gyrus, and the corpus callosum, while abnormal asymmetries of activity (left hemisphere lower than right) were also found in the amygdala, thalamus, and medial temporal lobe (Raine et al. 1997). Some subjects were classified as predatory murderers ( $N=15$ ) and others as affective murderers ( $n=9$ ) (Raine et al. 1998). Paralleling studies of predatory versus affective aggression in cats, functional differences were seen between groups: Affective murderers relative to comparisons had lower left and right prefrontal functioning, higher right hemisphere subcortical functioning, and lower right hemisphere prefrontal/subcortical ratios. In contrast, predatory murderers

had prefrontal functioning that was more equivalent to comparisons, while also having excessively high right subcortical activity. Results support the hypothesis that emotional, unplanned impulsive murderers are less able to regulate and control aggressive impulses generated from subcortical structures due to deficient prefrontal regulation. The excessive subcortical activity associated with violence is consistent with other suggestions that neural overactivity, such as seen in temporal lobe epilepsy, can increase violence risk.

An imaginal study found rCBF reductions in the ventromedial prefrontal cortex of 15 volunteers during imagined aggressive behavior (Pietrini et al. 2000). This suggests a possible role for functional deactivation of the area during aggression.

A magnetic resonance spectroscopy study examined correlates of repetitive violence to self and others in 13 mildly mentally retarded individuals and 14 controls (Critchley et al. 2000). Concentrations and ratios of N-acetyl aspartate (NAA) and creatine phosphocreatine (Cr+PCr) were assayed. NAA concentration and Cr+PCr concentration reflect neuronal density and high-energy phosphate metabolism respectively. Violent patients had lower prefrontal concentrations of NAA and Cr+PCr and a lower NAA/ Cr+PCr ratio in the amygdalo-hippocampal complex than controls. Within the violent group, prefrontal NAA concentration correlated with the frequency of observed aggression.

## DIAGNOSIS & CLINICAL FEATURES

### Assessment

Assessment of the child with CD needs to include a thorough psychiatric evaluation which should be multidimensional and employ multiple informants (AACAP 1997). Multiple lines of inquiry—diagnosis, symptom severity/diversity, associated features, comorbid conditions and the context within which the disorder is appearing—will influence the methods, intensity, and foci of intervention. The DSM-IV-TR criteria for CD require that the individual repetitively and persistently violates either the basic rights of others or age-appropriate societal norms or rules, as evidenced by at least three of the following criteria in the past year (and at least one criterion present in the past 6 months):

- Aggression to people or animals—criteria include bullying or intimidation, physical fights, use of a weapon, physical cruelty to people, physical cruelty to animals, theft while confronting a victim, forcing someone into sexual activity
- Destruction of property—criteria include deliberate fire-setting or by other means
- Deceitfulness or theft—criteria include theft with or without breaking and entering, lying in order to obtain goods or avoid obligation

Serious violation of rules—criteria include staying out at night despite parental objection (beginning before age 13), running away from home, truancy from school (beginning before age 13).

These behaviors must have caused clinically significant impairment in social, academic, or occupational functioning. In addition, if the individual is at least 18 years old, criteria are not met for antisocial personality disorder.

Antisocial personality disorder (ASP) in adulthood requires conduct disorder in childhood. Because ASP is one of the adverse possible outcomes of CD, it is important to recognize when a patient has already met ASP criteria prior to age 18. The DSM-IV-TR criteria for ASP require that the individual be at least 18 years of age, have a history of conduct disorder, and display a pervasive pattern of disregard for and violation of the rights of others occurring since age 15, as evidenced by at least three of the following: (i) repeatedly engaging in unlawful behaviors that are grounds for arrest; (ii) deceitfulness; (iii) impulsivity or failure to plan ahead; (iv) irritability and aggressiveness; (v) reckless disregard for safety of self or others; (vi) consistent irresponsibility (failure to honor obligations); and (vii) lack of remorse. These behaviors must not occur exclusively during the course of a schizophrenic or manic episode.

A careful history, review of systems, psychiatric and medical exam will often determine the need for further investigations. Laboratory examinations are a function of individual history as well as age: for example, adolescents with CD should have a urine drug screen and have screens for sexually transmitted disease but not all prepubertal individuals with CD will need those measures. EEG, MRI, CT and other brain imaging are not routine evaluations for individuals with conduct disorder, but are prompted by neurologic symptoms or history.

The usual clinical use of neuropsychological testing in CD, in the absence of brain damage/focal neurologic findings, is to assess learning disabilities and intellectual ability. Individuals who have committed severe violence (e.g. homicide) may require greater scrutiny because of high rates of head injuries and other CNS insults (Lewis et al. 1988).

Assessment needs to consider features that are not part of the CD diagnosis. For example, strengths and protective factors are important to assess, so they can be mobilized in treatment (U.S. Department of Health and Human Services 1999). Some domains to be assessed are listed in Table 12.2.

### Neuropsychological Testing

Intelligence quotient (IQ) has long been related to risk for juvenile delinquency with IQ scores showing associations with juvenile delinquency of the same magnitude as those of class or race (Moffitt 1993). The generally accepted 8 point discrepancy between delinquents and their law abiding peers, is not propelled by those with transient law breaking but a large (e.g. 17 point) difference between habitual offenders and controls (Moffitt 1990).

**TABLE 12.2**  
**DOMAINS FOR ASSESSMENT IN CONDUCT DISORDER INDIVIDUALS**

- supervision and behavioral management needs;
- history of sexual and physical abuse;
- separation, divorce or death of key attachment figures;
- evidence of attachment capacity;
- intellectual ability, educational potential, disabilities, achievements, and learning style;
- peer relationships, especially the extent peers are reinforcing negative behaviors;
- family problems and strengths;
- environmental factors including disorganized home and lack of supervision;
- presence of neurotoxins such as lead; and
- ability to form and maintain relationships.

Adapted from Steiner et al, 1997 and McMains et al

Although there is substantial agreement about the association between IQ and delinquency, associations between CD and more circumscribed neuropsychological functions are controversial. In the preceding decade, two domains were thought impaired in individuals with CD: “executive” self-control functions and language based verbal skills (Moffitt 1993). Executive cognitive function is defined as a higher order cognitive construct involved in the planning, initiation, and regulation of goal directed behavior (Milner 1995). Executive function is thought to localize in prefrontal cortex and its limbostriatal connections.

Recent evidence suggests executive function problems are not as central to CD as previously thought. Executive function deficits are well documented in ADHD but not in CD without ADHD (Pennington & Ozonoff 1996). Meta-analysis of 39 studies of antisocial behavior which utilized well-defined criteria for executive function: (a) tests had to incorporate at least one of the theoretical domains of executive function (e.g. volition, planning, purposive action, and/or effective performance); and one or more of (b) and (c): (b) the test has been found in brain imaging research to preferentially activate the frontal cortex and/or (c) the test had differentiated patients with frontal lesions from patients with focal lesions in other brain areas or patients with diffuse brain damage delineated the impact of differing antisocial inclusion criteria (Morgan & Lilienfeld 2000). Overall, antisocial groups performed 0.62 standard deviations worse on executive function tests than controls. Significantly, larger effect sizes were seen when crime/ delinquency was the inclusion criteria rather than ASP/CD or psychopathy.

The primacy of verbal cognitive deficits has also been brought into question. Cross-sectional studies support the view that there are verbal, but not spatial, cognitive deficits in antisocial groups (Rutter et al. 1998; Raine 1993; Moffitt 1993). In the Morgan & Lilienfeld (2000) meta-analysis of executive function tests and antisocial behavior the largest effect size ( $d = .8$ ) was seen for a visuospatial measure

(Porteus Mazes) whereas a verbal measure (word fluency) showed a small effect size ( $d = .26$ ). Until recently studies had not examined which came first. A recent population-based study assessed verbal and spatial abilities at ages 3 and 11 in 330 children whose antisocial behavior was assessed at ages 8 and 17 (Raine et al. 2002). Persistently antisocial individuals had spatial deficits, in the absence of verbal deficits at age 3, independent of social adversity, early hyperactivity, test motivation, or comprehension. This suggests early spatial deficits, as assessed by block assembly and copying shapes, are a precursor to delinquent behavior whereas the verbal deficits may be developmentally acquired or represent a later unfolding of latent neuropathology. Verbal deficits were seen at age 11 but not age 3. Persistent spatial cognitive deficits were specific to persistently antisocial individuals; the childhood limited and adolescent-onset antisocial groups did not show this finding.

## COURSE AND PROGNOSIS

Although childhood conduct disturbance is common, it persists into adulthood in only about one third of cases (Rutter 1989). In contrast, ASP is almost always preceded by CD in childhood (Robins 1966, 1978). Thus, the presence of conduct disturbance in childhood is not in itself predictive of chronicity. Moran reports a prevalence rate of antisocial personality disorder between 2 and 3% in the general adult population (1999). Study data on longitudinal course are influenced by the defining characteristics of the sample studied. Clinic-based samples usually differ in important ways from those collected epidemiologically. Thus, care must be taken when generalizing across studies. As previously noted, aggression and delinquency are concepts that overlap with CD but are not synonymous with it. Nonetheless, longitudinal studies of these behavioral dimensions yield information important to our understanding of CD.

Rates of psychiatric comorbidity with CD are known to be high, and may in part explain the significant functional impairment in children with CD. As such, understanding the nature and longitudinal course of comorbidity may be helpful in recognizing and treating children with CD. Six waves of structured diagnostic assessments over a period of seven years in a group of 168 clinic-referred boys, revealed a parallel longitudinal relationship between conduct disorder behaviors and symptoms of ODD, ADHD, depression, and anxiety (Lahey et al. 2002). CD and ODD behaviors were found to be symmetrically associated, in that early CD symptoms presaged ODD symptoms in later waves and vice-versa. In contrast, the CD behavior association with ADHD, depression, and anxiety symptoms was asymmetric. Early high symptom levels of ADHD, depression, and anxiety did not presage high levels of CD behaviors in later waves, though high early levels of CD did presage later high symptom levels of ADHD, depression, and anxiety. The results support the notion that ODD symptoms are often seen

as a precursor to later CD symptoms. In a group of 4,500 children, the Great Smoky Mountains Study examined models of the relationship between ODD and CD (Rowe et al. 2002). Over four waves of data collection, ODD was a strong risk factor for CD among boys but not girls.

The landmark study of CD outcome was Lee Robins's longterm follow-up of children who attended a St. Louis, Missouri, child guidance clinic in the 1920s and 1930s (Robins 1966). This study made the important observation that persistence of CD was predicted not by any one specific CD symptom but rather by the quantity of symptoms.

DSM-IV includes subtypes of CD based on age of onset (age 10 or younger versus age 11 or older). These subgroups differ markedly in level of physical aggression: those with early-onset CD are more likely to exhibit aggression than those with late-onset CD (Lahey et al. 1998). Evidence suggests a relatively early onset of CD among boys with ADHD (Biederman et al. 1996; Hinshaw et al. 1993).

Community-based studies in New Zealand (McGee et al. 1992) and Canada (Offord et al. 1992) have provided data on the shorter-term course of CD. In the Canadian study, close to half (45%) of the children with CD at age 4 to 12 years still had CD when followed up 4 years later (Offord et al. 1992). Moreover, the presence of CD also predicted emotional disorder at follow-up in 29% of subjects. Four-year follow-up of the New Zealand birth cohort revealed that the presence of a disruptive behavior disorder (CD, oppositional defiant disorder, or hyperactivity) at age 11 years predicted a disruptive behavior disorder at age 15 years for boys *but not for girls* (McGee et al. 1992).

Childhood-onset aggression is a significantly stable characteristic (Farrington 1991; Loeber 1991; Olweus 1979) that has considerable prognostic import both within CD and for a broad range of (overlapping) poor outcomes: subsequent aggression (Huessmann and Eron 1984; Loney et al. 1981; Pfeffer et al. 1983), illegal drug involvement (Farrington 1991; Loney et al. 1981), criminal activity (Douglas 1966; Ensminger et al. 1983; Farrington 1991; Feldhusen et al. 1976; Huessmann and Eron 1984; Morris et al. 1956; Stattin and Magnusson 1989; Farrington 1991). A significant limitation is the paucity of data on the outcome of aggressive behavior in girls; almost all of the available information derives from studies of males (Offord & Bennett 1994). Early pregnancy and adult diagnosis of antisocial personality disorder are known potential outcomes of girls with CD (Bardone et al. 1996; Kovacs et al. 1994; Robins et al. 1991; Zoccolillo and Rogers 1991).

## INTERVENTION

### Prevention

Prevention of CD appears to require very early intervention (Webster-Stratton & Taylor 2001). Because pediatric behavioral disturbances have been associated with low birth weight, prematurity, obstetric complications, physical

**TABLE 12.3**  
**INTERVENTION FOR CONDUCT DISORDER**

1. Thorough assessment using multiple information sources with special attention to risk and resiliency factors. Identify all significant problems. Address severity and course both in terms of past history and of future risk.
2. Identify strength and resilience factors in the environment as well as within the individual to mobilize and build upon for treatment. Consider the fit of the behavior within its environmental context.
3. Identify all significant problem domains and plan for each of them. Prioritize impact.
4. Mobilize, strengthen and support parenting of the youth.
5. Address supervision and behavioral management needs.
6. Treat comorbidity.
7. Consider pharmacotherapy as an adjunct for certain targeted behaviors (e.g. affective aggression).

Source: Adapted from AACAP practice parameters for Conduct Disorder (Steiner et al, 1997)

anomalies, maternal illness, child maltreatment, poor nutritional status, parental substance use, weak or harsh parenting, and maternal rejection it is logical that efforts to minimize such risks may help prevent CD. Home visitation is an instructive example. Early childhood home visitation programs have parents and their children visited in home by trained personnel during the first 2 years of the child's life. Support, information or training about child development, health and care are the usual elements. Review of 21 studies found home visitation of young mothers reduced child maltreatment by about 40% compared to controls, but insufficient evidence was available to determine the effectiveness in preventing violence by the children who had been visited (Hahn et al. 2003).

### Intervention

Broad guidelines for the treatment of conduct disorder are presented in Table 12.3 as adapted from the American Academy of Child and Adolescent Psychiatry's Practice Parameters (AACAP 1997), the Surgeon Generals Report on Mental Health (US Dept of Health and Human Services 1999), and Vermont State Interagency Team recommendations for treatment of Conduct Disorder (McMains et al. 2003).

### Psychosocial Intervention

Psychosocial interventions are first line treatments that must address a wide array of features, including CD symptoms, comorbid diagnoses, other concurrent problems, and the context in which the child lives. A spectrum of interventions may be needed, depending on the severity of the disorder, the individual's response to less intense treatment, and the risk he or she presents to self, others, and the community. Wide-ranging intervention strategies have

been termed *multimodal* or *multisystemic*, indicating that a variety of therapeutic modalities are to be applied to a range of systems that relate to or interface with the child (Henggeler et al. 1998).

Interventions for CD in pediatric age groups take advantage of the fact that CD is more environmentally responsive than adult ASP (Cadoret et al. 1995; Lyons et al. 1995; Reiss et al. 1995). Among the components of CD interventions, efforts that support parenting and behavioral monitoring/treatment are a mainstay. A review (Brestan & Eyberg 1998) entitled "Effective psychosocial treatments for conduct-disordered children and adolescents: 29 years, 82 studies and 5,272 kids" found two interventions that met criteria as having well-established efficacy, parent training programs based on Patterson & Guillon's manual *Living with Children* (1968) and videotaped modeling parent training (Webster-Stratton 1984). Parent management training focuses upon training parents to both develop and implement contingency management programs. Such programs involve establishing clear behavioral goals, reinforcing steps in the direction of the goals and providing consequences for inappropriate behavior. Parent management training programs also seek to improve the quality (and sometimes the quantity) of parent child interaction, supervision and monitoring. As seen in Table 12.4, much of the practical advice for conduct disorder management in primary care settings (Searight et al. 2001) reflects contingency management and parent education.

Subsequent review of more than 500 programs designed to treat and prevent youth antisocial behavior found just 3 that reduced adolescent criminal behavior (Mihalic et al. 2001). All three are manualized family-based ecological

**TABLE 12.4**  
**PRACTICAL INTERVENTIONS FOR MANAGEMENT OF PATIENTS WITH CONDUCT DISORDER IN PRIMARY CARE**

- Assess severity and refer for treatment with a subspecialist as needed.
- Describe the likely longterm prognosis without intervention to caregiver.
- Structure children's activities and implement consistent behavior guidelines.
- Emphasize parental monitoring of children's activities (where they are, who they are with). Encourage the enforcement of curfews.
- Encourage children's involvement in structured and supervised peer activities (e.g., organized sports, Scouting).
- Discuss and demonstrate clear and specific parental communication techniques.
- Help caregivers establish appropriate rewards for desirable behavior.
- Help establish realistic, clearly communicated consequences for noncompliance.
- Help establish daily routine of child-directed play activity with parent(s).

**TABLE 12.5**  
**COMMON PROPERTIES OF 3 TREATMENTS WHICH DECREASED CRIMINAL BEHAVIOR**  
**IN ADOLESCENCE**

- Treatment planning is informed by the science base about risk factors and tailored to the youth and family’s social ecology. E.g. All seek to limit contact with antisocial peers, to increase family monitoring, to use behavioral techniques to structure home and school settings and to increase prosocial contact and activities.
- Engaging the family in treatment is a necessary step
- Once engagement has occurred, parent training and behavioral techniques are utilized to push behavioral change
- Generalization is a later step which seeks to integrate indigenous resources
- Manualized treatment delivered by trained therapists accompanied by quality assurance and treatment fidelity methodology

Source: Adapted from Henggeler & Sheidow,

models: multisystemic therapy (MST) (Henggeler et al. 1998); functional family therapy (Alexander et al. 1998) and multidimensional treatment foster care (Chamberlain & Mihalic 1998). Elements common to the three treatments are outlined in Table 12.5.

Supervision, monitoring and behavioral management interventions for youth with CD can involve systems or settings beyond a parental home. Levels of intervention have been outlined for the treatment of acute psychiatric illness and follow a general principal of “least restrictive” setting ranging from general outpatient treatment up to hospitalization (APA & AACAP 1997). Some recent data support the least restrictive concept. A trial comparing traditional inpatient hospitalization to multisystemic therapy (MST) for youth referred for psychiatric hospitalization found MST was more effective at decreasing youths’ externalizing symptoms and improving their family functioning and school attendance four months after randomization (Henggeler et al. 1999). However, even with intensive treatment and commitment to family collaboration, hospitalization, or therapeutic foster care may be needed (Henggeler et al. 1999). Therapeutic foster care involves placement of youth in homes with foster parents trained to provide a structured environment that supports the child learning social and emotional skills. Some data suggest therapeutic foster care can reduce violence by chronically delinquent adolescents (Hahn et al. 2004). One randomized controlled trial assessed the effects of therapeutic foster care, which included active collaboration with program personnel on a daily basis, with group home placement using reported felony assaults as an outcome measure (Chamberlain & Reid 1998). Program intensive therapeutic foster care reduced felony assaults by 73%. Subsequent analysis of data from that study found that family management skills (discipline, supervision, and a positive adult child relationship) and deviant peer association explained 32% of the variance in outcome (Eddy & Chamberlain 2000).

Analyses of the ecological family-based treatments for juvenile delinquents discussed above are very encouraging in terms of cost effectiveness (Aos et al. 2001; Miller and Levy 2000). However, caveats exist. One limitation is that

many studies involve conduct *problems* rather than address those individuals meeting full criteria for CD. Only 28% of studies Brestan & Eyberg (1998) reviewed included subjects meeting DSM criteria for *CD or oppositional defiant disorder*. There are studies that include clinically severe “real world” samples. For example, the Multisystemic Treatment (MST) studies of Henggeler et al. (1999, 2002) treat substance abusing delinquents or youth presenting for psychiatric hospitalization. Results of MST are encouraging and consistent with the Surgeon General’s recommended treatment emphases (i.e., family-focused, attending to multiple determinants of problems, and strength based) (USPHS 2001). Four randomized trials demonstrated the capacity of MST to achieve improved longterm (> 2 year) outcomes (Henggeler et al. 2003). However, assuming the results generalize to those with the DSM-IV conduct disorder diagnosis or to predominantly mental health populations is likely to be unfair. In the study of MST as an alternative to hospitalization, 33 of 109 subjects had caregiver DISC interviews meeting criteria for conduct disorder (Henggeler et al. 1999). Thus, the bulk of subjects in that study did not meet CD criteria.

Treatment of comorbid conditions is a logical part of conduct disorder/aggression treatment algorithms (Kruesi & Lelio 1996; Pappadopulous et al. 2003; Kutcher et al. 2004), but may or may not impact CD symptoms. For example, a controlled trial of cognitive behavioral therapy (CBT) for depression in 93 adolescents with depression and conduct disorder found that CBT improved Beck depression scores post treatment but did not improve CD (Rohde et al. 2004). In contrast, 11 of 13 prepubertal boys with comorbid CD and depression had improvement in their conduct disorders when their depression went into remission (Puig-Antich et al. 1982). Although there is some uncertainty about the degree to which treatment of comorbid conditions impacts conduct disorder, there is a definite deleterious impact of psychiatric comorbidity upon the treatment of delinquents. The lasting results seen in the juvenile justice based samples treated with MST were not found to persist in a psychiatric population (Henggeler et al. 2003).

## Psychopharmacologic Interventions

Currently, there are no United States Food and Drug Administration (FDA) approved medication indications for conduct disorder. Despite the salience of violence and the suffering it causes, there is comparatively little investigation of pharmacologic intervention for aggression and inquiry has often been limited by meager financial support and stalled by political concerns (Enserink, 2000, Kruesi, in press). However, many readers may be surprised to note that chlorpromazine carries a long-standing FDA indication for “the treatment of severe behavioral problems in children (1 to 12 years of age) marked by combativeness and/or explosive hyperexcitable behavior” (FDA Web-site, [www.fda.gov](http://www.fda.gov)). Traditionally, pharmacological approaches to conduct disorder have focused on comorbid conditions, such as ADHD or affective disorders, or on specific target symptoms that mimic symptomatology of other disorders. The most well-studied classes of medications for use in CD include the mood stabilizers, neuroleptics, and stimulants.

### Mood Stabilizers

Evidence for the utility of mood stabilizers in aggression/conduct disorder is gradually growing. Lithium has been a treatment for adult bipolar disorder for several decades. Since manic aggression responds to lithium, it has been proposed that aggression associated with conduct disorder may also respond to this medication. Thus far, three placebo-controlled trials, including a combined total of 151 subjects, have yielded positive results (Campbell et al. 1984; Campbell et al. 1995, Malone et al. 2000). However, Rifkin and colleagues observed no separation from placebo for lithium among 33 adolescent inpatients with CD (1997). Additionally, problems with compliance as well as the potential for significant adverse effects and toxicity may limit lithium’s use among youths with CD.

Donovan and colleagues have investigated the use of divalproex among children with disruptive behaviors. An open trial among ten subjects (1997) and a double blind, placebo-controlled study among twenty youths (2000) revealed positive results. Steiner and colleagues conducted a seven-week randomized, controlled trial of divalproex in seventy-one youths with CD, noting significant symptom improvement among those receiving a dose usually associated with the therapeutic range for anticonvulsant usage (2003). Divalproex was well tolerated by the subjects in these studies. While these initial results are encouraging, further study must be undertaken to further elucidate the role of divalproex in treating CD.

Carbamazepine appeared effective in an open study among subjects with temper outbursts (Mattes 1990) and in controlled trials among youths with aggression and impulsivity (Groh 1976; Puente 1976), but was not superior to placebo in a double-blind study of twenty-two children with aggressive CD (Cueva et al. 1996).

### Neuroleptics

Neuroleptics are considered a treatment of later resort in patients with CD because of their potential side effects (Pappadopoulos et al. 2003; Schur et al. 2003; Kruesi & Lelio 1996). However, available evidence suggests neuroleptics will decrease some aggression. Pimozide, a neuroleptic, was effective in a study of ten children with antisocial behavior (Broche 1980). The typical neuroleptics haloperidol, thioridazine, and molindone were superior to placebo among inpatient CD patients (Campbell et al. 1984; Greenhill et al. 1985), though the potential for adverse events, including movement disorders, limits the use of typical neuroleptics among youths. Recent investigation of risperidone, an atypical neuroleptic, in CD (Buitelaar et al. 2001; Ercan et al. 2003; Findling et al. 2000) and in disruptive behavior among youth with subaverage intelligence (Aman et al. 2002; Snyder et al. 2002) have yielded positive results. Risperidone was generally well tolerated and likely poses less risk for movement disorders than typical neuroleptics. An open trial of olanzapine, another atypical neuroleptic, yielded improvement among six aggressive youths (Soderstrom et al. 2002). Further study of atypical neuroleptics may elucidate their role in treatment of CD. At present, risperidone appears particularly promising given its expanding evidence base. Caution is indicated, though, as atypical neuroleptics have increased risk for obesity, diabetes and dyslipidemia (American Diabetes Association 2004).

### Stimulants and atomoxetine

Stimulants and atomoxetine have FDA approved indications for ADHD. Given the frequent comorbidity of conduct or oppositional defiant disorders with ADHD (which may be as high as 80% in clinical samples (Abikoff & Klein 1992), stimulants have been investigated in youths with both diagnoses, with generally positive results (Gadow et al. 1990; Hinshaw et al. 1992; Kaplan et al. 1990; Klein et al. 1997; Kolko et al. 1999). Of note, one third of the subjects in the study conducted by Klein and colleagues met criteria for CD but not ADHD. Interestingly, these subjects exhibited positive effects, which may indicate a role for stimulant treatment in CD without ADHD. Similarly encouraging are the results of a meta-analysis of stimulant effects on aggressive behaviors in ADHD, which revealed effect sizes similar to those for the core symptoms of ADHD (Connor et al. 2002). But, a recent trial of pemoline in conduct disorder youth found that although ADHD symptoms improved, CD did not (Riggs et al. 2004).

### Other agents

Controlled studies with other agents are lacking. Antidepressants may play a role in treatment, given the frequent comorbidity between CD and affective disorders. An open trial of fluoxetine in eight adolescents with major depression, CD, and substance use disorder yielded positive

results (Riggs et al. 1997). Some children have had uncomfortable side effects with fluoxetine (Riddle et al. 1991). Safety and tolerability in children is reflected in both its FDA approval for treatment of childhood depression and its FDA public health advisory about the possibility of increased suicidality (<http://www.fda.gov/cder/drug/antidepressants/AntidepressantsPHA.htm>). Open trials of trazodone among aggressive inpatient youths also revealed symptom improvement (Ghaziuddin and Alessi 1992; Zubieta and Alessi 1992). Clonidine, an alpha-adrenergic agonist often used as an adjunctive agent in ADHD, was effective in reducing aggression in open studies (Hunt et al. 1986; Jaselskis et al. 1992; Kempf et al. 1993). Additionally, a pilot study investigated clonidine and methylphenidate, each alone or in combination, among three randomized groups of eight male children with ADHD and comorbid aggressive oppositional defiant or conduct disorder, revealing significant improvements in oppositional and conduct disordered symptoms (Connor et al. 2000).

### Summary and Conclusions

Our neuropsychiatric understanding and appreciation of conduct disorder grows and the time to cease confusing conduct disorder, psychopathy, delinquency and aggression has arrived. The disorder appears to involve frontal and temporal brain regions and may also be expressed in structural, autonomic, and reproductive features.

Recognition of the enormous impact of conduct disorder/sociopathy is in its beginning stages. Knowledge of the evolutionary fit of the disorder is primitive. But as a society, we need to recognize that mistreatment of children (e.g. abuse, neglect, and prenatal malnutrition) increases the risk for and perhaps the prevalence of conduct disorder/ASP (Jaffee et al. 2004). Genetic influences are present whether conduct disorder/sociopathy, delinquency/crime, aggression, and/or psychopathy are the behavioral outcomes of interest. Interactions of the environment and genes as well as gene-gene interactions are receiving increasing recognition for their relevance to conduct disorder/sociopathy. But, the mechanisms remain elusive.

Conduct disorders are heterogeneous. Evidence mounts that parsing psychopathy, particularly the callous-unemotional dimension from CD, will be useful in increasing our understanding and in designing better interventions.

# Pediatric Mood

13

## Disorders

*Robert A. Kowatch, MD*    *Melissa P. DelBello, MD*    *Taryn Mayes, MS*  
*Beth D. Kennard, PsyD*    *Graham J. Emslie, MD*

Pediatric mood disorders include depressive disorders (major depression and dysthymia) and bipolar disorders (bipolar I and II disorder, and cyclothymia). These are prevalent disorders in children and adolescents which cause significant morbidity and mortality. The course of illness for children and adolescents with mood disorders is generally chronic and most will continue to have mood disorders into adulthood. In this chapter, we examine mood disorders in the pediatric population from a neuropsychiatric perspective. In this context, we emphasize the use of established criteria for diagnosis and the neurobiology of these disorders. Specifically, we (1) discuss the diagnosis, epidemiology, and course of mood disorders; (2) review the neurobiology of mood disorders; and (3) describe how pediatric mood disorders are treated. These areas are examined as they relate to children and adolescents with mood disorders, with reference to adult information where relevant.

### DIAGNOSIS

The diagnosis of a mood disorder in a child or adolescent requires careful and systematic interviewing of the child, the parent, or the guardian. Other sources of information about the child (e.g., school personnel) are often useful as well. A number of instruments are available for assessing mood disorders in children and adolescents. Structured and semistructured interviews are used to elicit symptoms and to establish whether a child meets certain diagnostic criteria. Items from the diagnostic interviews have also

been used as clinical-severity measures (the Kiddie Schedule for Affective Disorders and Schizophrenia [K-SADS]). Diagnostic interviews vary in the degree of clinical experience required for their administration, whether or not they are computerized, and which mood disorders they target. These instruments are not restricted to research applications; the availability of computerized interviews can assist clinicians in ascertaining that all diagnostic domains are covered. Structured psychiatric interviews require continual modifications as diagnostic criteria change. Clinician-rated and self-report measures of clinical symptom severity can be a useful addition to ongoing clinical management, even though the unreliability of self-report measures in pediatric and adolescent populations is well documented. Self-report measures have been used to screen large populations. Kandel and Davies (1986) reported on 1,004 adolescents identified as having depressive symptoms on a self-report scale. When followed to adulthood, subjects with depressive symptoms showed a poorer outcome compared with those without depressive symptoms, a finding that supports the partial validity of these measures.

Depressive disorders are generally characterized as either major depressive disorder or dysthymic disorder. Major depressive disorder (MDD) and dysthymic disorder differ with regard to the prominent and persistent nature of the mood disturbance or pervasive anhedonia and the number and intensity of associated symptoms. Dysthymic disorder is longstanding (greater than 1 year's duration), with depressive moods and feelings and variable vegetative symptoms that fluctuate with no prolonged stable (well) states. Patients with dysthymic disorder have a significantly elevated risk of

experiencing a superimposed major depressive episode. Criteria for MDD are the same in children and adolescents as in adulthood, except that youth may present with irritable mood, even in the absence of depressed mood. The presentation or dysthymia is consistent across the life span, but may be present for only 1 year in youth, rather than the required 2 years for adults. Age-related and gender-related differences in depressive symptom presentation are difficult to detect, if they do indeed exist. Eliciting symptoms from children and adolescents is somewhat difficult, particularly in younger children, as they are often not cognitively developed enough to express their experiences. Kovacs (1996) suggested children might have less hypersomnia, more appetite and weight changes, and delusions as compared to adolescents. Luby et al. (2003) concluded that depressed preschool children show less “masked” symptoms (e.g., sleep problems, appetite changes) and more typical symptoms (e.g., anhedonia, sadness/irritability).

Many children and adolescents are labeled “bipolar” without careful consideration of the diagnostic complexities and subtypes of this disorder. The symptoms of bipolarity in children and adolescents can be difficult to establish because of the variability of symptom expression depending on the context and phase of the illness, the effects of development upon symptom expression, and the mood and behavioral effects of the various psychotropic medications that the patient is taking. Children and adolescents with a bipolar disorder (BPD) often present with a mixed or “dysphoric” picture characterized by frequent short periods of intense mood lability and irritability rather than classic euphoric mania. Clinicians who evaluate children with pediatric bipolar disorders often try to fit them into the DSM-IV “rapid cycling” subtype and find that this subtype does not fit bipolar children well, as these children often do not have clear episodes of mania. Rather, researchers are reporting that bipolar children cycle far more frequently than four episodes per year. In 81% of a well-defined group of patients, continuous daily cycling from mania or hypomania to euthymia or depression was reported. Findling et al. (2001) reported that in a sample of 90 bipolar I subjects with a mean age of 10.8 years that the age of the first manic episode was 6.7 years with 50% of these patients categorized as “rapid cycling.” The picture that emerges from several independent research groups is that prepubertal bipolar children typically have multiple daily mood swings and that irritability is much more common than euphoria.

There are also a number of medications and medical disorders that may exacerbate or mimic bipolar symptoms, and it is important to assess these potential confounds before initiating treatment. Potential medical disorders and medications that should be evaluated before making the diagnosis of a pediatric BPD are listed in Table 13.1.

A complete evaluation of children and adolescents with a mood disorder should include a detailed family history of psychiatric illnesses that includes first-degree, second-

degree, and third-degree relatives. The offspring of adults with affective illness show a high rate of depression and bipolar disorder. Conversely, the first-degree and second-degree relatives of children with major depressive disorder have a high aggregation of depression, alcoholism, anxiety, and other psychiatric diagnoses. It has been noted that children and adolescents with a mood disorder have a family history of mood disorders in 50 to 60% of cases, depending on which criteria are used (i.e., treated versus untreated, definite versus possible) and whether first-degree or second-degree relatives are evaluated.

In summary, as advised by the American Academy of Child and Adolescent Psychiatry (AACAP), a complete evaluation for a mood disorder is essential in developing an appropriate treatment plan. The assessment involves systematic interviewing of the child and the parent(s) independently to ascertain the presence (or absence) of specific symptoms of depressive and other psychiatric disorders. Family history, course of illness, number of episodes, presence of comorbid diagnoses, and psychosocial stressors may impact outcome, and need to be carefully evaluated to adequately diagnose and treat this population.

**COMORBIDITY**

The most common comorbid diagnoses in children with major depression are anxiety disorders (30 to 80%), disruptive disorders (10 to 80%), and substance use disorders (20 to 30%).

Anxiety disorders commonly co-occur in children with major depression (41%) and typically persist even after the depressive episode remits. Furthermore, the presence of social anxiety disorder in adolescence predicts major depression in young adulthood. Half of children diagnosed with dysthymic disorder have a co-occurring disorder. Anxiety disorders are commonly comorbid in children and adolescents with dysthymic disorder, especially separation anxiety disorder in children (33%) and generalized anxiety disorder in adolescents (67%). Conduct disorder (30%), attention deficit hyperactivity disorder (ADHD) (24%), and enuresis or encopresis (15%) are also commonly present in children with dysthymic disorder.

The most common comorbid diagnosis among bipolar youth is ADHD. Despite the high co-occurrence of juvenile mania and ADHD that has been reported in several studies, the relationship between these disorders remains unclear. Several studies have determined that ADHD is more common in prepubertal onset bipolar disorder than in adolescent onset bipolar disorder.

Another disorder that is frequently comorbid in children with bipolar disorder is conduct disorder. Kovacs and Pollock (1995) found a 69% rate of conduct disorder among 26 bipolar children and adolescents. Several studies report that conduct disorder in youth with bipolar disorder predicts a worse clinical course. Moreover, adolescents with bipolar disorder are five times more likely to develop a substance use disorder than those without bipolar disorder. Children and adolescents with pervasive developmental disorders may be at increased risk for developing mania.

## EPIDEMIOLOGY OF MOOD DISORDERS

The prevalence of depressive disorders in children and adolescents ranges from 0.4 to 8.3% and is greater in adolescents than in children. Dysthymic disorder is reported in 0.6 to 8.0% of children and adolescents. This prevalence compares with that in adults, in whom the 12-month prevalence of major depressive disorder is reported to be  $10.3\% \pm 0.8\%$  ( $12.9 \pm 0.8\%$  in women and  $7.7 \pm 0.8\%$  in men). This finding also highlights the gender differences in prevalence; whereas major depressive disorder in children appears to occur at about the same rate in girls and boys, the approximately 2:1 adult female:male ratio becomes evident in adolescents. Of particular relevance to children and adolescents is the suggestion of a secular trend in the onset of depressive disorders, which has been reported in both referred and nonreferred samples of children and adolescents. Ryan et al. (1992b) reported on siblings of prepubertal depressed and normal children and demonstrated that affective disorders are more frequent in siblings born more recently. Similarly, in a psychiatric referred depressed school-age sample, Kovacs and Gatsonis (1994) noted that the successive birth cohorts were younger when they first developed MDD. Thus,

the rate of depression in youth is likely increasing, and patients are presenting more frequently for treatment for these disorders.

In a large and well-designed population study of the incidence of mood disorders in adolescents, Lewinsohn et al. (1995) reported an overall lifetime prevalence of 1% for bipolar spectrum disorders which included bipolar I disorder, bipolar II disorder and cyclothymia. In this study, the largest groups of adolescent subjects were what Lewinsohn et al. (1995) called the “core-positive” group. These adolescent subjects reported a distinct period of elevated, expensive or irritable mood and best fit the DSM-IV criteria of bipolar disorder, not otherwise specified (NOS). These subjects had an overall prevalence of 5.7% and accounted for 84% of Lewinsohn’s bipolar sample. These bipolar NOS subjects also had high rates of psychosocial impairment and mental health service utilization like the bipolar type I subjects.

Wozniak et al. (1995) reported that of 262 consecutively referred children to a specialty pediatric psychopharmacology clinic, 16% met DSM-III-R criteria for mania. Isaac (1992) reported that eight out of 12 students in a special education class met DSM-III-R criteria for a bipolar disorder. In more specialized psychiatric settings like a pediatric psychopharmacology clinic, the occurrence of pediatric bipolar disorder is expected to be much greater than that found in the general population.

## E. COURSE/NATURAL HISTORY

The developmental course of mood disorders suggests that there is a continuum of pathology from childhood to adults. Similar to adults with depressive disorder, depressed children and adolescents often have a chronic course. Most studies report the average length of a major depressive episode in children and adolescents is 7 to 9 months. In a study of 42 child outpatients with MDD, Kovacs et al. (1984) found that 59% had recovered (asymptomatic for 2 months) by 1 year, 92% had recovered by 18 months. Strober et al. (1993) found that 81% of 58 adolescent inpatients with MDD had recovered by 1 year and 98% by 2 years from the time of admission, with the average time to recovery of 27.5 weeks from admission. They also reported that 28% of those with psychotic depression developed mania over the 2-year follow-up period. Similarly, McCauley et al. (1993) found that 80% of predominantly outpatient children with major depression had recovered by 1 year.

While most children and adolescents recover from the depressive episode, recurrence is common, possibly even more so than in adult depression. Recurrence (i.e., a new episode of depression) has been reported in 54 to 72% of depressed children and adolescents followed for 3 to 8 years, with similar rates seen in inpatients and outpatients.

Poznanski et al. (1976) report that 50% of a sample of depressed adolescent outpatients were depressed when contacted 6.5 years later. Eastgate and Gilmour (1984) contacted 19 of 36 child inpatients with depression 7 to 8 years after their episode and reported that 42% were psychiatrically ill, 21% with major depression. These rates are based on naturalistic follow-up studies, which do not take into account whether or not patients are on medication at the time of the recurrence or the length of time on medication prior to the recurrence. One study of relapse prevention in children and adolescents demonstrated that continued treatment with fluoxetine reduced relapse rates and delayed time to relapse over placebo. Factors contributing to recurrence of depression include comorbidity, severity of depression, hopelessness, low self-esteem, family dysfunction, stressful life events, and suicidality at baseline. In a longitudinal study investigating recurrence of MDD during adulthood (19 to 23 years of age) in formerly treated depressed adolescents, Lewinsohn et al. (2001) found that recurrence was predicted by multiple episodes of depression, family history of recurrence of major depression, borderline personality disorder symptoms, and increased conflict with parents (for females only).

Early onset depression often continues into adulthood for most (70%) children and adolescents. Kandel and Davies (1986) described poor adult outcomes in a large sample of adolescents ( $n = 1,004$ ) identified as having depressive symptoms using a self-report scale. Similarly, in a retrospective, longterm follow-up study of 80 depressed and 80 nondepressed outpatient adolescents, Harrington et al. (1990) reported that depressed adolescents were more likely than nondepressed adolescents to have depression in adulthood; however, they noted that most adult depressions are not preceded by adolescent depression. Weissman et al. (1980) studied 73 patients with adolescent onset depression into adulthood and found that while 37% survived without an episode of major depression in adulthood, there was substantial increased risk of suicide and adult major depressive disorder in adulthood than those without adolescent major depressive disorder.

Although there are few investigations of the outcome of childhood onset dysthymic disorder, children with dysthymic disorder are more likely to develop depressive disorders and recurrent affective illnesses. Moreover, co-occurring externalizing disorders predict worse outcome in children with dysthymia. Mean episode length is typically 4 years and children with dysthymia usually develop their first episode of major depression within 2 to 3 years after the onset of dysthymic disorder.

The outcome of bipolar disorder in children and adolescents has received little study. McGlashen (1979) interviewed 62 adult patients who met DSM-III criteria for mania and divided them into two groups: 35 with adolescent onset mania and 31 with adult onset mania. He reported that the adolescent-onset group had more hospitalizations,

displayed more psychotic symptoms, and were more frequently misdiagnosed as having schizoaffective disorder than the adult-onset group. Surprisingly, the adolescent-onset group had outcomes superior to those of the adult-onset group in terms of social relationships and their ability to work. In contrast, Geller et al. (2004) reported diagnostic stability in 93 prepubescent and early adolescent subjects. At 4-year follow-up, 86 of the patients were assessed and rate of recovery was 87%. However, rate of relapse after recovery was 64%. In these studies recovery was defined as no mania or hypomania for at least 2 weeks and relapse was defined as having full DSM-IV criteria for mania or hypomania and a Childhood Global Assessment Scale score of less than or equal to 60 for at least 2 weeks.

## NEUROBIOLOGY OF MOOD DISORDERS

There are several excellent reviews of the neurobiology of mood disorders, but the majority of this information is from adult studies as there have been relatively few investigations of the neurobiology of childhood and adolescent mood disorders. Biologic studies in children are difficult to implement since they often require several blood draws, subjects remaining still more long periods of time, and the overall cooperation of the children and adolescents.

### Neurotransmitter and Neuroendocrine Studies

Studies of neurotransmitters in depressed adults have focused on norepinephrine, serotonin, and acetylcholine. Serotonin (5-hydroxytryptamine) regulation has also been studied in adults with depression. Ryan et al. (1992a) reported that in response to L-5-hydroxytryptophan (5-HT) in 37 prepubertal depressed children secreted less cortisol and more prolactin than age-matched and gender-matched normal controls, suggesting a dysregulation of central serotonergic systems in childhood depression. Abnormalities of the hypothalamic-pituitary adrenal (HPA) axis, the hypothalamic pituitary-thyroid (HPT) axis, and the hypothalamic pituitary-growth hormone (HPGH) axis have been reported in depression in adults. However, cortisol hypersecretion, as measured by repeated samples over a 24-hour period or by nocturnal sampling, has not been identified in depressed children and adolescents although depressed adolescents showed a cortisol elevation at the approximate time of sleep onset. In one study (Rao et al., 1996) there was a trend toward elevated cortisol levels near sleep onset in adolescents with a course of recurrent depression as compared to those with no further episodes of major depression. DeBellis et al. (1996) found that prepubertal depressed children had lower cortisol levels during the first 4 hours of sleep than healthy controls.

Birmaher et al. (1996) found no significant difference between prepubertal children with major depression and normal controls in baseline or postcorticotropin releasing hormone (CRH) stimulation values of cortisol or adrenocorticotropin releasing hormone (ACTH). PostCRH ACTH may be increased in depressed children who have been abused as compared to depressed children who have no history of abuse. Nonsuppression of cortisol by dexamethasone has been found in many studies in depressed children and adolescents.

### Molecular Genetic Studies

There have been few molecular genetic studies of children with mood disorders, despite the fact that familial risk studies have suggested that early-onset major depression may be a more familial form of the illness than adult onset major depression. Two molecular genetic studies in children with bipolar disorders by Geller et al. (1999) have been reported. In the first study of a sample of bipolar children, the serotonin transporter linked promoter region (HTTLPR) short and long alleles were studied and the transmission disequilibrium test was negative in the children with bipolar disorder. The second study examined the linkage disequilibrium of catechol-O-methyltransferase (1-COMT) in bipolar children and transmission and the disequilibrium tests were not significant for preferential transmission of 1-COMT in this sample. The brain-derived neurotrophic factor (BDNF) belongs to a family of so-called neurotrophic factors, which were suggested to play an important role in modulating neuronal development, growth, survival, and synaptic plasticity of a broad variety of CNS neurons—processes nowadays believed to play important role in the neuropathogenesis of mood disorders. The BDNF gene was first reported to be localized on the short arm of chromosome 11 (11p13) and was later mapped at the boundary of 11p13 and 11p14. Findings of some linkage and association studies, including the studies of two samples from the NIMH Genetics Initiative bipolar pedigrees, provide evidence that the BDNF gene is located in a locus where other genes, contributing to the pathophysiology of BPD are located (11p13-p15). Two family-based association studies provided evidence that one or more sequence variants within or near the brain-derived neurotrophic factor (BDNF) gene show an association with susceptibility to BPD in adults. Geller et al. (2004) reported preferential transmission of the Val66 allele in 53 children with bipolar disorder indicating possible involvement of BDNF in prepubertal BPD.

It is still early in our knowledge about the molecular genetics of psychiatric disorders, and it is likely that multiple genes are involved that interact with each other and are expressed differentially during development. It is unlikely that a single genetic locus will be identified that causes either depressive or bipolar disorders in children or adolescents.

## NEUROIMAGING STUDIES

---

### Major Depressive Disorders

There have been few structural neuroimaging studies of children and adolescents with MDD. Steingard et al. (1996) retrospectively evaluated the magnetic resonance imaging (MRI) scans of children with MDD or dysthymia ( $n = 65$ ) and found that frontal lobe volume was decreased and lateral ventricular volume was increased as compared to hospitalized psychiatric controls ( $n = 18$ ). No group difference was found in total cerebral volume. In contrast, in a more recent study, the same authors reported whole brain volumes were significantly smaller in depressed adolescents compared with the healthy comparison subjects. Additionally, in the latter study they found significantly smaller frontal white matter volumes and significantly larger frontal gray matter volumes in the depressed adolescents after controlling for age and whole brain volume. These results are similar to findings from MRI studies of adults with MDD that suggest prefrontal abnormalities. Similarly, in another study, Nolan et al. (2002) reported patients with nonfamilial MDD had larger left-sided prefrontal cortical volumes than patients with familial MDD and controls. Moreover, in a positron-emission tomography (PET) study of familial bipolar and MDD depressed subjects, Drevets et al. (1997) reported decreased activity and grey matter volume in the subgenual prefrontal cortex, indicating that nature of prefrontal abnormalities may be different depending on the presence of family history of affective illness. Together, these studies suggest the importance of considering family history in neuroimaging studies. Additionally, other studies have reported structural abnormalities in the subgenual prefrontal cortex in young women with adolescent onset MDD, suggesting that this prefrontal region may be particularly important in the neurophysiology of early onset and familial MDD.

In general, structural MRI studies of adults with MDD have found decreased subcortical volumes. There have been relatively few morphometric investigations that have examined structures other than the frontal cortex in MDD youth. In one study, MDD adolescents had 25% increased pituitary gland volumes, suggesting pediatric MDD may involve neuroendocrine dysfunction. Frodl et al. (2002) found enlarged amygdala volumes compared to patients with recurrent MDD and healthy controls, suggesting this finding may be a marker for MDD early in illness course. Indeed, increased amygdala: hippocampal volume ratios that were associated with severity of anxiety and not depression were observed in pediatric MDD patients prior to treatment as compared to healthy controls. This study suggests the importance of considering comorbid illnesses in imaging studies of pediatric patients with affective disorders. Similarly, the presence of prior suicide attempts has been associated with increased number of white matter

hyperintensities (WMH) in MDD youth. However, the temporal relationship between suicide attempts and WMH remains unclear.

To our knowledge, there have been four published functional neuroimaging studies in children or adolescents with MDD. Kowatch et al. (1999) used technetium-99m hexamethylpropylene amine oxime (99mTc-HMPAO) single photon emission tomography (SPECT) to compare relative rCBF between unmedicated MDD adolescents ( $n = 7$ ) and healthy controls ( $n = 7$ ) and described relative increases in rCBF in the mesial, right superior-anterior and left infero-lateral temporal lobe and decreases in the left parietal lobe, anterior thalamus, and right caudate in MDD adolescents. These findings suggest that adolescents with MDD exhibit rCBF abnormalities similar to those found in adults with MDD with involvement of the limbic-thalamic-cortical circuit and portions of the basal ganglia.

In another 99mTc-HMPAO SPECT study, evaluating untreated MDD adolescents ( $n = 14$ ) and age-matched normal controls ( $n = 11$ ), Tutus et al. (1998) calculated a relative perfusion index (PI) as the ratio of regional cortical activity to the whole brain activity and reported significant reduced PI in the left anterior frontal and left temporal cortical regions of untreated MDD adolescents. SPECT scans repeated after MDD adolescents were treated and their depression remitted demonstrated a return toward normal. This study suggests that adolescents with MDD may have state-dependent regional cerebral blood flow deficits in frontal and temporal regions and right-left perfusion asymmetry compared with normal subjects, similar to results in studies of MDD adults.

In a more recent study, Dahlstrom et al. (2000) used SPECT to study serotonin and dopamine transporter levels in drug-naïve children and adolescents with MDD ( $n = 31$ ) and children and adolescents without depression ( $n = 10$ ). They found significantly higher serotonin transporter availability in MDD children in the hypothalamic/midbrain region, suggesting that abnormalities in serotonin might play a role in the physiology of pediatric MDD. In a small study using functional magnetic resonance imaging (fMRI), children with anxiety disorders showed an exaggerated amygdala response to fearful faces compared with healthy children, whereas depressed children showed a blunted amygdala response to these faces. In addition, the magnitude of the amygdala's signal change between fearful and neutral faces was positively correlated with the severity of everyday anxiety symptoms, suggesting that amygdala dysfunction is present in youth with anxiety disorders and those with MDD, although the nature of the dysfunction may differ between disorders.

There have been several MRS studies of MDD youth. Reduced anterior cingulate glutamine/glutamate/GABA concentrations associated with severity of functional impairment was reported in one study of MDD youth.

MRS studies of adults with MDD also suggest reduced anterior cingulate Glx peaks. Another study reported increased levels of orbitofrontal choline in depressed adolescents, suggesting abnormalities in cell membrane metabolism may underlie the neurophysiology of MDD in youth. Similarly, Farchione et al. (2002) demonstrated elevated choline in the left dorsolateral prefrontal cortex (DLPFC) of MDD youth. Increased thalamic choline specific to youth with obsessive-compulsive disorder (OCD) and not MDD youth or healthy controls was reported by Smith et al. (2003), suggesting that this finding may be useful as a diagnostically specific biological marker for pediatric OCD.

## Bipolar Disorders

Structural magnetic resonance imaging (MRI) studies of adults with bipolar disorder have revealed several abnormalities including decreased prefrontal cortex volumes, increases in the volume of the amygdala and putamen, and atrophy of the V3 vermal area and larger lateral ventricles. Additionally, increased white matter hyperintensities are commonly identified in adults with bipolar disorder, although their significance is unknown. Structural MRI studies of children and adolescents with bipolar disorder have also revealed several neuroanatomical abnormalities, including an increased incidence of subcortical white matter hyperintensities, reduced intracranial volumes, increased frontal and temporal sulcal size, reduced thalamic area, reduced amygdala volumes, and increased putamen volumes.

The results of SPECT and PET studies of bipolar adults suggest rCBF abnormalities in both the frontal and temporal cortex. In general, investigators report increased rCBF in patients during mania and decreased rCBF during depression in adults with bipolar disorder. However, many of the SPECT and PET studies failed to report whether subjects and healthy comparison groups were diagnosed using standardized diagnostic interviews as well as the effects of confounding variables, such as medications. To our knowledge, there have been no published SPECT or PET studies in children or adolescents with bipolar disorder.

fMRI is a noninvasive imaging technique that does not involve exposure to ionizing radiation and has the advantage of better spatial and temporal resolution than PET or SPECT. The ability to recognize unique identities and forms of affect in human faces is an essential component of human social behavior, and the use of neurobehavioral probes, such as human facial affect recognition, with fMRI allows greater sensitivity and specificity in identifying the neural systems involved in mood disorders. There have been several fMRI studies in children where faces were used as neurobehavioral probes, and the Ekman facial recognition paradigm with the Ekman face set is most often used. Thomas et al. (2001) studied a group of

12 normal children with a mean age of 11 years with fMRI. In this experiment, the subjects passively viewed fearful and neutral Ekman faces. They reported predominantly increased left amygdala and substantia innominata brain activation during the presentation of nonmasked fearful faces relative to fixation and a decrease in activation in these regions with repeated exposure to the faces. In a similar fMRI study with the Ekman faces, Thomas et al. (2001) studied 12 children with generalized anxiety or panic disorder, 12 healthy controls, and five girls with major depressive disorder. In this experiment, children with anxiety disorders showed an exaggerated amygdala response to fearful faces compared with healthy children, whereas depressed children showed a blunted amygdala response to these faces.

There are few published fMRI studies in patients with bipolar disorder. Yergelun-Todd et al. (2000) found increased left amygdala and decreased dorsolateral prefrontal cortex activation in adults with bipolar disorder as compared to normal controls using the Ekman fearful and happy faces as visual stimuli. However, the differences observed may have been due to group differences in performance since all of the normal controls and only 10 of 14 (71%) bipolar patients were able to correctly identify the fearful Ekman faces. Blumberg et al. (2003a) evaluated regional brain activation in adults and adolescents with bipolar disorder using a Stroop task. They reported dorsal anterior cingulate and prefrontal cortical activation in controls and bipolar adults. Right ventral prefrontal activation was decreased in the manic bipolar adults, and left ventral prefrontal cortical activation was increased in depressed bipolar adults compared with euthymic bipolar adults. Rostral left ventral prefrontal cortical activation was decreased in bipolar adults as compared to the healthy controls, independent of mood state, suggesting that adults with bipolar disorder exhibit a trait abnormality in left ventral prefrontal cortex and that additional ventral prefrontal abnormalities may be associated with specific acute mood states. In a similar fMRI study, adolescents with bipolar disorder demonstrated an increase in activation in left putamen and thalamus compared with healthy adolescents. Age was positively correlated with signal increases in the bilateral rostroventral prefrontal cortex and the striatum in the healthy adolescents but not in the bipolar adolescents, suggesting that a developmental disturbance in prefrontal function may emerge in bipolar disorder over the course of adolescence.

Magnetic resonance spectroscopy (MRS) is a noninvasive neuroimaging technique that provides *in vivo* information regarding the concentration of specific biochemicals in localized brain regions. A benefit of MRS is that no ionizing radiation is used, thereby allowing serial studies to be performed on a subject. Typical isotopes evaluated with MRS include hydrogen or proton ( $^1\text{H}$ ), lithium ( $^7\text{Li}$ ), carbon ( $^{13}\text{C}$ ), fluorine ( $^{19}\text{F}$ ), sodium ( $^{23}\text{Na}$ ), and phosphorus ( $^{31}\text{P}$ ). Most of the studies of neurochemical changes in

patients with bipolar disorder have used  $^1\text{H}$  spectroscopy. There have been several studies of bipolar patients using magnetic resonance spectroscopy (MRS).

In general,  $^1\text{H}$  studies of adults with bipolar disorder report abnormalities in choline concentrations in the basal ganglia, suggesting abnormal cell membrane phospholipids metabolism. Additionally, decreased N-acetyl aspartate (NAA) has been reported in the dorsolateral prefrontal cortex (DLPFC), prefrontal gray matter, hippocampus, and lenticular nuclei of adults with bipolar disorder, suggesting neuronal loss or dysfunction or mitochondrial dysfunction may be present in these brain regions. In contrast, increased NAA has been reported in the thalamus of male adults with bipolar disorder, suggesting neuronal hypertrophy or hyperplasia or abnormal synaptic or dendritic pruning is present in this brain region. Decreased NAA is also found in the cerebellar vermis and DLPFC and of bipolar children with familial bipolar disorder, indicating that neuronal dysfunction or loss in these brain regions occurs early in the course of illness. Castillo et al. (2000) found increased prefrontal and temporal Glx concentrations in children with bipolar disorder, suggesting that in addition to structural abnormalities, neurochemical dysfunction may be present in these brain regions. The Glx resonance is composed of glutamate, glutamine, and GABA, and elevated Glx may be a sign of neurotoxicity.

MRS can also be useful to identify the neurochemical effects and predictors of response to medications commonly used to treat bipolar disorder. The *myo*-inositol (mI) peak is of particular interest when evaluating the effects of lithium. The phosphoinositide cycle is a major second messenger system by which lithium is thought to exert its therapeutic role in bipolar disorder. Lithium inhibits *myo*-inositol monophosphatase, thereby increasing inositol monophosphate (I-1-P) levels and decreasing *myo*-inositol levels in the brain. Lithium, by depleting *myo*-inositol, may slow down the phosphoinositide cycle in overactive synapses of bipolar patients. To evaluate the *in vivo* effects of lithium on brain *myo*-inositol, Moore et al. (2002) used  $^1\text{H}$  MRS to assess mI levels in depressed bipolar patients at baseline prior to receiving any medications, after 5 to 7 days of acute lithium treatment, and following 3 to 4 weeks of lithium treatment. A significant decrease in right frontal mI was observed as early as 5 to 7 weeks following lithium treatment. Since the reduction was detected prior to the onset of observed clinical improvement, the authors concluded that decreased mI may be an early marker for a more downstream second messenger mechanism by which lithium may exert its mood stabilization effects. In a similar study in bipolar youth, Davanzo et al. (2001) used  $^1\text{H}$  MRS to examine the anterior cingulate of 11 children and adolescents with bipolar disorder and 11 healthy adolescents and reported an elevation in *myo*-inositol/Cr in patients. Additionally, the authors report a significant reduction in mI following

acute lithium treatment in lithium responders, suggesting a reduction in mI may also be an early marker of lithium response in bipolar youth. However, this study is limited by most of the patients receiving concomitant medications. Future MRS studies evaluating the effects of lithium monotherapy, as well as the effects of other medications commonly used to treat bipolar disorder may facilitate targeted treatment intervention by identifying neurochemical predictors of treatment response.

In summary, neuroimaging studies of MDD youth suggest structural, function and neurochemical deficits in prefrontal regions. Additionally, abnormalities in amygdala structure and function have been observed, but seem to be associated with anxiety in MDD youth. Future studies examining other brain regions, including the striatum, are necessary.

## MOOD DISORDERS DUE TO GENERAL MEDICAL CONDITIONS

DSM-IV defines a mood disorder due to a general medical condition as a prominent and persistent disturbance of mood (depressed mood; markedly diminished interest or pleasure; or elevated, expansive, or irritable mood) that is judged to be due to the direct physiological effects of a general medical condition. Implicit in this definition is the assumption that treating the medical condition would result in elimination of the mood symptoms. Several general questions arise with regard to secondary mood disorders in the context of medical illness. First, are all mood symptoms and disabilities a consequence of the medical problem? Second, are there symptoms of both a primary mood disorder and a medical condition? Third, is the primary mood disorder causing increased morbidity in a known medical disorder? For example, in chronic infectious mononucleosis or chronic fatigue syndrome with depressive symptoms, is the disability a consequence of the infection, or does a primary mood disorder interact with the infection to cause a more protracted course?

Thyroid disease and infectious mononucleosis with an indolent course are commonly associated with mood disorders, and whether to routinely screen for these common or other rare disorders in children with mood disturbance remains a clinical decision based on history and physical examination. Laboratory testing rarely identifies occult medical disorders that are not evident from history and examination in child psychiatric populations. In this context, no routine laboratory evaluation studies are indicated. In children and adolescents presenting with mood disorders, features suggestive of an occult medical cause include atypical presentation of mood symptoms and poor or idiosyncratic responses to psychiatric treatment. In adults, the most frequent secondary causes of mania are corticosteroid use, human immunodeficiency virus (HIV) infection, and temporal lobe epilepsy.

## SUBSTANCE-INDUCED MOOD DISORDERS

### Substance Abuse/Dependence

Mood disorders can occur in association with acute intoxication with alcohol, amphetamines, cocaine, hallucinogens, inhalants, or other drugs of abuse. Also, mood symptoms can be associated with withdrawal from such drugs. Again, as with medical conditions, the assumption is that the substance is etiologically related to the mood symptoms. Mood symptoms in substance-abusing adolescents present significant clinical and diagnostic challenges. Although both primary and secondary mood disorders are common in substance-abusing patients, clinical treatment must initially focus on abstinence from continuing substance abuse, as evaluation and appropriate treatment of the primary mood disorder (if it is present) cannot take place while an individual is actively abusing substances.

### Mood Disorders Associated with Neurological Conditions

Studies have identified a high rate of psychiatric disorders in children and adolescents with various neurological conditions. The neurological disorders most commonly associated with psychiatric symptoms are brain injuries, epilepsy, migraine headaches, and learning disabilities.

#### Brain Injury

Although emotional and behavioral symptoms often associated with psychiatric disorders are frequently observed after brain injury, such symptoms are usually interpreted as either a direct effect of the injury or a normative reaction to the injury. Several groups have found increased rates of psychiatric disorders including depressive disorders in children following a head injury.

#### Epilepsy

The association between epilepsy and depression has received extensive study. Suicide has been reported to occur at a higher rate in patients with epilepsy than in those without epilepsy. Rutter et al. (1976), in the Isle of Wight study, found psychiatric disturbance in 58% of the 8-year-old to 10-year-old children with epilepsy. In adults with epilepsy, depression is common but mania appears to be rare. The association between epilepsy and depression is important for several reasons. First, in some patients with epilepsy, comorbid depression is associated with poor seizure control. One study has suggested that treatment with fluoxetine can reduce seizure frequency in patients with resistant epilepsy. Ojemann et al. (1987) also reported that seizure control and general functioning were improved when psychotropic medications were added to the subjects' anticonvulsant regimens. Second, an unrecognized depression can lead to

increased morbidity that often is wrongly attributed to the epilepsy. Third, some medications for epilepsy can cause a worsening of mood. Children and adolescents with epilepsy who continue to function poorly despite having adequate seizure control should be examined for mood disorders.

### **Migraine**

One of the first criteria for identifying depression in prepubertal children was suggested from a study of children manifesting severe headache. Of the 25 children presenting with headache, 4 of 16 (25%) with migraine headaches were depressed and 6 of 9 (64%) with nonmigraine headaches were depressed. Some of these children manifested classic migraine. Couch and Hassanein (1979) subsequently demonstrated that TCAs were efficacious in preventing migraine headaches in adults, regardless of the presence of depression. This finding raises the question of whether a common etiological mechanism may be operating in migraine and depression. Clinically, children and adolescents with frequent, incapacitating headaches (migraine or nonmigraine) often manifest depression. Treatment of the depression resolves both the frequent headaches and the depression. Commonly used medications for the prevention of migraine include beta-adrenergic blockers and periactin; these agents do not benefit depression.

### **Learning Disabilities**

The relationship between learning disabilities and affective disorders is a complex one. Children doing poorly in school often present with both learning disability symptoms and emotional/behavioral problems. It is an oversimplification to say either that the learning disability leads to the emotional problems or that the emotional problems are the only cause of the school failure. Initially it is helpful to assess both dimensions separately rather than assuming causation from an association. Affective disorder is the comorbid condition most commonly seen with learning disability.

The prevalence of mood disorders is higher in learning-disabled than in nonlearning disabled populations. The reasons for this difference in prevalence are not clear. It is possible that learning disabilities and the difficulties they cause induce mood disorders in susceptible individuals. Also, chronic mood disorders can, over time, interfere with school adaptation. There is evidence that neuropsychological deficits may accompany altered mood states, which in the developing individual could lead to delays in learning. However, for clinicians the association between learning disabilities and mood disorders is a familiar one, because a learning-disabled child with a mood disorder is more likely to be referred for evaluation than one without a comorbid affective illness.

## **TREATMENT**

### **General Management**

The treatment of children and adolescents with mood disorders is ideally multimodal. Family, school, and social environments are affected by these disorders and in turn may play a role in precipitating episodes of illness. Children, parents, and schools must all participate in treatment. The primary aim of treatment is to shorten the mood disorder episode, to prevent recurrence, and to decrease the negative consequences of depressive or manic episodes.

Education about mood disorders is essential for parents and affected children. Such information decreases self-blame and the tendency to blame others. It is common for schools to blame parents and parents to blame schools for a child's deteriorating behavior, and this can lead to inappropriate solutions to the problem, such as changing schools. Parents need to know that mood disorders represent biological conditions and not personality flaws. Coping with a mood disorder is a daily struggle. Specific therapies can be beneficial as an adjunct to management. Treatment should be individualized and based on need, resources, and assessment of stressors involved in a particular case.

In addition to eliciting the family's participation in managing the individual's symptoms, a family assessment is conducted to evaluate the premorbid level of family functioning, the parents' marital relationship, the impact of the mood disorder on the family, the family's understanding of the disorder, and their attempts to manage it. The family should assist in developing a treatment plan, including the identification of problem areas for change. Studies have found that at the time of treatment, 30 to 50% of depressed adolescents have a parent who is affectively ill. Thus, appropriate identification of parents who need treatment is important in the management of these patients.

As previously mentioned, the school setting is extremely important in the treatment process. Often, treatment includes adapting the patient's school setting in order to reduce stress. This strategy could take the form of shortening the school day; limiting the amount of schoolwork assigned, developing assignment-completion checklists, or arranging a more structured classroom setting; or using bypass compensatory strategies such as computers, calculators, and books on tape. For learning-disabled children, a continual focus on deficits can lead to worsening mood symptoms. Developing a positive school environment is essential for these children.

Many children with mood disorders have interpersonal problems resulting from social deficits. These deficits compound the depression and often contribute to feelings of worthlessness, hopelessness, and alienation. It is important for therapists, parents, and teachers to clarify reality for these patients. Group-therapy approaches that help build skills through role play, problem-solving techniques,

communication and assertiveness training, and strategies for self-control and conflict resolution can be effective.

### Psychotherapy of Depressive Disorders

Several studies indicated that specific psychotherapies are effective treatments for depression in adolescent populations. The most extensive research has been with cognitive-behavior group therapy, individual cognitive behavioral therapy and interpersonal psychotherapy (IPT) in adolescent populations. Individual psychotherapy for depression has been strongly influenced by earlier work in adults that primarily focused on cognitive therapy and interpersonal therapy. Modifications of these therapies for adolescents have been found to be effective and have resulted in the development of treatment manuals.

Cognitive behavioral therapy (CBT) is the most commonly used specific psychotherapy for children and adolescents with depression, and the most widely studied. As with adult populations, it is generally time limited and focused on identifying thought patterns and behaviors that contribute to the child's depression. Behavioral activation and problem-solving strategies are emphasized, as well as skill development. Several studies have demonstrated the effectiveness of child and adolescent CBT. For example, a study by Brent et al. (1997) compared CBT, systematic-behavioral family therapy (SBFT), and individual nondirective supportive therapy (NST) and found rates of remission to be 60%, 37%, and 39%, respectively. A meta-analysis of six controlled CBT studies in depressed adolescents yielded a reasonably robust overall posttreatment effect size of 1.02, whereas the overall effect size at 5 weeks to 3 months posttreatment was 0.61. Group CBT for adolescents has also been found to be effective with a response rate of 66.7% of subjects assigned to a CBT group, compared to only 48.1% of the waitlist controls.

Interpersonal therapy (IPT) is based on the premise that depressive illness operates in an interpersonal context. In particular, this treatment focuses on the resolution of four possible problem areas, including grief, interpersonal role disputes, role transitions, and interpersonal deficits. Thus, the goal of IPT when treating depression is to understand current relationships and renegotiate interpersonal problems occurring at the onset of depressive symptoms. IPT has demonstrated some effectiveness in the treatment of depressive symptoms in adolescents. In a controlled, single-blind study of clinical-referred depressed adolescents, IPT was found to be more effective than clinical monitoring for depressive symptom reduction and social functioning improvement. Similarly, in a 12-week open study of IPT for 25 moderately to severely depressed adolescents, 84% meet criteria for remission by the end of the treatment. In addition, IPT has also been shown to be effective in Puerto Rican populations.

Another potential treatment for severe depression, particularly in patients with a history of suicide attempts, is

dialectical behavior therapy (DBT). DBT was originally developed for adult chronically parasuicidal women diagnosed with borderline personality disorder (BPD) and was found to significantly reduce anger, suicide attempts, parasuicidal acts, and the number of inpatient psychiatric days. DBT has also been shown to improve social adjustment, treatment compliance, and dropout rates. The efficacy of DBT was reported in an open study of 27 14-year-old to 19-year-old suicidal adolescents diagnosed with BPD or borderline features. Improvement was reported in areas of confusion about self, impulsivity, emotional instability, and interpersonal problems. The most helpful DBT skills were identified as mindfulness and distress tolerance.

### Pharmacotherapy of Depressive Disorders

Several factors should be considered prior to initiating medication treatments in children and adolescents. These factors include history, course, and severity of illness, family history of psychiatric illness, and environmental and psychosocial factors. It is imperative to get an accurate diagnosis, and the use of structured interviews can greatly facilitate this process. Understanding the family's view of the illness and their beliefs about medications is also critical.

To date, limited guidelines are available for treatment of pediatric depression. In 1998, the AACAP published treatment guidelines for pediatric depression. At that time, only two trials of selective serotonin reuptake inhibitors (SSRIs) had been reported: one positive and one negative. Limited data were available on specific psychotherapy trials, as well. In that guideline, psychotherapy was indicated as the first line of treatment for mild to moderate depression. Medication (specifically, SSRIs) was recommended for psychotic depression, bipolar depression, and severe depression. The Texas Children's Medication Algorithm Project (CMAP) project also provided guidelines specifically for medication treatment. This algorithm, which was published in 1999 was also based on limited available data. However, with regard to medication treatment for pediatric depression, the later research supports the CMAP recommendations of SSRIs as first-line treatment.

Since these guidelines were published, we now have reports of many other treatment trials for both therapy and psychopharmacology. We also now have a trial with a head-to-head comparison of the two treatments (TADS). Although these guidelines provide a good framework, new guidelines to include the more recent data are warranted. For example, should single modality treatments be used versus combination treatments? The APA Practice Guidelines for adults state that combination treatment is suggested for individuals with significant psychosocial problems, a history of partial response to pharmacotherapy or psychotherapy alone, or poor adherence to a single mode of treatment. While medications often work quickly to reduce symptoms, the failure rate of medication alone is about 40%. Combination treatment may enhance the probability of response,

as well as the magnitude of response. In other words, two treatments may be more robust than one, and if one method is not helpful in reducing symptoms, the other one may be.

The first study to demonstrate an antidepressant medication treatment to be superior to placebo in treating early-onset depression was by Emslie et al. (1997a). In this study of 96 children and adolescents (ages 8 to 18) with MDD, 56% of those randomized to fluoxetine versus 33% of those randomized to placebo were considered much or very much improved following 8 weeks of treatment. A large multisite trial replicating the design of this first trial was then conducted with 219 children and adolescents (ages 8 to 17). Subjects were randomized to 9 weeks of treatment with fluoxetine or placebo. Similar to the initial study, 52% versus 37%, respectively, were considered much or very much improved (Emslie et al., 2002). As mentioned, a 12-week trial comparing fluoxetine, CBT, combination treatment, and placebo (sponsored by the National Institutes of Health [NIH]) also supported the use of fluoxetine, both alone and in combination treatment. Sixty-one percent of those on fluoxetine alone and 71% of those on fluoxetine plus CBT were considered responders, while only 35% of subjects on placebo responded. Thus, fluoxetine has shown efficacy over placebo in three controlled trials to date. Fluoxetine is the only antidepressant approved for treatment of pediatric depression. In addition, both the British Medicine and Healthcare Products Regulatory Agency (MHRA) and the U.S. Federal Drug Administration (FDA) stated that the risk-benefit ratio for using fluoxetine to treat pediatric depression was satisfactory.

In another large, multisite industry-funded study, 275 adolescents (ages 12 to 18) with MDD were randomized to paroxetine, imipramine, or placebo for an 8-week acute trial. Paroxetine was superior in efficacy to placebo (66% versus 48%), but imipramine (52%) was not. This study demonstrates additional support for the efficacy of SSRIs, while also reinforcing that TCAs may not be effective treatments for depressed youth, although they may have a role in specific individuals. Two other studies have been conducted with paroxetine, but have had negative results. In both cases, the placebo rate was quite high, suggesting methodological issues may have contributed to the negative outcome (GSK Website).

Two multisite trials of sertraline versus placebo have also been conducted, and the data were pooled for analyses. In this study, 376 children and adolescents (ages 6 to 17) with MDD were randomized to sertraline or placebo for 10 weeks. Sixty-three percent of subjects randomized to sertraline were considered much or very much improved, compared to 53% on placebo. Finally, Wagner et al. (2001) report on a multisite, double-blind, placebo-controlled study of citalopram in 174 children and adolescents (ages 7 to 17) with MDD. In this study, a significant difference was seen between the active treatment group and the placebo group beginning after 1 week of treatment. Rates of response were not as high as in other studies (36% for

citalopram versus 24% for placebo;  $p < .05$ ); however, this is due to the definition of response defined in this trial. In this study response was defined as  $CDRS-R \leq 28$ , which is generally used to define remission (symptom-free or "well") in other trials.

A treatment algorithm was developed for the pharmacological management of pediatric depression. The Texas Children's Medication Algorithm Project (CMAP) developed a medication algorithm that provides initial strategies of single medications that have been found to be safe and effective. Treatment follows a stage approach where patients progress to the next strategy or medication based on lack of sufficient symptom improvement or medication intolerance. The algorithm and increasing evidence from controlled trials support the use of selective serotonin reuptake inhibitors (SSRIs) as the first-line of treatment. This recommendation is based on lack of efficacy of tricyclic antidepressants and positive trials in four of the SSRI medications, including fluoxetine, paroxetine, sertraline, and citalopram. To date, only fluoxetine is approved by the FDA for the treatment of pediatric depression.

Despite the several trials showing significant improvement of depression in SSRIs over placebo, controversies about SSRIs being used in children and adolescents have surfaced. In June 2003, Great Britain's Department of Health (under the direction of the country's Medicines and Healthcare Products Regulatory Agency (MHRA)) stated that paroxetine was contraindicated in children and adolescents with depression due to lack of efficacy and increased risk of suicidal behavior in this population. The FDA followed suit, stating that paroxetine should not be used in children under 18. In October 2003, the FDA reported that they would be conducting analyses on all antidepressant data to determine the risk-benefit profile of the SSRIs and other newer antidepressants. Finally, in March 2004, the FDA has requested that the manufacturers of many of the newer antidepressants, including SSRIs, include a warning in the label recommending that health care providers closely monitor all patients taking these medications for worsening of depression and emergence of suicidal behavior.

It is important to note that in 2,885 depressed patients reviewed (who participated in clinical controlled trials), there were no completed suicides. In a reanalysis and reclassification of all the suicide-related events in pediatric controlled trials of antidepressants (for any disorder), there were 95 clear suicide-related behaviors in 4,250 youth studied. Combining all antidepressants for all disorders showed a risk ratio of 1.78 (Confidence Interval [CI]: 1.14 to 2.77), which is significantly greater than placebo. For SSRI MDD trials, the risk ratio was 1.41 (CI: 0.84 to 2.37; not significant). Most individual antidepressants were not associated with increased risk of suicidal behavior. However, paroxetine and venlafaxine did show significantly higher risk of suicidal behavior over placebo 2.65 (CI: 1.00 to 7.02) for paroxetine, 4.97 (CI: 1.09 to 22.72) for venlafaxine.

Although SSRIs are currently under scrutiny, these medications continue to be used in this population, and, as a group, remain the pharmacological treatment of choice for depression in this age group. Unfortunately, alternative treatments, such as CBT, have limited data and are simply not readily available in most communities. In a trial, which was sponsored by NIH and not funded through pharmaceutical agencies, adolescents were randomized to fluoxetine alone, CBT alone, combination fluoxetine and CBT, or placebo. Combination treatment and fluoxetine alone were significantly more effective than CBT alone and placebo. Seventy-one percent of those on combination treatment responded well to treatment, compared with 61% on fluoxetine alone, 43% on CBT, and 35% on placebo. Thus, this single trial suggests that treatment with an antidepressant is more effective than CBT or no treatment for moderate to severe depression in teens. Addition of a specific psychotherapy such as CBT may further enhance response.

Thus, despite the controversies facing SSRIs, several trials have demonstrated positive effect of SSRIs. There are no data in adults suggesting that the individual SSRIs are different (e.g., widely different mechanisms of action), so it is expected that the pediatric age group would be no different. To state it more clearly, the different rates of response to placebo does not cause people to think that the placebos are different across trials. Rather, it is more likely that the methodologies across trials are the primary cause of different response outcomes. Thus, it has been clearly established that SSRIs are effective in treating children and adolescents with MDD, and due to the relatively low side effects profile and safety in overdose, these medications are considered the first-line of treatment in this population.

Unfortunately, up to 40% of depressed youth do not respond to initial antidepressant treatments. To date, no trials have been reported on second-line treatment. The CMAP algorithm suggests that an alternative SSRI be used next, followed by one of the other new antidepressants, such as venlafaxine. Two placebo-controlled trials have been conducted with venlafaxine (ages 7 to 17). The studies were pooled for analyses, and results indicated that there was no significant difference between venlafaxine and placebo. However, when age groups were separated out, venlafaxine was more effective than placebo in adolescents in relieving depressive symptoms ( $P = .02$ ). Wyeth Ayerst Pharmaceuticals, manufacturers of venlafaxine, have stated that venlafaxine should not be used to treat depression in youth under 18, as the company states there is an increased chance of suicidal behavior in youth taking this medication (2 versus 0%; not significant). Other medication options for second-line and third-line treatments are nefazodone, mirtazapine, and bupropion. A study of adolescents (ages 12 to 17) treated with either nefazodone or placebo demonstrated greater response in teens treated with nefazodone (65 versus 46%, respectively;  $P = .005$ ). Two controlled studies have been conducted in mirtazapine, but they have not yet been published. Communication with

the sponsor indicates these trials were negative due to a high placebo response rate. No controlled studies have been reported on depression treatment with bupropion. Thus, although these medications are optional treatments for pediatric depression, substantially less positive results have been reported with these medications. To date, no studies have assessed which second-line treatments are most effective in youth who do not improve during acute treatment. Therefore, in youth who do not improve with initial SSRI treatment, a second SSRI trial or switching to an alternative type of medication such as these may be viable options. Finally, augmenting with a mood stabilizer (i.e., lithium) or electroconvulsive therapy (ECT) are treatment options for severely refractory depression, though these alternatives have not received adequate investigation in this population. All of these recommendations are based mainly on adult data and need further study in the pediatric population.

## Bipolar Disorders

There is increasing information about the effectiveness of psychosocial treatments that complement and support medication treatment in children and adolescents with bipolar disorders. Several trials have been conducted, suggesting support for psychotherapeutic intervention as an intervention to augment medication in reducing the symptoms of bipolar disorder and in improving adherence to the medication regime. There is some evidence that the most beneficial of multifamily psychoeducational treatments, is that which provides education about bipolar illness in a group discussion format, along with skills training for both parents and children.

The clinical use of mood stabilizers and atypical antipsychotic agents in children and adolescents with bipolar disorders (BPD) has increased significantly over the past few years, despite the fact that there are few controlled trials in this population. Many of the same psychotropic medications used to treat adults with bipolar disorders are also used for children and adolescents. To date, there have been only two double-blind placebo controlled studies of the treatment for acute mania in children and adolescents with bipolar disorder and one uncontrolled maintenance treatment study.

Lithium is the most studied medication for children and adolescents with bipolar disorder and is the only medication approved by the Food and Drug Administration for the treatment of acute mania and bipolar disorder in adolescents or children (ages 12 to 18 years). Approximately 40 to 50% of children and adolescents with mania or hypomania will respond to lithium monotherapy. In general, lithium should be titrated to a dose of 30 mg/kg/day in two to three divided doses, which typically results in a therapeutic serum level of 0.8 to 1.2 mEq per L. Common side effects of lithium in children and adolescents include hypothyroidism, nausea, polyuria, polydipsia, tremor,

acne, and weight gain. Lithium levels and thyroid function tests should be monitored as in adults.

In the only prospective, placebo-controlled, investigation of lithium in children and adolescents with bipolar disorders ( $n = 25$ ), Geller et al. (1998) found that after 6 weeks of treatment, subjects treated with lithium showed a statistically significant decrease in positive urine toxicology screens and a significant improvement in global assessment of functioning (46% in the lithium treated group versus 8% in the placebo group). This study demonstrated the efficacy of lithium carbonate for the treatment of bipolar adolescents with comorbid substance use disorders, but it did not measure the effect of lithium on mood in these adolescents. Risk factors for poor lithium response in children and adolescents with bipolar disorder include prepubertal-onset and the presence of co-occurring ADHD.

Surprisingly, despite their wide use, there are no published placebo controlled studies of antiepileptic medication for the treatment of pediatric bipolar disorder. Open label studies of divalproex in manic adolescents have reported response rates ranging from 53 to 82%. There have also been several case reports and series describing the successful use of carbamazepine as monotherapy and adjunctive treatment in children and adolescents with bipolar disorder. Kowatch et al. are currently completing an NIMH sponsored clinical trial of the efficacy of lithium and valproate in children and adolescents with BP I disorder. This trial will provide much needed data about the efficacy and safety of these widely used two-mood stabilizers.

In general, divalproex is initiated at a dose of 20 mg/kg/day, which will typically produce a serum level of 80 to 120 ug per ml, and carbamazepine is usually titrated to a dose of 15 mg/kg/day to produce a serum level of 7 to 10 ug per ml. Common side effects of divalproex in children are weight gain, nausea, sedation, and tremor. There has been much debate regarding the possible association between divalproex and polycystic ovarian syndrome (PCOS). The initial reports of PCOS were in women with epilepsy who were treated with divalproex. The hypothesized mechanism for divalproex induced PCOS is that obesity secondary to divalproex results in elevated insulin levels, which leads to increased androgen levels and ultimately PCOS. Further investigations of the risk of developing PCOS for female bipolar adolescents are necessary. Until this issue is settled, clinicians should monitor female patients treated with divalproex for any signs of PCOS that include weight, menstrual abnormalities, hirsutism, or acne.

Carbamazepine is used widely for seizure management but less commonly than divalproex in children and adolescents with bipolar disorder. This anticonvulsant must be titrated slowly and requires frequent monitoring of blood levels because of CYP450 drug interactions. Its most common side effects are sedation, rash, nausea, and hyponatremia. Aplastic anemia and severe dermatologic reactions such as Stevens-Johnson syndrome occur uncommonly. Side effects of carbamazepine include developing

aplastic anemia and severe dermatological reactions, such as Stevens-Johnson's syndrome, hyponatremia, nausea, and sedation, and it is therefore, less commonly used in children and adolescents with bipolar disorder. Oxcarbazepine, an analog of carbamazepine, is a promising agent for acute mania in adults, but no pediatric data are available.

Several new antiepileptic agents have been developed for the treatment of epilepsy that may have mood stabilizing properties. Data are presently limited regarding the efficacy and tolerability of these agents for the treatment of pediatric bipolar disorder. However, they may be useful as adjuncts for the treatment of manic and hypomanic episodes. There have been several case reports of lamotrigine as adjunctive treatment for children and adolescents with bipolar disorder. However, its use for pediatric bipolar disorder has been limited due to the risk of potentially lethal cutaneous reactions, such as Stevens-Johnson syndrome and toxic epidermal necrolysis. The risk of a serious rash is approximately two to three times greater in children and adolescents younger than 16 years old compared with adults, but a more conservative dosing schedule appears to have substantially reduced the rate of serious rashes. Double-blind placebo controlled studies of gabapentin have demonstrated that gabapentin is no more effective than placebo for the treatment of acute mania in adults. However, gabapentin may be effective for the treatment of anxiety disorders in adults and is generally well tolerated in children and adolescents. Therefore, gabapentin may be particularly useful for treating children and adolescents with bipolar disorder who are also diagnosed with a comorbid anxiety disorder. Preliminary data from open studies suggest that topiramate may be effective as an adjunctive treatment for pediatric bipolar disorder, although more recent double-blind placebo controlled studies in adults with mania suggest that as monotherapy it is no more effective than placebo. Word finding difficulties have been reported in up to one third of adult patients treated with topiramate. Topiramate is associated with anorexia and weight loss, and therefore it may be useful as adjunctive treatment for children and adolescents with bipolar disorder who have gained weight as a result of treatment with other psychotropic medications.

The atypical antipsychotics are powerful psychotropic agents that have been found to be efficacious in the treatment of adults with schizophrenia and acute bipolar mania. These atypical agents not only have antipsychotic activity but may also possess thymoleptic properties with favorable effects on the depressive and manic symptoms of patients with bipolar disorders. To date, there have been three large controlled studies of olanzapine, two controlled trials of risperidone, and one controlled trial of ziprasidone in the treatment of adults with acute mania.

Several case series and open-label reports suggest that atypical antipsychotics clozapine, risperidone, olanzapine, and quetiapine are effective in the treatment of pediatric mania. However, there may be significant weight gain

associated with olanzapine and risperidone. Ziprasidone can cause QTc prolongation and there are limited safety data in children and adolescents. Therefore, ziprasidone should be used with caution in children and adolescents with bipolar disorder and electrocardiograms should be monitored at baselines and when significant dosage increases are made. In the only double-blind placebo-controlled study of an atypical antipsychotic for the treatment of bipolar adolescents, quetiapine in combination with divalproex ( $n = 15$ ) resulted in a greater reduction of manic symptoms than divalproex monotherapy ( $n = 15$ ), suggesting that the combination of a mood stabilizer and atypical antipsychotic is more effective than a mood stabilizer alone for the treatment of adolescent mania. In this study, quetiapine was titrated to a dose of 450 mg per day in 7 days and was well tolerated.

If a child or adolescent has euphoric mania without psychotic symptoms, then a trial of lithium is many times helpful. Adult patients with dysphoric mania appear to respond better to divalproex than to lithium. But if psychotic symptoms are present as part of the child or adolescent's mania, then treatment with an atypical antipsychotic agent is indicated. If a patient does not respond to monotherapy with either a traditional mood stabilizer like lithium or valproate, or an atypical antipsychotic, then a combination of a traditional mood stabilizer and any atypical antipsychotic may be effective.

Most children with BPD will have comorbid ADHD, and mood stabilization with mood stabilizers or atypical antipsychotics is a necessary prerequisite prior to initiating stimulant medications. A randomized controlled trial of 40 bipolar children and adolescents with ADHD demonstrated that low-dose Dexedrine can be safely and effectively used for treatment of comorbid ADHD symptoms after the child's BPD symptoms are stabilized with divalproex. Sustained release psychostimulants may be more effective at reducing rebound symptoms in bipolar children and adolescents. A typical dose of such stimulants for a child with BPD and ADHD would be 36 mg per day of Concerta or Adderall XR, 10 to 20 mg per day.

Many agents used to treat children and adolescents with bipolar disorder are associated with weight gain. A series of general medical, metabolic problems may occur as a result of increases in weight. These include type II (noninsulin dependent) diabetes mellitus, and changes in lipid levels, and transaminase elevation. Children who experience significant weight gain should be monitored especially closely for these possibilities and should be referred for exercise and nutritional counseling. The American Diabetes Association, in collaboration with the American Psychiatric Association, published a monitoring protocol for all patients prior to initiating treatment with an atypical antipsychotic. This protocol includes inquiring about a personal and family history of obesity, diabetes, dyslipidemia, hypertension, or cardiovascular disease; weight and height, so that body mass index (BMI) can be calculated; measurement of waist circumference (at the level of the umbilicus); blood pres-

sure; fasting plasma glucose; and a fasting lipid profile. This group recommended that the patient's weight should be reassessed at 4, 8, and 12 weeks after initiating or changing therapy with an atypical antipsychotic and quarterly thereafter at the time of routine visits. If a patient gains more than 5% of his or her initial weight at any time during therapy, the patient should be switched to an alternative agent. These guidelines should be followed in all children and adolescents treated with atypical antipsychotics. It should be also be recognized that although these guidelines are extremely helpful, they were not written for a pediatric population, and the 5% weight gain threshold may not be sensitive enough for children and adolescents.

## CONCLUSION

Despite increased awareness of the occurrence of mood disorders in children and adolescents, pediatric mood disorders frequently go undiagnosed and untreated. Misdiagnosis is particularly likely when clinicians attempt to differentiate primary mood disorders from mood disorders due to general medical conditions or to substance-induced mood disorders. It is important that these disorders are recognized and appropriately treated as they can cause significant suffering, morbidity, and suicide.

# Anxiety Disorders

14

Sanjeev Pathak, MD    Bruce D. Perry, MD, PhD

## ANXIETY

Anxiety can be defined as the apprehensive anticipation of future danger or misfortune accompanied by a feeling of dysphoria or somatic symptoms of tension. The focus of anticipated danger may be internal or external (DSM-III-R, 1987). It is the uneasiness associated with the anticipation of danger or perceived rejection and loss of love. Anxiety, an emotion, is the subjective sensation that accompanies the body's response to real or perceived threat. All individuals experience some degree of real or perceived threat, and, therefore, we all have had the sensation of anxiety. Fears and anxieties of a mild and transient nature are part of normal development, though this expectation may mask the presence of emerging or existing anxiety disorder (Zahn-Waxler et al., 2000). For some individuals, however, the frequency, duration, intensity, or context of the anxiety is extreme and can interfere with normal development and functioning. These individuals are considered to have anxiety disorders.

Anxiety disorders are the most common psychiatric syndromes in children and adolescents, with estimated point prevalence of 3 to 13% (Kashani and Orvaschel, 1988, 1990). There is a much higher prevalence of anxiety disorders in medical and psychiatric settings. The disability and impairment in health-related quality of life due to anxiety disorders can be severe (Beidel et al., 1991; Francis et al., 1992; Strauss et al., 1988). Feelings of worthlessness, low self-esteem, and difficulties with concentration and motivation are common in anxiety disorders, and these symptoms along with core symptoms of fear and anxiety impair school performance. These symptoms also strain relationships with peers and family members leading to poor social life. In addition, anxiety disorders may interrupt educational attainment and thus affect human capital accumulation and future earnings. Longitudinal data of children with anxiety conditions indicate that anxiety disorders can be chronic and disabling, and they can increase risk of comorbid disorders (Pine et al., 1998). Reports in the adult literature

also demonstrate the risk for lifelong impairment, reduced quality of life, and increased rates of suicidality (Katzelnick et al., 2001). Rates of anxiety increase as children move into adolescence, which can adversely affect their development.

Scientific efforts to classify abnormal anxiety symptoms resulted in the clustering of similar clinical presentations of anxiety symptoms into anxiety disorders. The *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition, Revised (DSR-III-R) recognized two child-specific anxiety disorders: separation anxiety of childhood and overanxious disorder of childhood (DSM-III-R, 1987). It also recognized that anxiety disorders occur in both children and adults, such as panic disorder, agoraphobia, specific phobias (e.g., social phobia), posttraumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD). Although each of these disorders had distinguishing clinical phenomenology, profound anxiety was the core symptom common to all. With DSM-IV (American Psychiatric Association, 1994) and DSM-IV-TR, there has been a refinement of this phenomenology.

## PHENOMENOLOGY, CLASSIFICATION, AND DIAGNOSIS

Anxiety is a universal feeling experienced by all. It is thought to be a safety mechanism designed to prepare an individual for flight or fight in reaction to perceived risk or damage. At mild to moderate levels, anxiety may be a useful and adaptive mechanism. At extreme levels, however, it is usually maladaptive and debilitating. One means of judging whether a patient has an anxiety disorder is whether the response of an individual is proportionate to the presenting stressor or anxiety-provoking stimulus.

Numerous physiological changes take place in association with anxiety. These changes may present as many signs and symptoms of anxiety disorders involving many organ systems. A sense of palpitations, tachycardia, increased

blood pressure, and flushing or pallor may be seen. A subjective sense of shortness of breath and an increased respiratory rate can be seen. Blotching of the skin, rashes, changes in skin temperature, and increased perspiration may be noted. Patients may demonstrate tremulousness, muscle tension, and cramping. Patients may have gastrointestinal symptoms such as by diarrhea, nausea, bloating, and abdominal pain. Additional nonspecific physical symptoms such as headache, chest pain, insomnia, dizziness, fainting, and urinary frequency may be observed.

Patients may also present with psychological and cognitive symptoms such as worrying and reports of feeling scared, feeling tense, nervous, or stressed. In states of panic, patients may express a fear of dying, a fear of imminent disaster, or the feeling that one is going crazy. Patients may be easily startled or hyperaroused and may show behavioral symptoms with significant social impact, such as appearing dependent, needy, clingy, shy, withdrawn, and uneasy in social situations. Individuals with anxiety disorders may appear nervous and high strung.

Children and adolescents with anxiety disorders can have a clinical picture that is somewhat different from those seen in adults. For instance, children may not report any worries or anxieties but may have pronounced physical symptoms. Severe tantrums may be their only manifestation of anxiety problems and thus can be confused with mood disorders or oppositional behavior. Anxiety-related tantrums may occur in children who may be generally compliant and cooperative but then unexpectedly have a severe tantrum. These tantrums can be extraordinarily long and involve the child demanding that the guardian help her or her to avoid an anxiety-provoking situation or stimuli. Examples of such tantrums include a child with social phobia (SP) having a temper tantrum to avoid school or children with obsessive-compulsive disorder (OCD) having a tantrum to avoid breaking a ritual or seek parental assistance with cleaning up. Some children present to the pediatrician with physical symptoms such as nausea, stomachache, or headache occurring on Monday morning or Sunday night, which may represent separation anxiety disorder. Children with generalized anxiety disorder (GAD) may feel sick after the news of a thunderstorm or natural disaster.

The diagnosis of normal versus abnormal anxiety largely depends on the degree of distress and its effect on a child's functioning in life. The degree of abnormality must be gauged within the context of the child's age and developmental level (Table 14.1). The following section delineates the diagnostic rubrics utilized to describe anxiety disorders.

### SEPARATION ANXIETY DISORDER (SAD)

Separation anxiety is characterized by excessive anxiety or fear concerning separation from home or from those to whom the child is attached. By definition, it begins before age 18 (DSM-IV-TR, 2000). The disorder usually manifests

**TABLE 14.1**  
**NORMAL DEVELOPMENTAL ANXIETY AND ITS COMMON CAUSES**

<b>0–6 Months</b>	Loud noises, rapid position changes, rapidly approaching unfamiliar objects
<b>7–12 Months</b>	Strangers, unfamiliar objects, confrontation with unfamiliar people
<b>1–5 Years</b>	Strangers, storms, animals, dark, loud noises, toilet, monsters, ghosts, insects, bodily injury, separation from parents
<b>6–12 Years</b>	Bodily injury, disease, ghosts, supernatural beings, staying alone, criticism, punishment, failure
<b>12–18 Years</b>	Tests and examinations, school performance, bodily injury, appearance, peer scrutiny and rejection, social embarrassment

to the clinician with somatic complaints that the child experiences when there is impending separation from home or the parents, such as going to school. The child can have difficulty when left with relatives, day care providers, babysitters, and other caregivers. This disorder also frequently involves refusal to attend sleepovers or outings requiring a separation from parents. Children who have severe symptoms may refuse to sleep in their own rooms or refuse to go to school, leading to significant impairment. Sunday night and Monday morning illnesses are typical in these children, who may feel great on Fridays and weekends. These children have a difficult time going back to school after holiday breaks and especially after summer vacations. Separation anxiety should be distinguished from social phobia, in which the child avoids school because of a fear of being scrutinized by peers.

Separation anxiety disorder is associated with the development of subsequent depression and panic disorder (McCauley et al., 1993; Mitchell et al., 1988). As it may be an antecedent to subsequent pathology and causes significant distress, appropriate diagnosis and treatment is necessary (Labellarte et al., 1999).

### GENERALIZED ANXIETY DISORDER (GAD)

This disorder was referred to as “overanxious disorder of childhood” in previous versions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM). Generalized anxiety disorder can be defined as excessive worry, apprehension, and anxiety occurring most days for a period of 6 months or more that involves concern over a number of activities or events (DSM-IV-TR, 2000). The focus of the worry and fear is not a specific stimulus as it is in other anxiety disorders such as the extreme anxiety in social situations in social phobia. The person has difficulty controlling the anxiety, which is associated with at least one of the

following: restlessness, feeling “keyed up” or on edge; being easily fatigued; difficulty concentrating or having the mind go blank; irritability; muscle tension; or difficulty falling asleep or staying asleep, or restless sleep. The anxiety causes significant distress and impairs functioning.

## PANIC DISORDER

---

Panic disorder is different from panic attacks; panic attacks are defined as sudden, discrete episodes of intense fear or discomfort accompanied by 4 out of 13 bodily or cognitive symptoms, often manifesting with an intense desire to escape, feeling of doom or dread, and impending danger (DSM-IV-TR, 2000). These symptoms peak within 10 minutes and often subside within 20 to 30 minutes. The 13 symptoms are heart palpitations or fast heart rate; sweating; trembling or shaking; shortness of breath or smothering; choking sensation; chest discomfort or pain; nausea or abdominal distress; feeling dizzy, lightheaded, faint, or unsteady; feelings of unreality or being detached from oneself; fear of losing control or going crazy; fear of dying; numbness or tingling sensations; and chills or hot flashes. Panic disorder consists of recurrent unexpected panic attacks with interepisode worry about having others; the panic attacks lead to marked changes in behavior related to the attacks. Panic attacks are frequently associated with agoraphobia (the fear of the marketplace or public places and avoidance of situations from which escape might be difficult or help might not be available and often experienced as a fear of leaving the home). Although agoraphobia can occur alone, it most often occurs in the presence of panic disorder.

## OBSESSIVE-COMPULSIVE DISORDER (OCD)

---

This disorder is defined by persistent obsessions (intrusive, unwanted thoughts, images, ideas, or urges) or compulsions (intense, uncontrollable repetitive behaviors or mental acts related to the obsessions) that are noted to be unreasonable and excessive (DSM-IV-TR, 2000). These obsessions and compulsions cause notable distress and impairment and are time consuming (more than 1 hour a day). The most common obsessions concern dirt and contamination, repeated doubts, need to have things arranged in a specific way, fearful aggressive or murderous impulses, and disturbing sexual imagery. The most frequent compulsions involve repetitive washing of hands or using handkerchief/tissue to touch things; checking drawers, locks, windows, and doors; counting rituals; repeating actions; and requesting reassurance. Eighty percent of subjects suffering from OCD have both obsessions and compulsions.

Young children with OCD may not recognize their obsessive thoughts or the compulsions and rituals as problematic or unusual. Therefore children between 4 and 10

may frequently have severe tantrums with atypical precipitants as the chief complaint. A child might be usually very compliant, but have a tantrum if asked to speed up his or her cleaning. Young children may also be unable to verbalize their obsessions, but parents can describe avoidance behaviors, compulsions, and rituals.

Pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) are a group of disorders that are believed to be the result of an autoimmune response to group A beta-hemolytic streptococcal infections (Swedo et al., 1998). These disorders can present with tics and obsessions and compulsions. The onset of OCD symptoms is typically more abrupt if associated with PANDAS.

## POSTTRAUMATIC STRESS DISORDER (PTSD)

---

In this disorder, a person experiences, witnesses, or is confronted by a traumatic event or events that involve an actual or perceived threat of death or serious bodily injury, and the person’s response involves intense fear, helplessness, or horror. In children, probably the most common traumatic event is abuse. The traumatic event is continually re-experienced in the following ways: recurrent and intrusive distressing remembrances of the event involving images, thoughts, or perceptions; distressing dreams of the event; acting or believing that the traumatic event is recurring; intense anxiety and distress to exposure to situations that resemble the traumatic event; or bodily reactivity on exposure situations that resemble the traumatic event (DSM-IV-TR, 2000). The person avoids situations that are associated with and remind him or her of the traumatic event, leading to avoidance of thoughts, feelings, or conversations associated with the trauma; activities, places, or people that remind him or her of the traumatic event; an inability to remember details of the event; markedly diminished participation and interest in usual activities; feeling detached and estranged from others; restricted range of emotional expression; sense of a foreshortened future or life span; persistent signs of physiologic arousal, such as difficulty falling asleep or staying asleep, irritability or anger outbursts, difficulty concentrating, excessive vigilance, and exaggerated startle response. These symptoms persist for more than 1 month and cause significant distress and impairment of functioning.

## ACUTE STRESS DISORDER

---

A person is exposed to a traumatic event in which he or she experiences, witnesses, or is confronted by an event or events that involve an actual or perceived threat of death or serious bodily injury, and the person’s response involves intense fear, helplessness, or horror. The traumatic event is

continually re-experienced in the following ways: recurrent and intrusive distressing remembrances of the event involving images, thoughts, or perceptions; distressing dreams of the event; acting or believing that the traumatic event is recurring; intense anxiety and distress to exposure to situations that resemble the traumatic event; bodily reactivity on exposure situations that resemble the traumatic event. The person avoids situations that are associated with and remind him or her of the traumatic event, leading to avoidance of thoughts, feelings, or conversations associated with the trauma; activities, places, or people that remind the person of the traumatic event; inability to remember details of the event; markedly diminished participation and interest in usual activities; feeling detached and estranged from others; restricted range of emotional expression; sense of a foreshortened future or life span; persistent signs of physiologic arousal, such as difficulty falling asleep or staying asleep, irritability or anger outbursts, difficulty concentrating, excessive vigilance, and exaggerated startle response. This disorder differs from PTSD in that the symptoms persist for less than 1 month.

### **SOCIAL PHOBIA (SP)**

---

This disorder is characterized by a persistent and significant fear of one or more social situations in which a person is exposed to unfamiliar persons or scrutiny by others and feels he or she will behave in a way that will be embarrassing or humiliating (DSM-IV-TR, 2000). Exposure to the feared social situations almost always causes significant anxiety, even a panic attack, despite the fact that the anxiety is seen as excessive and unreasonable. This belief may lead to avoidance of such situations or endurance under extreme distress, leading to marked interference in the person's functioning and routine. In children and adolescents, the symptoms must be present for a minimum of 6 months and cause significant impairment in functioning or marked distress in order to warrant the diagnosis. The DSM-III-R diagnosis of avoidant disorder of childhood has been subsumed under this rubric in DSM-IV-TR. Children and adolescents with social phobia usually have few friends and tend to avoid group activity and report feeling lonely. They are also fearful of social situations such as reading aloud in class, asking the teacher for help, eating in the cafeteria, unstructured activities with peers, and so on (DSM-IV-TR, 2000).

### **SELECTIVE MUTISM**

---

Selective mutism is the failure to speak in social situations when there is no underlying language problem and the child has the capacity to speak (DSM-III-R, 1987). The onset of this disorder is in childhood. The child usually speaks normally in the company of familiar adults or family and familiar settings. At school or in other public settings, the

child may be silent. The disorder is considered by some to be a severe form of social phobia as these youth are often painfully shy. The disorder cannot otherwise be explained by a developmental abnormality. There is a high rate of family history of anxiety disorders in these children.

### **SPECIFIC PHOBIA**

---

This disorder is characterized by persistent and significant fear that is recognized as unreasonable and excessive and that is triggered by the presence or perception of a specific feared situation or object; exposure to this situation or object immediately provokes an anxiety reaction (DSM-IV-TR, 2000). The distress, avoidance, and anxious anticipation of the feared situation or object significantly interfere with a person's normal functioning or routine. This disorder may present as one of many types: the animal type is manifested as a fear of animals or insects; the natural environmental type is manifested as a fear of storms, heights, water, and the like; the blood-injection-injury type is manifested as a fear of getting injections, seeing blood, seeing injuries, or watching or having invasive medical procedures; the situational type is manifested as a fear of elevators, flying, driving, bridges, escalators, trains, tunnels, closets, and so on. In children, specific phobia may be expressed as anxiety or by symptoms such as crying, temper tantrums, or a marked increase in clinging behavior.

### **ADJUSTMENT DISORDER WITH ANXIETY (WITH OR WITHOUT DEPRESSED MOOD)**

---

This disorder can be diagnosed when the development of emotional or behavioral symptoms occur within 3 months in response to an identifiable stressor (DSM-III-R, 1987). These symptoms and behaviors cause marked distress in excess of that which could be expected and results in significant occupational, social, or academic performance. Once the initiating stressor has ceased, the disturbance does not last longer than 6 months.

### **ANXIETY DISORDER DUE TO A GENERAL MEDICAL CONDITION**

---

This disorder may result when the physiologic consequences of a distinct medical condition is judged to be the cause of prominent anxiety symptoms.

### **DRUG-INDUCED ANXIETY DISORDER**

---

This disorder may result when the physiologic consequences of the use of a drug or medication is judged to be the cause of prominent anxiety symptoms.

## ANXIETY DISORDER NOT OTHERWISE SPECIFIED

---

This disorder may result when the prominent symptoms of anxiety and avoidance exist but do not fully meet the preceding diagnostic criteria.

## DIAGNOSTIC ISSUES IN ANXIETY DISORDERS

---

As more than 50% of individuals who meet criteria for one anxiety disorder also meet criteria for a second anxiety disorder, an underlying vulnerability to anxiety is probably common to all anxiety disorders (Kashani and Orvaschel, 1990; Last et al., 1992). However, it is not clear whether there is a specific inheritance related to a particular anxiety disorder or whether a broader genetic predisposition toward problems with overarousal and reactivity to stimuli may be responsible. In addition, the categorical DSM-IV-TR nomenclature may result in artificially carving various anxiety disorders into discrete categories.

## COMORBIDITY

---

Childhood anxiety disorders have astounding comorbidity with other childhood neuropsychiatric disorders (Last et al., 1987a; Leckman et al., 1983). Attention-deficit/hyperactivity disorder (ADHD) co-occurs with anxiety disorders with high frequency (Biederman et al., 1991). In some studies, more than 60% of the children with affective disorders also had an anxiety disorder, and 70% of children with school refusal had comorbid affective disorders (Bernstein et al., 1996).

The presence of anxiety disorders in childhood appears to confer risk for the development of affective and anxiety disorders in adolescence and adulthood (Reinherz et al., 1989). In turn, depressive symptoms in childhood apparently play a role in vulnerability to anxiety disorders throughout the life cycle (Kovacs et al., 1989; Kovacs and Goldston, 1991). In addition, adolescents with anxiety disorders who develop major depression are at a high risk for attempting suicide (Pawlak et al., 1999). That many disorders co-occur with anxiety disorders and that vulnerability to anxiety disorders also confers vulnerability to affective disorders, and vice versa, should not be surprising, considering that the brainstem monoamines (e.g., norepinephrine, serotonin, dopamine) are common mediators of both arousal and affect. Primary “anxiety” symptoms induced by abnormal regulation of these brainstem monoamine systems would likely be accompanied by affective symptoms, and vice versa.

Other neuropsychiatric conditions in which anxiety is a prominent symptom include psychotic disorders, mental retardation, traumatic head injury, developmental delay,

profound neglect, and physical abuse. The common thread in all of these disorders is a compromised capacity to effectively and efficiently interpret experience. Regardless of which specific capacity (processing, storing, or recalling stored information) is affected by the cortical and subcortical impairments in these disorders, the effect is the same—every experience is too “new.” Any condition that alters the brain’s capacity to make associations in response to an event, store them, and then generalize from that event to a future event causes the affected individual to experience each moment as novel. Novel cues are interpreted by the brain as threat related until proven otherwise. To a psychotic child in whom abnormal pairing of sensory information is taking place, the environment is ever-changing from moment to moment, with all experience continually being processed and perceived as “novel.”

Although anxiety plays a major role in the clinical presentation of all of these neuropsychiatric disorders, no single neuropathological process has been found that is specific to a given diagnostic category or to specific anxiety-related symptoms. The threat-response systems in the human brain are redundant and widely distributed, and there are many mechanisms and sites in which dysregulation may occur.

## ANXIETY DISORDER SECONDARY TO NEUROLOGICAL ILLNESS

---

One of the best described neurological disorders that presents with symptoms of anxiety is pediatric autoimmune neuropsychiatric disorders associated with streptococcal (group A  $\beta$ -hemolytic streptococcal [GABHS]) infections (PANDAS) (Swedo et al., 1998). Swedo et al. described the clinical characteristics of 50 pediatric patients diagnosed with PANDAS, OCD, and tic disorders with a prepubertal onset in association with GABHS. The children’s symptom onset was acute and dramatic, typically triggered by GABHS infections at a very early age (mean = 6.3 years, SD = 2.7, for tics; mean = 7.4 years, SD = 2.7, for OCD). The PANDAS clinical course was characterized by a relapsing-remitting symptom pattern with significant psychiatric comorbidity accompanying the exacerbations; emotional lability, separation anxiety, nighttime fears and bedtime rituals, cognitive deficits, oppositional behaviors, and motor hyperactivity were particularly common. Giedd et al. used computer-assisted morphometric techniques to analyze the cerebral magnetic resonance images of 34 children with PANDAS and 82 healthy comparison children who were matched for age and sex (Giedd et al., 2000). The average sizes of the caudate, putamen, and globus pallidus, but not of the thalamus or total cerebrum, were significantly greater in the group of children with streptococcus-associated OCD or tics than in the healthy children. The basal ganglia enlargements were consistent with a hypothesis of a selective cross-reactive antibody-mediated

inflammation of the basal ganglia underlying the development of poststreptococcal OCD or tics in some individuals. However, there was a lack of correlation between basal ganglia size and symptom severity, indicating that the relationship between basal ganglia size and pathophysiology is not direct. In addition, because of poor sensitivity and specificity of the MRI findings, an MRI scan is not warranted for the diagnosis or clinical monitoring of children with poststreptococcal OCD or tics.

Apart from PANDAS, there are limited descriptions of pediatric anxiety disorders secondary to neurological illness. Gamazo-Garran et al. described a 16-year-old-boy who had a midline germinal tumor affecting the caudate nuclei; left lenticular, right internal capsule's genu; and bilateral involvement of the interventricular septum close to the interventricular foramina. He developed OCD symptoms and elevated tumor markers when he had a tumor relapse, and fluorodeoxyglucose positron emission tomography showed caudate nuclei involvement. He responded to treatment with 80 mg of citalopram. As noted in this case report, the treatment for anxiety secondary to neurological/infectious causes is the same as that for primary anxiety disorders (Storch et al., 2004).

## EPIDEMIOLOGY

Although quite common, anxiety disorders in children often are overlooked or misjudged, even though they are treatable conditions with good, persistent medical care. What does seem to be developing in the medical literature is the consensus that many "adult" psychiatric disorders likely have their first (although perhaps subtle or ignored) manifestations in childhood, and that if left untreated these anxiety disorders in children likely progress to adult versions.

Epidemiological studies that used DSM-III-R diagnostic criteria have demonstrated that over 10% of all children meet criteria for some anxiety disorder (Kashani and Orvaschel, 1988; King et al., 1995; Milne et al., 1995). In two cross-sectional epidemiological studies, 21% of the sampled children reported symptoms meeting DSM anxiety disorder diagnostic criteria (Kashani and Orvaschel, 1988; Kashani et al., 1989). In these samples, the prevalence rates for separation anxiety disorder were 12.9%, 12.4% for over-anxious disorder, 3.3% for specific phobia, and 1.1% for social phobia. The National Institute of Mental Health (NIMH) adolescent OCD study showed a lifetime prevalence of 1.9% for the general adolescent population (Flament et al., 1988). Valleni-Basile et al. reported a higher rate of 3% of clinical OCD and 19% for subclinical OCD symptoms in their community sample of 3,283 adolescents (Valleni-Basile et al., 1994). A few studies have investigated the epidemiology of panic disorder. These studies have found a lifetime prevalence ranging from 0.3 to 1% in adolescence (Lewinsohn et al., 1993; Verhulst et al., 1997;

Whitaker et al., 1990). Warren et al., in a sample of 388 adolescents reported a higher (4.7%) prevalence of panic disorder. Unfortunately, because of controversies regarding the occurrence of panic disorder in the pediatric age group, panic disorder was not mentioned in the most widely cited epidemiological studies of panic disorder in youth (Anderson et al., 1987; Kashani and Orvaschel, 1988)

## COURSE

Understanding the course of anxiety disorders is critical to planning treatment and assessing future medical need. In addition, knowledge about the course of various anxiety disorders will answer parental concerns about how long the child will need treatment and when the child might be free from impairment. Emerging evidence is suggesting that several anxiety disorders begin early in childhood, increase the risk for developing other comorbid disorders, and if untreated may result in a chronic course (Achenbach et al., 1995; Pine et al., 1998b; Spence et al., 2001).

Separation anxiety disorder (SAD) can have an early and acute onset following a significant stressor, such as move to a new neighborhood, death of a parent, or a period of developmental change (Last et al., 1987a). SAD tends to have a variable course with remission and periods of recurrence during periods of increased stress and sometimes seems to come out of the blue. Moreover, SAD increases the risk for subsequent depression and social phobia, and girls with SAD are at increased risk for panic disorder and agoraphobia (Black and Robbins, 1990). Simple phobia also seems to be chronic for a significant proportion of children and adolescents, though there have been reports of spontaneous remission also (Agras et al., 1972; Essau et al., 2000).

OCD has a chronic fluctuating course marked by remissions and recurrences (Swedo et al., 1989). In a 2-year follow-up of adolescents who had a lifetime diagnosis of OCD, Berg et al. found that 31% of subjects received a diagnosis of OCD at follow-up (Berg et al., 1989). Wewetzer et al., in a long-term follow-up study, assessed 55 patients whose mean age of onset of OCD was 12.5 years and the mean follow-up time was 11.2 years. At the follow-up investigation, 71% of the patients met the criteria for some form of psychiatric disorder, while 36% were still suffering from OCD.

Patients with social phobia are at increased risk of developing major depression, as well as substance abuse and dependence (Kessler et al., 1994; Last et al., 1992). There are little data available on the course of GAD. However, the minimal data suggest that GAD is unstable over time, with the majority of the patients having a different diagnosis at follow-up in addition to increased risk for alcohol abuse (Cantwell and Baker, 1989; Kaplow et al., 2001). Though data are lacking in children for the course of panic disorder, the data from adults suggests that this is a chronic and recurrent diagnosis (Breier et al., 1986).

## Genetic Factors

Systematic study of the temperament of infants has suggested that certain properties of the sensitivity of the arousal system may be constitutional (Kagan et al., 1987). The rudimentary organization and sensitivity of the arousal systems appear to be present at birth. Differential internal states of anxiety seem to be associated with distinct behaviors, such as initiation of social contact, exploration, and the capacity to form and maintain peer attachments (Last et al., 1987b; Waldron et al., 1975). Panic disorder, generalized anxiety disorder, phobias, and OCD all have significant familial aggregation (Hettema et al., 2001). Furthermore, twin studies have established that genes account for a significant variance in anxiety measures. In a large twin study, Torgersen considered 32 monozygotic (MZ) and 53 dizygotic (DZ) adult same-sexed twins (Torgersen, 1983). The frequency of anxiety disorders was twice as high in MZ as in DZ twins of the total proband group, alike in the MZ and DZ co-twins of the generalized anxiety disorder proband group, and three times as high in MZ as in DZ co-twins of the other proband groups. Anxiety disorders with panic attacks were more than five times as frequent in MZ as in DZ co-twins in a combined group of probands with panic disorders and agoraphobia with panic attacks. Thus, for generalized anxiety disorder, heritability was not apparent, while genetic factors seemed significant in other anxiety disorders, especially panic disorder and agoraphobia with panic attacks. Stevenson et al. studied 319 same-gender twin pair and showed that around 29% of the variance for fear and phobic symptoms was heritable (Stevenson et al., 1992).

With advances in molecular genetic techniques and high throughput genotyping methodology (see Chapter 29), scientists have conducted genetic association and linkage studies in an effort to identify specific genes and genetic regions that may increase susceptibility for anxiety disorders. (See Table 14.2 for commonly cited genetic studies). Because the animal literature has supported a role for serotonin in anxiety and fear, the usual focus of the studies has been candidate genes that code for neurotransmitters in the serotonin pathway including monoamine oxidase A (MAO-A), catechol-O-methyl-transferase (COMT), serotonin transporter (SLC6A4), receptors involved in serotonin transduction (such as 5HT1B), and GABA-A (Lesch, 2001). As is the case with genetics of complex diseases, findings from linkage and association studies have been inconsistent and conflicting, and therefore need further replication. Thus, several human studies have reported findings of association of polymorphisms in the promoter region of the serotonin transporter gene with anxiety, though other studies have been negative (Battaglia et al., 2005; Katsuragi et al., 1999; Lesch et al., 1996; Nakamura et al., 1997). In association studies of COMT genes in patients with OCD, two studies found an association in males (Karayiorgou et al., 1997, 1999), one found an

association for females (Alsobrook et al., 2002), and another found no association in any gender (Ohara et al., 1998). In one study, Samochowiec et al. looked at association studies of MAO-A, COMT, and serotonin transporter genes polymorphisms in patients with anxiety disorders of the phobic spectrum (Samochowiec et al., 2004). While there were no significant differences between controls ( $n = 202$ ) and patients ( $n = 101$ ) in the allele and genotype frequencies of the serotonin and COMT gene polymorphisms, the frequency of  $>3$  repeat alleles of the MAO-A gene polymorphism was significantly higher in female patients suffering from anxiety disorders, specifically panic attacks and generalized anxiety disorder.

## NEUROBIOLOGY

### Overview: Neurobiological Correlates of Anxiety

The prime directive of the human brain is to promote survival and procreation. When potentially threatening cues are present in these environments, the brain activates a complex set of neurophysiological, neuroendocrinological, and neuroimmunological responses to optimize the survival of the individual. In humans, activation of these threat-response systems is accompanied by the subjective perception of anxiety or fear.

An anxiety-inducing or fear-inducing stimulus generates sensory information that is transmitted from the peripheral sensory receptors to the dorsal thalamus. However, sensory information from the olfactory system is not relayed through the thalamus and is relayed to the amygdala and the entorhinal cortex (Turner et al., 1978). Visceral afferent pathways relay information to the amygdala and locus ceruleus directly or through the nucleus paragigantocellularis and nucleus tractus solitarius (Elam et al., 1986; Nauta and Whitlock, 1956; Saper, 1982). The thalamus relays sensory information to the primary sensory receptive areas of the cortex. These primary sensory regions project to adjacent cortical association areas. The visual, auditory and somatosensory cortical association areas send projections to the amygdala, orbitofrontal cortex, entorhinal cortex, cingulate gyrus, and other brain structures.

The hippocampus and amygdala are sites of convergent reciprocal projections form cortical association areas. These interconnections help a single sensory stimulus such as a smell, sight, or sound to elicit a specific memory or flashback along with symptoms of anxiety and fear (in case the smell, sight, or sound was associated with a traumatic event). We examine the possible neurobiological correlates of anxiety disorders in the following section by considering the abnormal organization, regulation, or development of neurobiological systems and subsystems within various brain regions that appear to be involved in sensing, processing, and responding to threat.

**TABLE 14.2**  
**GENETIC STUDIES**

Candidate Gene	Diagnosis/Trait or Symptom	Results	Reference/Lead Authors
<b>5-HTTLPR (promoter region of the serotonin transporter gene)</b>	Harm avoidance	Association with S allele	(Katsuragi et al., 1999)
	Harm avoidance, neuroticism	Association with S allele	(Lesch et al., 1996)
	Anticipatory worry	Linkage with SLC6A4* <i>C</i> , no association	(Mazzanti et al., 1998)
	Harm avoidance, neuroticism	No association with S allele	(Nakamura et al., 1997)
	Harm avoidance, neuroticism	No association with S allele	(Stoltenberg et al., 2002)
	OCD	No association with S allele	(Cavallini et al., 2002)
	OCD	No association with S allele	(Billett et al., 1997)
	Panic	No association with S allele	(Deckert et al., 1997)
	Panic	No association with S allele	(Hamilton et al., 1999)
	Social phobia	No association with S allele	(Stein et al., 1998)
<b>Catechol-O-methyltransferase (COMT)</b>	GAD	No association with COMT allele	(Ohara et al., 1998)
	OCD	Association with low activity allele, 22q11 microdeletions, low/low genotype in males only	(Karayiorgou et al., 1997)
	OCD	Association with low activity allele in males	(Karayiorgou et al., 1999)
	OCD	Association with the low-activity allele in females probands (P = 0.049)	(Alsobrook et al., 2002)
	OCD	No association with COMT allele	(Ohara et al., 1998)
	Panic	Association with marker D22S944	(Hamilton et al., 2002)
	Panic	No association with COMT allele	(Ohara et al., 1998)
	Phobia	No association with COMT allele	(Ohara et al., 1998)
<b>Monoamine oxidase-A (MOA-A)</b>	OCD	Association with MAO-A*297CGG allele	(Karayiorgou et al., 1999)
<b>HTR1B (Serotonin 1B receptor)</b>	GAD	No association with HTR1B 861G>C polymorphism	(Fehr et al., 2000)
	Panic	No association with HTR1B 861G>C polymorphism	(Fehr et al., 2000)
<b>5HT1D<math>\beta</math></b>	OCD	No association with a silent G-to-C substitution at nucleotide 861	(Di Bella et al., 2002)

Candidate Gene	Diagnosis/Trait or Symptom	Results	Reference/Lead Authors
<b>5HTR2A (Serotonin 2A receptor)</b>	Social phobia	No linkage	(Stein et al., 1998)
<b>Genome Wide Scans</b>	Panic	Linkage at 7p15, LOD = 2.2 (469 markers)	(Crowe et al., 2001)
	Harm avoidance	LOD = 3.2, Linkage with locus on 8p21–23, epistasis with 8p21–23 (291 markers studied)	(Cloninger et al., 1998)
	OCD	LOD = 2.25 on 9p (349 markers studied)	(Hanna et al., 2002)

OCD, obsessive-compulsive disorder; GAD, generalized anxiety disorder.

## THREAT-RESPONSE NEUROBIOLOGY IN THE MATURE CENTRAL NERVOUS SYSTEM

### Reticular Activating System: Arousal and Alarm

The reticular activating system is a network of ascending, arousal-related neural systems in the brain that consists of locus ceruleus noradrenergic neurons, dorsal raphe serotonergic neurons, cholinergic neurons from the lateral dorsal tegmentum, and mesolimbic and mesocortical dopaminergic neurons, among others. Much of the original research on arousal, fear, and response to stress and threat was conducted using various lesion models of the reticular activating system (Moore and Bloom, 1979). With the advent of more sophisticated neuropharmacological techniques that allowed precise manipulation and lesioning of individual neurochemical systems, the concept of the reticular activating system as a functional unit lost popularity. Recently, however, interest has been rekindled in the reticular activating system as an integrated neurophysiological system involved in arousal, anxiety, and modulation of limbic and cortical processing (Munk et al., 1996). Working together, the brainstem monoamine systems in the reticular activating system provide the flexible and diverse functions necessary to modulate the variety of functions responsible for anxiety regulation.

### Locus Coeruleus: Regulation of Arousal

The locus coeruleus is involved in initiating, maintaining, and mobilizing the total body response to threat (Aston-Jones et al., 1986). A bilateral grouping of norepinephrine-containing neurons originating in the pons, the locus coeruleus sends diverse axonal projections to virtually all major brain regions and thus functions as a general regulator of noradrenergic tone and activity (Foote et al., 1983). The

locus coeruleus plays a major role in determining the “valence,” or value, of incoming sensory information; in response to novel or potentially threatening information, it increases its activity (Abercrombie and Jacobs, 1987a, 1987b). The ventral tegmental nucleus also plays a part in regulating the sympathetic nuclei in the pons/medulla (Moore and Bloom, 1979). Acute stress results in an increase in locus coeruleus and ventral tegmental nucleus activity and the release of catecholamines throughout the brain and the rest of the body. These brainstem catecholamine systems (locus coeruleus and ventral tegmental nucleus) play a critical role in regulating arousal, vigilance, affect, behavioral irritability, locomotion, attention, and sleep, as well as the startle response and the response to stress (Levine et al., 1990; Morilak et al., 1987a, 1987b, 1987c).

A number of other neurotransmitters and neuropeptides play a role in modulating locus coeruleus activity, thus influencing the sensitivity of the threat response. Serotonin (Adell et al., 1988), enkephalins (Abercrombie and Jacobs, 1988), corticotrophin releasing hormone (CRH) (Butler et al., 1990), and epinephrine (Perry et al., 1983; Vantini et al., 1984) all can alter locus coeruleus sensitivity.

### Dopaminergic Systems: Sensitization

Dopaminergic systems play a critical role in the response to threat. In animal models, various stress paradigms have demonstrated alterations in dopamine metabolism and dopamine-receptor densities and sensitivity (Kalivas and Duffy, 1989; Kalivas et al., 1988). Dopaminergic systems originating in the mesencephalon send projections to key limbic and cortical areas involved in the afferent and efferent wings of the threat response. These systems are very important in sensation, perception, and interpretation of stress-related and threat-related cues.

Studies of psychostimulant-induced and stress-induced sensitization of dopaminergic systems provide important clues to the neurophysiological mechanisms that may

underlie the development of a sensitized anxiety response (Kalivas et al., 1988). Sensitization—an increased sensitivity to a constant stimulus—occurs in response to specific patterns of activation of these dopaminergic systems. In rats (Kleven et al., 1990), primates (Farfel et al., 1992), and humans (Post et al., 1988), psychostimulants (e.g., methamphetamine, cocaine) administered in moderate dosages can induce dramatic sensitization syndromes that include agitation, impulsivity, autonomic arousal, and even seizures (see case example below). Stress can induce similar sensitization in animal models (Antelman et al., 1980; Kalivas and Duffy, 1989).

#### **CASE EXAMPLE: PSYCHOSTIMULANT-INDUCED PANIC ATTACKS**

S., a 16-year-old, was admitted to the emergency room with diaphoresis, tachycardia, a sense of impending doom, and profound anxiety. He had no previous history of psychiatric disorder and denied previous anxiety or panic attacks. S. described a 4-month history of cocaine use characterized by binge nasal use. His last binge was 5 days prior to the admission. Since that time, he had been experiencing an escalating “sensitivity” to stress, with increased irritability and difficulty sleeping. Following an extensive medical and neuropsychiatric workup, S.’s episodes were formulated as reflecting a psychostimulant-induced panic disorder related to a sensitizing pattern of cocaine use. After discharge, S. experienced more panic attacks (approximately two per week) and elected to pursue recommended outpatient treatment. Successful drug rehabilitation and pharmacotherapy with a benzodiazepine anxiolytic for 6 weeks resulted in disappearance of the panic attacks.

Sensitization involves a cascade of cellular and molecular processes that are probably related to long-term potentiation (Brown et al., 1988; Kandel, 1989; Kandel and Schwartz, 1982; Madison et al., 1991). It has been hypothesized that sensitization of the biogenic amines (norepinephrine, epinephrine, and dopamine) in the reticular activating system and related systems plays a key role in the development of seizure disorders (Kalivas et al., 1988), affective disorders (Post, 1992), anxiety disorders (Post et al., 1988), and PTSD in both adults and children.

Organization of the developing brain occurs in a use-dependent fashion (see Chapter 1), and this organization may be affected by hypervigilance or anxiety that is pervasive, out of context, and extreme in reaction to neutral or minor threatening cues (Adell et al., 1988; Konarska et al., 1989). Therefore, many anxiety syndromes may reflect a maladaptive generalized activation of the alarm response (i.e., a sensitization), with symptoms representing exaggerations of originally adaptive and appropriate functions; for example, hypervigilance instead of appropriate prediction and early detection of future danger, and avoidance and reenactment rather than adaptation and survival.

#### **Hypothalamic/Thalamic Nuclei: Sensory Integration**

Sensory thalamic areas receive input from various afferent sensory systems, and at this level, “feeling” begins. Although thalamic nuclei are important in the stress response, these regions have been studied primarily as way stations that transmit important arousal information from the reticular activating system neurons (e.g., locus coeruleus noradrenergic neurons) to key limbic, subcortical, and cortical areas involved in sensory integration and perception of threat-related information (Castro-Alamancos and Connors, 1996). The neuroendocrinological—and likely neuroimmunological—afferent and efferent wings of the threat response are mediated by hypothalamic and other anatomically related nuclei. Animal studies have demonstrated important roles for various hypothalamic nuclei and hypothalamic neuropeptides in the stress response (Bartanusz et al., 1993; Miaskowski et al., 1988); (Rosenbaum et al., 1988), and this suggests that future studies in humans may demonstrate a key role of hypothalamic nuclei in anxiety disorders (Young and Lightman, 1992).

#### **Limbic System: Emotion Processing**

The central role of the subcortical network of brain structures in emotion was hypothesized by Papez (Papez, 1937). In 1949, MacLean coined the term *limbic system*, a name that integrated Papez’s circuit (hypothalamus, anterior thalamus, cingulate gyrus, and hippocampus) with other anatomically and functionally related areas (amygdala, septum, orbitofrontal cortex). Over the years, various regions have been added to or removed from this “emotion”-processing circuit.

#### **Amygdala: Perception of Threat and Emotional Memory**

The amygdala has emerged as the key brain region responsible for the processing, interpretation, and integration of emotional functioning (Clugnet and LeDoux, 1990). Just as the locus coeruleus plays the central role in orchestrating arousal, the amygdala plays the central role in the brain in processing afferent and efferent connections related to emotional functioning (LeDoux et al., 1988; Pavlides et al., 1993; Phillips and LeDoux, 1992). The amygdala receives input directly from the sensory thalamus, the hippocampus (via multiple projections), the entorhinal cortex, and the sensory association and polymodal sensory association areas of the cortex as well as from various brainstem arousal systems via the reticular activating system (Selden et al., 1991). The amygdala processes and determines the emotional valence of simple sensory input, complex multisensory perceptions, and complex cognitive abstractions, even responding specifically to complex socially relevant stimuli. In turn, the amygdala orchestrates the organism’s response to this emotional information by sending projec-

tions to brain areas involved in motor (behavioral), autonomic nervous system, and neuroendocrine areas of the CNS (Davis, 1992a, 1992b; LeDoux et al., 1988). In a series of landmark studies, LeDoux and colleagues demonstrated the key role of the amygdala in “emotional” memory (LeDoux et al., 1990). Animals, including humans, store emotional as well as cognitive information, and the storage of emotional information is critically important in both normal and abnormal regulation of anxiety. The site at which anxiety is perceived is the amygdala (Davis, 1992a). It is in these limbic areas that the patterns of neuronal activity associated with threat—and mediated by the monoamine neurotransmitter systems of the reticular activating system—become an emotion.

### Hippocampus: Association, Generalization, and Storage of Threat-Related Cues

A key neuroanatomic region in memory and learning is the hippocampus. This brain area is involved in the storage of various kinds of sensory information and is very sensitive to stress activation (Pavlidis et al., 1993; Phillips and LeDoux, 1992; Sapolsky et al., 1984). The hippocampus appears to be critical in the storage and recall of cognitive and emotional memory (Selden et al., 1991). Any emotional state related to arousal or threat may alter hippocampal functioning, changing the efficiency and nature of hippocampal storage and retrieval. These state-dependent memory and learning functions are vital for understanding various clinical aspects of childhood anxiety disorders. Threat alters the ability of the hippocampus and connected cortical areas to “store” certain types of cognitive information (e.g., verbal) but does not affect the storage of other types (e.g., nonverbal). Many of the cognitive distortions that appear to be associated with the development of anxiety disorders (e.g., agoraphobia) may be related to anxiety-related alterations in the “tone” of hippocampal and cortical association areas.

Neuronal systems are capable of making remarkably strong associations between paired cues (e.g., the growl of a tiger and threat). Although associations between patterns of neuronal activity and specific sensory stimuli occur in many brain areas, the most complex associations involving the integration of multiple sensory modalities are made in the more complex brain areas (i.e., the amygdala and cortex). Under ideal conditions, this threat-response capacity for association allows rapid identification of threat-related sensory information in the environment, enabling the organism to act quickly to protect its own survival. Yet this remarkable capacity of the brain to generalize from a specific event renders humans vulnerable to the development of false associations and overgeneralizations from specific threat situations to other nonthreatening situations.

In anxiety disorders, specific complex cues (e.g., snakes) may become linked with limbic-mediated emotions (e.g., anxiety). Limbic activation may result from cortically

mediated images (e.g., interpreting a specific event as potentially threatening or imagining a specific fear-inducing object such as a snake). Once these limbic areas have been activated, however, it is the sensitivity of the individual’s stress-response systems that determines whether the afferent and efferent wings of the alarm response will be activated.

### Cortical Systems: Interpretation of Threat

The quality and intensity of any emotional response, including anxiety, depend on subjective interpretation or cognitive appraisal of the specific situation eliciting the response (Maunsell, 1995; Singer, 1995). Most theories addressing the etiology of anxiety disorders focus on the process by which stimuli are “misclassified” as being “threat” related, thereby inducing a fear response and anxiety in situations where no true threat exists. How individuals “cortically interpret” the limbic-mediated activity (i.e., their internal state) associated with arousal plays a major role in their subjective sense of anxiety (Gorman et al., 1989). Klüver-Bucy syndrome, which results from damage to or surgical ablation of the temporal lobes, is characterized by absence of fear in response to current and previously threatening cues (Klüver and Bucy, 1937). The general disinhibition characteristic of this syndrome suggests a loss of the capacity to recall cortically stored information related to previous threat or to efficiently store threat-related cues from new experience.

Other areas of the cortex play a role in threat. Primary among these are the multimodal association areas, which have direct connections to the amygdala. Important neurotransmitters in cortical as well as other regions involved in threat are gamma-aminobutyric acid (GABA) and glycine. The capacity of benzodiazepines to alter arousal and sensitivity to threat has long been known. Benzodiazepines target the GABA receptor complexes. Although GABA binding sites are ubiquitous in the CNS, the specific brain site at which the benzodiazepines exert their therapeutic effects is unknown. It is likely that the therapeutic effects of these agents are the result of action in multiple areas of the brain, including the cortex.

#### CASE EXAMPLE: ANXIETY AFTER FRONTAL LOBE DAMAGE

X., an 8-year-old boy, presented to a neuropsychiatric clinic 8 months after a car accident in which he suffered a traumatic head injury. He had sustained significant frontotemporal injury with resulting loss of fluent speech and of motor and complex integrated sensory processing capabilities. Rehabilitative progress was being impeded by symptoms of profound anxiety, unwillingness to travel to the hospital for rehabilitation services, and a combative and “frightened animal”-like reaction when X. was forced to leave the house. All novel situations appeared to trigger his fearful, regressive, and combative tantrums. Once

an episode started, it was nearly impossible to stop, and it took almost a whole day for him to calm down and return to his baseline state.

After extensive neuropsychiatric evaluation, X.'s episodes were conceptualized as being fear equivalents complicated by—and related to—(1) difficulty in processing complex, novel stimuli and (2) failure of previously intact cortical modulatory mechanisms to contain his arousal and impulsivity once they were activated.

## Neuropeptides

Hormonal signals affect heterogeneous corticosteroid nuclear receptors; that is, type 1 (mineralocorticoid) or type 2 (glucocorticoid) in the hypothalamic-pituitary-adrenal (HPA) axis. Stressful life events such as isolation increase HPA axis activity (McEwen, 2001). The hippocampus, amygdala, and mPFC are limbic structures that are targets for and also modulate adrenal steroids. Glucocorticoids can result in neurotoxic damage to the hippocampus with suppression of neurogenesis (McEwen, 2001; Sapolsky, 2000). Exposure to stress results in release of corticotrophin releasing hormone (CRH), adrenocorticotrophic hormone (ACTH), and cortisol via activation of the HPA axis. During periods of stress there is partial resistance to feedback inhibition of cortisol release and increase in plasma cortisol levels, in addition to a decrease in glucocorticoid receptors (Sapolsky and Plotsky, 1990). Glucocorticoid receptors are present in the brain in high density in areas relevant to stress and anxiety such as the hypothalamus, hippocampus, serotonergic, and noradrenergic cell bodies on both neurons and glia. Based on animal studies, mineralocorticoid expression is high in limbic regions such as hippocampus, septum, and amygdala (Reul and de Kloet, 1985; Veldhuis and de Kloet, 1982). Animal studies suggest that stress experienced during critical years of development can have long-lasting effects on HPA axis. For instance, rats that experience in utero stress or early maternal deprivation have increased corticosterone concentrations when exposed to stress. Early postnatal stress is associated with changes in basal concentrations of hypothalamic CRH, mRNA, hippocampal glucocorticoid receptor mRNA, and median eminence CRH, in addition to the stress-induced CRH, corticosterone, and ACTH release (Levine et al., 1993a, 1993b; Stanton et al., 1988). Adults with PTSD and nonhuman primates with early adverse experiences have elevated CRH concentrations and decreased cortisol levels in the cerebrospinal fluid (Coplan et al., 1996).

The CRH1 and CRH2 receptors have a reciprocal role in anxiety and stress (Koob and Heinrichs, 1999). While CRH1-deficient mice exhibit diminished anxiety related behaviors, CRH2-deficient mice have heightened anxiety (Bale et al., 2000; Smith et al., 1998; Timpl et al., 1998).

Cholecystokinin (CCK) is an octapeptide that has been implicated in anxiety as well. It is found in high concentrations in the cerebral cortex, amygdala, and hippocampus in mammals (Woodruff et al., 1991). Studies in healthy human subjects suggest that CCK induces anxiety and panic, which can be reduced by lorazepam (de Montigny, 1989). In addition, CCK antagonists seem to have an anxiolytic effect (Bradwejn, 1992).

Neuropeptide Y is another neuropeptide which when administered intraventricularly has anxiolytic effects (Heilig et al., 1989). Thus, disturbance in its regulation may be involved in pathophysiology of anxiety disorders (Heilig et al., 1994).

## Perinatal Factors

At birth, infants are capable of exhibiting distress (anxiety) when exposed to loud noises, pain, heights, and strangers (Ball and Tronick, 1971; Bronson, 1972). While it is unwise to presume that what they are feeling is anxiety, it is certainly reasonable to hypothesize that they are experiencing subjective sensations of distress. Distress may be due to feeling cold, having low blood sugar, or hearing loud noises. Any simple set of sensory cues, internal or external, that threatens the integrity of the organism can activate the threat-response apparatus in infants.

A variety of in utero experiences may influence the sensitivity of the threat-response neurobiology in children. For example, prenatal exposure to psychoactive drugs may disrupt normal development of the brainstem catecholamines (Perry, 1988). In animal models, prenatal and perinatal stress can cause altered development of hippocampal organization and the hypothalamic-pituitary-adrenal axis (Plotzky and Meaney, 1993; Shors et al., 1990).

Whether temperament is related to genetic or to intrauterine factors is unknown. As is true of all complex human behavioral phenomena, it is likely that temperament is the result of a combination of genetic and intrauterine factors and that there is significant individual variation as to which factors are primary.

## Developmental Experience

Whereas the brainstem nuclei essential in the reticular activating system and the threat response are intact at birth, thalamic, limbic, and cortical systems are not yet fully developed and organized. The human brain develops sequentially, organizing in a use-dependent fashion and altering neuronal migration, differentiation, synaptogenesis, apoptosis, and other processes of neurophysiological organization in response to a host of external molecular cues (e.g., nerve growth factor, cellular adhesion molecules, pattern, and quantity of neurotransmitter receptor stimulation) (Thoenen, 1995). Therefore, as the child matures, limbic (emotional) and cortical (cognitive) development is very experience sensitive. What is different in the young

child compared with the adult may not be the subjective emotion related to the threat so much as the response of the still-developing CNS to the internal state of distress (Perry and Pollard, 1998) and the capacity of the immature cortex to make complex interpretations of the associations between paired stimuli (Singer, 1995).

### **Response to Threat**

The immature threat-response systems have developmentally appropriate precursors of the mature systems but are quite sensitive to experience. Because the brain organizes and develops in a “use-dependent” manner (Perry and Pollard, 1998), the presence and pattern of threat experienced during childhood play a major role in determining the sensitivity and final organization of the individual’s threat-response apparatus. Thus, children who are exposed to traumatic experiences develop anxiety-regulation problems with remarkable consistency (Perry and Pollard, 1998).

The classic adult response to impending threat is fight or flight (Cannon, 1914). Clearly, infants are incapable of effectively fighting or fleeing. Therefore, in response to the same internal state of anxiety and sense of impending doom experienced by the adult, infants will display a different behavior set; they will cry and thrash, and if these are unsuccessful in eliciting a response from the caregiver, they will typically use a very primitive adaptive response comparable to the defeat reaction observed in animals that are subjected to inescapable stress (Henry et al., 1986). When they are extremely anxious, infants and young children typically freeze and may dissociate as opposed to fighting or fleeing (Perry and Pollard, 1998). As children get older, their actions and reactions begin to change (although they may experience the same subjective sensation of anxiety that they did when younger), demonstrating a more “adult-like” efferent wing of the threat response.

### **Use-Dependent Development**

Before developing a mature internal stress-response capacity, the infant has an external stress-response apparatus, the primary caregiver (Bowlby, 1982; Erickson et al., 1985). When feeling internal distress associated with hunger, cold, or fear, the infant cries and the parent responds. If the caregiver responds in a reliable and consistent manner, there occurs over time a “building in” of the neurobiology that allows the infant to carry around, or internalize, what once was an external stress-response capacity (Bowlby, 1969).

Abnormal stress-response capacities and anxiety result when there are anomalies in these early experiences (Lee and Bates, 1985; Schneider-Rosen et al., 1985). These experiences may involve inconsistent or absent soothing by a caretaker or persistent “overmothering”, a situation in which a child’s behavior is excessively restricted (allegedly for the child’s own protection), such that he or she never has the opportunity to build in and organize (in a use-dependent way) a healthy stress-response apparatus. When such a child reaches school age, he or she has the

stress-response apparatus of a much younger child. This mismatch between the developmental maturity of the stress response and the increasing demands of the child’s environment can lead to significant school-based anxiety.

As children get older, they develop fears in reaction to specific situations and objects. These fears are common, and some may even involve genetic “fixed-action” patterns developed over eons of evolution (e.g., fear of snakes or of dogs). Most of these specific fears, however, are related to the paired (or mispaired) internalization of cues with anxiety from previous experience. During infancy and childhood, children mirror their caretakers’ responses when interpreting internal states of pain, arousal, or anxiety (Ainsworth, 1969; Bowlby, 1969). The child who falls on the playground and hurts her knee will look over to her father to see how to interpret her internal state. She can receive either a calm, reassuring look or an anxious, frightened response. Over time, then, the child will come to label a host of external cues as potentially threatening and certain internal sensations as fearful. This labeling process has been hypothesized to be an etiology of specific phobias and generalized anxiety disorders in children. Another illustration of these principles is seen in the offspring of adults with PTSD; such children often develop PTSD-like symptoms in response to the same cues that trigger PTSD symptoms in their parents.

## **CLINICAL IMPLICATIONS**

### **Conceptualizing Anxiety as Related to the Neurobiology of Threat**

Diverse areas of brain appear to be involved in the response to threat. For example, the subjective symptom of anxiety may result from either cortically-originated signals (e.g., a thought) or brainstem-originated signals (e.g., tachycardia, hypoxia). In each of these situations, a different primary pathophysiology can produce the same subjective sense of anxiety. The specific phenomenology and treatment issues associated with anxiety disorders and anxiety symptoms in other neuropsychiatric disorders reflect this diverse pathophysiology. The current classifications of childhood anxiety disorders depend on the phenotypic manifestations of emotional and behavioral functioning. Similar phenotypic manifestations, however, are likely to result from a variety of etiologies. The anxiety that manifests as the predominant symptom in any given disorder may be related to dysregulation within any of the key threat-response systems previously described or any combination of these systems. In addition, the principal “deficit” in any given system (e.g., locus coeruleus) may be attributable to dysfunction within any single neurobiological process or combination of processes (e.g., altered adrenergic receptor/effector coupling, abnormal neurotransmitter reuptake or release, inefficiencies in membrane transduction). Clearly, complex neurobiology underlies anxiety regulation.

## ASSESSMENT AND TREATMENT

The assessment of anxiety in children and adolescents is based on a thorough neuropsychiatric history and examination. Semistructured interviews are usually used in research settings for diagnosis such as the Anxiety Disorders Interview for Children (Silverman and Nelles, 1988), the Schedule for Affective Disorder and Schizophrenia for School-Age Children (K-SADS) (Kaufman et al., 1997), and the Diagnostic Interview for Children and Adolescents (Welner et al., 1987). A thorough diagnostic interview is usually sufficient in a clinical setting to confirm a diagnosis of anxiety disorders. Anxiety disorders should be considered in cases (even though anxiety may not be the primary complaint) with recurrent complaints of gastrointestinal symptoms, headaches, especially if these tend to resolve on weekends or vacations and present in anticipation of an anxiety-provoking stimulus. Frequent primary care visits for a variety of somatic complaints could also be a manifestation of anxiety disorders (Beidel et al., 1991). Inattentiveness in school could be secondary to anxiety, as anxious children can be preoccupied with anxiety provoking cognitions and appear distractible. It is also important to evaluate the intensity of symptoms, whether they cause functional impairment and evaluate their existence in a number of different contexts such as school or social gatherings. In addition, it is important to take a good history of concomitant medications as some medications may induce anxiety symptoms, such as St. John's wort, ephedra preparations, caffeine containing preparations, sympathomimetics, and asthma medicines.

A family history of anxiety disorders can assist with clinical diagnosis. In addition, it is helpful to ascertain the family history of response to treatment interventions as this has the potential to inform treatment.

Children often are not good historians; therefore, it is important to interview caregivers separately in addition to interviewing the patient in a developmentally sensitive manner. Young children can convey with gestures whether anxiety is a great big problem or a little problem. Older children can use a scale of 0 to 10 with 0 being never worried and 10 being intense fear or worry about many things. Children respond well to questions asking whether they worry or are fearful of things more than other kids. Children and parental ratings of each symptom (on a scale of 1 to 10) and examples of functional impairment (hours of rituals, missing school, avoidance of parties) can be written down at each visit to monitor progress. Patient rated, subjective scales such as the Supervised Children Manifest Anxiety Scale (Reynolds and Richmond, 1997) and the Multi-Dimensional Anxiety Scale (MASC) (March et al., 1997) can also be used to monitor progress. Clinician rated instruments that have utility in clinical and research settings include the Hamilton Anxiety Rating Scale (HAM-A) (Hamilton, 1959), the Children's Yale Brown Obsessive Compulsive Scale (CY-BOCS) (Scahill et al., 1997), and the

Screen for Child Anxiety Related Emotional Disorders (SCARED) (Birmaher et al., 1999).

Laboratory studies are obtained only if indicated by the history or examination. Thyroid screening (thyroid stimulating hormone levels) should be considered, unless anxiety symptoms are clearly contextual, such as in specific phobia or social phobia. Neuroimaging studies are not used for diagnostics because of poor sensitivity and specificity in anxiety disorders.

Among the most effective treatments of childhood anxiety disorders are cognitive-behavioral interventions (CBT) (Compton et al., 2004; Pediatric OCD Treatment Study (POTS) Team, 2004). CBT includes a diverse collection of complex interventions including cognitive restructuring and exposure-based interventions that promote habituation or extinction of inappropriate fears (Graziano et al., 1979). CBT also emphasizes psychoeducation as it can enhance compliance, family participation, and treatment success. Information resources for families are provided in Table 14.3. CBT also fits well into the current medical practice environment that encourages and values empirically supported, brief, problem-focused treatments.

The practice parameters for the assessment and treatment of pediatric anxiety disorders developed by the American Academy of Child and Adolescent Psychiatry recommend that pharmacotherapy should not be used as the sole intervention but as an adjunct to behavioral or psychotherapeutic interventions (Bernstein and Shaw, 1997). This is because of persuasive empirical support for CBT and the belief that benefits from CBT may be more enduring than pharmacotherapy (Bernstein and Shaw, 1997). Though these parameters were published in 1997, this treatment approach has been supported by subsequent comparative research where CBT appears at least as effective as pharmacotherapy (Pediatric OCD Treatment Study (POTS) Team, 2004). In addition, concerns about safety of antidepressants make CBT the first-line intervention (Newman, 2004). Utilization of pharmacotherapy is recommended when there is inadequate improvement with CBT (Bernstein and Shaw, 1997).

Although, data supporting the efficacy of anxiolytic pharmacotherapy in children are limited, progress has been made with publication of large multisite controlled trials using selective serotonin reuptake inhibitors (SSRIs). SSRIs are the first-line pharmacological interventions for pediatric anxiety disorders. Table 14.4 presents an overview of SSRIs.

The first large pediatric OCD trial utilized fluvoxamine, an SSRI, in a controlled trial of 120 subjects, ages 8 to 17 years (Riddle et al., 2001). This double-blind, placebo-controlled study utilized 10 weeks of core treatment, followed by a 1-year extension phase. The average daily dose of fluvoxamine was approximately 150 mg/d, and the dose range was between 50 and 200 mg/d. Significant improvement of OCD symptoms began at week 1 and continued over the course of the study. Improvement was

noted on three outcome measures: the Children's Yale-Brown Obsessive-Compulsive Scale (CY-BOCS), the National Institute of Mental Health Obsessive-Compulsive Scale (NIMH-OCS), and the Clinical Global Impressions-Improvement Scale (CGI). Fluvoxamine was well tolerated and few subjects dropped out due to lack of efficacy (9%) or untoward effects (3%). These data resulted in an FDA indication for fluvoxamine for treatment of OCD in children and adolescents ages 8 to 17 years old. This trial was followed by another large controlled SSRI trial for OCD was a sertraline study of 187 children and adolescents, ages 6 to 17 years old (March et al., 1998). Patients were treated with sertraline during a 4-week titration up to 200 mg/d, followed by 8 weeks at a stable dose. Significant differences between sertraline and placebo emerged at week 3 and persisted for the duration of the study. In intent-to-treat analyses, patients treated with sertraline showed significantly greater improvement than did placebo-treated patients on the CY-BOCS (adjusted mean,  $-6.8$  versus  $-3.4$ , respectively;  $P = .005$ ), the NIMH OCS ( $-2.2$  versus  $-1.3$ ,

respectively;  $P = .02$ ), and the CGI-I ( $2.7$  versus  $3.3$ , respectively;  $P = .002$ ) scales. Significant differences in efficacy between sertraline and placebo emerged as early as 3 weeks and persisted for the duration of the study. These data earned an Federal Drug Administration (FDA) indication for sertraline treatment of OCD in children and adolescents ages 6 to 17 years old. This study was followed up by a randomized controlled trial of sertraline, cognitive behavioral psychotherapy (CBT), and a combination of CBT and sertraline in 112 children and adolescents diagnosed with OCD (Pediatric OCD Treatment Study [POTS] Team, 2004). Intent-to-treat random regression analyses indicated a statistically significant advantage for sertraline alone ( $P = .007$ ), and combined treatment ( $P = .001$ ) compared with placebo. Combined treatment also proved superior to CBT alone ( $P = .008$ ) and to sertraline alone ( $P = .006$ ), which did not differ from each other. The rate of clinical remission for combined treatment was 53.6% (95% confidence interval [CI], 36% to 0%); and for sertraline alone.

**TABLE 14.4**  
**SELECTIVE SEROTONIN REUPTAKE INHIBITORS**

Agent	FDA Pediatric Labeling	Clinical Use	Dose-Mg/d	Schedule	Adverse Effects
Fluoxetine	OCD (7–17 years)	OCD, GAD, SP, SAD, PD	5–60	QD	Suicidality, irritability, insomnia akathesia, GI disturbance
Paroxetine	N/A		10–30	QD	Headache
Sertraline	>6 years for OCD		25–200	QD	Rash, fluelike symptoms on rapid discontinuation, CYP inhibition
Fluvoxamine	>8 years for OCD		12.5–200	QD	
Citalopram	N/A		10–40	QD	
Escitalopram	N/A		5–30	QD	

OCD, obsessive-compulsive disorder; GAD, generalized anxiety disorder; SP, social phobia; SAD, separation anxiety disorder; PD, panic disorder.

Rosenberg et al. utilized paroxetine (10 to 20 mg) in a 12-week, open-label trial with 20 patients diagnosed with OCD, ages 8 to 17 years. Paroxetine was effective in this small sample as mean CY-BOCS scores decreased significantly ( $z = 3.49$ ,  $P = .0005$ ) from 30.6  $\pm$  3.5 to 21.6  $\pm$  6.8. Another psychotropic agent with controlled safety and efficacy data for pediatric OCD is clomipramine (DeVeugh-Geiss et al., 1992; Flament et al., 1985; Leonard et al., 1989), a tricyclic antidepressant with potent serotonin (5-HT) reuptake inhibitor and noradrenergic activity. DeVeugh-Geiss et al. enrolled 60 children, ages 10 to 17 years old and diagnosed with OCD, and demonstrated significant improvements in OCD symptoms (DeVeugh-Geiss et al., 1992). The side effects from clomipramine were those seen typically with tricyclic antidepressants such as tachycardia, decreased systolic blood pressure, dry mouth, somnolence, dizziness, fatigue, tremor, and constipation. In a meta-analysis, Geller et al. demonstrated that clomipramine was statistically superior to SSRIs in reducing OCD symptoms but did not recommend it as a first-line treatment due to its side effect profile (Geller et al., 2003). The SSRIs examined in this meta-analysis had equivalent efficacy in this population (Geller et al., 2003).

Data are also emerging on the efficacy of SSRIs in anxiety disorders such as social phobia (SP), separation anxiety disorder (SAD), and generalized anxiety disorder (GAD). However, no pharmaceutical agent is currently approved by the FDA for treatment of these disorders in children and adolescents. The Research Unit on Pediatric Psychopharmacology Anxiety Study Group (RUPP, 2001) studied 128 children who were 6 to 17 years of age; who met the criteria for social phobia, separation anxiety disorder, or generalized anxiety disorder; and who had received psychological treatment for three weeks without improvement. The children were randomly assigned to receive fluvoxamine (at a maximum of 300 mg per day) or placebo for 8 weeks. Subjects in the fluvoxamine group had a mean ( $\pm$ SD) decrease of 9.7  $\pm$  6.9 points in symptoms of anxiety on the Pediatric Anxiety Rating Scale (range of possible scores, 0 to 25, with higher scores indicating greater anxiety), as compared with a decrease of 3.1  $\pm$  4.8 points among children in the placebo group ( $P \leq 0.001$ ). On the Clinical Global Impressions-Improvement scale, 48 of 63 children in the fluvoxamine group (76%) responded to the treatment, as indicated by a score of less than 4, as compared with 19 of 65 children in the placebo group (29%,  $P \leq 0.001$ ) (RUPP, 2001).

Birmaher et al. evaluated the efficacy of fluoxetine for the acute treatment of pediatric GAD, SAD, or SP by randomizing youths (7 to 17 years old) who had significant functional impairment due to the above diagnoses to fluoxetine (20 mg/day) ( $n = 37$ ) or placebo ( $n = 37$ ) for 12 weeks (Birmaher et al., 2003). Using intent-to-treat analysis, 61% of patients taking fluoxetine and 35% taking placebo showed much to very much improvement. Youths with social phobia and generalized anxiety disorder

responded better to fluoxetine than placebo, but only social phobia moderated the clinical and functional response. Severity of the anxiety at intake and positive family history for anxiety was a predictor of poorer functioning at the end of the study (Birmaher et al., 2003).

In a multicenter, 16-week, randomized, double-blind, placebo-controlled trial with flexible-dose paroxetine, Wagner et al. enrolled 322 children (8 to 11 years of age) and adolescents (12 to 17 years of age) with social anxiety disorder as their predominant psychiatric illness (Wagner et al., 2004). Patients were randomized to receive paroxetine (10 to 50 mg/d) or placebo. At the week 16 last observation carried forward end point, the odds of responding (Clinical Global Impression-Improvement score of 1 or 2) were statistically significantly greater for paroxetine (77.6% response than for placebo 38.3% response [59/154]; adjusted odds ratio, 7.02; 95% confidence interval, 4.07 to 12.11;  $P \leq 0.01$ ). The proportion of patients who were "very much" improved (Clinical Global Impression-Improvement score of 1) was 47.8% (77/161) for paroxetine compared with 14.9% (23/154) for placebo.

Based on these data, SSRIs are a useful intervention for pediatric anxiety disorder. While prescribing SSRIs, it would be prudent to weigh the risks against the benefits of prescribing these agents. SSRIs may produce stomachache, nausea, vomiting, diarrhea, and anorexia (Birmaher et al., 2003; Scharko, 2004). According to a joint advisory committee for the Food and Drug Administration, antidepressants can increase the risk of suicidal behavior in the pediatric age group. On September 14, 2004, the advisory committee voted in favor of a "black box warning" stating the risk of suicidality with antidepressants in acute treatment trials. This warning was based on a pooled analysis of short-term (4 to 16 weeks) placebo-controlled trials of nine antidepressant drugs (SSRIs and others) in children and adolescents with MDD and other anxiety disorders including OCD. This analysis included 24 trials with approximately 4,400 patients, and it revealed a greater risk of adverse events representing suicidal thinking or behavior (suicidality) across all antidepressants and almost all trials during the first few months of treatment in those receiving antidepressants. The average risk of such events on drug was 4%, twice the placebo risk of 2%. No suicides occurred in these trials.

## FUTURE DIRECTIONS

The completion of a working draft of the human genome sequence promises to provide unprecedented opportunities to explore the genetic basis of individual differences in anxiety disorders, in addition to vulnerability to fear and anxiety (Hariri and Weinberger, 2003). Functional neuroimaging, because of its unique ability to assay information processing at the level of brain, will be a powerful approach that will supplement functional genomics.

Published fMRI studies are already beginning to establish important physiological links between functional genetic polymorphisms and differences in information processing within specific brain regions (Hariri et al., 2005). Further utilization of such technical advancements is likely to improve understanding of the biological basis of anxiety disorders, which could lead to novel and more effective treatments for these disorders. Since the mid-1990s, results of several large clinical trials have been published or presented in scientific conferences. These trials demonstrate that often the best available treatments fail to produce full symptom remission. Therefore advancement in scientific knowledge is sorely needed to aid development of new and better treatments.

# Eating Disorders

15

**David C. Jimerson, MD**    **Barbara E. Wolfe, PhD, RN, CS**  
**Silke Naab, Dr Med**

There has been increasing awareness of the prevalence of anorexia nervosa and bulimia nervosa and of the need for intensified clinical investigation of the pathophysiology of these neuropsychiatric disorders. Much has been learned regarding etiological factors and new treatment approaches. For both anorexia nervosa and bulimia nervosa, distinguishing clinical features involve abnormalities in eating patterns, with related alterations in perceptions regarding body weight and appearance. In this chapter, we provide a clinical overview of these disorders from a neuropsychiatric perspective.

## NEUROBIOLOGY OF EATING BEHAVIOR

Patterns of ingestive behavior result from a complex interaction of neurobiological substrate with social, cultural, and psychological influences. Neurochemicals that influence eating behavior include a wide range of endogenous central nervous system (CNS) monoamine neurotransmitters, neuropeptides, and hormones. For many of these chemical messengers, neuronal receptors mediating effects on eating behavior are localized in the hypothalamus. Thus, lesions of the hypothalamus may disrupt normal patterns of eating behavior.

Laboratory methods have been developed to identify selective effects of endogenous neurochemical pathways on hunger, satiety, and food preferences (1, 2). Important variables for describing eating patterns include meal size, rate of food intake during initial and later phases of the meal, interval between meals, and timing of meals over the course of the day. Hunger is associated with initiation of eating and a rapid initial rate of food ingestion. Satiety

reflects the slowing of food intake that normally takes place during a meal, with subsequent termination of the meal. Eating patterns are influenced by palatability of the meal and food reward (i.e., the feeling of pleasure associated with a meal). These characteristics can be assessed by evaluating food selection, including relative preferences for protein, carbohydrate, and fat.

The influence of the monoamine neurotransmitters on eating behavior has been studied in detail (3). Serotonergic pathways arising from cell bodies in the raphe nuclei and terminating in the medial basal hypothalamus contribute to postingestive satiety (4). Thus, serotonin (5-hydroxytryptamine [5-HT]) antagonists increase food intake, as do drugs that inhibit serotonin release by stimulating inhibitory 5-HT<sub>1A</sub> somatodendritic autoreceptors. Pharmacological studies, and observations in mutant mice (5), suggest that postsynaptic 5-HT<sub>2</sub> receptors are particularly important in the satiety produced by serotonergic drugs. Clinically, serotonin-active medications (e.g., sibutramine) have been used to facilitate weight loss in the treatment of obesity (6).

The catecholamines act at several sites in the CNS to influence food intake. In the paraventricular nucleus of the hypothalamus, norepinephrine acts at  $\alpha_2$ -adrenoceptors to augment feeding behavior (7). Systemic administration of noradrenergic drugs is typically associated with decreased food intake, however, reflecting activation of  $\beta$ - and  $\alpha_1$ -adrenoceptors (3). Research in rodents suggests that  $\beta_3$ -adrenoceptor agonists may facilitate weight loss by increasing energy metabolism in peripheral fat stores (8). Dopamine acts at receptors in the lateral hypothalamus to suppress food intake (7), while dopamine release in mesolimbic pathways appears to contribute to the hedonic/reward responses that sustain food intake (9).

A wide range of hypothalamic neuropeptides, gut-related peptides, and adipokines are active in modulating food intake, and may play a role in symptom patterns in the eating disorders (Table 15.1) (10). Interest has focused

Orexins	Corticotrophin-releasing hormone

on the role of neuropeptide Y, galanin and ghrelin in increasing food intake, and on the effects of cholecystokinin (CCK), corticotrophin-releasing hormone (CRH), and the melanocortins in terminating feeding behavior (11, 12). Additional research is needed to map the interactions among the neurochemical regulators of eating behavior. For example, studies have shown that serotonin interacts with CCK and melanocortin pathways in postingestive satiety (13, 14).

Body weight regulation reflects a balance between energy intake and energy expenditure. The major components of energy expenditure include resting metabolic rate, physical activity, and the thermic effect of food. The sympathetic nervous system and the hypothalamic-pituitary-thyroid axis modulate metabolic rate. Research has shown that leptin, the protein product of the obese gene, is important in body weight regulation. Defects in leptin function have been implicated in several rodent models of obesity (15, 16). In that leptin may act at specific hypothalamic receptors to decrease eating behavior, the leptin system provides a potential target site for new pharmacological agents for the treatment of eating disorders and obesity.

## ANOREXIA NERVOSA

### Diagnostic Features

Anorexia nervosa is an eating disorder characterized by “refusal to maintain body weight at or above a minimally normal weight for age and height” (Table 15.2). Additional criteria for the diagnosis of anorexia nervosa include intense fear of excessive weight gain, markedly abnormal attitudes and perceptions regarding body shape and weight, and amenorrhea (in postmenarcheal women). In DSM-IV (17), anorexia nervosa is designated as “binge-eating/purging type” or “restricting type,” based on presence or absence of regular binge-purge behaviors. There is relatively limited information regarding physiological or neuropsychiatric differences between “binge-eating/purging” and “restricting” subtypes of anorexic patients, although the latter group may gain weight more slowly during initial treatment and may have a lower rate of recovery (18, 19). Clinical and family studies in individuals with anorexia nervosa have shown significant co-occurrence of several Axis I disorders, particularly major depression and anxiety disorders (20). Studies of eating behavior in patients with anorexia nervosa have demonstrated a variety of patterns in premeal and postprandial hunger and satiety (21). In general, eating patterns in patients with this disorder do not appear to reflect loss of appetite or abnormality in taste perception.

### Epidemiology and Etiology

Epidemiological studies indicate that the prevalence of anorexia nervosa is approximately 0.2 to 0.5% among adolescent and young adult females, with a lifetime prevalence rate of 0.5 to 3.7% (22–25). The clinical syndrome of anorexia nervosa has been recognized in the medical

**TABLE 15.2**  
**DSM-IV DIAGNOSTIC CRITERIA FOR ANOREXIA NERVOSA**

- Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected or failure to make expected weight gain during period of growth, leading to body weight less than 85% of that expected).
- Intense fear of gaining weight or becoming fat, even though underweight.
- Disturbance in the way in which one’s body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or denial of the seriousness of current low body weight.
- In postmenarcheal females, amenorrhea—that is, the absence of at least three consecutive menstrual cycles. (A woman is considered to have amenorrhea if her periods occur only following hormone, e.g., estrogen, administration.)

### Specify Type

**Restricting Type:** During the episode of anorexia nervosa, the person has not regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics, or enemas).

**Binge-Eating/Purging Type:** During the current episode of anorexia nervosa, the person has regularly engaged in binge-eating or purging behavior (i.e., self-induced vomiting or the misuse of laxatives, diuretics or enemas).

literature since the nineteenth century (26). Although some studies have suggested that the prevalence of the disorder has increased in recent decades, this has not been a consistent finding (27). The female-to-male ratio for anorexia nervosa is approximately 10 to 1. Among patients with early onset of the disorder, however, boys may represent up to 30% of all cases (28).

Specific etiological factors have not been identified for anorexia nervosa, although psychosocial, cultural, and occupational factors that contribute to preoccupation with body shape and weight have been implicated. Family and twin studies point to a combination of psychosocial and genetic factors in the etiology of the disorder (24, 29–31).

## Neurobiology

### Neurotransmitter Studies

A central focus of neurotransmitter studies in anorexia nervosa has been the serotonin system (32). Studies of cerebrospinal fluid (CSF) concentrations of the major serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) have demonstrated low concentrations in patients with anorexia nervosa, with recovery toward normal values as patients regain weight (33). Pharmacological challenge studies have assessed neuroendocrine and behavioral responses to serotonin agonist medications as a probe for responsiveness in CNS serotonergic pathways. In general, these studies have shown blunting of serotonin-stimulated neuroendocrine responses in low-weight patients, with restoration toward normal responses as patients regain weight (34–37).

It is not known whether changes observed in the low-weight state are strictly secondary to nutritional deprivation and weight loss or whether they have a specific association with the disorder. In anorexic patients evaluated after long-term weight restoration, there is a return to normal neuroendocrine responses. Trait-related changes in serotonin function appear to persist, however, as reflected in abnormally elevated CSF 5-HIAA values and abnormal behavioral responses to a serotonergic drug (38–40). Consistent with this hypothesis, brain imaging studies have shown that the decreased 5-HT<sub>2A</sub> receptor binding that is found in low-weight patients is also seen in individuals studied following long-term weight recovery (41–43).

From a clinical perspective, in that serotonin is thought to play an important role in postingestive satiety responses, excessive serotonin function could contribute to the small meal sizes and weight loss presaging the onset of anorexia nervosa (44). Additionally, dysregulation of serotonin function could contribute to comorbidity with other psychiatric disorders, particularly major depression and obsessive-compulsive disorder (32, 45).

Other neurotransmitter abnormalities that have been demonstrated in low-weight patients with anorexia nervosa include low CSF concentrations of norepinephrine

and the dopamine metabolite homovanillic acid (46). Additionally, as recently reviewed, alterations in CSF concentrations of neuropeptide immunoreactivity have been demonstrated in low-weight patients with anorexia nervosa, including low levels of opiate-related peptides, low thyroid-releasing hormone, and elevated neuropeptide Y (10).

### Neuroendocrine Function

Anorexia nervosa is characterized by dysregulation of hypothalamic-pituitary neuroendocrine systems (47). Amenorrhea in female patients with anorexia nervosa is associated with decreased circulating levels of follicle stimulating hormone and luteinizing hormone (48). Elevated serum cortisol levels reflect increased activity in the hypothalamic-pituitary-adrenal axis (49, 50). The hypothalamic-pituitary-thyroid axis is down-regulated, consistent with an energy-conserving metabolic state. Low serum levels of triiodothyronine (T<sub>3</sub>), usually with normal thyrotropin levels, reflect a “sick euthyroid” syndrome (51).

The neuroendocrine abnormalities of anorexia nervosa are generally thought to be a consequence of changes in nutritional status and weight loss. Hormone levels return toward normal as the recovering patient regains body weight, although delays may be experienced; for example, in the restoration of normal menstrual cycles. The physiological signals involved in the neuroendocrine changes of weight loss are not fully understood, although laboratory data suggest a possible role for decreased circulating levels of leptin, an adipokine that reflects body fat stores (52, 53). The clinician should be alert to the possibility that neuroendocrine abnormalities may also reflect factors other than weight loss. Hypercortisolemia may reflect comorbid major depression, for example. For a patient with primary amenorrhea associated with hypogonadotropic hypogonadism and atypical symptoms of anorexia nervosa, the possibility of the rarely occurring Kallmann’s syndrome should be considered (54).

Clinical studies have suggested that in some children with tics and obsessive-compulsive behaviors, these symptoms could be associated with a syndrome known as “pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection” (PANDAS) (55). Initial reports suggest that some patients with anorexia nervosa have laboratory findings consistent with the PANDAS syndrome (56). Until additional studies are published, however, the nature of this possible association remains uncertain.

### Morphometric Brain-Imaging Studies

In that neuropsychiatric consultation for anorexia nervosa may include questions regarding alterations in brain morphology reported in imaging studies, results of investigations in this area are outlined in some detail. Initial studies in anorexia nervosa based on radiograph-computed tomographic (CT) data showed abnormal enlargement of

cortical sulci and the interhemispheric fissures (57–59). Subsequent controlled CT studies provided further evidence for cortical sulcal atrophy in anorexic subjects, as reflected in enlargement of subarachnoid spaces (60–65). Additionally, cerebral ventricular enlargement has been demonstrated in a number of these studies (61–64).

Investigations using magnetic resonance imaging (MRI) have also shown increased ventricular size and enlarged cortical sulci in patients with anorexia nervosa compared with control subjects (62, 66–71). One study reported localized decreases in the size of the thalamus and midbrain regions (72), and several studies have reported reduced pituitary gland height (62, 69, 73).

Data indicate that structural brain changes in anorexia nervosa may particularly involve white matter regions (74). This study showed that in comparison to controls, low-weight patients had significant decrements in frontal, parietal, temporal, and total white matter, with less prominent decreases in gray matter. It is of interest that studies using proton magnetic resonance spectroscopy (MRS) have shown significant changes in white matter composition in anorexic patients (75, 76).

In general, patients with the greatest weight loss have the most pronounced enlargements of the ventricles and cortical sulci on brain-imaging studies (60, 63, 64, 66, 68, 69, 77, 78), although this correlation has not been observed in all investigations (61, 62). Physiological factors that may contribute to alterations in low-weight anorexia include malnutrition, fluid and electrolyte abnormalities, and hormonal influences; for example, hypercortisolemia or decreased insulin-like growth factor-1 (74, 79). In some patients the abnormalities could be associated with developmental insults or other preexisting alterations (57, 65). One study reported that chronic self-induced vomiting was associated with abnormal brain ventricular enlargement (67).

It is noteworthy that although brain imaging studies have consistently shown structural abnormalities in low-weight patients compared with matched control subjects, the magnitude of these changes has typically not been large enough to be identified as “clinically abnormal” in a nonresearch setting (69). Although significant cognitive impairments have been found in anorexic patients, there is limited evidence for an association between structural abnormalities and measures of cognitive function (64, 65, 69, 70, 80).

Longitudinal studies suggest that enlargement of cortical sulci and brain ventricles and decreased total brain volume observed at low weight tend to return toward normal following weight gain (57, 59, 61–64, 66, 69, 71). There are, however, some data to suggest that individuals who have achieved stable weight recovery from anorexia nervosa have persistent increases in ventricular volume and decreased gray matter volume in comparison to controls (81, 82). One study indicated that there is an enduring selective decrease in volume in the hippocampus-amygdala area in weight-recovered individuals (83). Additional studies are needed to evaluate the potential clinical implications of these findings.

### **Functional Brain-Imaging Studies**

Studies to assess resting regional brain activity in anorexia nervosa have utilized [ $^{18}\text{F}$ ]-2-deoxyglucose positron-emission tomography (PET) to measure glucose metabolism and single-photon emission computed tomography (SPECT) and functional magnetic resonance imaging (fMRI) to measure regional cerebral blood flow (rCBF). PET imaging showed global hypometabolism in anorexic patients, particularly prominent in the frontal and parietal cortices (84). Absolute hypometabolism was also found in low-weight depressed patients, suggesting the importance of weight loss per se (85). A notable finding was relative hypermetabolism in the caudate nuclei and inferior frontal cortex (86, 87). The investigators postulated that this finding could be associated with symptoms of increased vigilance and attention to detail, consistent with brain imaging findings in patients with obsessive-compulsive disorder (88, 89). Following weight recovery, differences between patients and controls were no longer significant (87), although there was a persistent trend toward relative parietal hypometabolism and inferior frontal hypermetabolism (86).

Comparison of resting rCBF in patients with anorexia nervosa and controls based on SPECT have generally shown decreased blood flow in areas of the cerebral cortex. Most, but not all studies (90), have shown decreases in areas including the parietal, frontal, and temporal regions (91–94). A series of 21 subjects with adolescent-onset disorder, many studied following stable weight recovery, showed hypoperfusion of temporal, parietal, and orbitofrontal regions that appeared to persist following recovery (95). In contrast to these findings, a recent  $^{15}\text{O}$ -PET study showed bilateral elevation of rCBF within medial temporal lobes in anorexic patients compared to healthy controls, although data were averaged across baseline and provocation conditions (96). Differences in specific regional findings across these studies are likely to reflect sample size constraints, heterogeneity of the patient groups, and limitations in the availability of satisfactory control data.

From a pediatric perspective, a finding of interest was that in 15 children and adolescents with anorexia nervosa, 87% had asymmetric temporal lobe hypoperfusion (97). A follow-up study of an additional 15 patients, with a mean age of approximately 15 years, found consistent evidence for blood flow asymmetry (hypoperfusion) in 11 of the subjects, including asymmetrical temporal lobe perfusion in 9 subjects (98). In that scans from control subjects were not available for these studies because of concerns related to radiation exposure, follow-up studies using fMRI will be of interest.

Imaging studies in association with symptom provocation paradigms provide another approach to identification of regional alterations of cerebral function in anorexia nervosa. Initial studies have employed paradigms including ingestion of a test meal, visualization of high-calorie and low-calorie foods, and visualization of distorted body images. Areas of differences in response between patients and

controls have included the left inferior frontal region (91); the right inferior prefrontal, superior prefrontal, and parietal regions (99); the left insula, anterior cingulate gyrus, and left amygdala-hippocampal region (100); the left occipital cortex and right temporo-occipital cortex (96); and the inferior parietal region (101). Additional studies will be useful in clarifying the extent to which these paradigms result in reproducible emotional, cognitive, and physiological responses in anorexia nervosa, paving the way for future replication studies with independent patient samples.

### Course and Prognosis

The typical age of onset of anorexia nervosa is in late adolescence, with an average age of 18 to 21 years at the time of diagnosis (24, 102). Reviews of anorexia nervosa with early onset (between 8 and 14 years of age) point to similarities in symptom patterns and clinical course when compared with later onset illness (28, 103–107).

Estimates of long-term outcome of anorexia nervosa are complicated by limitations in sample size and methodological differences across studies. Studies suggest, however, that 40 to 75% of patients are recovered at 10-year to 21-year follow-up, with 10 to 20% of patients having significant persisting symptomatology (108–112). However, a comprehensive review of follow-up studies of more than 5,000 patients with anorexia nervosa suggests that fewer than half actually achieve full recovery (106). Although at 7.5 years follow-up, 30% of patients with the disorder were found to be in full remission, 40% would relapse (113). Poor prognosis has been associated with duration of illness, binge-eating and purging behaviors, and obsessive-compulsive personality symptoms (106). Risk for relapse is associated with low weight at presentation and at time of discharge from inpatient hospitalization (113–115).

Anorexia nervosa is among the neuropsychiatric conditions having the highest mortality rate (116). Based on a review of outcome studies, the aggregate mortality rate has been estimated to be approximately 5.6% per decade (117). Clinical characteristics such as prolonged duration of illness, bingeing and purging behavior, and comorbid substance abuse and affective disorder have been associated with death in patients with the disorder (118).

There are insufficient data to detect differential patterns of long-term outcome for early-onset and later-onset cases (28, 119, 120). Potential physiological consequences of prolonged malnutrition associated with premenarcheal-onset anorexia nervosa have been described (121).

### Clinical Features and Assessment

A “Practice Guideline” for the assessment and treatment of patients with anorexia nervosa has been published by the American Psychiatric Association (122). As this manual outlines, the clinical assessment of cachectic patients with

symptoms suggestive of anorexia nervosa entails a comprehensive neuropsychiatric and general medical history and physical examination. Evaluation of current symptomatology includes a detailed review of eating patterns, exercise patterns, and attitudes toward body shape and weight. It is often useful for the clinician to inquire about specifics of meal content and schedule. The clinician should assess whether the patient is engaging in binge-eating and purging behaviors, including possible use of laxatives, diuretics, appetite suppressants, or syrup of ipecac. Patterns of body weight during development, including previous high and low weights in relationship to height, should be noted, as well as details regarding the initial onset of weight loss.

Comorbid psychiatric disorders in patients with anorexia nervosa include mood and anxiety disorders (123, 124), particularly obsessive-compulsive disorder (125, 126). Thus, the clinician should be particularly alert to symptoms suggestive of current or past depression, anxiety disorders, obsessive-compulsive disorder, and substance abuse disorders.

The psychosocial history includes a review of recent personal stresses and family/social tensions (127) and evidence for previous physical or sexual abuse. The family history obtains information on the presence of eating disorders or other neuropsychiatric disorders or obesity in family members (128). A family assessment may be useful to evaluate the residential environment for younger patients living at home.

When performing the medical history and review of symptoms, the clinician should be alert to history of fainting related to dehydration, symptoms of anemia, cold intolerance, and disrupted sleep patterns. Symptoms suggestive of medical illness that could contribute to unexplained weight loss, such as tumors or infectious illness, should be evaluated. For adolescent and adult females, information is obtained on age at menarche, regularity of menstrual periods, and episodes of secondary amenorrhea.

In the context of a complete mental status examination, the clinician should be alert to symptoms such as delusions or psychotic thought processes, which could signal the presence of another primary psychiatric disorder. Assessment of current mood includes questions about suicidal, destructive, or impulsive ideation. Cognitive function is evaluated for changes suggestive of a neurological or metabolic disorder. Impaired cognitive performance in patients with anorexia nervosa has been noted by some investigators (129–133), but not by others (65, 134). In anorexic patients studied longitudinally, there is evidence that cognitive function improves with weight restoration (59).

The initial evaluation of a patient with apparent anorexia nervosa generally includes a physical examination, laboratory studies, and an electrocardiogram (122, 135, 136). Bradycardia and postural hypotension are common findings in patients with severe weight loss. A dental examination, if not recently performed, can indicate whether self-induced vomiting has resulted in erosion of

the dental enamel. Selection of laboratory tests depends on the severity of symptoms and results of the medical history and physical examination; such testing often includes a complete blood count, serum electrolytes, blood urea nitrogen (BUN), serum creatinine, blood levels of thyroid hormones, and urinalysis. For cachectic patients, additional laboratory studies include liver function tests and blood levels of calcium, magnesium, and phosphorus. In some situations, bone mineral densitometry may be considered to evaluate the risk of fracture from osteoporosis related to malnutrition and possibly to low estrogen levels (137, 138). Data suggest that following longterm remission (11 years), bone mineral density is inversely associated with duration of anorexia nervosa; thus, duration of illness may be predictive of risk for osteopenia in this patient population (139).

In general, brain-imaging studies and electroencephalography are not routinely obtained in the assessment of the patient with anorexia nervosa. More extensive laboratory or imaging studies may be appropriate when atypical history or initial findings suggest the possibility of medical or neurological illness. Brain tumors in the area of the hypothalamus or brainstem, for example, may manifest as anorexic behavior prior to the appearance of other neurological symptoms (140, 141). Case reports of patients with eating disorders have described a broad spectrum of neurological symptoms, ranging from disorientation, motor ataxia, and stupor to seizures, bulbar paresis, and coma (142–144). Brain-imaging studies, particularly MRI, may be helpful in identifying any associated anatomical lesions (144, 145). Although not a routine component of the clinical assessment, sleep electroencephalographic studies have shown decreased sleep time and decreased time in stage 1 sleep in low-weight patients compared with control subjects (146, 147).

Patients with anorexia nervosa may have significant disturbances of serum electrolytes, such as hypokalemia associated with laxative abuse. In rare cases, neuropsychiatric symptoms have been associated with osmotic demyelination syndrome (or central pontine myelinolysis) in patients with severe hyponatremia and hypokalemia (145, 148, 149). Excessively rapid repletion of electrolytes may play a role in the pathophysiology of this syndrome, resulting in damage to myelin in the ventral region of the pons.

## Treatment

Guidelines for the treatment of anorexia nervosa have been summarized (122). When medical problems such as electrolyte abnormalities, hypoglycemia, anemia, bradycardia, or hypotension reach a critical threshold, acute hospitalization is required (135). Indications for hospitalization include progressive weight loss, chronic persistence of extremely low weight in spite of intensive outpatient treatment, and symptoms of severe depression with suicidal ideation. Cachectic patients with anorexia nervosa can suffer serious cardiac arrhythmias, possibly resulting in

sudden death (150). After medical stabilization, psychiatric treatment for the anorexic patient in an inpatient or day treatment setting typically involves a behaviorally oriented weight-restoration program, usually including individual and group psychotherapy (151).

Outpatient psychotherapeutic approaches for patients with anorexia nervosa include a range of shortterm and longterm individual, group, and family therapies (122, 152–157). Family therapy is particularly likely to be a helpful component of treatment for adolescent patients (158). This randomized, controlled 1-year trial showed that in patients with onset of illness prior to age 19 years, family therapy was more effective than individual supportive therapy provided as the control condition. Adjunctive treatments include psychoeducational interventions and nutritional counseling.

In general, controlled studies in low-weight patients have not demonstrated significant advantages for medication treatment compared with psychotherapeutic interventions alone, including studies with the selective serotonin reuptake inhibitor (SSRI) fluoxetine (159–161). A randomized, controlled study did show that cyproheptadine administration was associated with a small but statistically significant enhancement in the rate of weight gain for hospitalized patients with the restricting subtype of anorexia nervosa (162). Psychotropic medications may be useful in alleviating comorbid conditions, such as major depression or severe anxiety disorder, although the clinician needs to remain alert to possible risks (e.g., the potential risk of increased suicidal behavior) associated with medication treatment. In the low-weight patient, considerations related to medical stability (e.g., sensitivity to orthostatic hypotension) often dictate a cautious approach with medication intervention. There are preliminary data from a randomized, controlled 1-year trial in 35 patients with restricting-type anorexia nervosa suggesting that fluoxetine may be helpful in stabilizing mood and possibly in preventing relapse to low weight after weight restoration (163).

## BULIMIA NERVOSA

### Diagnostic Features

Bulimia nervosa is characterized by recurrent binge-eating episodes that are associated with inappropriate compensatory behaviors used to avoid weight gain (Table 15.3). These behaviors occur with an average frequency of two or more episodes per week over a period of 3 months, at a time during which the individual does not meet criteria for anorexia nervosa. Additionally, the individual's self-evaluation is overly dependent on perception of body weight and shape. In DSM-IV, bulimia nervosa is subclassified as either "purging type" or "nonpurging type" based on the presence or absence of regular self-induced vomiting or misuse of laxatives, diuretics, or enemas (17).

**TABLE 15.3**  
**DSM-IV DIAGNOSTIC CRITERIA FOR BULIMIA NERVOSA**

- A. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
- (1) Eating, in a discrete period of time (e.g., within any 2-hour period) an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
  - (2) A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
- B. Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise.
- C. The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months.
- D. Self-evaluation is unduly influenced by body shape and weight.
- E. The disturbance does not occur exclusively during episodes of anorexia nervosa.

### Specify Type

**Purging Type:** During the current episode of bulimia nervosa, the person has regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

**Nonpurging Type:** During the current episode of bulimia nervosa, the person has used other inappropriate compensatory behaviors, such as fasting or excessive exercise, but has not regularly engaged in self-induced vomiting or the misuse of laxatives, diuretics, or enemas.

Up to 30% of overweight individuals in treatment for weight loss have symptoms of binge-eating disorder, a provisionally defined syndrome manifested by recurrent binge eating associated with prominent symptoms of psychological distress (164). Preliminary criteria for binge-eating disorder are listed in Appendix B of DSM-IV (“Criteria Sets and Axes Provided for Further Study”). In overweight individuals, careful review of symptom patterns may be required to differentiate nonpurging bulimia nervosa from binge-eating disorder.

### Epidemiology and Etiology

The prevalence of bulimia nervosa in young women is 1 to 2% (27, 165, 166). The female-to-male ratio is approximately 10 to 1. Historically, it had been recognized that up to half of patients with anorexia nervosa reported symptoms of binge eating and purging. During the 1970s, a number of reports describe individuals in a normal weight range with symptoms of binge eating and purging (167), leading to the inclusion the syndrome of “bulimia” in DSM-III (168).

In bulimia nervosa, as in anorexia nervosa, psychosocial, cultural, and occupational factors are thought to contribute to preoccupation with body shape and weight. Family and twin studies have demonstrated a role for genetic factors in the etiology of the disorder (29, 124, 169).

## NEUROBIOLOGY

### Neurotransmitter Studies

Laboratory studies of eating behavior suggest that patients with bulimia nervosa have impaired postingestive satiety

(170). Thus, binge-eating episodes may in part result from absence of normal feelings of satiety following a meal, a possibility that has prompted clinical investigations of the satiety-related neurotransmitter serotonin and the neuropeptide CCK. CSF concentration of the serotonin metabolite 5-HIAA is abnormally low in bulimic patients with frequent binge-eating behavior (171). Additionally, pharmacological challenge studies with serotonin-active medications have shown blunted neuroendocrine responses in patients with bulimia nervosa in comparison to control subjects (172–176). Initial results from brain imaging studies have shown decreased availability of the serotonin transporter in the hypothalamus and thalamus (177). In individuals who have recovered from bulimia nervosa, serotonin-related neuroendocrine abnormalities are no longer observed (178, 179). Similar to findings in anorexia nervosa, however, individuals who have recovered from bulimia nervosa appear to have persistent, trait-related alterations in serotonin function as reflected in elevated levels of CSF 5-HIAA (178), abnormalities in 5-HT<sub>2A</sub> receptor binding (180), and recurrence of symptoms during acute tryptophan depletion testing (181). It has been postulated that persistent changes in serotonin function may contribute to the recurrence of bulimic symptoms and episodes of depression in many of these individuals.

As noted earlier, findings of diminished satiety responses in bulimia nervosa have prompted studies of the gut-related satiety peptide CCK. Serum CCK response after a test meal is blunted in bulimic patients (182–184), and CSF concentration of CCK-octapeptide is abnormally low (185). As recently reviewed, abnormalities in other CNS neurotransmitter and neuropeptide systems have also been identified in symptomatic patients with bulimia nervosa

(10, 46). Follow-up studies in symptom-recovered patients should help to differentiate state-related versus trait-related aspects of these alterations.

### Neuroendocrine Function

Alterations in neuroendocrine function in normal-weight patients with bulimia nervosa are much less prominent than those in patients with anorexia nervosa. When abnormalities do appear, they are often thought to reflect recent weight loss, low weight relative to weight “set point,” or the presence of comorbid psychiatric disorder. Thus, low serum thyroid hormone levels with normal thyrotropin levels have been reported in patients with bulimia nervosa (186), consistent with evidence for slightly reduced metabolic rate in comparison to age-matched control subjects (187).

Abnormalities in menstrual cycle patterns may occur in as many as 50% of patients with bulimia nervosa, with evidence for an association between relatively low body weight and disturbances in luteal phase gonadal hormone patterns (188, 189). Small but statistically significant decreases in serum prolactin levels relative to healthy controls have also been reported (173). In studies of the hypothalamic-pituitary-adrenal axis, most patients with bulimia nervosa have normal serum cortisol levels and show normal cortisol suppression following the administration of dexamethasone, although abnormalities in adrenocorticotrophic hormone (ACTH) secretion have been reported (50, 190). Circulating levels of the adipokine leptin are decreased in patients with bulimia in comparison to weight-matched controls (191–193), possibly contributing to the reduced resting metabolic rate and menstrual cycle alterations associated with the disorder.

### Morphometric Brain-Imaging Studies

Brain-imaging studies in patients with bulimia nervosa reveal less prominent and consistent changes than in patients with anorexia nervosa. Thus, studies with CT reported modest cerebral ventricular enlargement and sulcal widening, with increased ventricular/brain ratio, in patients with bulimia nervosa compared to control subjects (194–196). A study using MRI found a significant reduction in the sagittal cerebral/cranial ratio but no difference in the ventricular/brain ratio in bulimic patients compared with control subjects (197). A subsequent study found no significant differences between patients with bulimia nervosa and control subjects in size of the thalamus, midbrain, pons, corpus callosum, septum pellucidum, or fourth ventricle (72). Reductions in the MRI proton longitudinal relaxation time (T1) in the inferior frontal gray matter have been demonstrated in a small group of patients with bulimia nervosa compared with control subjects (198).

Imaging studies in bulimia nervosa have generally not shown significant correlations between brain morphology

and clinical characteristics such as alcohol use, duration of illness, cognitive performance, or symptom severity (80, 194, 196, 199). One study did find an inverse relationship between the ventricular/brain ratio and plasma thyroid hormone concentrations (196), and another found a correlation between frequency of binge eating and the ventricle/brain ratio (67). It is of interest that structural alterations in the prefrontal area have been associated with impulsive behaviors and excessive appetite (200).

### Functional Brain-Imaging Studies

Several studies have used PET to evaluate regional brain metabolic activity in bulimia nervosa. Women with bulimia nervosa studied during standardized cognitive tasks exhibited higher cortical metabolic activity in the left hemisphere than in the right hemisphere, in contrast to the reverse asymmetry observed in healthy control subjects (201, 202). Measurement of rCBF in patients with bulimia nervosa with SPECT imaging also showed abnormalities in left-right asymmetries (92). This laterality in rCBF in bulimic patients may be a state-dependent variable, which can be influenced by binge eating (92, 203, 204).

Patients with bulimia nervosa appear to have significant bilateral elevations in metabolic rate/rCBF in the inferior temporal area in comparison with control subjects (92, 202). Consistent with findings in patients with depression, an association was found between left anterior lateral prefrontal cortex hypometabolism in bulimia nervosa and the severity of depressive symptoms (202). Elevated rCBF was also found bilaterally in the inferior frontal region in one study (92). Data from patients during a resting baseline condition showed a significant decrease in relative glucose metabolic rate in the parietal cortex for the bulimic patients in comparison to the controls, paralleling results in anorexia nervosa (205, 206).

In contrast to the findings described earlier, a study of women who had achieved stable recovery from bulimia nervosa found that rCBF values did not differ from results for age-matched control women (207). This finding indicates that underlying trait-related neurobiological risk factors for bulimia nervosa are apparently not reflected in abnormalities in resting rCBF.

### Course and Prognosis

As is the case for anorexia nervosa, the symptoms of bulimia nervosa typically begin in late adolescence. The average age at diagnosis has been reported as 20 to 23 years (124, 166, 208). Premenarcheal onset of bulimia nervosa is thought to be uncommon (28). Patients with early onset (age 15 years or younger) resemble older patients in terms of eating-disorder symptomatology but appear to have a history of increased exposure to psychosocial stressors (209).

As summarized later, controlled treatment trials have shown substantial rates of response both to psychotherapy

and to pharmacotherapy in individuals with bulimia nervosa. However, relatively high relapse rates have been noted; for example, a rate of 31% over 2 years for patients treated in an intensive day-hospital program (210). Naturalistic follow-up studies ranging from 3 to 10 years in duration indicate that whereas 50 to 60% of patients achieve recovery, 10 to 20% are likely to still meet full criteria for the disorder at the end of the study period (211–214). It is also important to note that presence of an eating disorder during adolescence has been linked to increased risk during early adulthood for anxiety disorders, depressive disorders, and suicide attempts, as well as range of medical and neurological symptoms, including cardiovascular symptoms and infectious diseases (215).

### Clinical Features and Assessment

As noted earlier, a “Practice Guideline” for the assessment and treatment of patients with eating disorders has been published by the American Psychiatric Association (122). As this manual outlines, the evaluation of a patient with bulimia nervosa requires a comprehensive neuropsychiatric evaluation and careful medical assessment, with particular attention to detailed assessment of eating patterns, exercise patterns, and attitudes toward body shape and weight. Differentiation between the patient’s subjective assessment and the interviewer’s objective assessment of binge-eating episodes is frequently useful (216). Patterns of weight fluctuation and previous low and high weight relative to age should be noted, with specific attention to a history of low weight suggestive of past anorexia nervosa. Current and past use of diet pills, laxatives or enemas, diuretics, or syrup of ipecac should be noted.

Current or past symptoms of other psychiatric disorders should be evaluated, particularly mood disorders, anxiety disorders, and substance abuse disorders. The most common comorbid Axis I disorders among patients with bulimia nervosa include major depression, substance use disorders, and anxiety disorders (20, 128).

Of particular importance in the psychosocial history is an evaluation of recent stressful events at school or home, evidence of previous physical or sexual abuse, and illness-related impairments in social and school/occupational settings. The family history includes information on eating disorders, other psychiatric disorders, or obesity in family members.

During the medical history and review of systems, specific attention should be paid to symptoms of orthostatic hypotension, persistent lethargy, evidence of blood in emesis, and history of excessive dental caries associated with erosion of dental enamel. For adolescent and adult females, additional pertinent history includes age of menarche, regularity of menstrual periods, changes in eating patterns observed premenstrually, and episodes of secondary amenorrhea. Details of previous treatment response should be elicited.

The mental status examination includes an assessment of mood and cognition and any evidence of suicidal, impulsive, or destructive ideation. Specifics regarding physical examination and laboratory studies for evaluation of the patient with bulimia nervosa are individualized based on the clinical setting (122). Laboratory tests commonly include a complete blood count, serum electrolytes, BUN, serum creatinine levels, and urinalysis. Anemia associated with abnormal nutrition is not uncommon in bulimia nervosa. Electrolyte abnormalities, particularly hypokalemia and hypochloremia, are associated with recurrent self-induced vomiting or use of laxatives or diuretics (217) and tend to occur in patients with more frequent bulimia episodes (218). Serum total amylase concentrations are frequently elevated in bulimic patients, reflecting increased levels of the salivary amylase isoenzyme (219). An electrocardiogram is helpful in identifying arrhythmias associated with electrolyte disturbances. In general, sleep electroencephalographic studies have not demonstrated significant differences between nondepressed patients with bulimia nervosa and control subjects (147, 220).

Brain-imaging studies are not routinely performed in the assessment of bulimia nervosa. However, brain lesions associated with unexplained vomiting or appetite changes could cause symptoms that initially resemble those of bulimia nervosa. The clinician should also be alert to the possibility of the relatively rare Kleine-Levin syndrome (221). This syndrome, which is of unknown etiology, characteristically appears during adolescence and is more common in men than women. Patients with this condition experience recurrent episodes of hypersomnia (thought to average two to four episodes per year) that may be associated with hyperphagia, mood changes, and other psychiatric symptoms.

### Treatment

As described in a recent practice guideline, based on controlled trials, a trial of short-term outpatient psychotherapy in an individual or group setting is often the first treatment approach recommended for bulimia nervosa (122, 222). However, hospitalization may be indicated if medical instability or comorbid neuropsychiatric disorders (e.g., severe depression) are present. Controlled trials have demonstrated the efficacy of cognitive-behavior therapy and interpersonal psychotherapy in the treatment of bulimia nervosa (223–225). Cognitive-behavior therapy focuses on symptom control and the restructuring of beliefs, attitudes, and values that maintain the condition. Components of restructuring include the use of dietary monitors, journal records, behavioral contracts, and patient education. Stimulus control, positive and negative reinforcement, self-monitoring, response prevention, and relaxation training may be incorporated into the treatment plan. Other treatment approaches used with bulimic patients include psychoeducation and psychodynamic therapies,

although fewer controlled data regarding outcome are available for these modalities.

Placebo-controlled trials with a range of antidepressant medications have demonstrated significant decreases in frequency of binge-eating and purging episodes in bulimia nervosa (122, 160, 226). Only a minority of the patients studied, however, achieved complete cessation of binge-eating behavior. In general, these trials used medication doses similar to those used in depressed patients, although the SSRI fluoxetine was more effective in bulimic patients at a higher dose than that used in depression (227). Based on the results of clinical trials, the Food and Drug Administration approved fluoxetine for the treatment of bulimia nervosa in adults (122). As noted earlier, the clinician needs to remain alert to possible risks (e.g., the potential risk of increased suicidal behavior) associated with medication treatment. Preliminary results suggest that continued fluoxetine treatment over the course of a year may help to prevent relapse in patients who recover from bulimia nervosa, although follow-up studies are needed to replicate this finding (228).

Randomized studies comparing psychotherapy alone versus medication alone versus combined treatment in patients with bulimia nervosa tend to favor psychotherapy. Initial results have been interpreted cautiously, however, because of limited sample size and unique characteristics of the treatment setting (225, 229, 230). Combined treatment with psychotherapy and medication may be particularly helpful in alleviating symptoms of anxiety and depression.

## SUMMARY

Anorexia nervosa and bulimia nervosa appear to develop as a result of interactions between predisposing psychosocial and biological influences. Nutritional alterations appear to contribute to many of the metabolic, hormonal, and other neurobiological changes observed in these disorders. Additional research is needed to differentiate state-related versus trait-related aspects of abnormalities revealed in brain-imaging studies and neurotransmitter/neuropeptide investigations. Initial psychiatric assessment and subsequent treatment planning include careful attention to medical and neuropsychiatric features of the disorders. The evaluation and treatment of patients with an eating disorder may involve extensive consultation and collaboration among members of a clinical team, frequently including a primary mental health care provider, a medical primary care provider, a nutritionist, and an eating disorders specialist.

# Substance

# Use Disorders

16

**Oscar G. Bukstein, MD**    **Ralph E. Tarter, MD**

Substance use by adolescents is a common behavior. According to an annual survey of high school students, the lifetime prevalence of alcohol use among twelfth graders in 2003 was 76.6%, while the lifetime prevalence of use of substances other than alcohol and tobacco was 51.1% (1; see Table 16.1). At some time during their teenage years, an overwhelming majority of adolescents use alcohol, and a substantial proportion use other drugs. Unfortunately, a significant percentage of adolescents also use substances on a regular basis. In 2003, 27.9% and 11.9% of twelfth and eighth graders, respectively, reported drinking at least five drinks on a single occasion within the preceding 2 weeks. Similarly, 24.1% of twelfth graders and 9.7% of eighth graders reported using an illicit substance other than alcohol or tobacco within the previous 30 days. Recent trends in lifetime and daily substance use are found in Table 16.1.

In community studies, lifetime diagnosis of alcohol use disorder (AUD) ranges from 0.4 (2) to 9.6% (3). Lifetime diagnoses of alcohol dependence ranged from 0.6 (2) to 4.3% (4). The lifetime prevalence of substance use disorder (SUD) (abuse or dependence) ranges from 3.3 in 15-year-olds to 9.8% in 17- to 19-year-olds (5, 6). The predicted cumulative prevalence of any SUD by age 16 is 12.2% (7).

When substance use induces problems, the individual qualifies for the diagnosis of SUD. The core feature of a SUD is persistent pattern of use despite negative consequences. To qualify for a diagnosis of SUD (*abuse*) based on DSM-IV (8) criteria, an individual must display a maladaptive pattern of substance use that leads to clinically significant impairment or distress. This maladaptive pattern may manifest as use that results in failure to fulfill major role obligations or use that continues despite

causing or exacerbating social or interpersonal problems (see subsequent discussion). The neuropsychiatric sequelae of habitual substance use may exacerbate these problems. To qualify for a diagnosis of SUD (*dependence*), maladaptive behaviors continue despite knowledge of having persistent or recurrent physical or psychological problems due to substance use. Neuropsychiatric disturbance may be among these problems.

In this chapter, we review the neuropsychiatric aspects of substance abuse among adolescents. In addition, we discuss the neuropsychiatric factors that amplify the risk for development and maintenance of substance use disorders.

## DEVELOPMENT OF SUBSTANCE USE AND USE DISORDERS

Substance use behavior does not proceed in random fashion. Rather, consumption typically begins with legal readily available compounds (e.g., beer, wine), and a subset of the adolescent population progresses to hard liquor and tobacco that in turn may lead to “soft” drugs (marijuana) and ultimately, in a smaller segment, to “hard” illicit drugs. Conceptualized as “stages” within the Gateway Hypothesis (9), it has been speculated that each stage is associated with a specific complement of risk factors that promote subsequent drug use (10). The putative risk factors encompass, for the most part, the interaction between individual and environmental (peer and parent-related) characteristics (see Table 16.2). For example, quality of peer relationships and minor delinquent activities both predict initiation into the earliest stages of use whereas poor relationship with parents and deviant attitudes and behavior are theorized to be more important in the later stages. Furthermore, while

the notion of stage-specific characteristics is intuitively appealing, the bulk of the evidence points to the presence of common factors (11). In effect, the likelihood of progressing from abstinence to illicit drug use is a function of the severity of the common liability (12, 13).

### Neuropsychiatric Risk Factors for Substance Use/Abuse

Neuropsychiatric disturbance appears to represent an important risk factor that predisposes to substance use. Although there is no evidence linking risk for substance abuse with a focal brain lesion, several neurobehavioral factors have been identified that can increase the risk for substance abuse. We review the literature on these factors next.

#### Electrophysiological Abnormalities

Event-related potentials (ERPs) measure the neurophysiological substrates of information processing (14). The P300 component of the brainstem auditory-evoked responses or potential waveform has been investigated as an electrophysiological indicator of cognitive processing in subjects

at known high risk for alcoholism (15, 16). This waveform component has been shown to reflect complex cognitive functions such as stimulus updating, short-term memory, and working memory. In studying ERPs, and particularly the P300 component, researchers recognize that both amplitude and latency may vary with maturation of the central nervous system (CNS) (17, 18).

Several laboratories have found decreased P300 amplitudes and increased latencies among youth at high risk for substance use or abuse (19). Other investigators have noted that high-risk young people manifest P300 deviations as well as deviations in the N1 and N2 components of the ERP (20). The N1 and N2 waveform components are thought to reflect attentional processes. The investigations conducted to date have ascertained subjects on the basis of a familial history of alcoholism, which through genetic loading confers on these subjects a higher degree of risk for substance abuse than that in the general population. Although many studies have reported ERP differences between high- and low-risk subjects, it is important to note that many investigations have also failed to detect such differences (15). ERP potentials are not established biological markers for substance abuse and may be more important in

**TABLE 16.2**  
**RISK FACTORS FOR ADOLESCENT SUBSTANCE USE DISORDERS**

**Individual risk factors**

Early childhood characteristics  
 Early conduct problems, aggression  
 Poor academic performance/school failure  
 Early onset of substance use  
 Adolescent's attitudes and beliefs about substance use  
 Risk-taking behaviors  
 Neuropsychiatric deficits  
     Executive function deficits—attention, short-term memory, verbal processing  
     Temperamental traits—hyperactivity, impulsivity, mood instability

**Peer-related risk factors**

Peer substance use  
 Peer attitudes about substance use  
 Greater orientation (attachment) to peers  
 Perception(s) of peer substance use/attitudes

**Parent/family risk factors**

Parental substance use  
 Parental beliefs/attitudes about substance use  
 Parental tolerance of substance use/deviant behavior  
 Lack of closeness/attachment with parents  
 Lack of parental involvement in youth's life  
 Lack of appropriate supervision/discipline

identifying risk to a range of persistent deviant behaviors (21). The ultimate value of any putative differences between high- and low-risk subjects resides in the capacity of these variables to predict which children will eventually develop alcohol or drug problems.

Several investigators have studied high-risk youth to examine ERPs and their relationship to deviant behavior and SUD risk. In a follow-up study of high- and low-risk children, Berman and associates (22) found that the children with the lowest P300 amplitudes at baseline were more likely to be using substances four years later. In an 8-year follow-up study, Hill and colleagues (23) obtained ERPs at baseline and follow-up for a group of 20 children (including 11 high-risk children). Differences in P300 amplitude between high- and low-risk subjects persisted from baseline to follow-up. Four of the 11 high-risk children met criteria for a substance use disorder at follow-up, and all four had lower P300 amplitudes than did the nonaffected high-risk subjects. The fact that P300 amplitudes did not differ between subjects having versus those not having externalizing disorders indicates that abnormalities in this waveform may not be merely a general correlate of behavioral deviancy.

In a study of high-risk children from families of alcoholics, developmental trajectories of P3b amplitude (a highly heritable variant of the P300 component) obtained over the ages 9 to 14 years were related to the child's familial risk for developing alcohol dependence in combination with the presence or absence of the child's specific psychopathol-

ogy (24). Among high-risk children, those with the highest risk for developing a childhood disorder could be predicted based on membership in the class 3 P3b developmental trajectory pattern. Risk status confers a greater likelihood of having lower P3b at the youngest ages studied, and a slower rate of change in amplitude during childhood and adolescence, especially in high-risk male children. High-risk female children exhibit this pattern but only in the presence of a childhood psychiatric diagnosis (25). These findings have relevance to recent suggestions that reduced amplitude of P3b seen in association with familial risk for developing alcoholism is actually due to the greater likelihood that youth with a family history of alcoholism will have externalizing psychopathology, namely, conduct disorder (26). This suggestion is part of a continuing dialogue concerning the overlap between antisocial personality disorder, alcohol dependence, and P300. Based on cross-sectional data obtained from youth who were assessed for presence of conduct symptoms and family history of alcohol dependence, Bauer and Hesselbrock (26) concluded that reduced amplitude of P300 was seen in association with conduct disorder symptoms (subjects did not meet DSM-IV criteria for conduct disorder) and no evidence had been found that the family history variable was responsible for the reduction in amplitude. In the Hill and associates (24) study, because persons in the "any diagnosis" category were as likely to have an internalizing disorder as an externalizing disorder, the presence of an externalizing disorder alone does not appear to explain the increased likelihood of membership in the lower P300 amplitude, slower developmental change group.

**Neurological Dysfunction**

A few investigators have found differences in the ability to "stand without swaying" between both adult and adolescent individuals with a family history versus those without a family history of substance abuse (31–33). The neurological mechanisms underlying these postural sway differences are not known; whether such ataxic symptoms reflect dorsal column or cerebellar disturbance has not, for example, been investigated. Also, it is not known whether standing steadiness among offspring of alcoholic individuals reflects a facet of generalized neurological disinhibition. Thus, although these findings suggest that neurological dysfunction may be a component of susceptibility to substance abuse, further research is needed to clarify the mechanisms and implications of such motor disturbances.

**Neuropsychological Deficits**

Adolescents with alcoholic or addicted parent(s) demonstrate impairments on tests measuring attention, short-term memory, and verbal information processing compared with offspring of nonalcoholic, non-drug-dependent parents (34). Theoretical reviews of the emerging literature on neuropsychological risk suggest that this pattern of deficits is consistent with a functional disorder of neural systems in the prefrontal cortex (35). The impairments in "executive"

cognitive processes that accompany the behavioral and emotional dyscontrol point to the possible presence of neurodevelopmental deficits in high-risk adolescent subjects who are ascertained on the basis of a familial history of substance use disorders (see subsequent discussion).

### Individual Pharmacological Variation

Several studies have demonstrated that high-risk adult males with alcoholic fathers experience lower subjective levels of intoxication in response to an alcohol challenge compared with low-risk males (36, 37). Similar findings appear to be present for female offspring (38). This diminished reaction is likely a specific effect of alcohol rather than a general response to CNS depressants such as diazepam (39). These findings suggest that neurochemical variation in the population may be associated with differences in drug reinforcement effects, and hence with differences in propensity to habitually consume abusable compounds.

### Temperamental Traits

Temperamental traits are behavioral, affective, and cognitive characteristics that manifest in an individual soon after birth. Temperamental disposition, although modifiable, tends to be relatively stable from birth throughout childhood. The particular expression of a temperamental trait is the product of gene–environment interactions (40, 41). Temperamental deviations are associated with an increased risk for psychopathology and substance abuse (42–44). For example, compared with children whose temperaments are normative, children having “difficult” temperaments more commonly manifest externalizing and internalizing behavior problems by middle childhood (45) and during adolescence (42, 43). The following temperamental traits have been shown to be especially salient risk factors for substance abuse:

- *High behavioral activity level*—Tarter and colleagues (46) reported that male offspring of alcoholic individuals were rated higher on dimensions of behavioral activity compared with sons of nonalcoholic controls. Similarly, adolescents who abuse substances scored higher on ratings of behavioral activity level than nonabusing control subjects (47). In addition, the magnitude of activity level has been shown to co-vary with the severity of substance use, psychiatric disorder, and psychosocial maladjustment (47).
- *Low attention span persistence*—Adolescent sons of alcoholic individuals have been found to perform less well on neuropsychological tests measuring attention capacity compared with sons of nonalcoholic controls (48). In addition, adults with a family history of alcoholism exhibited poorer performance on tests of abstracting, problem solving, and perceptual motor capacity (49) compared to subjects without a family history of alcoholism.
- *High impulsivity*—Poor impulse control differentiates children at high risk for alcoholism from those at low

risk (50, 51). Poor impulse control in childhood also predicts marijuana use at age 18 (52).

- *Mood instability*—Children described as irritable and prone to temper tantrums were more likely to use drugs as adolescents (53) compared with those not displaying such traits. Shyness in early childhood is another predictive factor for adolescent substance use (54). Recent studies have reported an association between early age-onset substance use and emotional reactivity (55, 56). Tarter and associates (57) reported that irritability may be a component of vulnerability to substance use disorders; by early adolescence, irritability is associated with use of alcohol and drugs as a coping response. Deviations in affective dimensions of temperament (e.g., soothability, emotionality), which may underlie instability in arousal regulatory processes, may also constitute risk factors for subsequent substance use disorders (35).

The traits of high activity level, low attention span persistence, and high impulsivity converge to confirm the categorical diagnosis of attention deficit hyperactivity disorder (ADHD) as a risk factor for substance abuse. A number of studies have reported an elevated rate of paternal alcoholism in children diagnosed with hyperactivity (58–60). Retrospective reports of alcoholic adults also suggest an increased frequency of childhood hyperactivity in individuals who subsequently become alcoholic (61, 62). Similarly, the results of prospective studies indicate that childhood hyperactivity increases the risk for alcoholism (58, 63–65). However, substance use disorders among individuals with a history of ADHD may be mediated largely by a history of conduct disorder, although the presence of both ADHD and conduct disorder may confer a level of risk beyond that conferred by either disorder alone (58). Martin and colleagues (66) found that the primary components of ADHD—namely, impulsivity, hyperactivity, and inattention, in addition to aggressivity—distinguished preadolescent sons of substance-abusing fathers from sons of non-substance-abusing fathers.

Many of these temperamental deviations are associated with other nonnormative traits; thus, children and adolescents at risk for substance use/abuse often have multiple risk characteristics (67). In addition, temperamental deviations can be associated with more complex patterns of behavior such as aggression, or with categorical psychiatric diagnoses such as ADHD, conduct disorder, or mood disorders. These diagnoses are all associated with increased risk for substance abuse. The point to be made, however, is that the matrix of risk factors is multifaceted, spanning the dimensional as well as the categorical neuropsychiatric processes that encompass cognition, affect, and behavior.

Several investigators have attempted to define specific temperamental subtypes that may help distinguish subgroups of individuals with substance use disorder. Tarter and colleagues (68) classified alcoholic adolescents into two broad clusters. One subgroup consisted of youth who

demonstrated behavioral dyscontrol and hypophoria; a smaller subgroup consisted of individuals with primarily negative affect. These subgroups differed with respect to age at first drug use and age at first substance use disorder diagnosis, as well as with regard to the severity of their substance use disorder, behavioral disturbance, or psychiatric disorder. Adolescents classified as having “difficult” temperaments loaded on the negative-affect factor. On the basis of the distribution of various risk factors, Zucker and coworkers (69) hypothesized the existence of three subtypes of alcoholism: antisocial alcoholism, negative-affect alcoholism, and developmentally limited alcoholism. Cloninger (70) proposed two subtypes of alcoholism—type I (milieu-limited) and type II (male-limited)—defined according to gender, family history of alcoholism, presence of antisocial behavior, age at alcoholism onset, and personality traits. To date, Cloninger’s subtypes have not been validated and have been subjected to much criticism (71, 72). Thus, the number of putative subtypes in the literature reinforces the heterogeneity of early-onset alcohol use disorder and illustrates the multiplicity of pathways to this outcome.

Many of the temperamental traits reported to place youth at risk for substance use disorders can be subsumed within the larger construct of impaired executive self-regulation of goal-directed behavior. Executive cognitive functioning encompasses attention, self-monitoring, motor control, abstract reasoning, and cognitive flexibility (73). Deficits in these capacities are generally accepted to reflect prefrontal cortex dysfunction (73, 74). Significantly, preadolescents at risk for substance use disorders have been shown to perform poorly on measures of executive cognitive functioning (34, 75). Executive cognitive functioning is also associated with aggression, another risk factor for substance use disorders (76–78). From these findings, considered in total, it is plausible to conclude that deviations in temperament—reflecting poor regulation of affect and behavior—and deficits in executive cognitive functioning place youth at risk for conduct disorder and substance use disorders. Executive cognitive deficits are noted after head injury and in conditions such as ADHD and conduct disorder, which are also associated with early or adolescent onset of substance use problems (79).

Changes in executive cognitive functioning may also be the result of acute or chronic substance use. Acute alcohol intoxication results in decreases in prefrontal glucose metabolism and disrupts a number of executive cognitive functioning processes (79).

### **Neuropsychological and Neurobiological Factors in the Development of Substance Dependence**

Psychoactive substance consumption is primarily motivated by the reinforcing consequences of substance use (80). In effect, these substances are consumed either to induce a state of euphoria (i.e., positive reinforcement) or to relieve the

person from an aversive mood state (i.e., negative reinforcement). The dependence liability of a psychoactive compound is identified by the propensity of laboratory animals to self-administer that substance (81). Some abusable drugs have no primary reinforcing effects (e.g., hallucinogens, anabolic steroids); for these substances, consumption is regulated primarily by secondary (learned) reinforcers. All abusable compounds have specific neuropsychiatric effects; that is, they change behavior, mood, and cognition. Thus, used as positive reinforcers, drugs enhance mood, cognition, or behavior. Used as negative reinforcers, drugs ameliorate deficiencies in one or more of these processes. In addition to their behavioral effects, abusable drugs have both acute and long-term effects that manifest as neuropsychiatric disturbances (i.e., symptoms or disorders).

### **Neurobiological Substrates of Drug Reward**

Drug reinforcement involves activation of the dopaminergic system subserving reward centers of the brain (80–83). Different substances may have different mechanisms for activating or influencing dopaminergic systems. During drug intoxication, increases in striatal dopamine are associated with a drug’s reinforcing effects only if dopamine changes occur rapidly (84). Increases in extracellular dopamine are achieved by blocking dopamine transporters (DAT) (85). The faster the DAT blockade, the stronger the “high”; whereas the rate of clearance from DAT modulates the frequency at which these drugs are self-administered (84). Craving may be related to dopamine-induced activation of the orbitofrontal cortex. In a study of functional magnetic resonance imaging (fMRI) comparing adolescents with AUDs with infrequent drinkers, adolescents with AUDs showed greater brain activation of left anterior, limbic, and visual systems in response to pictures of alcohol beverages. These findings demonstrate an association between the urge to drink and activation of brain areas linked to reward, positive affect, and episodic recall (86).

The orbitofrontal cortex and the anterior cingulate gyrus, which are connected to other limbic structures, are activated in addicted subjects during intoxication, craving, and binging and deactivated during withdrawal (87). These frontal cortical regions are also involved in higher-order cognitive and motivational functions, particularly in determining the salience of a reinforcer. Addiction results from the overvaluation of drug reinforcers (i.e., substances of abuse) and undervaluing alternative reinforcers (e.g., going to work and earning a living, doing well in school, or eating in a sensible manner) in addition to the presence of deficits in inhibitory control for drug and other deviant behavioral responses (87). In a review of the literature underlying motivation, impulsivity, and addiction, Chambers, Taylor, and Potenza (88) speculate that immature inhibitory substrates (e.g., impulsivity) in frontal cortical and subcortical monoaminergic systems promote greater motivational drives for novel experiences, including substance use. Not only are “normal” adolescents vulnerable due to

**TABLE 16.3**  
**SITES AND PHARMACOLOGICAL ACTIONS OF COMMON DRUGS OF ABUSE**

Substance	Proposed Action	Brain Site
Alcohol	Facilitation Inhibition	GABA receptors NMDA (glutamate) receptors
Cannabis/Marijuana	Agonist	Cannabinoid receptors
Hallucinogens (e.g., LSD)	Partial agonist	5-HT <sub>2</sub> receptors
Opiates	Agonist	Opioid receptors
Cocaine	Inhibition	Monoamine reuptake systems (dopamine, norepinephrine, serotonin)
Nicotine	Agonist	Nicotinic acetylcholine receptors

Note: 5-HT<sub>2</sub> = 5-hydroxytryptamine (serotonin); GABA = gamma-aminobutyric acid; LSD = lysergic acid diethylamide; NMDA = N-methyl-D-aspartate.

the incomplete development of this neurocircuitry but those with comorbid psychiatric disorders such as ADHD with chronic deficiencies in impulsivity and motivational neurocircuitry are even more vulnerable to substance use and subsequent SUDs.

Other neurotransmitter systems (serotonergic, adrenergic, and gamma-aminobutyric acid [GABAergic]) are also involved in regulating motivated behavior and thus are also linked to the reinforcement effects of drugs (80). For example, serotonin may inhibit many of the systems that activate drug response and reinforcement. Substances of abuse act on many types of neurotransmitters and receptors (see Table 16.3).

Conditioned responses concomitant to drug use develop in relation to environmental cues such as certain people, places, or objects. Activation of conditioned responses produces *craving*. The mechanisms regulating craving are not well understood but are thought to entail an association between reward centers and memory centers located in the hippocampus (80, 83). In effect, the user comes to associate specific cues or stimuli with prior experiences of drug-induced positive or negative reinforcement. Craving ensues as an emotional-motivational anticipatory response to potential reinforcement. Craving as a phenomenon in adolescents has received little research attention; however, it is a central component of the dependence syndrome (89). A significant percentage of adolescents who meet criteria for alcohol dependence report craving (90).

Activation of brain reward centers that results in motivation to continue ingestion explains only one facet of substance dependence behavior. *Physical dependence*, manifesting as chronic tolerance or as onset of withdrawal upon cessation of use, is also a major factor in the progressive increase and maintenance of substance use. Tolerance results when the CNS adapts to the substance in an attempt to promote homeostasis. *Withdrawal*, a related phenomenon, is a rebound condition caused by substance-induced CNS alteration; that is, readaptation of the CNS occurs consequent to the absence of the substance. A sustained period of regular

drug use is required for both development of tolerance to a substance and termination of withdrawal symptoms after discontinuing its use, and their presence and severity vary according to the frequency of use and the amount of the substance consumed. The more variable pattern of substance use in adolescents compared with adults might explain the relatively infrequent occurrence (in less than 10% of adolescents with SUDs) of withdrawal syndromes or of high levels of tolerance in this population (90–92). Among heavy adolescent alcohol users (drinking five or more drinks 16 or more times a month), 18.6% met DSM-III-R criteria for alcohol withdrawal syndrome and reported an average of 2.72 withdrawal symptoms, most commonly nausea and vomiting, depression/irritability, muscle aches, and coarse tremor (91). Recent reports have found a high rate of withdrawal symptoms for adolescents with higher levels of cannabis and amphetamine use (91, 93) as well as with marijuana users in the community (94). Polysubstance use and cigarette use predicted a higher level of withdrawal symptoms.

Because of their disruptive physiological effects and the aversive state associated with drug withdrawal, abusable substances act as negative reinforcers (i.e., by promoting substance use behaviors). Concomitantly, as tolerance increases with continued drug use, the reinforcing effects become progressively more difficult to obtain and the abstinence syndrome becomes more severe (95). This dilemma results in a motivational spiral of progressively larger amounts of drugs being consumed both to achieve a reinforcing effect and to forestall the onset of withdrawal. At this stage, dependence is recognized to be severe.

Neuropsychological factors may not be important at all stages in the development of a substance use disorder. The factors that lead to initial and experimental use of psychoactive substances by children or adolescents are likely very different from those that lead to persistent or pathological use (96). The onset of substance use in youth is usually socially based and is linked to preexisting dispositional traits such as behavioral deviancy (97). Numerous factors that predispose to drug use have been identified. Social influences, including

the need for peer approval, may be sufficient to produce levels of use high enough to cause psychosocial impairment or negative consequences that meet diagnostic criteria for substance abuse. At later stages of use, neuropsychological and conditioning factors become more important as the adolescent begins to display a pattern of dependence manifested by craving, compulsions to use, and preoccupation with procuring and consuming the substance. The diagnostic criteria for dependence are most often met when the substance-induced effects are themselves reinforcing.

### Genetic Influences on Adolescent Substance Use

Researchers have long observed that alcohol and other substance use run in families (98, 99). The familial risk for substance use and substance use problems does not assume a genetic basis because both genetic and environmental factors within a family can influence substance use outcomes (100). Using twin or adoption studies to disentangle environmental versus genetic risk, there is substantial evidence for genetic influences on adolescent substance use, although the magnitude of the influences is moderated by such factors as specific environmental contexts, gender, specific substances, age, and regional influences (101).

Genetic factors appear to play a greater role in individual differences in the persistence of serious drug problems than in social or experimental use of substances (102–105). Genetic influences play a role when environments allow for the expression of the genetic risk. The genetic risk, as well as the shared environmental risk, appears to be nonspecific (106, 107), although some groups have reported substance-specific risk (108). Shared environment, particularly sibling interactions, have a large influence on adolescent alcohol use, smoking, and other substance use (101). Shared environment may have a more substantial impact in early adolescence or upon initiation into substance use, although genetic influences may be stronger for older adolescents (109). Genetic variation in personality dimensions such as impulsivity or disinhibition (see previous discussion) or in liability to externalizing disorders (e.g., conduct disorder) may influence the risk for SUDs for most substances (110). Genetic variation may also exist in systems such as the dopaminergic reward system, which are activated by most substances of abuse (111).

The recent increase in knowledge about the human genome has allowed identification of chromosomes, regions of chromosomes, and specific regions that may contribute to the complex behaviors of AUDs. As research has not identified a single gene responsible for substance use or SUDs, studies have centered on the search for genes that contribute the largest percentage of risk for developing SUDs. A specific form of a gene (i.e., polymorphism) may be only one of several genetic mechanisms for the development of AUDs. Given the significance of dopamine in the reward pathway, most studies have focused on dopamine gene polymorphisms. Variation at the dopamine D2 recep-

tor gene (i.e., DRD2) has been extensively studied in relation to the risk for AUDs and SUDs (104). As with much of the genetic literature, although some studies report an association between SUDs and D2, others have failed to find this association. Other evidence suggests that the DRD2 gene may be nonspecific in conferring risk for various addictive, compulsive, and impulsive disorders. Several genes have been associated with other deviant behaviors associated with the risk for SUDs, such as aggression and impulsive behavior (Monoamine oxidase A (MAOI-A); serotonin 5-HT-1B), ADHD (e.g., DRDR, dopamine transporter-1 [DAT-1]), sensation-seeking (DRD4) (104).

## NEUROPSYCHIATRIC EFFECTS OF SUBSTANCE USE

### Acute Effects

The acute effects of substance use pertain to level of intoxication and pharmacological recovery from a single exposure. There are numerous factors however that can modify both the effect of the substance and the experience of the user. Compared with adults, adolescents are more likely to be novice or inexperienced in the use of specific substances and their simultaneous combinations (e.g., alcohol and tobacco). Adolescents may not be knowledgeable about what constitutes a safe dose, nor about the level of change or impairment produced by specific substances. In part because of this inexperience, the manifestation of pronounced effects may precipitate in the adolescent user an extreme level of distress, particularly agitation and anxiety. These reactive, dysphoric states may compound the direct neuropharmacological effects of a drug use episode.

Expectations regarding use and the social context of use are also important mediators of the pharmacological actions (112) that culminate in mood, cognitive, and behavioral changes. Adolescents' expectations of the effects of substance consumption are different from those of adults. These expectations may influence an adolescent's decision to initiate consumption. Importantly, in the absence of knowledge or experience, expectations can be both incorrect and maladaptive. With respect to inaccuracy, young people may believe that alcohol is an aphrodisiac or an analgesic. Furthermore, expectations regarding substance use can impose personal risk. Among adolescents, disinhibition—for example, getting “falling down drunk”—may be seen as a goal of drinking rather than a negative consequence to avoid. Deviant social behavior while under drug influence (e.g., aggressive behavior) may also be more acceptable in certain adolescent populations than in adults in general. Thus, users' expectations about the effects of drugs, and the resulting behaviors while under acute influence, moderate the neuropharmacological effects of drug use.

Drug dose, of course, is an important determinant of a drug's acute effects. Dose is a multifaceted parameter that is often difficult to ascertain in naturalistic settings. Quantity and purity synergistically determine the individual's

response from both a pharmacological and a neuropsychiatric perspective. Intoxication is thus a graded effect, albeit one that is reversible and substance specific (113). Very little is known about intoxication sequelae in youth however, because laboratory research on the response of human subjects to pharmacological challenge is ethically unjustifiable.

Not every intoxication episode is pathological (i.e., producing maladaptive changes). Among adolescents, many such episodes do not appear to be accompanied by negative consequences (or at least not by negative neuropsychiatric sequelae). Nonetheless, it is important for

clinicians to be cognizant of the paucity of empirical research on this topic.

Adolescents commonly display a pattern of substance use behavior different from that of adults. Alcohol consumption is typically expressed as a binge pattern rather than as persistent and continuous drinking (114). Intoxication, depending on the specific substance, produces an array of neuropsychiatric effects involving alteration of perception, thought processes, mood/affect, and behavior. Table 16.4 summarizes the acute neuropsychiatric effects of drugs commonly used by adolescents.

A compound's neuropsychiatric effects are determined largely by its neuropharmacological properties. Amphetamines and other stimulants exert their action by releasing dopamine and norepinephrine from the presynaptic neuron and by blocking their reuptake by the presynaptic neuron. The net result is greater availability of neurotransmitter in the synapse. Thus, stimulant action on dopaminergic neurons in the mesolimbic area produces mood changes, whereas action in the mesocortical cortex affects higher cognitive processes.

Lysergic acid diethylamide (LSD) acts primarily on the serotonergic system, where it exerts both inhibitory and excitatory effects. Alcohol and other sedative/hypnotic compounds affect several neurotransmitter systems. Effects on GABA (a major inhibitory neurotransmitter) receptors and the associated calcium channel complex may be involved in alcohol-induced anxiolytic responses. Alcohol's effects on the dopaminergic and serotonergic systems probably influence its reinforcing properties (115, 116). Opiates stimulate endogenous opiate receptors, inducing permanent changes in receptor function (117). Marijuana exerts its action by way of its primary psychoactive ingredient, delta-9-tetrahydrocannabinol (THC), which acts through activation of the CB1 cannabinoid receptor (118). CB1 is a G protein-linked receptor located in the central and peripheral nervous systems and located presynaptically. CB1 reduces the uptake of GABA and dopamine, thus potentiating their action.

With respect to specific acute neuropsychiatric disturbances, an interesting phenomenon is the *blackout*, a form of anterograde amnesia during which the individual loses memory for all or part of the events taking place during a drinking episode (119, 120). A blackout is most likely to occur when a large volume of alcohol is consumed within a short time. Although usually associated with alcohol, blackouts can also occur with other depressant substances, such as benzodiazepines and barbiturates (121, 122). Blackouts may be an important warning sign of the development of alcohol dependence (123). Blackouts are common among adolescents with alcohol use disorders, although they occur at a somewhat lower frequency in youth

than in adults (48 versus 84) with these disorders (124). *Alcohol idiosyncratic intoxication*, or pathological intoxication, is a condition characterized by maladaptive behavioral changes (e.g., aggressive or assaultive behavior) induced by the ingestion of amounts of alcohol insufficient to produce intoxication in most people. Although listed in DSM-III-R (8), idiosyncratic intoxication was omitted as a separate diagnosis from DSM-IV because supporting evidence was lacking that the condition is distinct from intoxication or that it exists under experimental conditions.

### Chronic Effects

There is considerable literature on the neuropsychiatric sequelae of alcohol and other substance use among adults (125, 126) (see Table 16.5). In contrast, there is a dearth of research directed at the chronic or long-term neuropsychiatric sequelae of substance use and abuse among adolescents. This lack of attention is rather remarkable, given these substances' strong neuropharmacological effects and the fact that adolescents are still undergoing brain maturation in tandem with physical, psychological, and endocrinological maturation (127, 128).

The available evidence indicates for example, that mild deficits in Wechsler Verbal IQ or poor academic language performance distinguish alcoholic adolescents from nonalcoholic control subjects (129). It is possible, however, that these deficits may not be attributable solely to chronic exposure to alcohol but partially antedate substance involvement, especially in adolescents displaying other forms of deviant social behavior (130, 131). Female adolescent substance abusers have also been shown to have mild intellectual deficits (132).

Protracted substance abuse in adolescents over 4 years of follow-up was associated with significantly poorer subsequent functioning on tests of attention (133). In addition, alcohol and drug withdrawal accounted for significant variance in visual-spatial functioning, above and beyond demographic, educational, and health variables in detoxified late adolescents and young adults. These results suggest that

**TABLE 16.5**  
**LONGTERM NEUROPSYCHIATRIC SEQUELAE OF**  
**SUBSTANCES OF ABUSE**

Substance	Potential chronic effects/sequelae
Alcohol	Confusion, apathy, memory loss Wernicke-Korsakoff syndrome
Marijuana/Cannabis	Anxiety, panic episodes, paranoia chronic fatigue, lethargy, psychosis
Hallucinogens	Flashbacks (persistent perception disorder), paranoia
Opiates	Dependence syndrome Mood symptoms
Cocaine	Mood symptoms (depression/mania) Anxiety Psychosis, paranoia Insomnia, anorexia
Stimulants/ amphetamines	Mood symptoms (depression/mania) Anxiety Psychosis Insomnia, anorexia
Sedative/hypnotics	Dependence syndrome
Inhalants	Cognitive dysfunction (memory, concentration deficits), encephalopathy, confusion, depression, psychosis, paranoia
Anabolic steroids	Mood symptoms (depression/mania) Aggression

alcohol and drug withdrawal may be a more powerful marker of protracted neuropsychological impairments than other indices of youthful alcohol and drug involvement. After controlling for recent use, age, education, practice effects, and baseline neuropsychological functioning, substance use over the 8-year follow-up period significantly predicted performances on tests of memory and attention at Year 8 in youths with histories of substance use disorders and comparable youths with no such lifetime histories (134). Additionally, withdrawal symptoms during the follow-up predicted visuospatial and attention scores at Year 8.

An interesting example of a chronic, substance-induced cognitive-sensory effect is the “flashback.” Flashbacks from LSD or other hallucinogens spontaneously occur weeks or months following an episode of use and may be precipitated by stress, fatigue, or ingestion of other substances such as marijuana (135). This experience is more common in frequent users. Examples of flashback phenomena include intensification of stimuli, apparent motion of fixed objects, and superimposition of geometric shapes on the field of vision (136).

### Psychiatric Disorders

Despite ample evidence demonstrating the neuropsychiatric effects of substance use (and associated transient neuropsychiatric symptoms) and acute intoxication, little evidence exists that substance use or abuse directly causes persistent neuropsychiatric syndromes (137). With respect

to externalizing or disruptive-behavior disorders (i.e., ADHD, conduct disorder, oppositional defiant disorder) or delinquency, for example, it has been consistently found that these conditions almost always precede substance use, although conduct disorder can worsen or be more persistent in adolescents with SUDs (110). A relation appears to exist between substance use/abuse and mood disorders. Marijuana may worsen depressive symptoms in depressed patients (138). Cross-sectional studies have shown an association between cannabis use and depressive symptoms in a community sample of adolescents (139, 140). Marijuana use increases the risk of later depression (141) and of both depression and anxiety (142).

Depressive disorders among adolescents have been shown to emerge after the onset of a SUD; however, the natural history of comorbid mood–substance use disorders in adolescents appears to be different from that in adults (143, 144). Whereas depressive symptoms in adults with SUDs usually remit rapidly with abstinence, a substantial proportion of adolescents with comorbidity continue to display depressive symptoms after several weeks of abstinence. This finding suggests that these adolescents may have a predisposition toward affective disorders such that these disorders, once manifest, are less responsive to abstinence or treatment. Thus, whereas in adults the rapid amelioration of depressive symptoms indicates that psychoactive substances have a direct etiological effect on mood (145), the lack of a similar response in adolescents suggests that the etiological mechanisms leading to depressive symptoms in this age group may be different from those in adults.

Anxiety disorders are frequently present in adolescents with SUDs (146, 147). Generalized anxiety disorder and panic disorder may be consequences of chronic use (148). Similar to the findings in adults, adolescents in treatment for SUDs and in the community manifest high rates of social phobia and posttraumatic stress disorder (146, 147). However, panic disorder and generalized anxiety disorder appear to be rare among adolescents seeking treatment for alcohol abuse or dependence (146), a finding which suggests that social phobia likely precedes alcohol dependence and that initiation of alcohol use may represent an attempt to self-medicate this disorder. Children and adolescents with posttraumatic stress disorder (PTSD) are also at increased risk for the development or morbidity of SUDs in adolescence and adulthood (149, 150).

Substance use disorder among adolescents is a risk factor for suicidal behavior, including ideation, attempts, and completed suicide (151). Marijuana use for example is associated with an increase in suicidal behavior (152). Possible mechanisms underlying this relationship include the acute and chronic effects of psychoactive substances. Adolescents who commit suicide are frequently found to have been using alcohol or other drugs at the time of the suicide (153, 154). Acute effects of substances include a transient and intense dysphoric state, disinhibition, impaired

judgment, and an increased level of impulsivity. Drug use may also exacerbate preexisting psychopathology, including depression or anxiety disorders (145, 155). In adolescents, substance use disorders are often seen concurrently with other neuropsychiatric conditions, including mood, anxiety, eating, and conduct disorders (137). Each of these disorders confers an increased risk of suicidal behavior in adolescents (156) as well as an increased risk of substance use disorders (137). Comorbidity, especially that of mood disorders with other nonmood conditions such as substance use disorders, is one of several putative risk factors for completed suicide (157, 158).

Many adolescents with substance use disorders manifest aggressive behavior (155, 159). Consumption of abusable substances such as alcohol, amphetamines, or phencyclidine increases the likelihood of aggressive behavior (160). The direct pharmacological effects of drugs may be exacerbated by the presence of preexisting psychopathology, the use of multiple agents simultaneously, or other factors having to do with the relative inexperience of the adolescent substance user. Chronic aggressive behavior among adolescents is often associated with a diagnosis of conduct disorder, and this diagnosis almost always precedes the substance use (161–163). Aggressive behavior at an early age predicts subsequent substance abuse (10, 164). Severely aggressive behavior precedes serious involvement with drugs (165).

Individuals with suicidal or aggressive behavior share certain biochemical characteristics, such as deficits in noradrenergic, serotonergic, and GABA/ benzodiazepine systems (166). Psychoactive substances can affect each of these neurotransmitter systems, and each has a role in the pathogenesis of several neuropsychiatric disorders. For example, Ballanger and colleagues (167) reported that chronic alcohol use may result in serotonergic depletion, although this finding is complicated by the possibility that these states preceded alcohol use. Research has linked low serotonergic states with suicidal and aggressive behavior in adults (168). Among aggressive and impulsive adult offenders, investigators have found very high rates of suicidal behavior and early onset substance abuse that correlate with low levels of serotonin metabolites (169, 170).

In addition to the acute and chronic effects of psychoactive substances on neurotransmitter systems, abnormalities of these neurotransmitter systems may precede the development of SUDs. Such biochemical abnormalities may contribute to increased risk by means of a number of possible mechanisms. For example, serotonergic deficits may underlie impulsive and aggressive behavior and poor mood regulation, as well as predispose an individual to specific psychiatric diagnoses. These psychiatric problems may lead to an increased risk for the development of substance use disorders. In addition to problems with aggression, impulsivity, and mood, neurotransmitter abnormalities may manifest as sensitized brain reinforcement produced in response to various psychoactive substances,

thus promoting the risk for a behavioral pattern that leads to substance dependence.

Psychiatric disorders in childhood, primarily disruptive-behavior disorders as well as mood or anxiety disorders, confer an increased risk for the development of substance use disorders in adolescence (110, 137). The etiological mechanisms underlying this effect have not, however, been systematically researched. Within a general pattern of deviancy, alcohol and drug consumption can be considered as part of the nonnormative lifestyle. In an individual with an internalizing type of disorder (e.g., anxiety or depression), substances have the obvious short-term benefit of reducing negative or aversive mood states. Hence, there are many factors, including classical conditioning principles, that interact to predispose an individual to initiation and maintenance of substance use. The literature on the risk for adolescent substance use disorders has recently been reviewed within an epigenetic framework (68) in which a substance abuse outcome is viewed as the culmination of ongoing gene–environment interactions. Conceptualizing substance abuse in this way—as the end point of a succession of ontogenetic processes rather than the result of a single isolated event—has the potential to yield new perspectives on and possibly more effective approaches to prevention.

### **Brain Changes**

Both cross-sectional and longitudinal imaging studies have suggested greater brain shrinkage in adults with alcohol dependence relative to comparison subjects. Volumetric magnetic resonance imaging (MRI) comparisons between alcohol-dependent subjects and healthy subjects have reported that individuals diagnosed with alcohol dependence show greater age-related brain atrophy (171, 172). Morphometric characteristics of adult cocaine abusers, including blunted age-related increases in frontal and temporal white matter (173) and accelerated age-related reductions in temporal lobe gray matter (174), are similar to characteristics seen in adult subjects with alcohol dependence atrophy. Comorbid cocaine and alcohol use disorders (but not marijuana use disorder alone) may accelerate white matter shrinkage with age relative to alcohol dependence alone (175).

Two studies in adolescents show consistent findings. DeBellis and associates (176) used MRI to measure the hippocampal volumes and volumes of comparison brain regions in 12 subjects with alcohol use disorders and 24 comparison subjects matched on age, gender, and handedness. Both left and right hippocampal volumes were significantly smaller in subjects with alcohol use disorders than in comparison subjects. Total hippocampal volume correlated positively with the age at onset and negatively with the duration of the alcohol use disorder. There were no group differences in intracranial, cerebral, and cortical gray and white matter volumes and midsagittal area of the corpus callosum. Hill and colleagues (177) used MRI to measure cerebral, amygdala, and hippocampal volumes in 17 high-risk

adolescent and young adult offspring from multiplex alcoholism families and 17 matched control subjects without a family history for alcoholism or other substance dependence. As 22 of the subjects were part of a longitudinal prospective study examining P300 ERPs, this study was able to relate developmental trajectories in ERPs to structural brain volumes. High-risk adolescents and young adults showed reduced right amygdala volume in comparison with control subjects. Right amygdala volume was significantly correlated with visual P300 amplitude. These results suggest that high-risk offspring from high-density alcoholic families differ in both neurophysiological and neuroanatomical characteristics that could not be explained by personal drinking history or particular childhood and adolescent psychopathology. Because amygdala volume tends to increase during childhood and adolescence, the smaller volumes in high-risk children may indicate a developmental marker for alcoholism risk that parallels the association between risk and delays seen in visual P300 amplitude (24).

### Effects of Maternal Drug Use on Offspring

Establishing links between prenatal drug exposure and subsequent developmental, neurological, and neuropsychiatric outcomes is problematic because it is difficult to determine the dose or extent of the exposure (i.e., the type[s] of substances used by the mother, the frequency and quantity used, and the pregnancy stage[s] during which the use occurred) and to separate the effects of the exposure from those of other forces in the prenatal and postnatal environment. Additional influences include poor maternal nutrition, stress, and psychiatric illness (178).

*Fetal alcohol syndrome* occurs in approximately 1.9 live births per 1,000 worldwide, between 2.8 and 4.8/1,000 in the United States, and among 2 to 10% of alcoholic mothers (179, 180). In addition to intrauterine growth retardation and distinctive facial and other minor physical abnormalities, fetal alcohol syndrome is characterized by microcephaly, delayed development (including intellectual delays), attentional deficits, learning disabilities, and hyperactivity (181–183). Non-fetal alcohol syndrome offspring of alcoholic mothers show an increased incidence of intellectual impairment (184). Several reports have documented lower intellectual ability, poorer academic achievement, and greater problems with attention and hyperactivity (185, 186) in these offspring of alcoholic mothers.

For infants prenatally exposed to *cannabis* (*marijuana*), investigators reported a variety of neurobehavioral abnormalities, including decreased visual responsiveness, tremors, increased startle response, and changes in sleep patterns in the postpartum period (187–191). Long-term studies of children with intrauterine marijuana exposure are few and provide no consistent findings of neuropsychiatric sequelae (192).

Studies of prenatal *cocaine* exposure suggest that these infants exhibit impaired startle responsivity, habituation,

recognition, and reactivity to novel stimuli in the postpartum period (193–195). Postnatal irritability and poor recognition memory may persist into the early years of the child's life (194, 196). Serious language delays, especially in receptive language abilities, may be present in preschool children exposed in utero to cocaine, although their general development is similar to that of nonexposed peers in comparisons at 24 months of age (197, 198). Although a few studies show significant, unequivocal negative associations between toddler's developmental scores and prenatal exposure to cocaine, most of the results from controlled, large-scale prospective studies of cocaine exposure show more equivocal results after controlling for prenatal exposure to other drugs, gestational age and size at birth, and caretaker and maternal characteristics (199, 200).

In several studies, *opiate*-exposed neonates appeared to be more irritable and easily aroused, to have more active (versus quiet) sleep, and to spend more time in states of diminished alertness compared with nonexposed neonates (178, 201). Children prenatally exposed to opiates have been found to display poor motor coordination, hyperactivity, impulsivity, and difficulty with focused attention (202, 203, 198).

Although the prenatal drug exposure literature strongly suggests real but fairly modest effects on growth and development, it is extremely difficult to disentangle the effects of other concurrent drug use (such as alcohol and particularly tobacco), socioeconomic deprivation, and maternal psychopathology and genetic risk of the very outcomes prenatal exposure is supposed to cause. These modest effects are certainly not the perception of clinicians and the public that “crack babies” are forever grossly impaired. This exaggerated perception stigmatizes mothers and their offspring who are affected by cocaine or other substance use (200).

In summary, prenatal exposure to many agents of abuse may contribute to impairments in arousal modulation, activity level, and attention in the infant (178, 192, 204). While each of these impairments may significantly affect the child's functioning, the effects of the environment—including parental psychopathology, addiction, violence, abuse and neglect, and poverty—may greatly influence the ultimate manifestation of any neuropsychiatric sequelae of intrauterine exposure.

## RELEVANCE OF NEUROPSYCHIATRIC FACTORS TO INTERVENTION AND CLINICAL PRACTICE

### Assessment

Regardless of whether neuropsychiatric factors are viewed as causes or as effects of substance use, a number of clinical issues are especially relevant to the assessment of adoles-

cents presenting to health care settings. It is essential for clinicians working with adolescents to be knowledgeable about common psychoactive substances and their acute effects on perception, behavior, mood, and thought processes. Adolescents often come to the attention of the health care system as a result of the acute psychoactive effects of substances that can affect perception, judgment, and coordination. Accidents and trauma (including head trauma and brain injury) can result, necessitating emergency evaluation and treatment. The percentage of medically treated injuries among adolescents ages 15 to 19 years who abuse drugs and alcohol or alcohol alone is similar to the rate of medically treated injuries among older patients (57%) and 10% higher than their similar age cohorts who are not drug or alcohol abusers (205).

Accidents involving adolescents and substance use commonly occur during activities such as bicycling or skateboarding (206), swimming (as many as 40% of cases of drowning may involve alcohol) (207), or driving motor vehicles (208). Despite drinking less than adults, adolescents who drink alcohol are at higher risk of being involved in an accident (209). Also increasing adolescents' risk for brain or other injury is their propensity to speed, run red lights, not use seat belts, drink after marijuana use, and ride with intoxicated drivers (210). Given this association between trauma and substance use in adolescents, health care workers should have strong suspicion of substance use among adolescents presenting to trauma centers or emergency departments.

Similarly, the common co-occurrence of psychiatric disorders with SUDs among adolescents should prompt the use of comprehensive evaluation processes and multimodal treatment interventions. Given the multiple risk factors, frequent comorbidity, and many potential areas of dysfunction, including neuropsychiatric sequelae, in youth who use substances, the comprehensive assessment of adolescent SUDs requires evaluation of multiple areas or domains in areas of the adolescent's life (211). Prominent among these domains for assessment are psychiatric and behavioral problems. Other potential domains, including substance use behavior, school or vocational functioning, family functioning, social competency/peer relations, and leisure/recreation, can be influenced by either preexisting neuropsychiatric factors or substance-induced neuropsychiatric effects.

In summary, as recommended by the Substance Abuse and Mental Health Services Administration (SAMHSA) "screening for adolescent substance use should be conducted by health care delivery systems, juvenile justice and family court systems, and community organizations such as schools, vocational rehabilitation, and religious organizations. Those who should be screened include all teens who receive mental health assessments, enter the child welfare system, drop out of school, or stay at homeless shelters. Adolescents arrested or detained within juvenile justice and family court systems also should be screened."

## Prevention

Primary prevention is generally thought of as preventing the onset—or early onset of substance use or SUDs, themselves. A broader view also considers identification of the temperamental traits and psychiatric disorders presaging substance use and aggressive treatment focused on ameliorating or modifying these disturbances. Early identification of high-risk traits and disorders in children and adolescents with a family history of substance use disorders should be routine practice in both adult and child/adolescent clinical settings. In this manner, interventions can be directed toward reducing the liability conferred by these risk factors.

Targeting neuropsychiatric risk factors applies to preventive interventions with high-risk adolescents as well as to intervention or treatment with youth affected by SUDs. Most prevention efforts are based on various theoretical models of adolescent substance use/abuse development. Prevention efforts primarily involve strengthening resilience factors and reducing risk factors for the development of SUDs (212). Because use or experimentation of substances such as alcohol or even marijuana may be considered normative, prevention efforts might also serve to delay the experimental use of these agents, which would make progression to SUDs less likely. The National Institute on Drug Abuse has published an evidenced-based guide on preventing drug use among youths for parents, educators, and community leaders (NIDA. Preventing drug use among children and adolescents, 2nd Ed. Bethesda, MD: US Department of Health and Human Services, 2003).

Early intervention for psychopathology in youth at risk for SUDs or secondary prevention is also critical to prevent early onset substance use and SUDs. For example, the use of stimulant medication to treat ADHD in youth appears to decrease the risk for later substance use and SUDs (213).

## Treatment

### Acute Detoxification

Although withdrawal syndromes occur infrequently in adolescents, treatment of these syndromes should follow the same procedures used in adults (214). Unless the clinician can obtain a history of withdrawal symptoms or substance use patterns (e.g., specific agents used in sufficient quantity and frequency), a conservative approach should be taken, with careful monitoring of emergent symptoms before using medications for withdrawal. For more details on specific withdrawal management, the reader is referred to reviews and guidelines for withdrawal management in adults (214).

Adolescents with opiate addiction present the largest single group having a need for detoxification. While the use of opiate agonists such as methadone for substitution withdrawal therapy is common in inpatient settings, the use of buprenorphine, a partial opiate agonist is increasing in both

inpatient and ambulatory settings (215). For adolescents, the most common detoxification medication is clonidine.

For alcohol and sedatives, benzodiazepines remain the treatment of choice (216). Unless the adolescent has a history of significant withdrawal problems, the best approach is a symptom-triggered therapy, in which the medication is given only after withdrawal symptoms exceed a threshold of severity. The symptom-triggered approach is as effective but usually requires less medication than a fixed dose regimen. Because it requires regular monitoring and the use of a validated withdrawal scale, its use is limited to inpatient detoxification.

### Substance Use Rehabilitation

Specific pharmacologic treatment of substance use behavior includes drug substitution (e.g., methadone maintenance), antagonist therapy (e.g., naltrexone), aversive agents (e.g., disulfiram), or agents theoretically directed toward brain neurotransmitter systems that may underlie neuroadaptation to the particular substance, craving, or other substance use-reinforcement mechanisms. Particularly promising is the use of buprenorphine for opiate dependence. Because there are no controlled studies of the use of medications in the treatment or withdrawal or in substitution, antagonist or adverse therapy, the reader is referred to the adult literature for guidelines (see previous citations).

Psychosocial modalities are the cornerstone of addiction treatment for adolescents. Reviews of the literature of adolescent treatment outcome have concluded that treatment is better than no treatment (220, 223). In the Drug Abuse Treatment Study for Adolescents (DATOS-A), adolescents reported decreased heavy drinking, marijuana and other illicit drug use, and criminal involvement, as well as improved psychological adjustment and school performance in the year following treatment (224, 225). Longer duration of treatment is associated with several favorable outcomes. Pretreatment factors associated with poorer outcomes (usually substance use and relapse to use) are non-White race, increased seriousness of substance use, criminality, and lower educational status. The in-treatment factors predictive of outcome are time in treatment, involvement of family, use of practical problem-solving, and provision of comprehensive services such as housing, academic assistance, and recreation. Posttreatment variables that are thought to be the most important determinants of outcome include association with non-using peers and involvement in leisure time activities, work, and school. Variables reported to be most consistently related to successful outcome are treatment completion, low pretreatment use, and peer and parent social support and nonuse of substances (222, 223).

Most adolescents return to some level of substance use following treatment (226, 227). Currently, empirical support exists for family-based interventions such as Strategic Family Therapy, Multi-Dimensional Family Therapy (MDFT), and Multi-Systemic Therapy (MST), as well as

cognitive behavioral therapies for the treatment of adolescents with SUDs. Promising, but with less support, are Motivational Interviewing and Enhancement and specific behavioral interventions such as contingency contracting and community reinforcement. Although many clinicians use 12-step based treatment and self-support groups such as Alcoholic or Narcotics Anonymous (e.g., AA or NA), there are no published controlled treatment studies that have examined their efficacy. Cohort studies of adolescents having received SUD treatment have found that attendance in aftercare treatment or self-support groups is related to positive outcomes such as higher rates of abstinence (228–230).

Based on the combination of empirical research and current clinical consensus, the clinician dealing with adolescents with SUDs should develop a treatment plan that uses modalities that target motivation and engagement; family involvement to improve supervision, monitoring, and communication between parents and adolescent; skills to improve problem solving, social skills, and for relapse prevention; comorbid psychiatric disorders through psychosocial and/or medication treatments; and social ecology in terms of increasing prosocial behaviors and peer relationships, and academic functioning. Self-support groups can be encouraged as adjuncts to the previous modalities. Table 16.6 presents examples of treatment targets and suggested intervention modalities for adolescents with SUDs.

**TABLE 16.6**  
**INTERVENTIONS DIRECTED TOWARD**  
**NEUROPSYCHIATRIC RISK FACTORS FOR**  
**ADOLESCENT SUBSTANCE USE DISORDER**

Risk Factor(s)	Intervention
ADHD (including relevant temperamental traits)	Pharmacological agents <ul style="list-style-type: none"> <li>• norepinephrine reuptake inhibitors</li> <li>• CNS stimulants</li> <li>• TCAs</li> <li>• bupropion</li> <li>• adrenergic agents</li> </ul> Behavioral interventions As per ADHD
Information-processing deficits (may be part of ADHD or LD)	Behavioral interventions
Aggressive behavior	Behavioral interventions Pharmacological agents <ul style="list-style-type: none"> <li>• CNS stimulants</li> <li>• Atypical neuroleptics</li> <li>• Mood stabilizers</li> </ul> Cognitive behavioral interventions
Depression/other mood disorders	Pharmacological agents <ul style="list-style-type: none"> <li>• Serotonergic reuptake inhibitors</li> </ul> Cognitive behavioral interventions
Social skills deficits	Social skills training

ADHD = attention deficit hyperactivity disorder; CNS = central nervous system; LD = learning disability; TCAs = tricyclic antidepressants.

### Pharmacotherapy of Comorbid Psychiatric Disorders

The most common use of pharmacotherapy in adolescents with substance use disorders is for treatment of coexisting psychiatric disorders. Potential treatment targets include mood disorders, anxiety disorders, ADHD, and aggression. Open trials with pemoline and bupropion for ADHD and fluoxetine for depression in a population of drug-dependent delinquents have shown promise (217–219). More recently, a double-blind placebo-controlled trial of a stimulant medication demonstrated the efficacy of medication improving ADHD symptoms in adolescents with comorbid ADHD and SUD. This study also demonstrated that medication treatment of ADHD alone, without specific SUD or other psychosocial treatment, did not decrease substance use (220). Lithium, in a randomized controlled trial (221), and serotonergic reuptake inhibitors, in open trials (217, 219), have produced significant improvements in adolescents with SUDs and comorbid mood disorders.

Persistence of symptoms beyond several weeks of abstinence should prompt consideration of pharmacotherapy. Factors that may indicate a need to consider more aggressive use of pharmacotherapy include psychiatric symptoms that predate the substance abuse or that present during periods of abstinence, a family history of the psychiatric disorder, past treatment failure (i.e., nonresponse to pharmacotherapy) and multiple relapses, and past successful treatment with pharmacotherapy. Two critical concerns in using pharmacotherapy with adolescents with substance use disorders are the abuse potential of the prescribed pharmacological treatment and the possibility of interactions between this treatment and potential substances of abuse.

### Treatment of Neuropsychiatric Sequelae

In adults, many of the chronic neuropsychiatric sequelae of substance (such as alcohol) use, result from nutritional deficiencies or longterm damage of organ systems. In adolescents, with rare exceptions, the duration or amounts of use are insufficient to lead to such results. The most appropriate approach is abstinence or a substantial reduction of use, patience, and time. For example, postperceptual disturbances due to hallucinogens often resolve after short or extended periods (a year or more) without pharmacotherapy. Gross psychotic phenomenon may require antipsychotic agents. Even when mood or anxiety symptoms can be tied specifically to substance use, the clinician should consider targeting the specific symptoms with appropriate medications.

## CONCLUSION

Acute substance use and substance use disorders can produce a wide variety of adverse effects on perception, thought processes, mood, and behavior. These effects are usually transient but may place adolescents at risk for a

wide range of outcomes such as accidents, interpersonal/family conflict, and academic/vocational failure. Largely because of their variable pattern of substance use, children and adolescents rarely experience signs and symptoms of physical dependence (i.e., abstinence syndrome). While social and peer factors may be more important in the initiation and early stages of substance use, neurobiological mechanisms become increasingly important in the progression to substance dependence. Certain neurobiological characteristics increase an individual's risk of developing a substance use disorder, including information-processing deficits and temperamental traits such as high activity level and mood instability. Overall, research findings indicate that syndromes involving general dysregulation or disinhibition of cognitive, affective, and behavioral processes predispose an individual to substance abuse. Genetic factors appear to be partially responsible for these psychiatric syndromes, which by the time of adolescence, is featured by substantial comorbidity. A substantial and growing literature points to a number of interventions that are effective in preventing and treating substance use and substance use disorders in children and adolescents. Elucidating the neurobiological factors underlying the risk for substance use disorders and acute and chronic neuropsychiatric sequelae paves the way for a more complete understanding of etiology that in turn will lead to more effective prevention and treatment.

# Dyslexia

17

**Kytja K.S. Voeller, MD**

Dyslexia is the most common learning disability, accounting for 80% of all learning disabilities and, depending on the way it is defined, affecting approximately 5 to 20% of children and adults (1, 2). There are a number of relatively synonymous terms—reading disability, specific reading retardation, reading backwardness, and in some contexts, illiteracy or the more general term “learning disability” is used to mean dyslexia. In the United Kingdom, the term dyslexia is often applied to adults who have acquired lesions that impair reading—a group of patients that are described as alexic in the United States.

The definition of dyslexia, developed by the Orton Dyslexia Society Research Committee is as follows: “. . . a specific language-based disorder of constitutional origin characterized by difficulties in single word decoding, usually reflecting insufficient phonological processing”(3). Important features of this definition include the emphasis on *language* rather than the visual processing of written text and the focus on the mechanics of the reading process (“difficulties in *single word decoding*”) rather than on comprehending what is read.

Many of the essential behavioral characteristics of dyslexia were described with great accuracy in the late 1800s. In an article in the British Medical Journal, published in 1896, W. Pringle Morgan described a 14-year-old boy who was “always bright. . . quick at games, and in no way inferior to others of his age” but had been unable to learn to read, despite having been tutored since the age of 7 years. His instructors described him “as the smartest lad in the school if the instruction were. . . oral.” In addition to providing examples of the boy’s difficulty reading, Morgan also noted that when he attempted to write his own name, “Percy”, he spelled it “Precy” and seemed unaware of the error. Morgan used Kussmaul’s term to describe the child’s diagnosis—*caecitas syllabaris et verbalis*—word-blindness. (Kussmaul had coined this term in 1877 to describe acquired word-blindness in adults following a lesion in the left angular gyrus in right-handed people.) He

also called it *congenital* word blindness, noting that it was “due most probably to defective development of that region of the brain, disease of which in adults produces practically the same symptoms—that is. . . the angular gyrus” (4) (p. 1378).

In 1900, in an article in *Lancet* (nestled between one article describing surgical treatment of open sinuses in the pre-antibiotic era, and another discussing the incubation period of plague), Hinshelwood described four children with “congenital word-blindness” (5). His classical description of a dyslexic child could be applied to any dyslexic child 105 years later.

“A boy, aged 11 years, was at school for four and a half years, but was finally sent away because he could not be taught to read. His father informed me that he was a considerable time at school before the defect was noted. He had such an excellent memory that he learned his lessons by heart; in fact, his first little reading-book he knew by heart, so that whenever it came to his turn he could from memory repeat his lesson, although he could not read the words. His father also informed me that in every respect, unless in his ability to learn to read, the boy seemed quite as intelligent as any of his brothers and sisters. His auditory memory was excellent and better than that of any of other members of the family. When a passage was repeated to him aloud he could commit it to memory very rapidly. . . . When I examined the boy first on March 4th, 1900. . . he seemed a smart and intelligent lad for his years. He knew the alphabet by heart, repeating it rapidly and correctly. He could recognize by sight, however, only a very few letters and those not with any degree of certainty. He could spell correctly most simple words of one syllable, such as “cat,” “dog,” “man,” “boys,” etc., but he could not recognize by sight the simplest and commonest words, such as “the,” “of,” “in,” etc. He had no difficulty in recognizing all other visual objects, such as faces, places, and pictures. On each page of the little primer in which I tested him there was a picture of some object. . . He at once recognized each picture—e.g., a cat. I would then ask him to spell the word which he nearly always did quite correctly. On asking him to pick out the word “cat” on the page he was

unable to do it. . . On testing him with figures I found that he could repeat from memory fluently and correctly numbers up to 100. He could also perform mentally simple sums of addition. He could not, however, recognize all the figures by sight, but he know them better than the letters and recognized a greater number of them. . . (pp. 1506–1507).

The second case described a 10-year-old boy who, although he had learned to recognize many words, was still a very poor reader. Hinshelwood noted another important feature of the clinical profile:

Another very significant fact about this boy, who was otherwise very intelligent, was the fact, told to us by his father, that he never read for amusement. As his father expressed it, “reading seemed to take a good deal out of him” (p. 1507).

By 1904, Hinshelwood was well aware that congenital word-blindness ran in families. A family of 11 children had been referred to him by a teacher. The first seven children had posed no particular educational challenges, but the last four boys (numbers eight through 11) had great difficulty learning to read. The children’s teacher noted that “. . .he had never before met with anything like the difficulties encountered in attempting to teach these four boys to read. . .” (6) (p. 1230). Hinshelwood further noted in his 1911 paper that “. . .

it is evident that the abnormal condition of the visual memory centre is a matter of faulty development, and it is probable that in most cases of congenital work-blindness the condition is the result neither of disease nor injury at birth, but of defective development of this definite cerebral area occurring in the early stages of embryonic growth. This view, that congenital word-blindness is the result of faulty development and not of disease or injury, derives considerable further support from the fact that homonymous hemianopsia, which is so frequently associated with acquired word-blindness, has never been met in any case of congenital word-blindness” (7) (p. 609).

Hinshelwood was also interested in approaches to the treatment of congenital word blindness.

I have. . . insisted on the fact that all these children should be taught alone and not in a class along with other children with normally developed brains. The contrast between their own difficulty and the comparative ease with which other children learn to read is a constant source of discouragement both to themselves and to their teachers. The task is abandoned as hopeless, and such children often leave school without being able to read. . . I always advocate a number of short reading lessons every day rather than one long one. It is only the very frequent repetition of the visual impressions that we can hope for the retention of the visual word memories in the brains of these patients. Hence the best method is to give them short and frequent reading lessons during the day without anything leading to exhaustion. At the outset I have often found great assistance in teaching these patients to read by building up the words with block letters, and thus deepening the visual impressions by associating them with the tactile ones (p. 1232).

His report of J, an 18 year old, identifies another important feature of dyslexics:

The most interesting point in J’s career was that any progress made in reading had been accomplished during the last four years, after he had left school. He has thus practically taught himself. He is a great football enthusiast and. . . since leaving school he has got the Referee every Monday and Friday, which gives detailed accounts of all the football matches. Every night. . . after his work, he would spend a large part of the evening in poring over this newspaper and attempting with the help of others to spell out the results of the matches in which he was interested. At first he could do this only very imperfectly and laboriously with the help of others, but now he can do this without help. On testing his power of reading with a child’s first primer I found that he could only read about one half of the words, without spelling them, the other half he could read if allowed to spell them out letter by letter, so that he could not read fluently even the child’s primer. . . with an ordinary book. . . he recognized by sight very few words of more than one syllable. . . When I examined his ability to read football news, I found he could do this much better, as he could recognize by sight a much greater number of words. . .”) (7) (pp. 1230–1231).

J’s 16-year-old brother dropped out of school at the age of 14 years and was working as a miner. He did not make any attempt to learn to read and never looks at any written material. He refused to let Dr. Hinshelwood examine him.

These descriptions are remarkably accurate in that they capture the characteristic features of the dyslexic individual and the dyslexic’s attempts at reading. There is often a striking discrepancy between the dyslexic’s intellectual ability (normal or above-average) and ability to read. They can often grasp arithmetical computations with relative ease, and some have great expertise in this area. Hinshelwood recognized that the deficit not so much related to the visual system as it was to a specific segment of associational cortex. Although dyslexic children often have great difficulty recognizing letters and words they are quite able to recognize objects and other aspects of the environment. Many, but not all young dyslexic children, show a tendency to reverse letters, and although the absence of letter reversal does not rule out the diagnosis in any way. It is, however, unusual to observe reversals in a 14-year-old. Another similarity, which sadly persists to the present day, is the fact that the child described above by Hinshelwood was not recognized as having difficulty reading until the age of 11 years. Even now, a child who is able to use a series of clever compensatory strategies and does not pose behavioral problems in the classroom may not be identified as having a reading problem until third or fourth grade. Hinshelwood was fully aware of the fact that dyslexic children readily grasp the difference between their struggles with reading and that of their normally reading peers. Most children are aware of this by the time they are in first grade, although they usually do not volunteer the information. However, it is important for the clinician to be aware of this fact, because it

contributes to the young child's sense of defeat and inadequacy. The risk in the dyslexic children population for psychiatric disability is significant. Hinshelwood also noted that reading was extremely effortful and attention-demanding for these children. As the 10-year-old's father astutely noted, "reading seemed to take a good deal out of him" (p. 1507). Moreover, he recognized how this sense of frustration and defeat can lead to abandoning school in favor of a job as a laborer.

Hinshelwood also clearly recognized that these children could be taught to read, but that they required a high level of repetition at frequent intervals. He also understood that with enough motivation and repetition, a dyslexic can master a relatively specialized reading vocabulary but this did not generalize to global improvement in reading skills. The fact that with a lot of motivation the 18-year-old essentially developed relatively functional reading skills specific to football is quite characteristic.

Moreover, Hinshelwood also suggested that dyslexia involved some sort of anomalous development of the parietal-occipital region. Dejerine had published his paper describing acquired alexia in an adult with a lesion in the angular gyrus 10 years earlier (8). The main difference between these dyslexic children, who lived over a century ago, and those who attend school at present, is that they would not be currently banished from school because of reading backwardness.

In the 1920s, Samuel Orton (9, 10) suggested that dyslexia was the result of some sort of incomplete or delayed development of left hemisphere language processing functions. He coined the term *strephosymbolia*, "twisted symbols." In the 1950s and 1960s, the features of dyslexia were blended into other behavioral disorders of childhood, such as hyperkinetic syndrome of childhood, and the terms minimal brain damage or minimal brain dysfunction came into vogue and often overlapped in an unclear way with dyslexia. At the time, there was considerable controversy about the etiology of dyslexia and many educators and clinicians viewed dyslexia as the result of some sort of visual disturbance. Rutter and Yule observed that the concept of reading retardation suffered from a "vagueness of definitions and a general looseness in the use of words. . ." but even more so "from fundamental disputes about the nature of reading problems" (11) (p. 181).

Norman Geschwind and his colleagues played a crucial role in refocusing attention on the neural features of dyslexia. In 1976, Denckla and Rudel made the significant observation that dyslexic children did not perform as well as normally reading peers on a confrontation naming test and thus appeared to be relatively anomie (12). An additional extremely important contribution was that they were much slower than controls in their performance on rapid automatized naming tasks (13, 14). These tasks required that the child rapidly generate names for common, overlearned items, such as primary colors (generally mastered at the latest by kindergarten), numbers, letters, or common

objects. This series of tasks involved presenting the child a page of the same six targets (e.g., six primary colors, or six letters) arranged in random order. The child was asked to "read" these items aloud while being timed by a stop watch. In addition to a relatively rapid increase in rate across the early childhood years, there was also a highly significant difference between dyslexic children and controls. This simple task continues to be studied by dyslexia researchers and is one of the fundamental components of the diagnostic workup of a dyslexic child.

Although Hinshelwood had postulated the presence of some sort of anomalous neuronal development involving the angular gyrus, this concept had been largely lost in the focus on the visual impairments of dyslexics. In 1979, Galaburda and Kemper (15) described neuronal migration anomalies in the brain of a young man who had a well-documented history of severe dyslexia. Galaburda subsequently defined many of the cytoarchitectonic features of a series of dyslexic brains (16). The development of magnetic resonance imaging (MRI), positron emission tomography (PET), and functional MRI (fMRI) techniques has also contributed immensely to the understanding of normal reading and dyslexia. Many of these studies were conducted with support from the Learning Disability Centers that were funded by NICHD grants under the leadership of David Gray, Reid Lyon, and Duane Alexander.

## EPIDEMIOLOGY

---

Estimates of prevalence of dyslexia are dependent on the diagnostic and definitional criteria that are used, and, to some extent, the population that is sampled. Yule and colleagues (17) noted that there were large regional variations in the prevalence of dyslexia (e.g., two times as frequent in London as on the Isle of Wight). In general, fewer children are identified as reading disabled when disability is defined in terms of a discrepancy between cognitive ability (IQ) and reading level. The magnitude of the discrepancy that is used in identifying cases will also affect prevalence estimates. Using discrepancy criteria, prevalence estimates ranged from 3.5 to 6% when reading disability was defined as a reading level falling -2 S.D. below the level predicted by IQ. In an epidemiologic sample in the Connecticut public schools, the prevalence estimate when research criteria were used was 7.6%, which is slightly higher than the prevalence figures based on school identification procedures. When an absolute measure, such as single word reading or phonological awareness tasks are used, the incidence of the dyslexic trait is much closer to 20% (1, 18).

## GENDER DIFFERENCES

---

Early studies reported that more boys than girls have reading disability (male: female ratios ranging from 2:1 to 5:1

have been reported) (19, 20). However, based on their epidemiologic study in the Connecticut public school system, Shaywitz and colleagues observed that school systems tended to identify many more boys than girls; in a sample of 414 children, aged 7 to 8 years, reading disability was noted in 8.7% of boys versus 6.9% of girls and a year later (mean age 8.7 years), there were 9.0% boys and 6.0% girls (2). Shaywitz and colleagues suggested that identification of a reading disability might in part be colored by the presence of comorbid disruptive behavior problems in the boys, which would bring the boys to the attention of the school authorities. Dyslexic girls without behavior problems would be much less likely to be identified, and thus the prevalence of dyslexia in females would likely be underestimated in this context.

However, based on a review of several of large epidemiological studies, Rutter and colleagues concluded that there is, indeed, a male preponderance (21). This was based on two large epidemiological studies conducted in the United States; the National Collaborative Perinatal Project, which involved 32,223 women and their children (22), and a survey encompassing 5,718 children in Rochester, Minnesota (1). In addition, data from four large epidemiological studies totaling 9,799 subjects were drawn from New Zealand (the Dunedin Multidisciplinary Health and Development Study and Christchurch Health and Development Study), England (Office for National Statistics Study), and the Environmental Risk Longitudinal Twin Study from England and Wales. These studies varied in terms of definitional criteria as some involved IQ and others did not, but all the studies used standardized testing and did not involve samples with a referral bias. Moreover, although there was considerable variation in the magnitude of the differences between boys and girls, the authors concluded that in New Zealand, the United Kingdom, and the United States, dyslexia was much more likely in boys than in girls. In two family aggregation studies in which members of entire families were evaluated for the presence of language impairment, articulatory deficits, and dyslexia there were more affected males than females. Although much smaller in scope, this is nonetheless instructive as it included entire families (23).

## LINGUISTIC AND COGNITIVE FEATURES OF DYSLEXIA

The characteristic feature of dyslexia is the inability to learn to read efficiently. For the normal reader, reading is an easy, pleasurable, and efficient process. For the dyslexic, it is an effortful, frustrating, and time-consuming undertaking. The core deficit in dyslexia involves impaired phonological processing. Wagner and colleagues defined phonological processing as having three components: phonological awareness, phonological memory, and rapid naming (24). Numerous studies have demonstrated that these various

aspects of phonological processing are strongly correlated with the ability to learn to read (25, 26). In kindergarten and first grade, performance on phonological awareness tasks predicts later reading and spelling skills in both normal children and future dyslexics (27, 28). Elbow, in a study of Danish children, noted that letter naming, phoneme awareness, and distinctness of phonological representation (defined as the quality of unstressed vowels in phonologically complex words) were statistically highly significant contributors to a future dyslexic profile (29).

## Phonological Awareness and the Motor Theory of Speech

Phonological awareness is the ability to segment and manipulate the phonemes in one's native language and is the deficit that affects most dyslexics. Lack of phonological awareness makes it impossible for the young dyslexic child to sort out the phonologic structure of his native language. For example, if one tests an English-speaking dyslexic child (and many adults), the /p/ in the word "top" is not easily recognized as the same /p/ as in the word "pansy" or "pot." When asked to perform an elision task (e.g., "say tiger without saying /r/") the word generated might be "tie." Or, when asked to segment (that is, to say each sound separately), a word like "beast" the child might say "b-ee-st" or "bee-st," being unable to develop a representation of the four different phonemes in that word. This ability to represent the phonemic structure of one's native language is what is referred to as "the alphabetic principle" (30). The alphabetic principle also involves understanding that words are composed of phonemes and the phonemes are represented in a relatively systematic way by letters.

An important contribution to the understanding of phonological awareness came from Liberman and Mattingly at Haskin's Laboratory, who put forth "the motor theory of speech," which, in simplified terms, means that to decode the speech signal in language, the listener uses the articulatory gestures which create the speech signal to perceive the signal as well. Essentially, they postulated that there is a speech module and that speech production and speech perception are computationally similar. Liberman and colleagues also suggested that it is not so much the acoustic signal which is involved in the perception of phonemes, but rather the articulatory motor movements which are somehow "run backwards" and thus used in the process of perceiving or decoding the acoustic signal. This is the basis for the "McGurk effect" in which an observer will "hear" a different vocal signal than the one actually presented if they are observing a face making a different articulatory gesture (31). Moreover, Liberman and Mattingly point out that there is an innateness in this process. Very young infants show a distinct preference for looking at faces that are articulating sounds that match the sound they are hearing and are much less interested in faces in which there is a mismatch between the vocal signal and the

articulated gesture (32, 33). This was a very significant observation, because it provided a way of understanding at least some of the deficits in dyslexia and, more importantly, providing an effective approach for treatment.

If the articulatory motor theory of speech perception is correct, then one would expect that individuals who had weak phonological awareness might also have an imprecise awareness of the position of the articulatory structures that generate specific phonemes. Montgomery described an experiment in which adult dyslexics were asked to select pictures of the articulatory gestures associated with the production of English phonemes. The performance of the dyslexics was significantly impaired relative to that of controls (34). A decade later, Zatorre conducted a PET scan study on normal adults who were asked to attend to specific aspects of the speech signal. When the subjects were asked to discriminate between specific phonemes, increased activity was noted in Broca's area (the motor speech area), rather than in areas involved in the perception of auditory signal (35). An fMRI study employed a first sound-matching task (the task required subjects to view pictures of objects, compare the first sounds of the name, and indicate if they are the same or different). Control tasks involved baseline matching tasks and a visual matching task that controlled for the visual complexity of the stimuli. The inferior and superior frontal gyrus was selectively activated in response to the phonological comparison task, a finding in agreement with Zatorre's study and additional support for the articulatory motor theory of speech (36). Ruff and colleagues compared dyslexics and controls on a pseudopassive listening task to /pa/ and /ta/ syllables. In response to categorically deviant stimuli, activations of the left angular gyrus, right inferior frontal gyrus, and the right superior cingulate cortex occurred. These regions were not activated in the dyslexic group (37). In another study in which articulatory gestures were observed under fMRI monitoring, subjects activated left primary somatosensory cortex SI when viewing another individual speaking (38).

Thus, it would appear that, in comparison to normal subjects, dyslexics are impaired in their ability to develop accurate internal representations of the motor gestures associated with speech production (39). As a result, the ability of dyslexics to isolate and sequence phonologic information is impaired and phonological awareness is affected. Functional neuroimaging studies suggest that they do not activate critical areas like the left inferior frontal gyrus that appears to be the fundamental site for phonological processing.

A possible mechanism involves anomalous development of mirror neurons. Mirror neurons are located in the rostral part of monkey ventral premotor cortex (area F5) in the area homologous to Broca's area (the inferior frontal gyrus) in the human. These neurons fire when the animal performs a goal-directed hand action and when it observes another individual performing the same or a similar action. Mirror neurons also fire during mouth movements (40). They un-

derlie the ability to learn motor behaviors by observation and it would make sense that they underlie the acquisition of speech, given the fact that speech involves motor articulatory movements. The infant's preference to observing a moving mouth which is uttering sounds that are correctly synchronized with the verbalizations may underlie the acquisition of language and likely involve minor neurosis.

### Phonological Memory

Phonological memory or working auditory memory (or Baddeley's "phonological loop") is the ability to keep verbal information "in mind" for a few seconds (41). A weak phonological memory has also been shown to predict difficulty in phonologically encoding verbal material. Children with phonological memory weakness have difficulty sounding out words (which requires being able to keep the first part of the word in mind while generating the last sounds). They also perform poorly when asked to learn verbal sequences; the rate at which they learn new words is impaired (42, 43).

### Rapid Naming

Rapid naming is essentially a measure of "eye-to-mouth" time, the ability to rapidly encode visual information into oral articulatory sequences. In the young child as well as older individuals, rapid naming speed, particularly the speed of naming letters, rather than objects, is a strong predictor of later reading fluency (44–46). Because rapid automatized naming involves two neural processes—seeing and speaking—one important question is the extent to which rapid naming is related to the visual system versus the oral language system. Compton devised several different versions of a rapid automatized letter naming task. In one condition, letters were phonologically similar; in the other they were visually similar. Dyslexics performed more poorly than controls only on the task that demanded a greater level of phonological decoding skill (49).

Not all dyslexic children have deficits in all three areas. Some children, however, are impaired in both phonological awareness and rapid automatized naming. These children are described as having a "double deficit," and appear to have greater difficulty learning to read than those with deficits restricted to either phonological awareness or rapid naming (45, 50).

## THE DYSLEXIC CHILD ENTERS SCHOOL

Even before the dyslexic child enters kindergarten, he lags behind peers in his ability to recognize and name letters. By the time dyslexics are ready to move on to first grade, there is considerable variability: some future dyslexics know most of their letter names, others remain confused through first grade. However, to a trained observer, it is apparent

that letter recognition is not an automatic, fluent process. These children do not seem to grasp the alphabetic principle; that is they do not understand the process of “sounding out” words. This skill is essential for a beginning reader because every day, the child is confronted with unknown words. Many of these words are known to the child who uses them in daily life, words such as mother, ball, and dog. Although they are part of the child’s oral vocabulary, if the child cannot apply a phonic strategy to decode the word, it is impossible to match the word to his internal vocabulary (51–53). The only other solution (besides guessing) is to attempt to store the word in visual memory. This, however, is a limited resource.

By second grade, most normal readers have acquired a workable sight-word vocabulary and have some skill in tackling the decoding of words that they do not know by sight. Given anything that is remotely interesting to read, they are quite willing to undertake the task of decoding unknown words as they are usually successful even when working independently. Compared to normally reading peers, the dyslexic has a much more restricted repertoire of sight words and lacks age- and grade-appropriate strategies for applying phonic strategies for decoding unknown words. Most dyslexic children grow tired of attempting the decoding process and arrive at the strategy of guessing what a word is based on the first letter or two, or if they are really thinking strategically, trying to make an informed guess based on context. These are, obviously, strategies that will not work out well because their attempts at decoding are fraught with errors. On the other hand, a good reader can make a reasonably informed guess if she can decode at least part of a word correctly. Regardless of the strategy that is used, the dyslexic child does not have fluent word recognition. It should be apparent that this situation does not improve by itself, and every day the dyslexic child loses a little ground. This inexorable failure to keep up with peers is subtle and if one sees a child on a day-to-day basis, it is not apparent that he or she is steadily losing ground. Because even the most dyslexic child makes a little progress, these small gains are encouraging, and allow parents and teachers to overlook the fact that the rate at which the child is learning to read is much slower than that of peers. Parents of young children who are still denying the child’s difficulty in reading can state blithely that “Billy is making good progress.”

In first and second grades, normal readers practice analyzing and decoding more complex sound structures, such as the representations of long vowel sounds, consonant and vowel digraphs, word endings, root words, prefixes, and suffixes to gain information about the meaning of words. A normal reader in second grade routinely performs the following processes: when encountering an unfamiliar word, decoding it, matching it to the internal lexicon, and repeating this process until the word becomes a “sight word” that can be recognized rapidly and effortlessly. This requires consistent, accurate decoding and a great deal of

repetition (54). In addition, the child needs to be able to remember the components of the word while attempting to decode it, which requires the ability to store the sounds in working memory. Children who do not have an adequate working memory buffer find this process quite difficult. The young dyslexic child finds reading so difficult that she tends to avoid it and thus not acquire a “sight word” vocabulary. This sets up a vicious cycle: the fewer sight words the child learns, the more difficult it is to read, particularly because the teacher’s expectations for reading fluency are increasing, not remaining the same. Thus, by the time a dyslexic child is in third grade, there is usually a significant gap between the sight words that he has compared to those of normally reading peers.

An important aspect of the difference between the young normal reader and the dyslexic is the fact that except for the word-length effect, the second grader’s performance does not differ qualitatively from that of the older normal reader. Word familiarity effects are apparent by second grade which indicates that the rapid visual recognition of previously encountered words is occurring. Until the fifth to sixth grade, normal children can get bogged down attempting to decode long words. Experience essentially decreases processing speed (55). By 11 to 12 years of age, the normal reader differs from the adult only in needing to take time to decode unknown words. The normal adult reader is able to process text at an extremely rapid rate. Less than 250 milliseconds after viewing a written word, the visual system extracts the information necessary for the computations in the language system. This occurs regardless of the size of the letters, the number of letters that compose the word (that is, in the range of three to six letters) the font, or the viewing angle (56). Letters are identified more efficiently when they are embedded in words than when they occur outside of words (57).

### **DYSLEXIC INFANTS, TODDLERS, AND PRESCHOOLERS**

---

What are dyslexics like *before* they enter kindergarten? Are there any characteristic features in the young child which would make it possible to identify them very early and initiate treatment before they start to lose ground in the reading process?

There is a considerable body of research that suggests that children at risk for dyslexia can be identified long before they enter kindergarten. Molfese described a study in which 186 full-term newborns were tested within 36 hours of birth and then retested each year. At age 8 years, they underwent an IQ test and a reading screening test. The newborns who are later diagnosed with dyslexia could be identified at birth (and distinguished from the newborns who later were normal readers) by their response to speech and nonspeech sounds using auditory event-related potentials (58). A longitudinal study of Finnish infants born into

dyslexic families and those from nondyslexic families also demonstrated differences in the way the at-risk infants processed speech sounds (59). At 6 months of age, the babies from dyslexic families continue to manifest differences in processing speech sounds (60). In addition to these very early differences in sound-processing, the children at risk for dyslexia began to manifest subtle differences in development by the time they are 2 years of age. Up to that point, they did not differ from the control population in motor or early language development, or cognitive ability. However, around 2 years of age, subtle deficits in language began to be apparent. These consisted mainly in slightly shorter length of sentences. Any mild delay in language did not persist, unless the child came from a dyslexic family. By the time the children were 40 months old, the performance of those from dyslexic families began to differ significantly from that of the controls on phonological and naming tasks (61). Between 18 and 24 months, the investigators were able to identify two groups of children: those with relatively slow motor development and those with fast motor development. The children at risk for dyslexia who also had slow motor development had a smaller vocabulary and generated shorter sentences than all the other children (62). Gallagher and colleagues followed a group of children identified as genetically at risk for dyslexia and a control group who did not have a family history of dyslexia. At the age of 6 years, 57% of the at-risk group was delayed in reading acquisition, compared to 12% of controls. The children in the literacy-delayed group also manifested delays in speech and language development (63).

By age 4 to 5 years, it becomes possible to identify children who are likely to evolve into future dyslexics as differences between the “at risk” group and normal controls becomes more striking. In the study by Gallagher and colleagues, described previously, letter knowledge at 45 months was the strongest predictor of reading at age 6 years. Children at risk performed more poorly on tasks assessing letter-sound knowledge, naming, and phonemic awareness (29, 64–67).

As these dyslexic children move through school, the gap between the rate at which the normal reader and the dyslexic acquire new sight words and develop fluency widens with each passing month. School-based special education interventions, which cannot deliver phonological training at a level of sufficient intensity or repetition, do not substantially improve the child’s reading or decrease the magnitude of the gap. At best the rate at which the gap widens may be slowed (68, 69).

A factor that likely contributes to the widening gap in fluency between the dyslexic child and peers is the fact that dyslexic children do not practice reading to the extent that their normal peers do. This lack of exposure to print may also increase the degree to which the neural connections are not maintained. It is a “use it or lose it” proposition. This concept has considerable support from a PET study performed on the oldest daughter in Portuguese house-

holds. The custom in the past was that the oldest daughter remained at home to raise her younger siblings, who went to school and learned to read and write. The illiterate older sisters did not. When these women were tested on a phonological awareness task, it was apparent, both from the activation patterns and from their test performance, that they had a marked deficit in phonological awareness and also a much reduced pattern of activation compared to their younger literate siblings (70). There is no reason to believe that this group of women represented a cluster of adult dyslexics, as their younger siblings were efficient readers. Thus, it would appear that even a brain that would have little difficulty learning to read may not do so if appropriate stimulation is not present.

## THE DYSLEXIC ADOLESCENT AND ADULT

---

As the dyslexic child moves into adolescence and young adulthood, many begin to acquire some degree of reading skill, but they are often not very efficient in reading and may take twice as long to read as nondyslexic peers. One bright dyslexic college student commented that his friends could read a chapter in an hour and it took him the entire afternoon. However, deficits in spelling and writing continue to impair their academic performance. In the older student, spelling is often a more sensitive indication of dyslexia than reading (71).

These deficits also do not go away with maturation, but persist, to a greater or lesser extent, into adulthood. Although many dyslexic adults ultimately learn to read, many do not read for pleasure, describe themselves as “terrible spellers,” and have difficulty trying to learn a foreign language. (The process of learning a foreign language is hard because it often requires applying the alphabetic principle to a new set of phonemes.) Some dyslexic adults have managed to acquire relatively good reading skills, but even these “compensated” dyslexics continue to exhibit both the phonological deficits and the characteristic pattern of brain activation compared to nondyslexic controls (72, 73) (*Paulesu 1996*).

It is important for professionals who work with dyslexic children to understand the persistence into adulthood and the potential long-term impact on function in adulthood. In one longterm study, subjects who were re-evaluated in their thirties, had lower grades in high school, completed fewer years of formal education, and tended to gravitate to unskilled or semiskilled jobs (*Felsenfeld 1994*) (74).

## SUCCESSFUL ADULT DYSLEXICS

---

A few dyslexics go on to become quite successful, even in careers that demand a high level of reading and writing. Fink described an extremely productive and well-published

scientist who was a distinguished professor and a member of the National Academy of Sciences. He had consented to being examined Dr. Fink using many of the same tests that are administered to dyslexic children. The characteristic dyslexic profile was still present; he continued to have significant deficits in sight-word reading and phonological decoding strategies. However, he had mastered the vocabulary in his field of work well enough to produce numerous scientific articles (75). This is not an isolated case. The author had the experience of administering the Lindamood Auditory Conceptualization Test (76) (a phonological awareness assessment) to a successful MD/PhD researcher whose score fell at an elementary school level. These cases are similar to that of the young man, described by Hinshelwood, who acquired a specialized vocabulary so that he could follow local football games.

Adult dyslexics, particularly those who are successful, seem to gravitate to specific occupations. They are likely to become architects, movie stars, electrical and mechanical engineers, high-ranking managers, accountants, and finance officers. Many CEOs of large corporations are self-described dyslexics. *The Sunday Times* (London), reportedly ran a story about this group: "You don't have to be dyslexic, but it helps. A study has revealed that millionaires are significantly more likely to suffer from the condition than the rest of the population. . . . About 40 percent of the 300 studied had been diagnosed with the condition. . ." (77, 78). In the medical field, dyslexics often gravitate to radiology, psychiatry, pathology, and surgery. A number of dentists are dyslexic. The fact that an individual has successfully negotiated high school and, in some cases, college, does not eliminate the possibility that he or she is dyslexic. One successful 40-year-old architect, whose son was evaluated for dyslexia and attention deficit-hyperactivity disorder (ADHD), presented himself for an evaluation, which revealed that he was indeed dyslexic and also had ADHD. He reported that he had worked with a psychotherapist who told him that he could not possibly be dyslexic because he had successfully graduated from college. The architect reported that he had gotten through college in a high state of anxiety, studying all the time. He had also been advised by his high school counselor that he was not college material.

## DEVELOPMENTAL LANGUAGE DISORDER AND DYSLEXIA

A substantial percentage of children with these phonological processing deficits also have a language disorder. The extent of the overlap between these two entities is not precisely worked out, but there is little doubt, based on numerous studies on somewhat different populations, that many children with phonological processing deficits also have a language disorder. The risk for later reading dis-

ability conferred by deficits in phonological awareness is well established and has been reviewed previously. Phonological awareness deficits are associated with language disorder. There is also an extensive literature indicating that language disorders identified in the toddler confer a high risk for future reading disability (23, 63, 65-67, 79-83). Some of the difficulty arises from the fact that although all of these disorders lie on the same developmental pathway, they emerge at different times in a child's life. In addition, at certain points in development, the range of "normal" is very broad and only children at the very severe end would be identified with confidence. The definitive diagnosis of language disorder in the young child is difficult and there is considerable examiner disagreement (84, 85). The normal range of language development is so broad and there are so few well-standardized test instruments that making a firm diagnosis at the age of 2 or 3 years is difficult and only children who manifest very severe expressive or receptive language deficits can be identified with certainty. By the age of 4 to 5 years, the diagnosis of a language disorder is easier, in part, because some standardized tests are available. However, children do not read at this age, so that it is technically not possible to apply a label of dyslexia. During the first two grades of elementary school, although some formal test instruments are available, the variance is again quite large, and only children at the very severe end of the spectrum can be identified with certainty. As a result, defining a developmental pathway that starts with atypical responses to phonemes in a laboratory in the newborn period and linking that to a child with a reading disability at age 10 years is not yet possible. However, if one considers the longitudinal studies that cover segments of this developmental trajectory, the suggestion that phonological awareness deficits is linked to early language disorder and both predict later reading disability with great consistency is easier to accept. However, at best, one can only use an "at risk" modifier to the diagnosis; that is, "this four year-old is *at risk* for dyslexia in the future."

There is one other factor that will increase the certainty of this diagnosis and that is knowing with some certainty that other family members have a language disorder and/or dyslexia. The results of two family aggregation studies that assessed the co-occurrence of oral language impairment and reading impairment in children with developmental language disorder concluded that affected members were more likely to have both oral language and reading impairment than either impairment alone (23). For any individual child, this increases the probability that he or she is at risk, but it lacks the certainty of a categorical diagnosis. However, this approach would have some appeal for clinicians and educators who are interested in preventing future dysfunction in a young child. At the point that the genetic markers for these disorders are known, the identification of the young child who is at risk will be somewhat easier.

## DYSLEXIA AND PSYCHIATRIC COMORBIDITY

---

In the previous discussion, the close relationship between phonological awareness deficits, language disorder, and dyslexia was reviewed. The next question is the degree to which early language disorder and/or reading disorder are associated with comorbid psychiatric disorders. There are a number of studies that support the concept that language disorder and dyslexia confer a risk for subsequent emotional problems. The psychiatric diagnoses described as most frequently associated with dyslexia include ADHD, oppositional defiant disorder, conduct disorder, depression, and anxiety disorder.

There is a significant overlap between ADHD and dyslexia, regardless of whether one examines dyslexic children for ADHD or children with ADHD for dyslexia (86–88). In some of these studies the investigation focused on whether the hyperactive/impulsive type or the inattentive type of ADHD was most closely associated with dyslexia. Wilcutt and colleagues reported that common genetic influences explained 95% of the phenotypic covariance between dyslexia and symptoms of inattention, whereas there was only a 21% of phenotypic overlap between dyslexia and hyperactivity/impulsivity (89). Maughan and colleagues, in a large epidemiologic longitudinal study of boys, found that reading disability was strongly associated with ADHD inattentive type, but not with hyperactivity/impulsivity (90). In the reading remediation study in which severely dyslexic children were closely monitored for impairing symptoms of ADHD, 80% of the subjects were inattentive and/or hyperactive/impulsive (91, 92). Wilcutt and colleagues conducted a comprehensive neuropsychological test battery on groups of children with dyslexia, those with ADHD and ADHD plus dyslexia. They noted that the group of children with comorbid ADHD and dyslexia showed a combination of the deficits associated with ADHD and dyslexia. Slow and variable processing speed was present in all three groups (89). Ghelani and colleagues compared reading strategies in children with dyslexia, ADHD, ADHD plus dyslexia, and normal controls. The subjects with ADHD performed adequately on single word reading tasks with evidence of subtle (but average-range) impairment in rate, accuracy, and comprehension. Those with dyslexia had difficulty on the mechanical aspects of reading but had average-range performance in comprehension. The group with combined ADHD and dyslexia also had deficits in rate and accuracy but had greatest difficulty on tasks requiring comprehension of text during silent reading (93).

There is evidence that the overlap between ADHD and dyslexia is possibly due to shared linkage to certain genes. Several different candidate genes have been identified that are linked to ADHD and dyslexia. These include 6p (94, 95), 2p, 8p, 15q, 16p, and 17q (96).

Older children and adolescents should be assessed for depression. As many as one third of dyslexic patients

evaluated in an inpatient setting were depressed (97). In the study described by Maughan and colleagues, the incidence of depressed mood was greater in the poor readers (23%) compared to those who were not defined as having reading problems (9.6%) in the first- and fourth-grade samples, but depressed mood dropped substantially in the seventh-grade subjects (74, 98). The investigators further noted that although low reading achievement was linked to depressed mood at all three time points, there was no increased risk for depression beyond the presence of depression at the first evaluation. An evaluation of other factors that might contribute to depression (such as family environment, other comorbid disruptive behavior disorders). These factors had a minor effect, but the most robust effect remained the association in the first time period between low reading achievement and depression. However, the childhood depression did not always persist: adult dyslexics were reported to be functioning at a level comparable to controls, although they continued to have reading and spelling problems, ADHD, and were more likely to report symptoms of anxiety and depression (99).

It is not unusual for dyslexic children, particularly girls, to become depressed and anxious in response to the effects of their reading disability (81, 100). There was also a higher incidence of somatic complaints in this group. Dyslexic children often complain of stomachaches or some other somatic symptoms that serve to keep them out of school.

It is sometimes difficult for parents, teachers, and mental health professionals to consider the possibility that a child may have both a learning disability and a psychiatric disorder. There tends to be an “either/or” conceptualization. It is important for parents to be aware of the significant comorbidity between dyslexia and psychiatric disorders. The management of both entities should be monitored closely. Although schools may have classrooms for children with externalizing behavior problems, comorbid learning disabilities are rarely effectively addressed in those settings. In one study, children were retested 3 years later and there was essentially no change in the number that met diagnostic criteria for learning disability (68) (p. 1460).

## NEUROBIOLOGY OF DYSLEXIA

---

### Neuropathology

Galaburda and colleagues have examined a number of brains of dyslexics using thin-serial section technique, and have demonstrated focal areas of microdysgenesias maximal in the temporoparietal region, coupled with “brain warts” (15, 16, 101, 102). Similar lesions are in NBZ mice, used as models for autoimmune disorders (Sherman 1987) (103). Such lesions can also be induced experimentally by freezing cortex during the period of cortical development during which neurons are migrating (104). Fitch and colleagues reported that mice with this type of lesion had much the same

difficulty processing rapid acoustic transients as children with specific language impairment (105, 106).

### Neuroimaging Studies

MRI-morphometric studies have also shown substantial differences between dyslexics and normal children in brain morphology. Many dyslexics show a reversal of the usual left greater than right asymmetry (107). The ratio of parietal to temporal plana in the left and right hemispheres is also reversed (108, 109). In an MRI study using diffusion tensor imaging to examine white matter in children with dyslexia, anomalies of the temporoparietal pathways were observed, which were significantly correlated with performance on reading, spelling, and rapid naming tasks (110). In an MRI study, Casanova et al. noted that the brains of dyslexics were significantly smaller than those of controls and had a reduced gyrification index. There were no changes in cortical thickness (111). Gray matter anomalies have also been noted in dyslexics. Brambati and colleagues noted abnormalities in gray matter volume bilaterally in the planum temporale, inferior temporal cortex, and cerebellar nuclei (112). Similarly, Vinkenbosch observed decreased gray matter density in the middle and inferior temporal lobe with reduced gray matter density in the middle and inferior temporal gyri. Increased gray matter density was found in the precentral gyri (113).

Neuroimaging studies have indicated that phonological processing tasks and reading in normal readers relies heavily on a network that involves visual cortex, angular gyrus, fusiform gyrus (specifically the visual word form area). These neuroimaging studies must be interpreted in the context of a number of methodological issues, such as diagnostic criteria used to select subjects, type of reading task, selection of stimuli and duration of exposure to word stimuli, and the statistical analysis that is used. Phonological processing appears to be subserved by the left inferior frontal regions (114). However, some of the processes involved can be dissociated. In one fMRI study, there appeared to be different components of phonological processing. Gelfand and Bookheimer concluded that sequential operations (both sequencing phonemes and sequencing hummed notes) were instantiated in posterior Broca's area, whereas the left supramarginal gyrus was more specifically activated by phoneme sequencing (115).

Normal efficient adult readers have a characteristic pattern of activation that has been demonstrated in multiple PET and fMRI studies. Normal readers demonstrate functional connectivity in the left hemisphere between occipital cortex, angular gyrus, and temporal lobe. There is some activation of prefrontal cortex right hemisphere structures. In contrast, studies in dyslexic readers have revealed a disruption in functional connectivity between the occipital lobe, angular gyrus, and temporal lobe, which is most strikingly apparent when the task requires assembling phonological

information. There is also increased activation of inferior prefrontal cortex and of posterior cortex in the right hemisphere which are likely compensatory responses (73, 116–125).

Shaywitz and colleagues conducted an fMRI study on a group of adult dyslexics and controls using five tasks that varied with the degree of phonological processing that was required. The analysis involved a within-subjects hierarchical design so that each subject served as his or her own control. There was no difference between the normal and dyslexic readers on a purely visuospatial task. However, on a task requiring phonological analysis, the control subjects manifested a systematic increase in activation in striate cortex (Broca's area 17), angular gyrus (Broca's Area 39) and Wernicke's area (Broca's Area 22) in response to increasing phonological demands, which was not seen in the dyslexic reader. In the normal readers, there was a preponderance of left-hemisphere activation, whereas the dyslexics manifested some degree of right hemisphere activation. The inferior frontal gyrus (Broca's Area 46/47) was activated in dyslexic subjects more than in controls in response to increasing demand for phonological processing. A gender difference was seen in that men showed greater activation of left inferior frontal gyrus and women showed a greater right hemisphere activation. These findings suggested a functional disruption in the extensive neural system involved in reading. These fMRI findings are substantially supported by the report from a large multisite diverse sample of dyslexics demonstrating altered density of the left arcuate fasciculus, the white matter pathway connecting posterior temporoparietal cortex (Wernicke's area) to Broca's area, coupled with increased grey matter density in the left middle and inferior temporal gyri (126). In adults, lesions disrupting the arcuate fasciculus are described as resulting in conduction aphasia, characterized by impaired repetition. This is not the picture that would come to mind in the dyslexic. However, it is also true that not all acquired lesions of the arcuate fasciculus lesions are associated with deficient repetition (127).

Another important component of the system subserving reading is the visual word form area, which has been proposed as the part of the system responsible for the efficient processing of visual stimuli (i.e., words). The visual word form area is a small area, located in the left fusiform gyrus. Acquired lesions of this area result in a form of alexia ("word form" or "pure" alexia) in which the patient loses the ability to read words but must hear the word spelled out or have it presented through tactual channels (128). There is a body of evidence that suggests that this area is highly specialized in extracting salient visual information from words. The fusiform face area is in proximity and is involved in the "expert" recognition of faces. Other populations of neurons in the same area are involved in the processing of other classes of objects. McCandliss and colleagues have postulated that the visual word form area contains a population of neurons, functioning as an

ensemble that is “tuned to invariant stimulus properties and structural regularities characteristic of written words” (p. 294) (129). Visual presentation of words activates this particular area in a reliable fashion, more so than other areas, and words activate it more consistently than similar control stimuli. The spatial localization is well defined, with a significant peak of activation in the area in over 90% of individual subject scans, and a narrow standard deviation, on the order of 5 mm. Activation occurs approximately 150 to 200 milliseconds after stimulus presentation. The area can be activated subliminally (that is, without conscious awareness), indicating some degree of automaticity. It is also the area that has been linked in other studies to perceptual expertise (130, 131).

A direct demonstration of the role of the visual word form area in phonological processing of words involved a fMRI study in which there were four conditions: word type (pseudo and real) by response modality (silent and aloud reading). Somewhat different patterns of activation were noted in each condition. Activation of the bilateral motor, auditory, and extrastriate cortex was greater when words were read aloud than when they were read silently. Only the posterior segment of the fusiform cortex (Brodmann’s area 19) was the only one modulated by different phonological processing demands. The investigators concluded that once a word form is recognized as an alphabetic stimulus, it is then subjected to phonological analysis (132).

The neural signature of reading disability persists, even in older adolescents and adults who appear to have developed reasonably adequate reading skills. Shaywitz and colleagues described a study that involved three groups of young adults (18 to 22.5 years of age). The groups consisted of normal readers; compensated dyslexics, who had a history of difficulty learning to read but had compensated to the point that they were accurate but not fluent readers; and a group of poor readers who read slowly and inaccurately. The compensated dyslexics, manifested relative underactivation of the left parietotemporal and occipitotemporal regions. The poor readers activated posterior reading systems but the pattern was quite different from that of the unimpaired readers, suggesting that they were relying more on reading strategies that relied on memory (133).

A sequential developmental model for acquiring reading skill has been proposed by Shaywitz and associates. This model fits well with observations described previously about the acquisition of reading skill in the young child. Initially, the dorsal circuit, involving the angular gyrus is predominant as the beginning reader learns to map the orthographic features of text onto phonological and lexical-semantic information. With increasing exposure and practice, this process is shifted to the ventral area, the main node of which is the visual word form area, which is adapted for rapid, automatic processing of visual information (134). Turkeltaub and colleagues studied children and young adults ranging in age from 6 to 22 years. In the

youngest readers, activation of the left-posterior superior temporal sulcus was prominent and related to increasing skill in phonological processing. Additional changes in reading pattern with maturation were associated with increased activity in the left-hemisphere middle temporal and inferior frontal gyri and decreased activity in right inferotemporal cortical areas (135).

## Visual Deficits

Although Hinshelwood’s description of dyslexia emphasized the visual aspects of the problem (“word-blindness”), he identified angular gyrus/associational cortex as the site of the dysfunction. Reading unquestionably involves a visual process, yet there is ample evidence that it is the underlying difficulty in phonological awareness and the impaired ability to link visual information with phonemes that is the major problem in dyslexia. The difficulty seems more associational than visual and may involve some early dysfunction of the mirror neuron system.

Having said that, it is also true that reading involves a visual process. Effective reading requires maintaining fixation on a small segment of text, systematically shifting gaze and then attending to another segment of text. This depends not so much the size of the perceptual span as the ability to rapidly integrate phonological and semantic information (136). In addition, attentional factors are also involved (137). Proponents of the visual deficits associated with reading point to the fact that dyslexics frequently transpose letters and complain that words move around on the page.

A number of studies have demonstrated visual and oculomotor dysfunction in dyslexics (138–140); but these results are often hotly contested, and have not been replicated (141–144). Lovegrove demonstrated that as a group dyslexics have mildly reduced contrast sensitivity at low spatial frequencies and low luminance levels, particularly during flicker fusion. In contrast, at higher spatial frequencies contrast sensitivity is intact (145). Flicker fusion rate is slow (146) and impaired vergence amplitudes are noted, compared to controls (147). Cornelissen and colleagues demonstrated that dyslexics had impaired visual motion sensitivity even when high contrast and illumination levels were present (148). This observation was supported in a visual-evoked potential study that used a binocularly presented checkerboard pattern at low and high contrasts. At high contrast, the groups did not differ. Examining steady-state visual-evoked potentials at a variety of contrast levels, they found that at high contrast there was no difference, but at 15 Hz using low-contrast stimuli, the responses of normal subjects were slightly reduced, but were virtually absent in the dyslexic subjects. The investigators interpreted this early negative wave as reflecting activity in layer 4C of primary visual cortex (V1) in response to thalamic projections (149).

Many of the deficits in visual processing during reading in dyslexics have been interpreted as associated with the

difficulties in processing phonological information. Eden and colleagues conducted a series of studies on dyslexics, "backward readers," and controls that involved visual tasks (measures of fixation, vergence amplitude, saccade, and smooth pursuit) that did not involve phonological processing. Results indicate that fixation instability at the end of saccades, poor smooth pursuit (particularly left to right), and vergence amplitudes were lower in the dyslexic group. All dyslexics with small vergence amplitudes were also impaired in phonemic awareness (as assessed by pig Latin). The "backward reading" group showed a similar profile (the question here is whether this group was biologically different from the dyslexics). Eye movement abnormalities were not correlated with attention deficit, gender, IQ, or handedness. The conclusion was that the oculomotor abnormalities appeared unrelated to the phonemic awareness deficit (150). In an fMRI study of visual motion processing in dyslexic men and controls, there were no group differences in activation pattern visual cortex, or extrastriate cortex, or stationary visual stimuli were presented, but the dyslexics did not activate the middle temporal area (V5/MT) to the same extent as controls when moving stimuli were presented (151). These findings have been interpreted as showing an abnormality in the magnocellular pathway at the level of primary visual cortex (area 17;V1) or earlier, indicating that the magnocellular system of dyslexics can respond to low-contrast stimuli, but the response is slow. These findings were further supported by neuropathological studies of the lateral geniculate nucleus that revealed disorganized, shrunken magnocellular layers without any changes in the parvocellular layers in the dyslexics in comparison to controls.

A subsequent visual evoked potential study in which low- and high-spatial frequency targets were presented in either a steady or flickering background showed no differences in the high spatial condition between dyslexics and controls, but when low spatial frequencies were used, there were longer latencies of early components of the visual-evoked potential in the dyslexics. However, Victor and colleagues attempted unsuccessfully to replicate these findings (152).

Although, as this brief review indicates, there is some evidence suggesting that visual deficits are present in some dyslexics, there is little reason to believe that visual processing is the underlying deficit. Some dyslexics have been shown to have associated motor, timing, praxis, and/or coordination deficits; some have more complex auditory processing deficits. However, these might be considered to be "add-ons," distinct from the primary pathophysiology. In a well-constructed and executed study by Ramus, young adult dyslexics and controls underwent extensive psychometric, phonological, auditory, visual and cerebellar testing. One hundred percent of the dyslexics had a phonological deficit, 63% an auditory deficit, 25% a motor deficit, and 12.5% a visual magnocellular deficit. Thus, a phono-

logical processing deficit is a sufficient explanation for dyslexia and has much theoretical and empirical support. In addition, the phonological processing deficit model has given rise to effective treatment strategies that have demonstrated efficacy.

## GENETIC ASPECTS

The familial nature of dyslexia has been known for over a century. In 1907, Stephenson described a family with six cases in three generations (153). The first formal genetic study was published in 1950 (154). Rutter and Yule, using data from the Isle of Wight study, noted that a family history of reading disability occurred in approximately one third of the children with reading disability compared to 9% of the controls. They cautioned that this did not eliminate the possibility that environmental factors were also involved.

Twin studies also have supported the genetic etiology of dyslexia, although there has been considerable variability from study to study. Bakwin reported that the probandwise concordance rate in twin pairs, in which at least one twin was reading disabled, was two times higher in monozygotic twins (91%) than in dizygotic twins (45%) (155). In a study of 13-year-old monozygotic and dizygotic twins, Stevenson noted that the genetic contribution was relatively modest if only reading scores were used. When spelling was added, heritability increased to 0.75 (71). Data from the large number of twin pairs that have been studied in the Colorado Family Reading Study provide particularly convincing support for the heritability of dyslexia (156, 157). These investigators employed a multiple regression analysis which made it possible to use an alternative test of genetic etiology of reading disability. They concluded that about half of the impairment in reading performance of the probands was the result of heritable influences, and 40% could be attributed to shared environmental influences. Even more importantly, these investigators were able to show that IQ was not a factor in either genetic etiology of reading disability or twin resemblance. Moreover, a comparison of the phonological and orthographic coding scores of the twins supported the concept that reading-disabled children have a deficit in phonological coding and that individual differences in word recognition are largely the result of heritable variation in phonological coding ability (158, 159).

Genetic linkage analyses on large families of subjects with reading disability have identified a number of candidate genes at different loci. It is not clear at this point if there are several different genes that lead to the dyslexic phenotype, if there are specific dyslexic phenotypes (which, at this point have not been definitively identified), or how a specific gene affects brain development and function to produce the dyslexic cognitive profile. The manner in which the diagnosis of dyslexia is made is of great importance in this

type of study because of the variability in clinical presentation and the age-related changes in reading skill. Moreover, large sample sizes are required in this type of work.

The chromosome region that has been most consistently linked to dyslexia is in the region 6p23–p21.3 (160, 161). A possible association with deficits in phonological awareness was suggested by Grigorenko and colleagues (162). However, investigators have not been particularly successful in targeting the specific gene locus responsible for the linkage in the 575-kb region under scrutiny on chromosome 6p22. The myelin oligodendrocyte glycoprotein (MOG) gene, which maps to 6p21.3, appeared to be a possible candidate but this has not been substantiated on closer inspection (165, 166). Francks and colleagues found an association with this area in three samples, two from the United Kingdom and an independent sample from Colorado (167). In a family-based and case-control study, Cope et al. identified two single nucleotide polymorphisms in the KIAA0319 gene on 6p.22 that best explained the linkage to dyslexia. Thus KIAA0319 is a strong candidate for a susceptibility gene: it is expressed in the brain, but its function is currently unknown (168, 167).

The first study reported linkage of reading disability to chromosome 15 in 84 individuals from nine families in which reading disability appeared to be transmitted in autosomal dominant manner (169). However, in only one of the nine families was there a high lod score. A later study based on a much larger sample indicated that approximately 20% of families with reading-disabled children showed linkage to chromosome 15 (170). In a Finnish study, a gene (DYX1C1 near the DYX1 locus on chromosome 15q21), disrupted by a translocation, was found to coincidentally segregate with dyslexia (171, 172). Subsequently, in a large study (898 individuals in 111 families), this gene has been found to be linked to single word reading (173). However, this association was not supported in a large sample from the United Kingdom (174, 175), and investigators have not been particularly successful in narrowing down the area and identifying any specific gene (176). In another study by the Toronto group, the gene in the region of the translocation was found to be associated with phonological awareness, word identification, decoding, rapid automatized naming, language ability, and verbal short-term memory but involved different alleles and haplotypes than was reported in the Finnish sample (177). Chromosome 15 has also been reported to be associated with ADHD in a sample of Dutch children (94).

The region on chromosome 1p34–p36 has also been considered as the site of a possible susceptibility gene for dyslexia (178, 179). Grigorenko and colleagues studied eight dyslexic families and suggested the possibility of a two-locus interaction with 1 p and 6 p (180). In a sample of 100 dyslexic Canadian families, assessed using phonological awareness, phonological coding, spelling, and rapid automatized naming speed, further confirmation of a possible linkage on 1p34–36 was found (181).

Kaminen and colleagues reported that they had confirmed a site on chromosome 2p11 (DYX3) that was associated with dyslexia (182). Chromosome 3 has also been identified as a possible candidate. In a study of a large pedigree, dyslexia was found to segregate with an autosomal dominant locus in the pericentromeric region of chromosome 3 (183).

A quantitative trait locus on 18p11.2 that was significantly associated with single-word reading was identified. The investigators felt that this might constitute a “general risk factor for dyslexia, influencing several reading-related processes” (184).

A locus on the X chromosome between markers DXS1227 and DXS8091 was described in a single large Dutch family. Males were predictably more severely affected, whereas females had a somewhat milder presentation but could still be diagnosed as dyslexic on the basis of the composite score (185).

Kaminen and colleagues noted that there was a possible linkage to chromosome 7q32, but did not observe any specific mutations when they sequenced the FOXP2 (forkhead box P2) coding region in six of their Finnish subjects with dyslexia (182).

Nonetheless, the FOXP2 gene remains an interesting candidate for a specific subtype of dyslexia. There is a compelling confluence of structural, functional, and neurodevelopmental information which suggests that FOXP2 may be related to dyslexia associated with severe speech/language dysfunction. The association of severe dyspraxia of speech, as a possible marker for dysfunction of the mirror neuron system (the result of anomalous neurodevelopmental processes), and subsequent difficulty acquiring adequate phonological awareness is intriguing (186). A mutation in exon 14 of the FOXP2 gene has been linked to severe speech/language disorders in the KE kindred, a large, three-generation family that has been extensively studied. A morphometric MRI study revealed bilateral reduction of grey matter in the caudate, the cerebellum, and left and right inferior frontal gyrus in affected family members with increased grey matter density in the planum temporale. A fMRI study involving silent and spoken verb generation and repetition was conducted on family members with the FOXP2 mutation and unaffected members from the same family. Those with the FOXP2 mutation showed significant underactivation of a variety of cortical language areas, including Broca’s area, its right homolog, and the putamen (187). FOXP2 is involved in the development of corticostriatal and olivocerebellar circuits, which are critically involved in motor control. Moreover, a study in songbirds suggests that it may be related to neural plasticity underlying vocalization (188).

However, studies of other subjects with speech-language disorders and/or verbal apraxia have not consistently revealed association with this locus. In a study of 96 subjects with speech-language impairment, a mutation in FOXP2

was not identified but an association with a marker adjacent to FOXP2 was observed (189). A heterozygous nonsense mutation resulting in a truncated protein product that cosegregates with severe verbal apraxia and concomitant language disability has been identified in three of 49 subjects with apraxia of speech (190).

## APPROACHES TO THE EVALUATION OF DYSLLEXIA

An adequate assessment of the child with dyslexia requires a multidisciplinary approach. A detailed history is used to elucidate any obstetrical or medical problems that might contribute to the problem, such as prematurity, hyperbilirubinemia, or a history of chronic otitis media, or significant medical illness or surgical problems. The child's language and motor development should be reviewed in great detail: was he an interactive pleasant baby who cooed responsively? When did babbling commence? When did the child start uttering words with communicative intent? When did he start using words to communicate effectively? At what point was the child intelligible to persons outside the family? Was he able to follow simple directions? Or was it necessary to use a lot of gesturing? Did the child engage in symbolic play activities? What about chewing and swallowing food? Is he a messy eater? Can the child swallow pills?

The family history should also be carefully reviewed. This should include asking about the educational and professional status of the parents and their siblings, and the grandparents. In addition, one should find out if the parents (and if possible other family members) read for pleasure, can master foreign languages, and are able to spell. In families from lower socioeconomic groups, dropping out of school, and finding work as a laborer are highly suggestive. However, because some dyslexic adults can be quite successful, it is important to review their educational history and past and present reading and spelling skills.

All children being evaluated for dyslexia should also be screened for ADHD. Given the extremely high comorbidity of reading disability and ADHD, it is important to be aware of attentional problems, which make it even more difficult for the child to perform adequately. In addition, screening for depression, anxiety, oppositional defiant disorder, and conduct disorder are warranted. Some anxious dyslexic children who perform well despite their handicap have a rather obsessive approach to school work.

The history should also inquire in detail about the child's school performance: what kind of school does the child attend? Has the child had any previous evaluations? How did the child fare in kindergarten and first grade? Was he able to recognize letters? How about spelling and writing and arithmetic? Is the child independent in homework skills (this depends, to some extent, on the child's grade level). One expects a child in second grade to require some supervision. However, a child in fifth grade who requires constant supervision by parents and teachers to keep track of, finish,

and turn in homework should be closely scrutinized for reading disability and ADHD. The amount of effort that a parent must put in at home around completing homework is also an important aspect of the history. The child whose parents describe time-consuming, nightly battles surrounding homework should be considered at high risk for dyslexia.

The formal assessment should involve a standardized IQ test. Examination of reading skills should include assessing the child's ability to read single sight-words and decode nonwords. An assessment of phonological awareness, phonological memory, and rapid naming should be carried out (Comprehensive Test of Phonological Processing) (24). The Lindamood Auditory Conceptualization Test-3 not only assesses phonemic awareness but also a child's ability to conceptualize syllables and phoneme-syllable relationships. (190a) The Test of Word Reading Efficiency is well-normed and measures not only accuracy but also decoding speed (190b). Oral reading fluency and reading comprehension, as measured on the Gray Oral Reading Test-4, is particularly helpful because it sometimes highlights an obvious discrepancy between poor mechanical reading skills and above-average reading comprehension (190c).

Spelling should be evaluated. The child's ability to write, both in terms of the motor mechanics and legibility, as well as speed should be assessed. In addition, the child's ability to organize a story or a report should be assessed. Arithmetic should be evaluated. Many dyslexics have relative strengths in arithmetic and in terms of managing psychosocial issues and school curricula, this is an important piece of information.

An assessment for dyslexia should also include a thorough examination of language. In addition to assessing the child's lexical, semantic, and syntactic processing through a formal language assessment, confrontation naming, verbal fluency, and short- and long-term verbal memory should be evaluated. An assessment of frontal executive function and visuospatial skills should also be conducted. These are often areas of strength.

The child should also be carefully evaluated for ADHD as well as any other psychiatric comorbidities. An interview with the parents, teacher, and child should focus on screening for ADHD, other disruptive behavior disorders, anxiety, and depression. Simply asking the child what part of their school day they like best can be very informative (an answer such as "lunch" or "recess" tells one a great deal). Some children will be quite clear about their dislike for certain school subjects. A diagnostic screening questionnaire completed by the parents and teachers is helpful. The child's level of attention, arousal, impulsivity, and restlessness as well as his or her ability to express ideas in language should be monitored during the interview and assessments. A continuous performance task is often helpful. This evaluation is obviously considerably more extensive than is typically administered in a school setting. However, because dyslexia is not simply a "learning disability" it is important to have a clear idea of what one is dealing with. Understanding the child's self-image, coping strategies, and insight is particu-

larly helpful. It is also important to understand how the parents view the situation. Some parents deny the child's difficulty and may see the school's concerns as unjustified and intrusive. Other parents see the child's struggles as mirroring their own experience in school and feel guilty.

Many bright dyslexic children are able to cope with school work, not because they can read well, but rather because they can understand what they are reading without actually having read it. This may not pose a problem in terms of classroom performance, but in situations in which there is a high level of pressure to perform, or a high stakes test, the child may decompensate. In many school systems, informal teacher-conducted reading assessments are heavily weighted toward reading comprehension rather than mechanical reading skills.

## TREATMENT/MANAGEMENT OF DYSLEXIA

Reading disability has a pervasive effect on a child's academic success and may cast a shadow on accomplishment and self-esteem throughout adult life. Treatment of dyslexia has therefore been a focus of attention for parents, teachers, and professionals who seek effective strategies for treating the disorder. Many methods have been devised, ranging from the teaching of explicit reading strategies, using a multisensory approach (such as the Orton-Gillingham method) (191) or the commercial programs that are based on the Orton-Gillingham, such as Alphabetic Phonics, Project Read, the Herman Approach, Slingerland Approach, the Spalding Approach, the Wilson Approach, or LANGUAGE! Other therapies include vision training, colored lenses, craniosacral therapy, motor treatments designed to address cerebellar deficits, and so on.

There are two general approaches to the treatment of dyslexia. One is a "top-down," whole language approach that uses semantic or syntactic clues for word reading but does not train phonologic awareness in an explicit, sequential fashion. The other is a "bottom up" approach that addresses phonological awareness in a direct, explicit fashion. An example of this direct approach using explicit training of phonological awareness is the program, developed by the Lindamoods, initially called Auditory Discrimination in Depth (ADD) (192). This program has undergone some revision and was renamed LiPS (Lindamood Phoneme Sequencing program) (193). The treatment approach needs to be adjusted to the age of the child. Very different strategies need to be used if one is dealing with an at-risk 4-year-old child with a language disorder or working with a 20-year-old college student. In addition, the treatment needs to be delivered in an intensive fashion with close monitoring, feedback, and an orderly, sequential approach. For example, in the treatment study reported by Eden and colleagues, dyslexic adults received 3-hour daily sessions in a small group setting for 8 weeks, an average of 112.5 hours of training. It is interesting that Hinshelwood,

a century ago, recognized the importance of frequent training. Lacking intensity, treatment can go on for many years and in severely dyslexic individuals, may result in only minimal gains (Lyon 1985, Snowling and Hulme 1989).

There is a relative paucity of well-designed peer-reviewed studies that support these various methods. The reader is referred to the review by Alexander and Slinger-Constant, which discusses in depth various current strategies for treating dyslexia and critically reviews the supporting research (194).

There are now a number of studies that indicate that appropriate, intensive, treatment designed to enhance phonologic awareness will result in a shift in the pattern of brain activity to a pattern resembling that of the normal reader. This suggests that the brain has sufficient plasticity to respond to appropriate explicit intensive treatment by modifying neuronal connectivity. These studies, which have been reported out of several different research centers, using somewhat different programs, are quite encouraging (195–198). However, this treatment approach is based on neurorehabilitation. It is important that once a child has completed the intensive program that they continue to practice the skills that they have acquired until they become automatic and self-sustaining. For a moderately severe dyslexic, intensive treatment will significantly improve decoding accuracy but fluency will follow much more slowly. The child will need continued support or there is a risk of return to the previous state. In adults, the response to intensive treatment is somewhat different, involving more right hemisphere activity (199). The fact that such changes can be made in the activation pattern suggests that it should be possible to effectively help children and adults with dyslexia, given how valuable reading is in our society.

In addition to the direct treatment of the underlying phonological awareness deficit, other issues must be incorporated into the management of the dyslexic patient. After chronic failure in school, older children and adults need work with a sensitive psychotherapist to help them reframe their perceptions of themselves. Therapy directed at helping them acquire a realistic view of their cognitive strengths and weaknesses, and coaching them on how to bypass areas of deficit, can be extremely helpful. A substantial number of dyslexics also have significant attention deficits, which may not be at all clinically obvious. They benefit from psychostimulant treatment. Books on Tape are often very helpful for the dyslexic with a heavy reading load. Effective text-reading and voice-recognition software packages are now available. Learning to touch-type and use a spell-checker also helps these students function effectively.
